Y-Box-Protein-1 (YB1) is a transcriptional and translational regulator implicated in cancer progression. Previously, we established elevated YB1 levels in pediatric Glioblastoma (GBM), an aggressive high-grade astrocytoma, possibly driving oncogenesis in this cancer. Increased YB1 expression has also been detected and found to correlate with unfavorable outcomes in a wide range of other human cancers. The purpose of this study is to investigate the role of YB1 in astrocytoma genesis and its possible association with poor prognosis. We overexpressed or silenced YB1 protein in pediatric GBM (SF188), adult GBM (U87) and normal human astrocytes cell lines (NHA immortalized with H-Tert). Proliferation, migration, soft agar assay were performed in vitro, accompanied by in vivo mice xenograft to assess the tumorigenic ability of these cells. Meanwhile, tissue microarrays including 150 pediatric GBM and 70 Grade I Pilocytic Astrocytoma were stained immunohistochemically (IHC) with YB-1 and EGFR to assess their expression and correlation. YB-1 silencing using shRNA reduced YB-1 level by 90%, and surprisingly increased cell proliferation. As YB-1 is predominantly cytoplasmic in physiological conditions in cells, and nuclear YB-1 is known to associate with increased cell growth, sub-cellular localization of YB-1 was investigated. In the YB-1 silenced clones, YB-1 was greatly reduced in cytoplasm, while YB-1 in the nucleus and EGFR expression was actually enriched, explaining the increase in cell proliferation. YB1 overexpression was mainly cytoplasmic, and decreased cell proliferation and increased migration. Importantly, in orthotopic mice injections, YB-1 overexpression decreased the tumorigenic ability of GBM cells. IHC on tissue microarrays of patient tumors showed strong YB1 expression in 66% of pediatric GBM samples, but only 8% in Grade I astrocytoma, suggesting a role of YB1 overexpression in a more invasive tumor phenotype. In addition, we showed that nuclear YB1 expression is associated with EGFR overexpression in patient samples. Our results suggest that YB-1 modulates cellular proliferation and migration, based on its sub-cellular localization. Nuclear YB-1 drives cell proliferation, whereas cytoplasmic YB-1 promotes cell migration. Showing the association of nuclear YB-1 with EGFR overexpression and more aggressive tumor phenotype, our data argue for caution in targeting YB1 for therapeutic intervention.

1183T

Integrative analysis of TCGA clinical and genomic data reveals conflicting roles of REST gene expression in recurrent glioblastoma. *J. Madhusoodanan, M. Shekar, J. Su, I. Kupershmidt.* NextBio, Santa Clara, CA.

Background: Increased expression of the NRSF/REST transcriptional regulator is implicated in maintaining tumor cell pluripotency in recurrent glioblastoma multiforme (GBM). Although several studies support this oncogenic role of increased REST expression, little is known about the diagnostic or prognostic significance of this perturbation in GBM patients. We evaluate the clinical significance of increased REST expression in GBM patients and identify novel biomarkers of prolonged recurrence-free survival. Methods: Publicly available genomic and clinical data from TCGA and experimental data sources were curated, normalized and analyzed using the NextBio Clinical platform. Genomatix software suite was used for promoter sequence analysis. GBM cohort of TCGA with increased expression of the REST gene (n =333) were screened for enrichment of known prognostic biomarkers. Results: In the NextBio Clinical module, 97% of GBM patients with increased REST expression were found to have increased methylation of the MGMT gene, a biomarker strongly linked to longer survival and better responses to temozolomide and radiotherapy. In silico analysis of the MGMT promoter sequence reveals conserved RE-1 binding sites suggestive of an association between increased REST expression and MGMT methylation. This cohort was further analyzed for other potential biomarkers predictive of disease recurrence. Comparing patients with increased REST expression who survived less than 3 mos. with those surviving 1 year or longer, we identified VWC2 gene expression as being significantly different between the two groups. Decreased VWC2 expression appears strongly associated with longer recurrence free survival. Only one study so far suggests VWC2 may be a marker of cancer stem cells, and a few others propose a proliferative role in neurogenesis and neuronal development in animal models. Conclusion: We identify an apparently contradictory association between increased REST expression, considered an oncogenic change in GBM, and MGMT promoter methylation, a biomarker strongly linked to improved prognosis in GBM. Within the cohort with increased REST expression, novel biomarkers for prolonged recurrence-free survival were identified, such as decreased expression of VWC2. VWC2 is associated with neuronal proliferation in mice and may serve as a putative biomarker for recurrent GBM.

1184F

Analysis of *MRE11/RAD50/NBN* genes in childhood acute lymphoblastic leukemia. *J. Nowak[1], M. Mosor[1], I. Ziolkowska-Suchanek[1], K. Nowicka[1], D. Januszkiewicz-Lewandowska[1,2].* 1) Inst Human Gen, Polish Academy Sci, Strzeszynska 32, Poznan, Poland; 2) University of Medical Sciences, Fredry 10, Poznań, Poland.

The *MRE11, RAD50* and *NBN* genes encode MRE11-RAD50-NBN (MRN) complex proteins involved in DNA damage cellular response. In our previous study it was showed that germline I171V mutation in *NBN*, may be considered as a risk factor in the development of childhood acute lymphoblastic leukemia (ALL). The aim of the study was to determine whether *MRE11* and *RAD50* alternations have a potential role in childhood ALL. The study was carried out by determining the frequency of constitutional mutations and polymorphisms in selected regions of *MRE11, RAD50*, and *NBN* in the group of 200 children diagnosed with ALL. It was the first time we have carried out simultaneous analysis of *MRE11, RAD50* and *NBN* genes in childhood ALL. Anonymous blood samples collected on Guthrie cards were used as a control group. The analysis was focused on exon 5, 10, 14, 15, 19 of *MRE11*, exon 3, 4, 5 and 7 of *RAD50* and 2, 5, 6, 7, 10, 13 of the *NBN* gene and was performed by specific amplification of region of interest by PCR followed by multi-temperature single-strand conformation polymorphism (PCR-MSSCP) technique. Each sample showing shifts in MSSCP analysis was sequenced. In a sample of the 200 children diagnosed with ALL we did not identify any mutations in the *RAD50* or in the *MRE11*. We identified 2 alternations in 3 out of 506 control group members in the *RAD50* gene - the V127I in exon 4, detected twice, was predicted to be tolerated using the SIFT and PolyPhen analysis. The V315L in exon 7 occurring only once among 506 control group members was predicted to be benign. In addition we were able to detect c.551+19 G>A single nucleotide polymorphisms in the intronic sequence of exon 4 with different frequencies both in ALL patients and controls. The frequency of the AA genotype was higher in leukemia patients, as compared to control group members (p= 0,0032). In the group of ALL patients the higher incidence of the I171V mutation in ALL group (5/200) than among controls (12/2400)(p< 0,0007)was observed. Although variant allele of the intronic SNP in the *RAD50* gene was observed as more frequent in childhood ALL in comparison to control group members, no clear association of mutations in *RAD50* and *MRE11* gene has been seen. Interpretation of these results is limited small sample group number. Nevertheless we confirmed participation of I171V germline mutation of *NBN* gene in ALL.

1185W

Validation of a prostate cancer metastasis signature in a FFPE cohort of primary tumors. *A. Pearlman[1], C. Campbell[1], J. Loke[1], S. Freedland[2], Y. Shao[3], H. Ostrer[1].* 1) Dept of Pathology, Albert Einstein College of Medicine, Bronx, NY; 2) Dept of Pathology, Duke University Medical Ctr, Durham, NC; 3) Division of Biostatistics, NYU School of Medicine, New York, NY.

Genomic copy number alterations (CNAs) resulting in changes in abundance or altered structure of RNA transcripts and proteins (e.g. truncating dominant negative mutations) may impact the fitness of the cell and provide some of the mechanisms necessary for distant site migration, invasion and growth. From multiple CNAs identified in fresh frozen tumors of radical prostatectomies, CNA-based gene signatures were developed into a metastatic potential score (MPS) that suggested the ability to predict metastasis free survival (in press, J. Prob. and Statistics). To assess the validity of our metastasis signature and MPS prediction model, we collected a retrospective cohort of primary prostate cancer tumor and matched normal tissues from thirty men treated with radical prostatectomy at Duke University Medical Center (Duke cohort). The cancer tissue was obtained from archived formalin fixed paraffin embedded (ffpe) blocks. Each block was processed by our pathologist by obtaining a 5 micron H&E stained sections and evaluated for tumor content. The genomic DNA (gDNA) was extracted using a Qiagen ffpe gDNA column extraction kit. The material was sent to Affymetrix Service Center in Santa Clara, CA and run on the OncoscanTM V2 SNP array developed specifically for gDNA samples extracted from ffpe archived tissue. The Duke cohort was made up of primary tumors that metastasized following radical prostatectomy (mPTs, n=12), and, a group of low risk tumors that didn't develop distant metastases (iPTs, n=7). The receiver operating characteristics-area under the curve analysis (ROC-AUC) applied to the Duke cohort mPTs and iPTs resulted in an accuracy of 0.91.

Molecular Characterization of Small Cell Carcinoma of the Ovary. *P. Ramos[1], M.L. Russell[1], L. Nordstrom[1], S. Smith[1], M.T. Barrett[1], T. Holley[1], E. Lenkiewitz[1], J.G. Pressey[2], J. Farley[3], S.P. Anthony[4], G. Hostetter[5], A.E. McCullough[6], K.A. Furge[5], B.B. Haab[5], J.M. Trent[1], H.E. Cunliffe[1].* 1) The Translational Genomics Research Institute, Phoenix, AZ; 2) Department of Pediatrics, University of Alabama at Birmingham, Birmingham, AL; 3) Department of Obstetrics and Gynecology, St. Joseph's Hospital and Medical Center, Phoenix, AZ; 4) Evergreen Hematology and Oncology, Spokane, WA; 5) Van Andel Research Institute, Grand Rapids, MI; 6) The Mayo Clinic, Scottsdale, AZ.

Background. Small Cell Carcinoma of the Ovary (SCCO) is a rare and highly aggressive malignancy that affects young women and girls. The majority of patients are diagnosed at an advanced stage and do not respond to chemotherapy, or only experience transient responses, quickly exhibiting therapeutic resistance. As a result, more than 75% of patients succumb to their disease within 1–2 years, even when diagnosed at an early stage. The differential diagnosis of SCCO remains a challenge, as the etiology of SCCO is not known. There is no robust molecular evidence to direct therapy for SCCO patients. **Hypothesis.** Comprehensive molecular characterization of multiple SCCO tumors will define the spectrum of SCCO-specific aberrations, leading to new insights for SCCO pathobiology, rationales for targeted treatment approaches, and markers to aid in differential diagnosis. **Methods.** SCCO tumors were obtained from 16 patient cases. Specimens were obtained following informed consent under an IRB-approved protocol (www.tgen.org/scco). We performed Agilent 44Kv2 gene expression profiling on 4 fresh frozen tumors compared to 1) age-matched normal ovary, and 2) 15 individual ovarian tumors of various histology. Agilent 400K array-comparative genomic hybridization (aCGH) was performed on all cases. A tissue microarray (TMA) was constructed for biomarker validation. **Results.** Consistent with previous reports, the average age at diagnosis of our cohort is 23 years. Expression profiling revealed 8,746 genes significantly differentially expressed between SCCO tumors and normal ovary (p-value <0.001). Ontology analyses indicated cell cycle regulation, chromosome organization, and DNA repair. Several candidate therapeutically actionable targets were identified that are currently being validated by Immunohistochemistry. To compare SCCO profiles to the most common histotypes of epithelial ovarian cancer, we performed an unsupervised 2-dimensional hierarchical clustering of 3526 genes most highly deviating across all tumors. SCCO tumors clustered tightly and distinctly from all other tumors and revealed clusters of genes unique to SCCO. We are currently defining biologic processes identified by these clusters to attain insight into the pathobiology and possibly etiology of SCCO tumors. aCGH analyses indicated SCCO genomes are predominantly diploid. **Conclusions.** We anticipate the outcome of this study will provide new insights into the diagnosis and clinical management of SCCO.

1187F

Effects of *Helicobacter pylori* infection on *MGMT* and *MLH1* promoter methylation status and microsatellite instability in paediatric and adult patients. *M.L. Ribeiro[1,2], M.C. Alvarez[1,2], J.C. Santos[1], N.M. Maniezzo[1], M.S. Ladeira[3], I.C.A. Scaletsky[4], J. Pedrazzoli Jr[1].* 1) Sao Francisco University. Clinical Pharmacology and Gastroenterolog, Braganca Paulista, Sao Paulo, Brazil; 2) Programa de Pós Graduação em Genética e Biologia Molecular, UNICAMP, Campinas, SP, Brazil; 3) Departamento de Clínica Médica, UNESP, Botucatu, SP, Brazil; 4) Departamento de Microbiologia, Imunologia e Parasitologia, UNIFESP, SP, Brazil.

It is well established that *H. pylori* infection leads to chronic inflammation in the gastric mucosa, which is associated with DNA methylation. Because this epigenetic alteration plays an important role in the regulation of gene expression and maintenance of DNA integrity and stability, the aim of this study was to analyse the effect of *H. pylori* infection on the methylation status of *MLH1* and *MGMT* and the relationship between this methylation and microsatellite instability (MSI) in children infected or uninfected by the bacterium and in adults with chronic gastritis or gastric cancer, both with and without *H. pylori* infection. Biopsy samples from children and adults with chronic gastritis and adults with gastric cancer, infected or uninfected with *H. pylori*, were included in the study. Methylation was not detected in the promoter regions of *MLH1* and *MGMT* in paediatric samples. In chronic gastritis adult patients, methylation of the *MGMT* promoter was associated with *H. pylori* infection. The levels of *MLH1* and *MGMT* mRNA were significantly reduced in chronic gastritis samples that were also hyper-methylated. We observed methylation of the *MHL1* promoter, as well as an increase in the level of MSI, in samples from gastric cancer patients when comparing them to samples from the adult chronic gastritis patients with *H. pylori* infection. Our study indicates that the methylation of the promoter regions of *MGMT* and *MLH1* might be considered an event that is dependent on the duration of infection because such alterations in methylation were not observed in children. Moreover, in gastric cancer patients, the mRNA levels of *MLH1*, the hyper-methylation of the promoter region of *MLH1* and the increase in the frequency of MSI are all related events.

1188W

Role of novel and GWAS identified PLCE1 genetic variants to gallbladder cancer susceptibility in north Indian population. *K. L. Sharma[1], S. Misra[2], A. Kumar[1], B. Mittal[1].* 1) Sanjay Gandhi Post Graduate Institute of Medical Sciences (SGPGIMS), Lucknow, India; 2) Chatrapati Shahuji Maharaj Medical University (CSMMU), Lucknow, India.

Introduction: Phospholipase C epsilon 1 (PLCE1) gene belonging to the phospholipase family plays crucial roles in carcinogenesis and progression of various cancers. Recent genome wide association studies have reported significant association of genetic variants in PLCE1 as novel susceptibility markers for various cancers like esophageal, gastric and head and neck. However, its association is not known in gallbladder cancer. Therefore, the present study aimed to find out the association of GWAS identified 2274223A>G polymorphism from haplotype block 2 and a novel SNP rs7922612T>C from haplotype block1 of PLCE1 in conferring susceptibility to GBC in north Indian population. Methods: Selected PLCE1 variants were genotyped in 416 GBC cases and 225 controls by PCR-RFLP. Statistical analysis was done by SPSS and SNPstats. In-silco analysis was performed using Bioinformatics tools (FAST-SNP, F-SNP). Results: PLCE1 rs2274223 A>G [AG] and rs7922612T>C, [CC] genotypes were found to be significantly associated with an increased risk of GBC [OR= 1.9, p=0.002, OR= 2.0, p= 0.04 respectively] as compared to healthy controls. PLCE1 haplotype [A-C] showed statistical significant association with GBC [OR= 1.5, p=0.02]. On stratification based on gender, PLCE1 rs2274223 A>G [AG] was significantly associated with GBC n a sex neutral manner [OR=2.3, p=0.04 (males), OR= 1.8, p=0.01(females)] but rs7922612T>C, [CC] genotypes showed increased risk of GBC in males only [OR=4.5, p=0.03]. On dividing GBC patients on the basis of gallstone status, PLCE1 rs2274223 [AG] was risk factor for GBC patients with or without gallstones [OR; 2.1, p=0.006, (with stone/control) OR; 1.8, p=0.012 (without stone/control)] whereas rs7922612 CC genotype imparted higher risk for GBC without gallstones when compared to controls [OR; 2.3, p=0.03]. PLCE1 haplotypes [A-C] and [G-T] [OR= 2.1, p=0.03, OR=2.4, p=0.03] respectively showed statistical significant association with GBC patients with stones. The genetic risk was not further modulated by tobacco consumption or age of onset. In-silico analysis of rs2274223 A>G showed significant change in functional category i.e. protein coding and splicing regulation [SNPeffect: deleterious, ESEfinder: change, ESRSearch: change; (FS score 0.3); FAST-SNP: Low-Medium risk]. Conclusion: The present study found significant association of PLCE1 rs2274223 and rs7922612 polymorphisms with GBC susceptibility.

1189T

Serum metabolomics and prostate cancer survival. *R. Szulkin[1], R. Karlsson[1], A. Heuberger[2], M. Hong[1], C. Broeckling[2], J. Prenni[1], J. Prince[1], F. Wiklund[1].* 1) 1Department of Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm, Sweden; 2) Department of Biochemistry and Molecular Biology, Colorado State University, Fort Collins, USA.

Introduction: Established prognostic factors perform poorly in predicting disease relapse among patients treated for prostate cancer. Identification of novel biomarkers improving the prognostic information is of great importance to guide individual therapy. Materials and Methods: Post-treatment serum samples from a nested case-case design comprising 269 prostate cancer patients with lethal outcome and 269 patients with non-lethal outcome were used. All patients were diagnosed between year 2001 and 2003 in Sweden and followed up for survival until December 2010 through record linkage with the national Cause of Death Registry. Untargeted gas- and ultra performance liquid chromatography (GC, UPLC) coupled with mass spectrometry (MS) were employed to screen for novel prostate cancer biomarkers. Normalized and log-transformed metabolite concentrations were explored for association with prostate cancer-specific survival in time-to-event analysis using death from prostate cancer as endpoint. Results: Untargeted metabolomic profiling of prostate cancer serum samples revealed a total of 9836 GC/MS and 5301 LC/MS profiles. Univariate analysis of individual normalized feature levels indicated 23 peaks to be study-wide significant associated with prostate cancer-specific survival. Of note, at the 1×10-8 significance level we observed 11 associated peaks as compared to 1×10-4 expected peaks under the null hypothesis of no association. Further assessment exploring pair-wise ratios between metabolomic peaks revealed additional features significantly associated with prostate cancer prognosis. Conclusion: Untargeted metabolomic profiling of prostate cancer serum samples have identified a considerable number of molecular features strongly associated with disease prognosis. Further analysis is underway to identify these profiles molecular identity and to explore molecular pathways involved.

1190F

Analysis of TCGA patient and curated public genomic data identifies differentially regulated processes in breast cancer metastases. *R. Wisotzkey, A. Umesh, J. Park, J. Shima, J. Delaney, E. Kelly, E. Chiu, M. Shekar, I. Kupershmidt.* NextBio, 475 El Camino Real, Santa Clara, CA.

To identify biological processes involved in breast cancer metastases, public genomic data was analyzed using NextBio's Research platform. Meta-analysis of datasets comparing primary tumors that metastasized (M1) versus primary tumors that did not metastasize (M0) identified biological processes, or biogroups, that are significantly differentially regulated. For example, compared to primary tumors from M0 patients, tumors from M1 patients had upregulation of cell cycle-related genes, while those involved in the immune response and extracellular matrix were predominantly downregulated. Amongst the genes involved in the immune response, meta-analysis identified CCR7 and TRAT1 as two of the top-ranked differentially regulated genes, with a fold change of -5.6 and -3.0 in M1 versus M0 samples, respectively.

We then mined individual patient data from the TCGA breast cancer dataset using NextBio's Clinical platform for the expression of CCR7 and TRAT1. Meta-analysis results were corroborated in TCGA breast cancer patients, where those with M1 disease had downregulated CCR7 (p=1.5E-3) and TRAT1 (p=2.3E-2) compared to those with M0 disease.

Both CCR7 and TRAT1 have potential roles in tumor progression: CCR7 is a potential biomarker for metastasis of gastric cancer, and TRAT1 is associated with patient survival in melanoma patients. Our analysis adds support to these genes having a role in the progression of metastatic breast cancer.

Using NextBio's Research and Clinical platforms to analyze curated public genomic data, we demonstrate that metastatic and non-metastatic tumors can be differentiated based on gene expression patterns. We identify the immune response as one biological process that is important for breast cancer progression, and CCR7 and TRAT1 as specific genes within this category that may constitute a signature for metastatic breast cancer.

1191W

Extreme breast/ovarian cancer phenotypes in non BRCA1 & BRCA2 families of Greek ancestry. *F. Fostira, A.V. Stavropoulou, I. Konstantopoulou, D. Yannoukakos.* NCSR DEMOKRITOS, MOLECULAR DIAGNOSTICS LABORATORY, ATHENS, Greece.

During the last decade, mutations in more than 20 genes have been linked with hereditary breast/ovarian cancer. Despite that fact, BRCA1 & BRCA2 are still the reference genes of breast/ovarian cancer susceptibility. Mean age of onset in BRCA1 & BRCA2 carriers is around 42 years for most populations. However, there are cases diagnosed with breast cancer before the age of 30. We report three probands with extreme breast cancer phenotypes that were initially referred for BRCA1 & BRCA2 genetic testing. Two were diagnosed with breast cancer at the age of 24 and 25 respectively, while one was diagnosed with unilateral breast cancer at the age of 32. All three cases had extensive family history. In more detail, in the first family 9 individuals have been diagnosed with primary cancers (2 breast cancers-ages 24 and 27-, 2 bone cancers-ages 18 and 22-, 1 leukemia, 2 lung, 1 jaw, and 1 liver cancer) in three successive generations. In the second family, 6 individuals were diagnosed with 9 types of cancer. The proband was diagnosed with adrenal and breast cancer at the age of 1 and 25 years, respectively. Other family members were diagnosed with testicular, lung, osteosarcoma, bone, breast cancer and leukemia. All cancers manifested between the first and fifth decade of their life. The third family consisted of 2 sisters diagnosed with unilateral breast cancer at the age of 32 and breast cancer at the age of 37, while their mother developed ovarian cancer at the age of 34. The genetic background of this-at first glance-typical HBOC pedigree became more evident after the observation of melanin spots around the patients' lips and hands, which are one of the characteristic phenotypic features of Peutz-Jeghers syndrome.Genetic analysis revealed two TP53 pathogenic mutations, located on exons 8 and 6 of the gene respectively, and one STK11 pathogenic mutation, located on exon 1 of the gene.This is the first report of a complete characterization, clinical and genetic, of Peutz-Jeghers and Li-Fraumeni syndromes in Greece. Although both hereditary syndromes are individually rare, the underlying genetic defects can explain the breadth of extreme cancer phenotypic expressions, as well as the remarkable accelerated ages of onset. Moreover, in the following years, there will be a certain benefit from the genetic information as more targeted therapies will be available which can be used on the selection of the appropriate treatment for patients who are mutation carriers.

1192T

Modeling carcinogenesis in BRCA1 and BRCA2 heterozygous mammary epithelial cells. *M.E. Keith, M. Tenniswood.* Cancer Research Center, SUNY-University at Albany, Rensselaer, NY.

Mutations in the breast cancer susceptibility genes BRCA1 and BRCA2 account for half of all hereditary breast cancers, and are estimated to account for over 10% of the breast cancer burden in the US. The current standard of care for BRCA1 or BRCA2 mutation carriers is based on limited understanding of specific mutations, and thus treats all carriers as if they have the same relative risk for development of breast cancer. Several lines of evidence suggest that this is not true: BRCA1 and BRCA2 tumors have very different phenotypes, and specific mutations grant certain differential risk profiles for lifetime cancer incidence. Thus, we have created a novel model system of BRCA1 and BRCA2 heterozygous mammary epithelial cell lines, called MCK cells, from women opting for prophylactic mastectomy. These lines have been isolated from pre-neoplastic breast tissue that is not yet transformed. To date, we have collected 12 breast samples, with equal distribution between BRCA1 and BRCA2; this is the only model system which allows for comparisons between mutation sites within the BRCA genes.

The MCK cell lines are being immortalized for long-term use in cell culture. The effects of BRCA1 or BRCA2 mutation and the impact of different mutations within each gene on DNA repair and transformation will be assessed using these immortalized lines. Ionizing radiation is used as a DNA damaging agent, in order to mimic the effects of increased mammographic screening on BRCA mutation carriers. We will also examine the impacts of common dietary chemopreventive agents, such as vitamin D and EGCG, on growth and transformation in the MCK cell lines.

Our MCK panel of mammary epithelial cell lines will fill an immediate need in hereditary cancer research. The ability to compare and contrast mutations in differing sites within each gene will allow us to make more focused recommendations to BRCA mutation carriers, depending on the location of their particular mutation. In this way, we hope to “personalize” the management and treatment of BRCA1 and BRCA2 mutations, to enhance the quality of life of women who harbor deleterious mutations.

1193F

Integrated transcriptional and functional screening identifies novel regulators of lymphoid lineage determination. *E. Laurenti[1], S. Doulatov[1], I. Plumb[1], M. Doedens[1], C. April[2], J.B. Fan[2], J. Dick[1].* 1) Ontario Cancer Institute, Princess Margaret Hospital, University Health Network,, Toronto, Ontario, Canada; 2) Illumina Inc, San Diego, CA.

Introduction: The hematopoietic system is a highly regulated cellular hierarchy, responsible for the day-to-day production of mature blood cells which can be divided in two major lineages, myeloid and lymphoid. In contrast to mice, very few transcription factors (TFs) regulating early lineage decisions have been identified in human hematopoiesis. Materials and Methods: We previously demonstrated that single Multi-Lymphoid Progenitors (MLPs) retain the capacity to differentiate into all lymphoid cell types as well as monocytes and dendritic cells, indicating that molecularly, the choice between any of these fates must be determined at this stage. To identify TFs responsible for lymphoid vs. myeloid commitment, we interrogated MLP gene expression in the context of a high-resolution transcriptome analysis of 10 human hematopoietic stem and progenitor populations. Consistent with their multipotentiality, MLPs displayed balanced stem, lymphoid and myeloid transcriptional programs. We then used a combination of computational approaches to extract 10 lineage-modulating TFs, the function of which we tested in a knock-down screen based on a novel clonal assay for simultaneous read-out of B, NK and myeloid cell. Results: Altered cell fate decisions from single MLPs, in particular decreased commitment towards the B cell lineage, were observed upon knock-down of half of our candidates. Interestingly, 4 of these (BCL11A, BCL6, EBF1, SOX4) have been so far implicated in later stages of murine B cell development, suggesting that these TFs not only contribute to maturation of B cells, but also favor initial commitment. Preliminary data also provides the first report for a function of TEAD1, a transcriptional mediator of the Hippo pathway, in a hematopoietic context. In summary, we have developed a genome-wide strategy which successfully identified novel regulators of adoption of human lymphoid fate in primary human cells.

microRNA in biofluids - robust biomarkers for disease, toxicology or injury studies - The case of minimally invasive colorectal cancer detection. *P. Mouritzen, T. Blondal, D. Andreasen, N. Tolstrup, M.W. Teilum, A. Baker, S.J. Nielsen.* R&D, Exiqon A/S, Vedbaek, Greater Copenhagen, Denmark.

microRNAs represent the most well described class of small RNAs (21–23nt) and have been shown to function as post-transcriptional regulators of gene expression. The high relative stability of microRNA in common clinical source materials (e.g. FFPE blocks, plasma, serum, urine, saliva, etc.) and the ability of microRNA expression profiles to accurately classify discrete tissue types and specific disease states have positioned microRNA quantification as a promising new tool for a wide range of diagnostic applications. Furthermore microRNAs have been shown to be rapidly released from tissues into the circulation with the development of pathology. We are currently screening for and validating microRNAs as biomarkers for cancer with the aim of developing minimal invasive tests that may be applied in early detection population screens. Procedures have been developed to control pre analytical variables, for quality checking and qualifying biofluid samples in particular serum and plasma but also urine and other biofluids. In this process we have developed a genome-wide LNA™-based microRNA qPCR platform with unparalleled sensitivity and robustness even in biofluids where microRNA levels are extremely low. Only a single RT reaction is required to conduct full miRNome profiling thereby facilitating high-throughput profiling in important clinical sources without the need for pre-amplification. Thousands of biofluid samples have been profiled including blood derived plasma/serum and urine to accurately determine normal reference ranges for circulating microRNAs in several biofluids. This has allowed development of qPCR panels containing the relevant subset microRNAs present in various biofluids together with tissue specific microRNA markers. The panels will support development of robust biomarkers in disease, as well as toxicology and injury studies. An extensive QC system has been implemented in order to secure technical excellence and reveal any unwanted bias in the dataset. We will demonstrate individual behaviour of serum and plasma, with a focus on how hemolysis and cellular contamination can affect miRNA profiles. Furthermore, we will demonstrate that when close attention is focussed on these important pre-analytical parameters the system can be quickly and robustly applied in biomarker discovery and validation projects using the specific case of colorectal cancer early detection in blood.

1195T

Detection of KRAS, BRAF, NRAS and PIK3CA cancer markers by castPCR technology. *J. Au-Young[1], D. Keys[2], B. Ching[2], M. Mouanoutoua[2], D. Merrill[1].* 1) Medical Sciences, Life Technologies, Foster City, CA; 2) Genetic Analysis, Life Technologies, Foster City, CA.

Mutation detection is becoming increasingly important for making therapeutic decisions in oncology. Companion diagnostic tests can dictate whether cancer drugs such as tyrosine kinase inhibitors (TKIs) will be effective. Efficacy of TKIs is dependent on the presence of activating EGFR mutations. However, efficacy of TKIs is also dependent on absence of activating KRAS mutations as well as absence of EGFR drug resistance mutations. Thus, mutation detection tools are needed that have high sensitivity and high specificity. DNA sequencing and standard genotyping are limited to 5–20% sensitivity for detecting mutations in tumor samples. We have recently developed TaqMan® Mutation Detection Assays using competitive allele specific TaqMan® PCR (castPCR) technology for cancer mutation research. We have previously established that castPCR can detect mutations in the background of wild type with results that show the technology can robustly detect mutations as low as 0.1% with >99% concordance to other technologies including PCR-based technology and sequencing. The high sensitivity enables 10 copies of a specific mutation to be detected in excess of 10,000 copies of wild type gDNA from FFPE tumor samples. KRAS, BRAF, NRAS and PIK3CA exon 20 mutations are associated with low response rates to several chemotherapeutic drugs. In this study, we tested the sensitivity of castPCR for absence of mutations and confirmation of wild type by measuring the ratio or relative percentage of wild-type to mutant allele. We show that castPCR can be used for confirmation of wild type alleles in the absence of specific mutant alleles of KRAS, BRAF, NRAS and PIK3CA. The results obtained by castPCR assays will also be compared to those reported by standard DNA sequencing methods. Our data will demonstrate how castPCR technology can discriminate the mutated vs. wild-type where confirmation of wild type status may predict likelihood of response to targeted therapies.

Identifying the Causes of Dyskeratosis Congenita: the Prototypical Telomere Biology Disorder. *S.A. Savage, N. Giri, B. Ballew, B.P. Alter.* Div Cancer Epidemiology & Genetics, Natl Cancer Inst, Bethesda, MD.

Dyskeratosis congenita (DC) is an inherited bone marrow failure syndrome (IBMFS) caused by germline defects in telomere biology. The classic triad of dysplastic nails, skin pigmentation, and oral leukoplakia is diagnostic. Individuals with DC are at very high risk of bone marrow failure (BMF), leukemia, myelodysplastic syndrome, and head/neck cancers. Esophageal or urethral stenosis, liver disease, pulmonary fibrosis, developmental delay, and other medical conditions may be present. The clinical consequences manifest at variable ages and in different patterns, even within the same family. Leukocyte telomere lengths <1st percentile for age are diagnostic of DC. The inheritance of DC is variable with X-linked (*DKC1*), autosomal dominant (*TERC, TERT,* or *TINF2*), and autosomal recessive (*NOP10, NHP2*, or *WRAP53*) inheritance patterns. Our IRB-approved longitudinal cohort study of DC includes detailed medical record review, comprehensive questionnaires, and thorough evaluations at the NIH Clinical Center (CC) of affected individuals and their relatives. To date, 56 families with DC have enrolled, including 83 affected, and 204 unaffected relatives. Individuals with short telomeres and features similar to, but not diagnostic of DC, who lack a DC-associated mutation, are classified as DC-like. There are currently 19 DC-like families consisting of 24 affected and 48 unaffected individuals. DC-like families are re-classified as DC if a mutation is identified. Sixty-eight % of DC and 42% of DC-like families have been evaluated at the NIH CC. All probands are tested for germline mutations after genetic education and counseling. A total of 58% of families had a mutation in a DC-associated gene, comprised of 20% *DKC1*, 14% *TINF2*, 12% *TERT*, 9% *TERC*, and 3% *WRAP53*. No mutations were identified in *NOP10* or *NHP2*. Exome sequencing is underway in the mutation-negative DC and DC-like families. We combine clinical features with telomere length data to determine the likely inheritance pattern. Variants are called using a custom-calling algorithm and filtering is based on the expected modes of inheritance. Technical validation of rare variants (<1% in 1000 Genomes and other databases) is performed to rule-out false positive findings. Several variants in biologically plausible genes are currently being evaluated. In addition, genotype-phenotype analysis is ongoing in DC and the spectrum of overlapping telomere biology disorders.

Germline *BAP1* mutation - Additional case report and expanding clinical phenotype. *R. Pilarski[1], C.M. Cebulla[2], T. Rich[3], L. Strong[3], M.H. Abdel-Rahman[1,2].* 1) Clinical Cancer Genetics, Ohio State Univ, Columbus, OH; 2) Dept. of Ophthalmology, Ohio State Univ, Columbus, OH; 3) Clinical Cancer Genetics, U. of Texas M.D. Anderson Cancer Center, Houston, TX.

Objective: We studied a family with three cases of uveal melanoma (UM), three cases of mesothelioma, and multiple relatives with other cancers for mutations in the *BAP1* gene, which has recently been shown to cause hereditary UM, mesothelioma and other cancers. Results: We identifed a heterozygous germline truncating mutation (p.Q684*) in *BAP1* in two family members and four obligate carrier relatives, supporting the causative role of BAP1 in this family's cancers. We review the literature on reported cases, summarize the expanding spectrum of hereditary cancers associated with germline *BAP1* mutations, and suggest management recommendations for mutation carriers. Conclusion: Germline *BAP1* mutations cause a new hereditary syndrome which predisposes patients to an increasing spectrum of cancers, including UM, cutaneous melanoma and atypical melanocytic lesions, mesothelioma, lung carcinoma, meningioma, and probably other cancers. Our results indicate that *BAP1* testing is indicated in high risk families with UM, mesothelioma, and a range of other cancers.

Detection of human breast cancer gene fusions from RNA-sequencing analysis of formalin-fixed paraffin-embedded (FFPE) tissue specimens. *Y. Ma, J. Stephans, R. Ambannavar, J. Jeong, J. Morlan, A. Dei Rossi, M. Liu, D. Sinicropi, J. Baker, K. Qu.* Genomic Health Inc., Redwood City, CA.

A fusion gene is a hybrid created by the conjoining of two previously separate genes as a result of genomic aberrations. Oncogenic fusion genes such as BCR-ABL1 in chronic myelogenous leukemia, and TMPRSS2-ERG in prostate carcinogenesis are believed to drive disease pathology. Fusion genes may up-regulate expression of oncogenic genes by fusing a strong promoter to an oncogene. While gene fusions are most common in hematologic malignancies, with the advent of next-generation sequencing technology, rare gene fusion events, such as KIF5B-RET in lung adenocarcinoma, have now been identified in common solid tumors. The identification of rare gene fusions promises to play an important role in personalized cancer treatment decisions. Capability to detect gene fusions in formalin-fixed paraffin-embedded (FFPE) tissue would facilitate their assay in commercial laboratory settings, as it is the standard clinical practice to create FFPE tissue specimens from biopsies and surgical resections. Using a novel bioinformatics approach we have examined FFPE RNA-sequencing datasets from two breast cancer cohorts of 136 and 77 patients and detected multiple gene fusion events at base-pair resolution. These fusion transcripts may result from genomic rearrangements or transcript level rearrangements such as trans-splicing. A large portion of the identified fusion genes have been experimentally validated. These results demonstrate the power of next-generation sequencing as a tool for biomarker discovery in FFPE tissues.

Analysis of quantitative trait loci (eQTLs) in pancreatic cancer by RNA sequencing. *H. Parikh[1,2], J. Jia[1,2], W. Xiao[3], I. Collins[1,2], J. Hoskins[1,2], J. Powell[3], S. Thorgeirsson[4], J. Shi[5], G. Petersen[6], L. Amundadottir[1,2].* 1) Laboratory of Translational Genomics, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD 20877, USA; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD 20877, USA; 3) Bioinformatics and Molecular Analysis Section, Division of Computational Bioscience, Center for Information Technology, National Institutes of Health, Bethesda, MD 20892, USA; 4) Laboratory of Experimental Carcinogenesis, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD 20892, USA; 5) Biostatistics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD 20877, USA; 6) Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55905, USA.

Pancreatic cancer is the fourth leading cause of cancer mortality in the U.S. Recent genome-wide association studies (GWAS) have identified four genomic regions associated with pancreatic cancer risk in populations of European ancestry on chromosomes 1q32.1, 5p15.33, 9q34.2 and 13q22.1. To explore the genetic mechanisms underlying natural variation in gene expression in the pancreas and their relationship to pancreatic cancer risk variants, we are conducting expression quantitative trait loci (eQTLs) analysis in normal and tumor derived pancreatic tissue samples. We performed massively parallel sequencing to catalog the transcriptome of 50 normal or tumor derived human pancreatic tissues. The median number of paired end reads (100 bp) was 124.4 M (58.1 to 203.6 M). Reads were mapped to the RefSeq database (National Center for Biotechnology Information (NCBI) build 37) using the Burrows-Wheeler Aligner (BWA) software. Reads that failed to map to RefSeq were mapped to the Ensembl database and then to the human genome assembly (NCBI build 37). Gene expression was calculated as tag counts. The EDASeq package was used to perform full-quantile normalization to adjust for differences between lanes and GC correction was performed. Blood derived DNA from the same subjects was genotyped using either the Illumina Omni1 or OmniExpress chips. As a first step in our eQTL analysis, we selected genes within 2 MB up- and downstream of the most significant SNPs in each of the four regions and analyzed SNPs in a region from 500 kb up- and downstream of the four above mentioned genomic regions associated with pancreatic cancer risk. We performed linear regression analysis between gene tag counts and SNP genotypes after correcting for age and sex. We identified 125 *cis*-eQTLs for chromosome 1q32.1, 2,757 *cis*-eQTLs for chromosome 5p15.33, 3,999 *cis*-eQTLs for chromosome 9q34.2 and 629 *cis*-eQTLs for chromosome13q22.1 with nominal *P*-value < 0.05. Together these results offer a unique picture of the functional aspects of pancreatic cancer risk loci. We plan to extend our analytical approach to identify *cis*- and *trans*-eQTLs at a genome-wide level which will provide a comprehensive resource for understanding regulatory variation in pancreatic tissues.

1200W

Identification of fusion transcripts and copy number variations in acute lymphoblastic leukemia by next generation RNA- and DNA sequencing. *M. Bonin[1], C. Schroeder[1], M. Sturm[1], U. Pflückhahn[2], M. Feldhahn[3], O. Kohlbacher[3], H.G. Rammensee[4], P. Lang[2], O. Riess[1], P. Bauer[1], M. Walter[1].* 1) Medical Genetics Department, University Tuebingen, Tuebingen, Germany; 2) Department of Hematology/Oncology, University Children's Hospital, Tübingen, Germany; 3) Applied Bioinformatics, Center for Bioinformatics and Quantitative Biology Center, University of Tübingen, Tübingen, Germany; 4) Department of Immunology, Tübingen, Germany.

Acute lymphoblastic leukemia (ALL) represents a highly heterogeneous entity on the basis of diverse cyto- and molecular genetic alterations with considerable influence on prognosis and therapeutic decisions. The different subtypes are characterized by different clinical features and specific laboratory findings. Recent clinical trials have confirmed the important impact of the underlying biology of each subtype for clinical outcome. Optimal therapeutic conditions are based on specific classification of the acute leukemia subtype at diagnosis and are guided by exact and sensitive quantification of minimal residual disease during complete hematologic remission. To gain new insights in ALL, e.g. by mutation load and modified pathways, we performed Exome- and RNA-sequencing methods using Illumina next generation sequencing technologies. Chromosomal Translocations and fusion transcripts have been a class of mutations in ALL. The development of RNA-sequencing methods provides an opportunity for deep characterization of cancer cell transcriptomes and exomes and the discovery of fusion transcripts arising from genomic rearrangements. Twelve patient samples (tumor cells and fibroblasts) were selected. All samples were characterized by a pathologist. From all samples RNA and DNA were extracted and analyzed by using 76nt paired-end reads with Illumina technologies. We identify 64 novel fusion transcripts in the 12 ALL samples. Supported by the GeneFuse algorithm, we were able to validate 51/64 (80%) fusion transcripts by qRT-PCR and Sanger-Sequencing. Most fusion transcripts were associated with Copy number transitions and were partially common in highly amplified DNA regions. Around 20% of the fusion transcripts partners have either been previously detected in oncogenic gene fusions, or reported by pathway analysis to be oncogenic. The results indicating that RNA-sequencing opens a great opportunity for discovering novel fusion transcripts in ovarian cancer and we are now able to analyze the impact of this alteration for the growth and resistance mechanisms of cancer cells.

Admixture Rate Estimation and Post-Call Correction for Complete Genomics Matched Tumor-Normal Whole Genome Sequencing data. *M. Chen[1,3], Z. Omay[2,5,6], A. Serin[2,5,6], M. Gunel[2,5,6], H. Zhao[1,2,4].* 1) Yale Center for Statistical Genomics and Proteomics,Yale University, New Haven, CT; 2) Department of Genetics,Yale University, New Haven, CT; 3) Program of Computational Biology and Bioinformatics,Yale University, New Haven, CT; 4) Departments of Epidemiology and Public Health,Yale University, New Haven, CT; 5) Department of Neurosurgery, Yale University School of Medicine, New Haven, CT; 6) Department of Neurobiology, Yale University School of Medicine, New Haven, CT.

Whole genome and exome sequencing of matched tumor-normal sample pairs is becoming routine in cancer research. The platforms of two companies, Illumina and Complete Genomics (CG), have become particularly commonplace, and >90% of the complete human genome sequences reported thus far have been sequenced using these platforms. However, most of current methods have been developed to analyze sequencing data generated on Illumina and similar instruments. Due to its novel gapped read technology and relative inaccessibility of data analysis pipeline, few studies have been designed either for CG data analysis or post-call improvement. In this study, we try to address three major questions: (1) Is there any CG platform-specific bias in somatic event calling? (2) What statistics can be used for sample quality diagnostics? (3) How to improve somatic events calling (especially CNV calls) by correcting effect of contaminated or impure samples? We have found that empirical joint distribution of tumor/normal genotype and somatic LAF(lesser Allele Frequency) are robust statistics that can be used for CG sample quality diagnostics. Admixture rate can be estimated from neutral LOH regions, which are identified based on CNV calls and LOH SNP calls. Estimated admixture rate can be further validated by somatic LAF in copy neutral regions. We're now developing methods to correct CNV calls and build additional quality control filter based on estimated admixture rate.

Transcriptome analysis of blast cells of patients with acute lymphoblastic leukemia in diagnosis and relapse. *M.A. Chiabai[1], G.R. Fernandes[1], L.H.T. Sakamoto[2], R. Pogue[1], R.W. Pereira[1].* 1) Ciências Genomicas e Biotecnologia, Universidade Católica de Brasília, Brasília, DF, Brazil; 2) Núcleo de Oncologia Pediátrica, Hospital de Apoio de Brasília, Brasília, DF, Brazil.

The transcriptome analysis using RNA-seq is a powefull tool for characterization of transcript levels and alternative splicing. RNA-seq analysis comparing patients with acute lymphoblastic leukemia (ALL) in diagnosis and at the relapse offers the potential to study the differences occurring between the two events. Acute lymphoblastic leukemia is the most common type of childhood cancer, corresponding to 25% of all cancers appearing in children. In this study we performed the RNA-seq analysis of transcriptome of two patients with diagnosis of ALL using the blats of the bone marrow collected at the diagnosis of the disease and at the relapse. The two patients has ALL-T and has the same immunophenotype of the blasts at the diagnostics and relapse. Paired-end RNA-sequencing was performed in separate four lanes. About 40 millions of reads were obtained for the samples on each lane, with 200x coverage. Sequences were mapped to the human genome and genomic analysis of genomic features was performed using several computational methods. Was identified 8055 differently expressed genes (DEGs) between the diagnosis and the relapse present in both patients; and 13057 SNPs, being 1725 SNPs validated in dbSNP and 11332 SNPs not validated. These results provide the transcriptome variation level between the diagnosis and the relapse of ALL, providing important clues to understand the molecular mechanisms of the ALL disease.

1203W

Comprehensive Germline Susceptibility Variant Discovery in Ovarian Cancer Using Exome Sequencing Data. *L. Ding, K. Johnson, K. Kanchi, M. Mclellan, C. Lu, Q. Zhang, D. Koboldt, C. Kandoth, T. Graubert, T. Ley, E. Mardis, R. Wilson.* The Genome Center, Washington University School of Medicine, St. Louis, MO.

Large-scale cancer genomics projects such as The Cancer Genome Atlas (TCGA) are producing a wealth of high throughput sequence data from a large number of cancer samples and their matched normals. These data hold great promise for discovering somatic changes that give rise to cancer and also for understanding the genetic basis of cancer susceptibility. We have analyzed germline alterations, including single nucleotide variants, insertions and deletions (indels), and copy number variations, in 429 TCGA ovarian cancer cases using both exome sequencing and SNP array data. Our analysis of 672 cancer genes identified 155 truncational variants from 133 cases in 55 genes. Comparison to the background truncational rate in human genomes from the 1000 genomes project indicated a significantly increased frequency of truncations in a few well-known ovarian susceptibility genes such as BRCA1, BRCA2, PALB2, CHEK2, PMS2, and BRIP1, as well as several novel genes such as NOTCH2, SBDS, SMO, CNTLN, FANCD2, and PCSK7. Tofurther explore additional novel germline susceptibility genes and pathways, we examined whether there was a significantly higher frequency of in silico predicted deleterious germline missense variants in TCGA ovarian cancer cases compared to non-case subjects who were part of the 1000 genomes and the NHLBI exome sequencing projects using a pooled burden test. Finally, we investigated the interaction between germline susceptibility variants and somatic mutations and found that genes bearing germline susceptibility variants were more likely to be somatically mutated and that truncationalgermline variants had a high tendency of undergoing loss of heterozygosity in the tumor. The systematic analysis of the ever-growing large-scale cancer sequencing data from various cancer types will facilitate the understanding of germline susceptibility variants in cancer.

1204T

Whole-exome sequencing of four patients with critera of familial hyperplastic polyposis. *C. Garrec[1,2], S. Küry[1], P. Lindenbaum[3], V. Vidal[4], F. Airaud[1], J. Chettrit[5], E. Cauchin[2], J.F. Mosnier[2], S. Bézieau[1,2].* 1) Service de génétique médicale, CHU Nantes, Nantes, France; 2) Université de Nantes, Faculté de Médecine, EA 4273 Biométadys, Nantes, France; 3) INSERM, UMR1087, L'institut du Thorax, Nantes, France; 4) Imaxio, Biopôle Clermont-Limagne, Saint-Beauzire, France; 5) Institut d'Histo-Pathologie, Nantes, France.

Background: Hyperplastic polyposis (HP) is a rare condition characterized by multiple or large hyperplastic polyps in the large intestine, typically with proximal localization, and associated with increased risk of colorectal cancer *via* the evolution of lesions through the serrated pathway of carcinogenesis. Some cases of familial hyperplastic polyposis have been described, but the familial transmission of this entity has not been elucidated by now. **Purpose:** We sought genes potentially responsible for familial transmission of HP by comparing exome sequences from constitutional and somatic DNAs. **Methods:** Four patients were selected, who fulfilled the diagnostic criteria of hyperplastic polyposis according to the WHO Classification of digestive tumours (2000). They showed either family history of HP and/or colorectal cancer, or early onset at disease. We assessed the carcinogenesis pathway involved by morphological characterization, immunohistochemistry and molecular biology analysis. Whole-exome sequencing was conducted on both DNA derived from blood samples and DNA extracted from FFPE (Formalin-fixed paraffin-embedded) hyperplastic polyps and sessile serrated adenomas. Genomic DNA was enriched for coding region using SureSelectXT Human All Exon v4 (Agilent technologies, Inc., Santa Clara, USA), and paired-end sequencing was realized with Genome Analyzer IIX (Illumina, Inc., San diego, USA). Reads were aligned on the hg19 reference using CASAVA software. KNIME software enabled us to apply several successive filters in order to identify functional variants. **Results:** Molecular phenotypes of hyperplastic polyps were consistent with the serrated pathway of carcinogenesis. Constitutional exome sequencing enabled us to select a preliminary list of 137 candidate genes, among which several strong candidates with relevant function to carcinogenesis. This first list will be refined using somatic exome sequencing, to identify tumor suppressor genes with a double hit event. These final results will be presented at the ASHG meeting.

1205F

RAD51 paralogs mutation screening in breast and ovarian cancer families. *L. Golmard[1], V. Caux-Moncoutier[1], G. Davy[1], E. Al Ageeli[1], B. Poirot[1], C. Tirapo[1], D. Michaux[1], C. Barbaroux[1], C. Dubois d'Enghien[1], L. Castéra[1], M-H. Stern[1,2], C. Houdayer[1,3], D. Stoppa-Lyonnet[1,2,3].* 1) Service de Génétique Oncologique, Institut Curie, Paris, France; 2) Unité INSERM U830, Institut Curie, Paris, France; 3) Université René Descartes, Paris, France.

Most currently known breast cancer susceptibility genes play a role in DNA repair. Recently, genetic studies were conducted on RAD51 paralogs, involved in homologous recombination repair. Germline mutations conferring breast and ovarian cancer susceptibility were published in RAD51C and RAD51D. Then, mutations in XRCC2 were identified in breast cancer families. No pathogenic mutation was found in RAD51B and XRCC3. We analyzed the five RAD51 paralogs (RAD51B, C, D and XRCC2, 3) in 142 breast and ovarian cancer family cases with no BRCA1/2 mutation. Our cohort was enriched in ovarian family cases since RAD51C and RAD51D mutations were detected essentially in ovarian cancer families. Mutation screening was performed on genomic DNA by EMMA (Enhanced Mismatch Mutation analysis). Detected variants were characterized by sequencing analysis. We found 1 splicing mutation and 1 missense variant in RAD51B (IVS05+3A>G and p.Arg159Cys), 2 splicing mutations in RAD51C (IVS04-2A>G and IVS08+5_IVS08+7del) and 1 missense variant in RAD51D (p.Ser-207Leu). We found no mutation in XRCC2 and XRCC3. Splicing alterations were confirmed by mRNA analysis for the two RAD51C mutations, resulting in exon skipping. No RNA was available to study the RAD51B splicing mutation IVS05+3A>G but this substitution is likely to be deleterious since it is located close to the consensus splice donor site and alters splicing in silico. Splicing reporter minigene assay are planned to confirm its effect on splicing. RAD51B missense variant p.Arg159Cys is likely deleterious: it changes a basic amino acid to an hydrophobic one, in a highly conserved functional domain and it is predicted deleterious in silico. As previously described, RAD51C mutations were detected in breast and ovarian cancer family cases. RAD51B IVS05+3A>G was found in a woman who had a breast cancer at 34 years and a 3rd degree relative with an ovarian cancer at 29 years. Interestingly, RAD51B p.Arg159Cys was found in a family with three breast cancer cases without ovarian cancer. To our knowledge, this is the first report of a deleterious RAD51B mutation in a breast and ovarian cancer family. Our study also confirms RAD51C as a breast and ovarian cancer susceptibility gene. Since RAD51 paralogs mutations frequency is low, this screening should be performed in larger different populations to better estimate their penetrance and their contribution to breast versus ovarian cancers, and establish clinical guidelines.

***MLH1*, *MSH2* and *MSH6* mutations identified by DNA sequencing and MLPA analysis: Experience from the colon Cancer Family Registry (CFR).** *S.R. Gunawardena[1], M.S. DeRycke[2], N.M. Lindor[3], M.A. Jenkins[4], J.L. Hopper[4], D.D. Buchanan[5], S. Gallinger[6], P. Newcomb[7], L. LeMarchand[8], R.W. Haile[9], S.N. Thibodeau[1], Colon Cancer Family Registry.* 1) Department of Laboratory Medicine & Pathology, Mayo Clinic, Rochester, MN; 2) Department of Health Sciences Research, Mayo Clinic, Rochester, Minnesota, USA; 3) Department of Health Science Research, Mayo Clinic, Scottsdale, Arizona, USA; 4) Center for Molecular, Environmental, Genetic, and Analytic Epidemiology, The University of Melbourne, Melbourne, Victoria, Australia; 5) Cancer and Population Studies Group, Queensland Institute of Medical Research, Herston, QLD 4006, Australia; 6) Cancer Care Ontario, Mount Sinai Hospital, Samuel Lunenfeld Research Institute, University of Toronto, Ontario, Canada; 7) Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, Washington, USA; 8) Epidemiology Division, University of Hawaii Cancer Center, Honolulu, Hawaii,; 9) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, California, USA.

Colorectal cancer (CRC) is the third most common cancer in both men and women and is responsible for the second largest number of cancer deaths in the US. Most CRC cases are sporadic, but 10–30% are familial and 4–5% are hereditary. The most common form of hereditary CRC, Lynch Syndrome, is caused by a germline mutation in an MMR gene (*MLH1*, *MSH2*, *MSH6*, or *PMS2*). Baseline molecular studies for the Colon CFR, an international resource for studies on the etiology of CRC, included testing of tumor tissue for the presence of defective DNA mismatch (dMMR) repair as assessed by tumor microsatellite instability or loss of protein expression by immunohistochemistry. Studies also included testing for the presence of germline mutations in *MLH1*, *MSH2*, *MSH6* and *PMS2* among selected patient groups. Cases in Group 1 had evidence of dMMR and were tested for mutations in the gene demonstrating loss of protein expression in the tumor. Cases in Group 2 had no available tumor tissue for study and were tested directly for mutations in *MLH1*, *MSH2*, and *MSH6*. Cases in Group 3 had relatives with a mutation in any of the MMR genes and were tested for the identical mutation. Mutation analysis was performed by conventional Sanger sequencing and MLPA to detect large insertion/deletions. Polymorphic variants were excluded and the remaining variants were classified as either deleterious (nonsense, frame shift, and splice site) or as variants of uncertain significance (VUS). Of 446 individuals tested in **Group 1**, 32% (93 of 295), 66% (78 of 119) and 56% (18 of 32) were positive for a variant in *MLH1*, *MSH2*, and *MSH6* respectively. Of 208 individuals tested in **Group 2**, 10% (21 of 208) were positive for *MLH1*, 9% (20 of 208) for *MSH2* and 11% (22 of 208) for *MSH6*. Finally, of 1327 individuals tested in **Group 3**, 33% (217 of 661), 29% (143 of 489) and 37% (66 of 177) of cases were positive for *MLH1*, *MSH2* and *MSH6* respectively. Results indicate that a mutation was not identified in a substantial fraction of all three MMR genes, suggesting that these may lie in regions not detected by conventional methods. One reason for the lower than expected positive results for *MLH1* is the presence of sporadic cases resulting from promoter hypermethylation, these cases were not excluded from this study. The reduction of positive cases in Group 2 compared to Group 1 highlights the value of IHC analysis to focus on which gene to test. A description of variants identified will be presented in more detail.

1207T

Whole-Exome Sequencing of a Rare Case of Familial Childhood Acute Lymphoblastic Leukemia. *J. Healy[1], C. Richer[1], J.F. Spinella[1], V. Saillour[1], R. Vidal[1], E. Bareke[1], S. Busche[2,3], B. Ge[3], T. Pastinen[2,3], D. Sinnett[1,4].* 1) Department of Hematology-Oncology, CHU Sainte-Justine Research Center, Université de Montréal, Montreal, QC; 2) Department of Human Genetics, McGill University, Montreal, QC; 3) McGill University and Genome Quebec Innovation Centre, Montreal, QC; 4) Department of Pediatrics, Faculty of Medicine, Université de Montréal, Montreal, QC, Canada.

Familial childhood acute lymphoblastic leukemia (ALL) is extremely rare and to date no leukemia susceptibility gene has been identified to explain this uncommon occurrence. We postulated that pure (non-syndromic) familial childhood ALL could result from the accumulation of disadvantaging rare DNA variants in predisposing genes or biological pathways. To address this hypothesis, we used next-generation sequencing technologies to deep-sequence the whole-exomes of a family consisting of two male non-twinned affected siblings and their parents. Using Agilent's SureSelect target enrichment system and the SOLiD 4 platform, we captured and sequenced a total of 29.5 Gb for the entire family, with a mean capture specificity of 97% and coverage >35X. In total, we identified 29,651 germline variants in sibling A that met our filtering criteria and 32,728 in sibling B, of which 1,847 (6.2%) and 1,823 (5.6%), respectively, were novel. We investigated non-synonymous homozygous and compound heterozygous positions shared between the siblings, as well as genes/pathways with increased burden of rare non-synonymous variants, and identified a combination of rare missense variants in *SLX4* (compound heterozygote at rs137976282 and rs79842542) and *GEN1* (homozygote variant at rs16981869). Both genes play a crucial role in resolving Holliday junctions originating from replication and recombination intermediates and from DNA damage. Deep re-sequencing of 30 additional childhood ALL quartets (matched normal-tumor, mother and father) and genotyping in a validation cohort of over 300 cases and controls confirmed that the affected-sibs are the only patients that carry this combination of predicted damaging missense variations. Through functional validation studies that are currently underway, we will be able to substantiate the role of these variants in childhood leukemia onset and show that concomitant inheritance of these rare variants in *SLX4* and *GEN1*, could lead to increased DNA damage and chromosomal instability, and thus play a key role in driving leukemogenesis in these siblings.

1208F

Comprehensive BRCA1 and BRCA2 Mutational Profile in Lithuania. *R. Janavicius, V. Rudaitis, L. Griskevicius.* VUH Santariskiu Clinics, Vilnius, VNO, Lithuania.

BACKGROUND. The germline mutations in BRCA1/2 genes are the most significant and well characterized genetic risk factors for breast and/or ovarian cancer. Detection of mutations in these genes is an effective method of cancer prevention and early detection. Different ethnic and geographical regions may have different BRCA1 and BRCA2 mutation spectrum and prevalence due to founder effect. The population of Lithuania has over several centuries undergone limited mixing with surrounding populations and is mostly of indigenous Baltic origin, which is different from Slavs. The aim of our study was to asses full BRCA1/2 mutational profile in Lithuanian population. METHODS. We performed comprehensive mutation analysis of BRCA1/2 genes in 605 unrelated breast and/or ovarian cancer patients (with/without family history) and predictive unaffected patients (with family history) using high resolution melting (HRM) screening (Light Cycler 480/ Light Scanner 384) followed by direct sequencing (ABI 3500) and MLPA for large genomic rearrangements (LGRs). RESULTS. Overall, we have identified 25 different mutations (16 in BRCA1 and 9 in BRCA2 genes). Seven frequent pathogenious mutations in BRCA1 gene (c. 4035delA, c. 5266dupC, c.181T>G, c.1687C>T, c. 5258G>C, c.3700_3704del5, c.4789C>G, del 1–3ex) comprised 48%, 29%, 7,7%, 3,5%, 2,1%, 1,4% and 1,4% respectively of all BRCA1 mutations; a single BRCA2 mutation (c.658delGT) comprised 43% of all mutations in this gene. Five novel BRCA1 (c.4516delG, c.2481delA, c.5560delC, del 16–19ex, del 3–12ex) and 4 novel BRCA2 genes mutations (c.6408_6414del7, c.5701_5714del14, c.6410delA, c.6999insT) were identified; 3 different LGRs (del 1–3ex, del 16–19ex, del 3–12ex) were found in BRCA1. The most common c.4035delA (48% of all BRCA1/2 mutations) appears to be true Lithuanian (Baltic) founder mutation and haplotype data confirmed ancient origin of this mutation c.a. 62 generations ago. CONCLUSIONS. Characterization of BRCA1/2 mutational profile in Lithuania enabled to develop screening protocol using HRM for 8 common BRCA1/2 point mutations, which comprise 88% of all mutations detected in our country. This knowledge will provide more efficient approach for the individualization of genetic testing affordable for all breast/ ovarian patients and their relatives.

A broad re-sequencing study of 409 genes in NCI-60 cell lines using the Ion Ampliseq™ Comprehensive Cancer Panel and Ion PGM™ semiconductor sequencing reveals previously unreported cell line-specific mutations. *B.S.G. Kong[1], M. Shannon[1], I. Casuga[1], D. Joun[1], S.M. Chen[1], C.Y. Li[1], D. Ruff[1], R. Bennett[2]*. 1) Ion Torrent a part of Life Technologies, South San Francisco, CA; 2) Ion Torrent a part of Life Technologies, Carlsbad, CA.

Highly multiplexed PCR is quickly becoming the new template preparation paradigm for targeted re-sequencing studies because it allows investigators to interrogate hundreds of genes at once with greatly simplified workflows and reduced consumption of rare samples. At the forefront of this transformation is the Ion Ampliseq™ technology, which enables the selective amplification of 10s to 1000s of target sequences in a single multiplexed PCR and meshes seamlessly with the Ion semiconductor sequencing platform. Here we describe features and applications of the Ion Ampliseq™ Comprehensive Cancer Panel (CCP), which provides ready-access to hundreds of genes, making it ideal for broad targeted re-sequencing studies aimed at understanding inherited and somatically-acquired genetic variations in cancers. The panel employs approximately 16,000 primer pairs distributed across 4 pools to amplify the coding exons of 409 genes, including known oncogenes and tumor suppressor genes, and requires just 40ng of sample DNA. In this study, we applied the panel to the characterization of five NCI-60 cell lines (MCF-7, MDA-MB-231, DU-145, PC-3, SK-MEL-28) derived from breast, prostate, and skin cancers. The CCP includes 61 genes that have been sequenced in one or more of the cell lines in previous studies using Sanger sequencing methods. In this study, we confirmed the presence of previously reported mutations in these genes in the five cell lines. For the 348 additional genes that were evaluated with CCP, we found previously unreported mutations, including missense and non-coding mutations, in several of the genes. Taken together, these findings not only confirmed the presence of known mutations in the NCI-60 cell lines from previous surveys, but also uncovered cell line-specific mutations in genes only evaluated by CCP. The ability to examine more than 400 high-profile genes at once empowers researchers to realize a more complete picture of the genetic variation that underlies different cancer types.

Germline Sequencing for Aggressive Prostate Carcinoma. *D. Larson[1], D. Koboldt[1], E. Appelbaum[1], M. O'Laughlin[1], R. Fulton[1,2], J. Haslag-Minoff[4], I. Borecki[2,3], A. Kibel[6], R. Wilson[1,2,5], E. Mardis[1,2,5]*. 1) Washington Univ Sch Medicine, The Genome Institute, Saint Louis, MO; 2) 2Department of Genetics, Washington University, St Louis, MO, USA; 3) Division of Statistical Genomics, Washington University, St Louis; 4) Division of Urology, Washington University, St Louis, MO, USA; 5) Siteman Cancer Center, Washington University, St Louis, MO, USA; 6) 6Depart of Urology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Prostate cancer is the most common cancer in men and has the second highest cancer mortality rate in the U.S. Sixteen percent of men will be diagnosed with the disease, but only a fraction are believed to have disease which can cause harm. Upwards of 50% of patients diagnosed via PSA screening are likely to have indolent tumors that do not require treatment. Unfortunately, the ability to determine who had indolent disease is imperfect and patients are over and undertreated. Thus, determining the genetic mechanisms underlying risk for aggressive prostate cancer would allow for patient treatment to be tailored to likely disease severity. Recent work has demonstrated that rare variants in coding genes contribute to susceptibility to aggressive prostate cancer. To identify rare variants that, in aggregate, may influence susceptibility to aggressive prostate cancer, we have sequenced the exomes of 300 Caucasians (150 cases and 150 controls) and 271 African-Americans (122 cases and 149 controls). Here we present preliminary results for single nucleotide variants (SNVs) and small indels. We predicted over 250,000 SNVs that were novel to dbSNP and the 1000 Genomes Project in African Americans and over 150,000 in Caucasians. We examine the distribution of rare deleterious variants within the Cancer Gene Census list of known cancer genes. Testing on the number of rare variants in cases versus controls indicates a rare variant contribution to susceptibility in the TET2 tumor suppressor gene in African Americans, but not Caucasians. In addition, we see evidence that rare variants in SETDB1 and LIFR may play a protective role.

1211F

A next-generation sequencing diagnostic panel to test all cancer susceptibility genes. *S.S. Mahamdallie, E. Ruark, K.-W. Lau, A. Renwick, S. Seal, E. Ramsay, S. Hanks, J. Douglas, N. Rahman.* Division of Genetics & Epidemiology, The Institute of Cancer Research, Sutton, United Kingdom.

Extensive efforts are being directed towards using exome sequencing in clinical diagnostics, but there are considerable technical, analytical, logistical and financial hurdles that are currently not easily circumvented. By contrast, panels of select genes can offer cost and practical advantages and can provide data of diagnostic standard. A panel of all cancer susceptibility genes is ideally suited to this strategy as many genes predispose to multiple cancers and many cancers are associated with multiple genes. We have designed a custom pulldown panel that targets all 85 cancer predisposition genes, including 2649 probes targeting 1375 exons. We undertook a pilot study in 48 samples, 46 with mutations in one or more genes, and two controls (1 duplicate and 1 negative). There were 53 mutations in total, 40 base subs or small indels and 13 large exonic duplications/deletions. We generated data from a HiSeq; 101bp paired-end (PE) reads, 24 samples per lane, a MiSeq; 101 and 151bp PE reads, 12 samples per lane and we compared these data to 48 exomes (HiSeq, 6 samples per lane). Sequence reads were mapped, called and annotated using Stampy, Platypus and an in-house algorithm, respectively. The HiSeq data were excellent. Only 3 probes failed. Mean coverage was 906x and at 50x an average of 99% exonic bases were covered and 97% of 1375 exons passed (defined as at least 90% covered in 90% of samples). The MiSeq data were much better for 151bp than 101bp, but were inferior to the HiSeq. For 151bp reads the mean coverage was 116x and at 50x an average of 82% exonic bases were covered but only 47% of exons passed. In the exome data 25 exons were not targeted at all and at 50x only 24% of exons passed. Our software detected all base subs and small indels in the HiSeq data, but missed one in the MiSeq data. The exonic duplications/deletions were visible in the HiSeq data, though automated calling with acceptable sensitivity and specificity is challenging and currently under optimisation. With regard to practicality and cost, up to 384 samples on a HiSeq could be run in 25 days at a consumable cost of £100 per sample. For the MiSeq, two lanes of sequencing should give sufficient coverage, and could provide faster turnaround time for fewer samples, albeit at higher cost. Our data show that a diagnostic assay for all cancer susceptibility genes is realistic in the near future and will greatly increase the number of people that can benefit from cancer gene testing.

Background. Germline mutations in the proto-oncogene *MET* are responsible for hereditary papillary type 1 renal carcinoma. We describe the French National Cancer Institute renal cancer network experience for the detection and characterization of *MET* mutations. Methods: Since 2001, 108 index-cases were screened from all over France with a familial history of papillary renal cell carcinoma (RCC), multiple papillary RCC or early-onset RCC with papillary histology (under 50 year-old). Lymphocyte DNA was analyzed either dHPLC or qPCR-HRM and Sanger sequencing from exon 2 to exon 21. In 2 mutated cases, somatic molecular profiles from RCC were documented using CGH-array. Results. We found 6/108 index cases with the following causal and activating *MET* variants (p.His1112Arg x2, p.Val1236Ile, Val123-8Ile x2, p.Tyr1248Cys). Three cases belong to kindred with family history of RCC and 3 cases did not have any family history. The age of onset was from 36 (in one case) to over 50 year-old in 5 cases. All documented mutated patients had papillary type 1 RCC (P1RCC). The CGH-array profile obtained in two tumors from carriers identified the same pattern of autosomal trisomy 7 and trisomy 17. Fifteen index cases were identified with 11 rare unclassified variants : 4 intronics variants, 3 exonic variants at the proximity of the tyrosine kinase domain (p.Thr1010Ile x2, p.His1086Leu, p.His1097Arg), 1 within the tyrosine kinase domain (p.Ile1102Thr) and 4 in the SEMA domain (p.Glu168-Asp x2, p.Ile316Met x2, p.Ala347Thr, p.Asn375Ser). Three of them (p.His10-86Leu, p.His1097Arg) close to and within the tyrosine kinase (p.Ile1102Thr) were modelized as potentially causal and involved in papillary type 1 RCC. Discussion. Half of the germline *MET* mutations were identified in patients without any family history of renal cancer. The mean age of onset of P1RCC was not younger than in general population. Tumor characterization could help to better identified carriers with germline *MET* mutation, particularly in sporadic papillary type 1 RCC. The role of some potential causal variants should be further analyzed. Conclusion: Germline *MET* mutation screening should be proposed in the case of papillary renal carcinoma type 1 even with an age of onset superior to 50 years-old, with or without familial history.

Currently, only approximately 30% of the familial risk for breast cancer has been explained, leaving the substantial majority unaccounted for. Recently, exome sequencing has been demonstrated to be a powerful tool for identifying the underlying cause of rare Mendelian disorders. However, diseases such as breast cancer present substantially increased complexity in terms of locus, allelic and phenotypic heterogeneity, and relationships between genotype and phenotype. As part of a collaborative multiple-case breast cancer family exome capture followed by massively parallel sequencing project involving the Leiden University Medical Centre, the Spanish National Cancer Research Center and The University of Melbourne we identified a family with a protein-truncating and a family with a likely deleterious missense mutation in XRCC2. Based on the finding from exome sequencing, the rarity of these variants and the biochemical plausibility of XRCC2, we conducted two further studies in parallel: (i) Case-control mutation screening of XRCC2 and (ii) mutation screening of XRCC2 in a series of index cases from multiple-case breast cancer families. The population-based case-control mutation screening study identified six likely pathogenic coding variants in 1,308 early-onset breast cancer cases versus none in 1,120 controls (with severity grading, $P<0.02$). The additional mutation screening in 689 multiple-case families identified further families with protein-truncating or likely deleterious rare missense variants in XRCC2. Our identification of XRCC2 as a breast cancer susceptibility gene thus increases the proportion of breast cancers that are associated with homologous recombination DNA repair dysfunction and Fanconi Anemia and therefore could benefit from specific targeted treatments such as PARP inhibitors. This study demonstrates the power of massively parallel sequencing to discover susceptibility genes for common, complex diseases.

Prostate cancer (PC) is the most common male cancer in western societies. Although the variation of PC incidence results from several factors, a large body of literature strongly implicates a genetic etiology. Disease heterogeneity, however, has hampered efforts to identify PC susceptibility genes. Next-generation sequencing provides a powerful tool to uncover disease-causing mutations and, when combined with a family-based study design, increases the chances of finding rare mutations. We hypothesize that much of the “missing heritability” of PC is due to rare variants and that these can be identified using whole-exome sequencing (WES). The International Consortium for Prostate Cancer Genetics (ICPCG) is in the unique position of having identified and sampled the most informative high-risk PC pedigrees known throughout the world. We outline a three-stage study design developed by the ICPCG to identify PC susceptibility loci utilizing this extraordinary collection of families coupled with WES. In stage 1, WES is performed on ~575 familial cases of PC derived from 375 independent families: 3 cases/family from 100 families and 1 case/family from 275 families. Two complementary approaches are utilized for the initial data analysis: a family-based and a case-control analysis. The pedigree-based analysis avoids the potential complication from population stratification, while the familial case-control analysis avoids the complication of phenocopies in pedigree data. Those genes with variants that are most damaging (e.g., nonsense, frame-shift, splice site variants and selected other variants), those that co-segregate with PC within the tested families, and those that are found to be significantly more frequent among our familial cases compared to control data are then prioritized for further study. In stage 2, the top 1000 candidate genes identified in stage 1 are further analyzed by re-sequencing the coding regions in an independent set of 500 hereditary PC cases and 500 controls, ranking genes based on those containing multiple damaging variants, co-segregation with disease and allele frequency among cases compared to controls. In stage 3, the most likely PC susceptibility loci are identified by exon and intron re-sequencing of the top 100 ranked genes identified in stage 2 in an independent set of 1000 hereditary PC cases and 1000 controls. Preliminary results from the WES of the ~575 men will be presented.

1215W

Discovery of novel long noncoding RNAs and aberrant alternative splicing events by RNA-sequencing in childhood acute lymphoblastic leukemia. *R. Vidal[1], J.F. Spinella[1], V. Saillour[1], C. Richer[1], J. Healy[2], E. Bareke[1], S. Busche[2,3], B. Ge[3], T. Pastinen[2,3], A. Droit[4], D. Sinnett[1,5]*. 1) Department of Hematology-Oncology, CHU Sainte-Justine Research Center, Université de Montréal, Montreal, QC; 2) Department of Human Genetics, McGill University, Montreal, QC; 3) McGill University and Genome Quebec Innovation Centre, Montreal, QC; 4) Department of Molecular Medicine, Centre de Recherche du CHUQ, Université Laval, Québec, QC; 5) Department of Pediatrics, Faculty of Medicine, Université de Montréal, Montreal, QC, Canada.

Acute lymphoblastic leukemia (ALL) is the most frequent pediatric cancer, accounting for approximately 25% of cases. Advances in our understanding of the pathobiology of ALL have led to risk-targeted therapy and increased survival rates. However, approximately 20% of patients do not respond to current treatment protocols and over two-thirds of survivors experience long-term treatment-related health problems. Despite progress in treating the disease, very little is known of its underlying etiology. Therefore, in an attempt to investigate the complex landscape of mutations linked to changes in expression profiles and alternative splicing events, the whole transcriptome profiles of 30 primary ALL tumor samples and a subset of 8 matched normal samples were generated using a RNA-Sequencing approach on the ABI SOLiD platform. An average of 45M high quality paired-end tags were obtained per sample after aligning to the human genome reference sequence. Using a multi-step analysis pipeline including the Lifescope Genomic Analysis Software (Life Technologies), edgeR and Cufflinks, we investigated differential transcript expression between tumor and normal samples. We found a total of 2112 differentially expressed transcripts and isoforms, including 435 putative new transcripts related to the disease. Using a protein-protein network approach we identified hub genes related to DNA damage control (CCNA2, PARP2), apoptosis (ADAM9, FLT3) and involved in disease-relevant signaling pathways (CX3CR1, EPOR) that were shown to be up-regulated in over 60% of the cohort. We also found novel recurrent tumor-specific alternative splicing events involving genes that overlap these disease-associated pathways, as well as long ncRNAs whose expression in tumor samples correlate with well known ALL oncogenes such as MME, CDK6 and FLT3. These results suggest that long ncRNAs could be new potential therapeutic targets. Interestingly, we also found heterogeneity across ALL tumor transcriptomes suggesting that common but also primary tumor-specific transcriptional events are involved in childhood ALL onset and disease outcome. Integration of these results with exome sequencing, methylation profiling, and high-density genotyping data from these patients will allow us to identify bona fide driver events in leukemogenesis and provide further insight into the inherent complexity of this childhood disorder.

1216T

Association of polymorphisms in the *FOXE1* gene, but not *NKX2-1*, with familial papillary thyroid carcinoma. *S.G. Wilson[1,2,3], C-Y. Yan[1], L. Ward[1], S. Chew[1], V. Panicker[1], S.J. Brown[1], S. Chiripal[1], J. Goldblatt[2], T.D. Spector[3], J. Walsh[1,2].* 1) Endocrinology and Diabetes, Sir Charles Gairdner Hosp, Perth, Western Australia; 2) School of Medicine and Pharmacology, University of Western Australia, Crawley, Western Australia; 3) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom.

Thyroid cancer is among the ten most common cancers in populations of European ancestry. The vast majority of primary thyroid cancers are papillary thyroid carcinoma (PTC) and a small proportion (~5%) of these show strong familial association (FPTC). The genetic factors that determine susceptibility to PTC remain uncertain, however genes encoding thyroid transcription factors are strong candidates. Among these the FOXE1 and NKX2-1 genes have previously been implicated for a role in PTC (1,2). We performed a sequencing-based association study of these two genes and FPTC. Genetic analyses used conventional Sanger sequencing of the genomic DNA of 15 individuals aged 34.7 +/− 10.9 (mean ±SD) years at diagnosis, from 11 pedigrees. PTC families were identified on the basis of a proband with PTC containing at least one additional first degree relative also with PTC. The BigDye Terminator v3.1 Cycle Sequencing method with subsequent capillary electrophoresis performed on a ABI3730 sequencer was used for the analyses of nucleotide sequence of the genes in DNA from the study subjects. A control group of 118 healthy females selected randomly from the TwinsUK cohort with no previously reported thyroid disease, served as a control group. SNP genotype data for the control group was available from analyses of genomic DNA using Hap610 SNP arrays. Statistical analyses used a Chi-square test and UNPHASED Software was used for haplotype analysis. We found a significant association between FPTC and the SNP rs907577 (p = 0.002) located 5' of the FOXE1 gene. There was no association of rs71369530, a common polyalanine deletion in exon 1, with the disease. Haplotype analysis of common variants in FOXE1 provided further evidence for association with thyroid cancer (p = 0.0008). In comparison, we found no association of genetic variants identified through sequencing in NKX2-1 with PTC. Amongst our study subjects a single missense mutation (NM_004473.3:c.743C>G; Ala248Gly), predicted to be of a benign nature, was detected in the FOXE1 gene of one subject. No rare variants were detected in the data for the NKX2-1 gene. These data confirm previous findings of a role for common genetic variation in the FOXE1 gene region in the risk for PTC and extends the finding to FPTC.

Camargo, São Paulo, Brazil.

Xeroderma Pigmentosum (XP) syndrome is a rare autosomal recessive disease clinically characterized by cutaneous hypersensibility to ultraviolet radiation that accounts for the induction of pigmentary alterations and to early onset of skin cancers. XP is genetically heterogeneous and germline mutations are found in one of seven autosomal genes encoding proteins of the Nucleotide Excision Repair (NER) pathway or mutations in a polymerase eta encoding gene, active in the translesion synthesis (TLS) pathway. In this study 18 Brazilian families apparently unrelated who received clinical diagnosis of XP were included. Clinical characterization and molecular profiling through direct sequencing of XPA and XPC gene for the screening of germline mutations was performed. Germline mutations on XPC gene were found in 55,5% (10/18) of the families and one family (5,5%) was detected as carrier of XPA p.Arg207Ter mutation. Five new genetic variants occurring in the coding region and splice site of XPC gene were identified. Five apparently unrelated families were found to be carriers of a common splice site mutation in homozygozity, c.2251-1G>C, which correlates with the absence of immunoexpression. The same mutation has recently been observed as a founder effect in the Mahori XP population, generating alternative aberrant transcripts and lack of protein expression on fibroblasts cell extracts. This study shows that the Brazilian XP patients share a high incidence of the same founder c.2251-1G>C as the Mahori population. Ancestry molecular studies are needed to define if there is a common origin involving these two populations.

Rare variants in genes from esophageal squamous cell carcinoma genome-wide association studies identified by exome/whole genome sequencing of high-risk upper gastrointestinal cancer families. *A.M. Goldstein[1], N. Hu[1], K.J. Jacobs[1,2], L.-J. He[3], X.-Y. Han[4], M. Rotunno[1], M. Cullen[1,2], J. Boland[1,2], H. Su[1], L. Wang[1], C. Wang[1], L. Burdett[1,2], M. Malasky[1,2], A. Hutchinson[1,2], M. Yeager[1,2], T. Ding[4], C. Giffen[5], M.A. Tucker[1], S.J. Chanock[1], M. Lee[6], P.R. Taylor[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Inst, NIH, Bethesda, MD; 2) Core Genotyping Facility, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD; 3) YangCheng Cancer Hospital, YangCheng, Shanxi, PR China; 4) Shanxi Cancer Hospital, Taiyuan, Shanxi, PR China; 5) Information Management Services, Inc., Silver Spring, MD; 6) Center for Cancer Research, NCI, NIH, Bethesda, MD.

Gastric cancer and esophageal cancer cause more than 700,000 and 400,000 deaths, respectively, each year, and represent the second and sixth leading causes of cancer-related death worldwide. These upper gastrointestinal (UGI) cancers occur in the Taihang Mountains of North-Central China at some of the highest rates reported for any cancer; more than 20% of all deaths in this mountainous area have been attributed to these cancers. Risk factors for UGI cancer in this region include family history and dietary deficiencies and suggest a complex interplay of genetic and environmental factors. Multiple genome-wide association studies (GWAS) of esophageal squamous cell carcinoma (ESCC) in cases and controls from the Taihang Mountains as well as other Chinese and Asian populations have identified numerous loci encompassing approximately 14 genes associated with ESCC. The reported genes include PLCE1, C20orf54, ALDH2, ACAD10, ADH1B, RPL6, PTPN11, C12orf51, PDE4D, RUNX1, UNC5CL, CASP8, TRAK2, and ALS2CR12. Several of these loci have been observed in more than one study population whereas others have been reported only once. To examine whether rare variants (defined as minor allele frequency < 0.05) in any of these 14 genes were observed in high-risk families with multiple members with UGI cancer from the Taihang Mountains, we evaluated exome sequencing data from multiplex UGI families from this region. Families were selected for study if they had at least two members with UGI cancer and available blood-derived DNA. Exome sequencing was conducted in 2–4 affecteds/obligate carriers from 10 multiplex families. Nine families had at least one member with ESCC. Analysis of exome data revealed 6 rare substitutions and one possible intronic splice variant in 5 of the genes (PLCE1, c12orf51, RUNX1, CASP8, and TRAK2). Five of the rare variants had not been reported in dbSNP, 1000 Genomes, or NHLBI's Exome Variant Server and were considered novel. None of the variants, however, showed complete co-segregation with all UGI cases within the families in which they were observed. In fact, only two substitutions, one in C12orf51 and one in PLCE1, were observed in multiple affected family members. Future studies are needed to examine the function of these variants and to determine whether they increase risk for ESCC/UGI cancer. Additional studies to further evaluate the frequencies of these variants in large numbers of Chinese UGI cases and controls are also essential.

1219T

Identification of breast cancer susceptibility genes. *L. Guidugli[1], J.N. Weitzel[2], X. Wang[1], S. Hart[1], F.J. Couch[1], C. Szabo[3].* 1) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) Clinical Cancer Genetics, City of Hope Cancer Center, Duarte, CA, USA; 3) Department of Biological Sciences, University of Delaware, Newark, DE, USA.

Breast cancer has a significant genetic component. The strongest epidemiologic risk factor is family history of the disease. Familial studies have identified a number of genes contributing to increased risk. Of these, the highly penetrant BRCA1 and BRCA2 genes account for the majority of families in whom disease-causal mutations have been identified. However, mutations in other genes have been associated with predisposition to breast or breast and ovarian cancer including CHEK2, ATM, and PALB2. Together these genes account for less than 20% of excess familial breast cancer risk and do not explain ~50% of high-risk families referred for genetic testing. This significant gap in our understanding of the genetic basis of breast cancer poses a significant barrier to our ability to identify women at increased risk, who would benefit greatly from appropriate clinical management. To identify additional breast cancer predisposition genes whole exome sequencing of familial high-risk breast cancer patients was undertaken. DNA samples from pairs of breast cancer patients from 70 high-risk breast cancer families with no pathogenic mutations in the BRCA1 or BRCA2 breast cancer predisposition genes were subjected to whole exome sequencing. After exclusion of common variants, candidate mutations in genes encoding proteins involved in the cellular response to DNA repair were validated. Segregation of validated candidates with breast cancer was evaluated in families carrying the mutations. Results of these ongoing studies will be presented.

Mutations in *SDHA* are a common cause of paragangliomas and pheochromocytomas and give rise to a diverse tumor spectrum. *A.R. Mensenkamp[1], J.U. Rao[2, 3], K.L.I. van Gassen[1], B. Kusters[4], J.W.M. Lenders[5, 7], H.P.M. Kunst[6], H.J.L.M. Timmers[3], M.J.L. Ligtenberg[1, 4].* 1) Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 2) Department of Endocrinology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) Department of Laboratory Medicine, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 4) Department of Pathology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 5) Department of Internal Medicine, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 6) Department of Otorhinolaryngology, Head and Neck Surgery, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 7) Department of Internal Medicine III, University Hospital Carl Gustav Carus Dresden, Germany.

Head and neck paragangliomas (HNPGL) and adrenal/extra-adrenal pheochomocytomas (PHEO) are highly heritable neural crest-derived tumors. Mutations in at least 10 genes are described to cause either HNPGL and/or PHEO. *SDHA*, encoding one of the subunits of succinate dehydrogenase, has only recently been recognized as a HNPGL/PHEO susceptibility gene. Although mutation analysis of *SDHA* is complicated by the presence of several pseudogenes, we have been able to design a primer set which exclusively amplifies all *SDHA* exons. Seventy patients who were negative for mutations in *SDHB*, *SDHC*, *SDHD*, *SDHAF2*, *RET*, *VHL*, *TMEM127* and *MAX* with no signs of NF1 were examined for mutations in *SDHA*. Tumors from patients with a mutation, if available, were subjected to immunohistochemistry of SDHA and SDHB, and analyzed for loss of heterozygosity. Analysis of SDH-activity is ongoing. In addition, metabolites were screened by ^{1}H-NMR and family history was recorded. In six patients an *SDHA* mutation was detected. The previously described nonsense mutation c.91C>T (p.(Arg31*)) was found in two patients with a HNPGL and in one patient with a right adrenal PHEO and a renal cell carcinoma. The pathogenic mutation c.1534C>T (p.(Arg512*)) was detected in a patient with a testis paraganglioma at the age of 23, who developed metabolically active retroperintoneal metastases three years later. His aunt, who also is heterozygous for the mutation, developed a tympanic HNPGL. The putative pathogenic missense mutation c.1753C>T (p.(Arg585Trp)) was found in a woman who developed a Wilms tumor at four years of age and a PHEO at age 20 years. Another putative pathogenic missense mutation, c.778G>A (p.(Gly260Arg)), was detected in a woman with a jugulotympanic HNPGL. All immunohistochemical and loss of heterozygosity analyses were in line with a loss of function of the latter mutations. Most patients with an *SDHA* mutation did not have relatives with HNPGL/PHEO, suggesting a reduced penetrance of *SDHA* mutations. In conclusion, *SDHA* mutations may account for about 8% of all patients with a HNPGL/PHEO without a mutation in any other known gene. The tumor spectrum appears to be highly variable. HNPGL, PHEO, and other tumors may develop at a young age and can be metastatic. Mutation analysis of *SDHA* should therefore be part of the genetic screening in all patients with a HNPGL/PHEO who are negative for *SDHB* and *SDHD* mutations.

Identifying novel cancer susceptibility genes through exome sequencing and copy number analysis of individuals with Li Fraumeni-like cancer phenotypes. *S.E. Plon[1,2,3], L.C. Strong[4], B. Powell[2], L. Jiang[3], H. Cheung[1], D. Ritter[3], D.M. Muzny[3], D.A. Wheeler[3], R.A. Gibbs[2,3].* 1) Dept. Pediatrics, Baylor College of Medicine, Houston, TX; 2) Dept. Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 4) Department of Genetics, MD Anderson Cancer Center, Houston, TX.

Background: The identification of mutations in specific genes responsible for inherited cancer susceptibility impacts patient treatment, as well as allowing increased surveillance and prevention for at-risk family members. In addition, knowledge of inherited predisposition to pediatric malignancies has provided important insights into the mechanisms of cancer, in both children and adults. Current utilization of high-throughput sequencing methodologies for detecting coding changes in cancer has been focused on somatic mutations in tumor tissue, and conversely; genome-wide association studies of cancer susceptibility have focused on common variations that individually have small impacts on cancer risk. Methods: We are carrying out a project at the intersection of these two different approaches, using massively parallel sequence analyses of constitutional DNA from ethnically diverse childhood cancer patients with medical and family histories suggestive of inherited cancer susceptibility syndromes. Patients are enrolled through cancer genetics protocols at several institutions in Texas. We are analyzing small cohorts of families with consistent and specific phenotypes including probands with childhood sarcomas and second or third primary malignancies by age 40, highly suggestive of the Li Fraumeni syndrome but where thorough sequence and copy number analysis of TP53 and other well-characterized cancer-associated genes has been negative. Results: We have identified eight unrelated individuals who meet these criteria, the majority of which have either negative family history or a single affected first-degree relative consistent with autosomal dominant inheritance. Capture of coding regions using a vCrome 2.1 platform was followed by Illumina paired end exome sequencing performed on constitutional DNA from blood or lymphoblastoid line and analyzed for novel or rare mutations which are predicted to impact gene function. Rare copy number variants were determined based on Affymetrix high-density arrays. Given the limited availability of family samples, genes will be prioritized for further analysis by the identification of deleterious variants or CNVs in multiple independent probands. Conclusions: Genome-scale sequencing and copy number analysis should allow identification of causative mutations in individuals with p53-like cancer phenotypes in the absence of extended family information. Supported by grants 5R01CA138836 and CPRIT RP101089.

1222T

Development and validation of NGS-based molecular diagnosis of inherited forms of colorectal cancer. *J. Tinat[1,2], F. Charbonnier[1,2], S. Coutant[1], R. Marlin[1], G. Bougeard-Denoyelle[1], S. Baert-Desurmont[1,2], M. Tosi[1], T. Frebourg[1,2], I. Tournier[1].* 1) Inserm, U1079, University of Rouen, Institute for Research and Innovation in Biomedicine (IRIB), Rouen, Normandy, France; 2) Department of Genetics, University Hospital, Rouen, Normandy, France.

Considering the number of genes involved in Mendelian predisposition to colorectal cancer and the overlapping phenotypes which require to sequentially analyse different genes, we have developed a one step NGS-based strategy. All the exons, introns and 15 kb of the 5' and 3' untranslated regions of 10 genes respectively involved in Lynch syndrome (*MSH2*, *MLH1*, *MSH6* and exons 6 to 15 of *PMS2*), adenomatous polyposis (*APC* and *MUTYH*) and hamartomatous polyposis (*STK11*, *SMAD4*, *BMPR1A* and *PTEN*) were captured using the Sure-Select technology from Agilent. We also included in this capture the *TP53* gene for logistic reasons, since our laboratory also performs this analysis at the national level. *TP53* results were subsequently masked for patients referred to our laboratory in the context of inherited forms of colorectal cancer. We multiplexed the samples prior to the capture (5 patients/capture) and after the capture (10 patients/flow cell lane) and performed a paired-end 2×75 bp sequencing on an Illumina GAIIx platform. This strategy allows us to analyse 80 patients in one run. The informatics pipeline includes the RTA and CASAVA 1.8 software from Illumina, and the ANNOVAR and Variant Effect Predictor software. The average sequencing depth was around 200 x, across the captured regions. In order to validate this strategy, we analysed 70 patients harbouring a total of 113 known variations including 70 point mutations, 31 insertions/deletions and 12 genomic rearrangements. All the point mutations were successfully identified. Among the 31 insertions/deletions, only 2 located within *STK11* and *MSH6* were missed because of a low read depth caused by a high GC content. In order to estimate the false positive rate, we selected 42 variations revealed by NGS and checked their presence by Sanger sequencing. All variations were confirmed, except two resulting from sequencing artefacts located in mononucleotide repeats. This evaluation shows that our capture set and sequencing strategy yield an excellent sensitivity and specificity and can be used in molecular diagnosis laboratories in order to optimise the molecular diagnosis of Mendelian forms of colorectal cancer.

Interpretation of Variants of Unknown Significance with a Large Database of Genotyped and Phenotyped Individuals. *B.T. Naughton, A. Chowdry, J.M. Macpherson, G.M. Benton.* 23andMe, Inc., Mountain View, CA.

The interpretation of variants of unknown significance (VUS) from whole-genome sequence data is a substantial challenge in genetics. VUS are usually too rare to be amenable to genome-wide association studies and so traditionally have been interpreted with reference to the primary literature (especially for high-penetrance or Mendelian mutations) or by computational methods (e.g., SIFT, PolyPhen). While these methods can provide useful insights, they are often limited by the presence of false positives in the literature or by imperfect prediction algorithms. 23andMe, a personal genomics company, has assembled a database of 150,000 genotyped individuals, over 90,000 of whom have consented to participate in research and answered at least one research question. Participants answer research questions on the 23andMe website on topics as diverse as their medical history, personality, lifestyle and exercise. Here we present data demonstrating that this database can be used to empirically determine the significance of variants found in human sequence data. As proof of concept we used the database to confirm that the BRCA1 mutations 185delAG and 5382insC and the BRCA2 mutation 6174delT are associated with greatly increased breast cancer risk. Conversely, we confirmed that the BRCA mutations R841W and S1040N are benign polymorphisms that are not associated with increased breast cancer risk. In a real-world example, we analyzed a VUS in MLH1 from a sequenced exome that was suspected to be cancer-causing. Using individuals' self-reported cancer status from the database, we determined that the variant is unlikely to be cancer-causing. Our finding agrees with previously reported results in the literature. Due to the extensive phenotyping of our cohort (over 50 million phenotypic data points) and the large number of rare variants on our custom genotyping chip (over 30,000 putatively disease-associated rare variants), this method is applicable to a large number of genes and phenotypes. We further discuss extending this method to variants not present on the genotyping chip by inferring the presence of mutations in individuals in the database based on identity-by-descent (IBD).

1224W

Exome sequencing identifies rare deleterious mutations in DNA repair genes FANCC and BLM as potential breast cancer susceptibility alleles. *E.R. Thompson[1], M.A. Doyle[1], S.M. Rowley[1], D.Y.H. Choong[1], G.K. Philip[2], A.H. Trainer[1], P.A. James[1,3], G. Mitchell[1,3], I.G. Campbell[1,3,4], kConFab.* 1) Peter MacCallum Cancer Centre, East Melbourne, Victoria, Australia; 2) Life Sciences Computation Centre, Victorian Life Sciences Computation Initiative, Carlton, Victoria, Australia; 3) Sir Peter MacCallum Department of Oncology, University of Melbourne, Parkville, Victoria, Australia; 4) Department of Pathology, University of Melbourne, Parkville, Victoria, Australia.

Despite intensive efforts using linkage and candidate gene approaches, the genetic etiology for the majority of families with a multigenerational breast cancer predisposition remains unknown. We completed whole exome sequence analysis of germline DNA from multiple affected relatives (n= 130) from 64 breast cancer families with the aim of identifying rare protein truncating and non-synonymous variants that are likely to include novel cancer predisposing mutations. Twelve individuals from nine families were found to harbour mutations in known breast cancer genes (BRCA2–7 individuals, CHEK2–2, BRCA1–1, PTEN - 1, ATM - 1) that were not identified by clinical genetic testing either because the index case was a phenocopy who did not carry the mutation, or because the gene is not routinely tested. Among the remaining families, a list of ~50 candidate genes has been identified on the basis of recurrence and biological function, and these are currently being assessed for segregation among family members and for prevalence among 1,000 BRCA1/BRCA2 mutation negative breast cancer families and controls. In particular, our analysis identified families with heterozygous, deleterious mutations in the DNA repair genes FANCC and BLM, which are responsible for the autosomal recessive disorders, Fanconi Anemia and Bloom's syndrome. In total, screening of all exons in these genes in 453 breast cancer families identified three with truncating mutations in FANCC, and two with truncating mutations in BLM. Additional screening of FANCC mutation hotspot exons identified one pathogenic mutation among an additional 957 breast cancer families. None of the deleterious mutations were identified among 464 healthy controls and are not reported in the 1000 genomes data. Given the rarity of Fanconi Anemia and Bloom's syndrome disorders among Caucasian populations, the finding of multiple deleterious mutations in these critical DNA repair genes among high risk breast cancer families is intriguing and suggestive of a predisposing role. Our data demonstrates the utility of intra-family exome sequencing approaches to uncover cancer predisposition genes but highlights the major challenge of definitively validating candidates where the incidence of sporadic disease is high, germline mutations are not fully penetrant, and individual predisposition genes may only account for a tiny proportion of families.

1225T

Cancer genetic testing panels: preliminary experience within an adult genetics practice. *C.G. Selkirk, S.M. Weiss, K.J. Vogel, A.C. Newlin, S.M. Weissman, P.J. Hulick.* Center for Medical Genetics, NorthShore University HealthSystem, Evanston, IL.

Background: The traditional clinical approach to genetic testing for suspected cancer syndromes has followed a single-gene testing approach, based on the constellation of cancers seen in a family history. With the recent clinical availability of cancer genetic testing panels, which includes next-generation sequencing for 14–22 genes, it is yet to be determined whether the paradigm for cancer genetic testing will shift. In some cases, ordering a panel may be more cost effective than performing testing in a step-wise approach of syndromes with overlapping phenotypes. Additionally, panels may identify mutations where the family does not have a classic presentation for the associated cancer syndrome. However, given the number of genes on each panel, it is anticipated to involve a high rate of variants of unknown significance (VUS). At present, the clinical utility is unknown for such panels and there are no set criteria or guidelines established for offering such testing. Methods: We have devised a clinical ranking system for determining appropriateness for cancer gene panel testing, balancing the potential yield of testing with the likelihood of using the information to guide medical management. Beginning April 2012, patients are ranked using a clinical risk ranking system based on their personal and/or family history. We are tracking our patient cohort who has had a discussion of cancer panel testing and tracking outcomes related to insurance preauthorization, testing uptake, and testing results. Results: We will report on our cohort of patients who has been introduced to panel testing. Based on the assigned clinical risk number, we will describe patients' decisions to pursue insurance pre-authorization, outcomes of pre-authorization, patient uptake of testing, test result outcomes, associated medical management recommendations, and the utility of our ranking system to guide recommendations for cancer panel genetic testing. Conclusions: Next-generation sequencing technology may be a cost-effective and time-saving approach for clarifying cancer risk in families with inherited cancer predispositions. In order to validate this approach to genetic testing, data is needed regarding patient interest and uptake in testing, insurance coverage for testing, test result outcomes (including variant rates), and utility of testing to guide medical management recommendations.

1226F

Thirty percent of breast cancer families negative by commercial BRCA1/BRCA2 testing are resolved by mutations in 13 other breast cancer genes, by BRCA1/BRCA2 phenocopies, and by BRCA1/BRCA2 CNVs. *T. Walsh, S. Casadei, A.M. Thornton, G. Bernier, C.H. Spurrell, S.M. Stray, J. Mandell, M.K. Lee, M-C. King.* University of Washington, Seattle, WA.

A challenge to the present practice of genetic testing for inherited risk of breast cancer is how to explain the illness in breast cancer patients with severe family history, but negative (wildtype) results by commercial testing for BRCA1 and BRCA2. We are studying this question for all breast cancer patients in >2000 severely affected families. Proband(s) of each family received negative results of commercial genetic testing of BRCA1 and BRCA2. We are using our recently developed approach of targeted capture of complete genomic loci and massively parallel multiplexed sequencing to identify all single base pair substitutions, insertion-deletions, and copy number variants in all known breast cancer genes. Here we report on sequence data from >1000 patients from the first 457 families. More than 90% of families are of European ancestry, including 9% Ashkenazi Jewish. We included here only germline truncating mutations, complete gene deletions, and missenses experimentally shown to be damaging. In 30% of families (135/457), mutations very likely to be causal were identified: 18% (81 families) by mutations in 13 known breast cancer genes other than BRCA1 and BRCA2; 2% (8 families) by conventional mutations in BRCA1 or BRCA2, with proband(s) proving to be phenocopies; and 10% (46 families) by CNVs in BRCA1 or BRCA2, generally in families without supplementary commercial CNV analysis. Genes other than BRCA1 and BRCA2 harboring germline loss-of-function mutations were CHEK2 (29 families), PALB2 (21), ATM (10), TP53 (5), PTEN (4), RAD51C (3), BRIP1 (2), NBN (2), BARD1 (1), CDH1 (1), MLH1 (1), RAD50 (1), and STK11 (1). All mutations were individually rare, with known founder alleles (e.g. CHEK2 c.1100delC) accounting for only a small proportion. In genes other than BRCA1 and BRCA2, 9% of mutations were gene-disrupting CNVs, in ATM, CHEK2, PALB2, RAD51C, and TP53. Subsequent sequencing of still-unresolved families has thus far revealed eight new candidate breast cancer genes (see abstract by Spurrell et al.). Our results indicate that families severely affected by breast cancer but with negative results from commercial genetic testing are well served by complete genomic sequencing of all known breast cancer genes. As such comprehensive testing becomes more widespread, it will be important to determine the risks associated with each of these genes so they can be incorporated effectively into clinical care.

1227W

Comparison of Next Generation Sequencing with Traditional Sequencing and MLPA for BRCA1 and BRCA2 Testing. *K. Chun[1,2], A. Brown[3], K. Ng[3], R. Denroche[3], J.D. McPherson[3,4].* 1) Genetics Program, North York General Hospital, Toronto, Ontario, Canada; 2) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Ontario, Canada; 3) Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 4) Department of Medical Biophysics, University of Toronto, Toronto, Ontario, Canada.

Objective: To compare next generation sequencing (NGS) with traditional sequencing and MLPA (multiplex ligation-dependent probe amplification) for BRCA1 and BRCA2 clinical testing in Ontario. Methods: 96 patients with different known pathogenic variants in BRCA1 or BRCA2 were identified. Full Sanger sequencing and MLPA data of all the exons of BRCA1 and BRCA2 was available for 87 of the patients, while the remaining 9 patients had information pertaining to the pathogenic variant alone. The HaloPlex PCR Target Enrichment and Library preparation protocol was used to select the regions of interest (BRCA1 and BRCA2) and construct barcoded sequencing libraries. Equimolar pools of the barcoded libraries were sequenced on the Illumina MiSeq platform using a paired end 150 bp read length protocol. Demultiplexed FASTQ files were generated from on instrument basecalls using Illumina's CASAVA software. The sequences were aligned to the human genome using the Novoalign short read aligner. Single nucleotide variants and short indels were identified using the Genome Analysis Toolkit and annotated with ANNOVAR. Results: 87 pathogenic variants and 18 variants of unknown significance were detected in the 96 patients. Sixty of these variants were frameshift mutations and 45 were single base pair changes. Furthermore, all of the polymorphisms (single base pair changes) present in these patients were also correctly identified. NGS was not, however, able to detect the 9 exonic deletions and one exonic duplication, although evidence of these large genomic rearrangements was observed upon closer examination by comparing average read depth across each exon. NGS was found to be more cost-effective and less labour intensive than traditional Sanger sequencing and MLPA. Conclusions: Next generation sequencing is an efficient and cost-effective method to potentially replace traditional sequencing and MLPA for BRCA1 and BRCA2 clinical testing in Ontario.

1228T

Genomic capture and massively parallel sequencing reveals inherited loss-of-function mutations in 8 genes in 19% of familial breast cancer patients from Greece. *A. Stavropoulou[1], T. Walsh[2], F. Fostira[1], M. Tsitlaidou[1], S. Casadei[2], S. Glentis[1], G. Fountzilas[3], I. Konstantopoulou[1], M.C. King[2], D. Yannoukakos[1].* 1) NCSR DEMOKRITOS, ATHENS, Greece; 2) Dept of Medicine (Medical Genetics), University of Washington, Seattle, WA, USA; 3) Aristotle University of Thessaloniki, Thessaloniki, Greece.

Inherited mutations in known and yet-to-be discovered genes predispose for breast and/or ovarian cancer. Mutations within BRCA1 and BRCA2 are the most common, but recently additional genes have been linked to breast and/or ovarian cancer susceptibility. We used BROCA to target, hybridize, and multiplex sequence 30 known breast and ovarian cancer genes. Coding exons, UTRs, introns, and several kb flanking each locus were captured and sequenced to median read depth >300x, so that >99% of basepairs have >10x coverage. Subjects were 88 Greek patients with familial, invasive breast cancer, for whom Greek founder mutations in BRCA1 and BRCA2 had been previously excluded. Eighteen nonsense, frameshift, multi-exon deletions, or missense mutations previously established as damaging were identified in 17 patients (19%). Genes harboring loss-of-function mutations were BRCA1, BRCA2, ATM, CHEK2, PALB2, PTEN, MLH1, and MSH2. One patient carried mutations in two genes (MLH1 and ATM). All mutations were different. All were confirmed by Sanger sequencing with diagnostic primers from patients' genomic DNA. Five of the 18 mutations were genomic deletions of sizes 1.8 to 12 kb in BRCA1, BRCA2, CHEK2, and MSH2 that were detected by read depth from BROCA data. These CNVs deleted from one to three exons. Four other patients carried mutations at or near splice sites in ATM, BRCA2, and RAD51C. These splice variants have been confirmed in genomic DNA; their effects on transcripts are being evaluated. The patient with both MLH1 and ATM truncating mutations had been diagnosed with both breast and colorectal cancer and had a family history of both cancers. The patient with a PTEN nonsense mutation was diagnosed with breast cancer at age 36; her mother died of breast cancer at age 29 and a maternal cousin died of childhood leukemia. We conclude that among Greek patients with familial breast cancer, the mutational spectrum is highly heterogeneous with respect to both loci and alleles. These patients are well served by an approach that detects all classes of mutations in all known breast cancer genes.

1229F

Elevated rate of somatic L1 retrotransposition in colorectal tumors. *S. Solyom[1], A.D. Ewing[2], E. Rahrmann[3], T. Doucet[1], H.H. Nelson[4], D.F. Sigmon[1], A. Casella[1], B. Erlanger[5], S. Wheelan[5], G. Faulkner[6], D. Haussler[2], D. Largaespada[3], H.H. Kazazian[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Center for Biomolecular Science and Engineering, University of California at Santa Cruz, Santa Cruz, California; 3) Department of Genetics, Cell Biology and Development and Pediatrics, Masonic Cancer Center, University of Minnesota, Minneapolis, Minnesota; 4) Division of Epidemiology and Community Health, Masonic Cancer Center, University of Minnesota, Minneapolis, Minnesota; 5) Department of Statistics and Oncology, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Genome Plasticity and Disease Group, Mater Medical Research Institute, Aubigny Place, Raymond Tce, South Brisbane, Australia.

Long INterspersed Element-1 (LINE-1 or L1) retrotransposons comprise 17% of the human genome, where they are the only autonomous mobile elements. L1s move by a “copy and paste” mechanism via an RNA intermediate, a process called retrotransposition. They are also responsible for the mobilization of the non-autonomous Alu and SVA retrotransposons, as well as numerous other RNA species. Although, insertional mutagenesis by these mobile elements is a known cause of various human Mendelian disease cases, their mutagenic load on the cancer genome has so far been elusive. Using a next generation L1-targeted resequencing method on the DNA of 16 colorectal tumors and matched normal colon tissue, here we show for the first time that certain cancers are excessively mutagenized by human-specific L1 (L1Hs) elements, the only currently active family of human L1s. We provide the most extensive confirmation of de novo L1 insertions in malignancy to date by analyzing 112 insertion sites with PCR. 72 of these were successfully PCR amplified at the 3' junctions and validated to be tumor-specific, and 65 were sequenced. For 34 insertions altogether, both 5' and 3' junctions were retrieved, enabling us for the first time to characterize target site duplications (TSDs, a hallmark of retrotransposition) and L1 insertion size in cancer tissue. Interestingly, all of the validated tumor-specific insertions were severely 5' truncated, and we yet have to find a full length L1 in these tissues. This is in contrast to germline polymorphic insertions, where 30% were full length, in agreement with the length of L1 insertions in the reference genome. This difference in truncation rate is statistically significant, and potentially indicates the footprint of a DNA repair pathway in somatic tissues or cancer. The number of validated L1 insertions varies widely from tumor to tumor with up to 17 insertions in some and none in others. Among the insertions, numerous genes playing a role in tumorigenesis have been targeted. Surprisingly, the elevated rate of L1 retrotransposition does not correlate with global L1 methylation or with microsatellite instability. Thus, somatic L1 retrotransposition occurs frequently in colorectal cancers, and the truncated structure of these insertions may be useful in determining the etiology of 5' truncation in L1 insertion events.

Mutational analysis of splicing machinery genes SF3B1, U2AF1 and SRSF2 in myelodysplasia and other common tumors. *S. Lee, E. Je, M. Kim, J. Oh, N. Yoo.* Pathology, College of Medicine, The Catholic University of Korea, Seoul, South Korea.

Recently, a whole-exome sequencing identified frequent somatic mutations of genes encoding multiple components of the RNA splicing machinery, including splicing factor 3B subunit 1 (SF3B1), serine/arginine-rich splicing factor 2 (SRSF2) and U2 small nuclear RNA auxiliary factor 1 (U2AF1) in bone marrows of myelodysplastic syndromes (MDS) patients (45–85%). RNA splicing is a mechanism for gene regulation and proteome diversity, and is ubiquitous to all types of human cells, suggesting a possibility that mutational events in the splicing genes might be involved in other tumors. For this, we have analyzed SF3B1, SRSF2 and U2AF1 genes in a variety of human tumors in hematologic (400 cases) and solid tumors (900 cases). In 61 MDS, 22 MDS (36%) harbored at least one somatic mutation of these genes. 80% of the MDS with ring sideroblasts harbored the mutations, while 32% of those without remarkable ring sideroblasts harbored them. 7% of the acute myelogenous leukemias, 25% of the chronic myelomonocytic leukemias, 50% of MDS/myeloproliferative disorders harbored the mutations, frequencies of which were similar to preexisting data. We newly identified that childhood acute lymphoblatic leukemias (ALL) also harbored SRSF2 mutations in two cases (1%). We also observed two mutations in solid tumors (prostate and gastric cancers), but the mutations were not the hotspot mutations. Our data indicate that the splicing gene mutations are tissue-specific and suggest that the mutations play unique roles in the pathogenesis of MDS and less frequently other hematologic neoplasia, but not in common solid tumors.

Calling Allele or Haplotype-specific Copy Number in Tumor Sequence Data. *N. Dewal[1], Y. Hu[2], M.L. Freedman[3,4], T. LaFramboise[5], I. Pe'er[2], R.A. Gibbs[1], D.A. Wheeler[1]*. 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Computer Science, Columbia University, New York, NY; 3) Dana-Farber Cancer Institute, Boston, MA; 4) Harvard Medical School, Boston, MA; 5) Department of Genetics, Case Western Reserve University, OH.

During tumor initiation and progression, cancer cells acquire a selective advantage, allowing them to out-compete their normal counterparts. Identification of the genetic changes that underlie these tumor acquired traits can provide deeper insights into the biology of tumorigenesis. Regions of copy number alterations (CNAs) and germline DNA variants are some of the elements subject to selection during tumor evolution. Integrated examination of inherited variation and somatic alterations holds the potential to reveal specific nucleotide alleles that a tumor "prefers" to have amplified or deleted. Next-generation sequencing of tumor and matched normal tissues provides a high-resolution platform to identify and analyze such somatic CNA regions. Within a CNA region, examination of informative (e.g. heterozygous) sites deviating from a 1:1 ratio may suggest selection of that allele. A naïve approach examines the reads for each heterozygous site in isolation; however, this ignores available valuable linkage information across sites. We therefore present an updated version of our Hidden Markov Model-based method - Haplotype Amplification in Tumor Sequences (HATS) - 2.0 that analyzes tumor and normal sequence data, along with training data for phasing purposes, to infer amplified or deleted alleles and haplotypes in regions of somatic copy number change. Our method is designed to handle rare variants and biases in read data. We assess the performance of HATS using simulated amplified or deleted regions generated from varying copy number and coverage levels, followed by CNA regions in real data. We demonstrate that HATS infers the amplified or deleted alleles more accurately than does the naïve approach, especially at low to intermediate coverage levels and in cases (including high coverage) possessing stromal contamination or allelic bias. Lastly, HATS 2.0 can now detect bi-allelic alterations, at the same time providing a better estimate of tumor purity, compared to the assumption of mono-allelic changes made by the original version of HATS. HATS will thus enable identification of the allele selected for copy number change.

1232F

Somatic Mutation Detection of Tumor and Matched-Normal Samples for Semi-Conductor Based Sequencing. *A.H. Joyner, S. Utiramerur, D. Brinza, H. Breu, B. Krishnaswami, A. Shukla, J. Zhai, Y. Lou, F. Hyland, D. Thomas, E. Beasley*. Bioinformatics, Life Technologies, Foster City, CA., USA.

The advent of next-generation DNA sequencing technology has enabled quick and low-cost variant analysis of tumor samples. One of the major challenges to the field of somatic mutation detection is in distinguishing novel tumor sample variants (somatic) from parentally-inherited variants (Germ-line). Ion Reporter™ Software is a hosted suite of informatics tools that streamline and simplify analysis, annotation, and archiving of semiconductor sequencing data. It is designed specifically for clinical researchers performing routine sequencing assays by automating variant analysis bioinformatics pipeline to connect detected variants with public annotations, allowing faster biological assessment. It is optimized for semiconductor sequencing for faster and more accurate results, and scales easily from a few to thousands of samples and from genes to genomes. Here is presented a method, integrated into the Ion Reporter™ Software suite, to confidently determine and annotate tumor-specific variants. This method analyzes normal sample reads and takes into consideration chance observations, informed from the error rate. In this way, evidence for the tumor allele in the normal sample is used to qualify a variant as a tumor-specific variant. User provided parameters allow this workflow to be modified for various experimental settings (i.e. asymmetrical coverage of tumor/normal, expected frequency of somatic variant), and provides functionality to make non-confident calls in the face of imperfect sequencing evidence.

1233W

Acute lymphoblastic leukemia - novel therapeutic approach based on an active patient-individualized multipeptide vaccination. *C. Schroeder[1], M. Sturm[1], U. Pflückhahn[2], M. Feldhahn[3], O. Kohlbacher[3], S. Stevanovic[4], H.G. Rammensee[4], P. Lang[2], O. Rieß[1], P. Bauer[1]*. 1) Department of Medical Genetics, Tübingen, Germany; 2) Department of Hematology/Oncology, University Children's Hospital, Tübingen, Germany; 3) Applied Bioinformatics, Center for Bioinformatics and Quantitative Biology Center, University of Tübingen, Tübingen, Germany; 4) Department of Immunology, Tübingen, Germany.

Acute lymphoblastic leukemia (ALL) is the most common cancer in childhood with an incidence of 3.5 / 100.000 at the age of 0–14 years. Treatment of ALL improved tremendously over the last decades, leading to a 5-year event free survival of more than 80 %. However, patients with high-risk acute lymphoblastic leukemia often relapse and in this case therapeutic options are limited. Thus, novel therapeutic concepts are needed. We established a workflow for an individualized multi-peptide vaccination in children suffering from high-risk ALL of B-Cell lineage. Tumor specific mutations are identified via the combination of whole-exome (tumor cells and fibroblasts) and transcriptome (tumor cells) sequencing. The variants found by differential analysis are validated on DNA-level using a custom-design deep-sequencing approach. All validated variants are further characterized by in-silico predictions (e.g. SYFPEITHI) and analysis of tumor tissue (HPLC plus mass spectrometry) to identify those mutations resulting in mutated peptides that are presented on the cell surface. The variants most likely to be immunogenic can be synthesized under GMP-conform conditions and administered to the patient. So far six patients have been included in this study and were sequenced according to the protocol (avg. percentage of reads on target: 70.1 %; avg. percentage of target regions at 10x: 90.41%). With stringent filter criteria an average of 83 tumor-specific mutations per sample pair were identified. The laboratory turnaround time for sequencing and validation is estimated to be around 8 weeks. The next steps ahead will be prediction and analysis of mutated peptides within the patient's tumor tissue. In summary, with this approach we should be able to detect tumor-specific and immunogenic mutations that are the basis for a successful individualized immunotherapy.

1234T

No evidence for the role of somatic mutations and promoter hypermethylation of FH gene in the tumorigenesis of nonsyndromic uterine leiomyomas. *S. Vaidya[1,2], K.P. Rao[3], Q. Hasan[2]*. 1) Vasavi Medical and Research, Hyderabad, India; 2) Kamineni Hospital, Hyderabad,Hyderabad; 3) Osmania University,Hyderabad,India.

Fumarate hydratase (FH) gene is reported to have specific involvement in syndromic uterine tumors, but its role in nonsyndromic forms is still unclear. Hence, the present study has aimed to screen the role of promoter methylation status and mutations in exon 2 and 7 regions of FH gene in the genesis of nonsyndromic uterine leiomyomas. Leiomyoma and myometrium tissues were collected from 85 hysterectomized uterine specimens. DNA from each of the biopsy was subjected to PCR, methylation-specific restriction assay, and DNA sequencing. In silico analysis was carried out to identify the impact of sequence variants on the protein structure. Chisquare ($\chi 2$) test was used to compare the promoter methylation proportions of leiomyoma and myometrium tissues. No sequence variants were observed in exon 2 region, but three novel heterozygous germ line sequence variants, i.e.,c.1010A>C, c.1021 G>A, and c.1066 T>C in exon 7 region of the FH gene were detected in 14/85 (16.5 %) of the cases examined. In silico analysis results showed that c.1010A>C and c.1021 G>A mutations damage the structure and function of FH, whereas c.1066 T>C mutation is mostly tolerant or neutral. No significant difference of FH promoter methylation status between the leiomyoma (11.76 %) and myometrium (5.88 %) tissues was observed (P00.176). Therefore, it is concluded that somatic mutations in FH do not show pronounced effect in nonsyndromic uterine leiomyomas compared to that of their syndromic counterparts. However, higher frequency of FH mutations in leiomyoma cases raises the need to conduct larger number of prospective case-control and family-based studies to assess them as risk markers to nonsyndromic leiomyomas. Keywords: Nonsyndromic uterine leiomyoma. Fumarate hydratase. Missense variants. SIFT scores. Promoter methylation.

Somatic mutation spectrum of metastatic melanoma through exome sequencing of 48 tumor-normal pairs. *M.D. Willard[1], J.N. Calley[1], S-S. Wong[1], R.H. Higgs[3], X. Ma[3], P.J. Ebert[1], S.M. Bray[1], I.H. Wulur[1], Y. Yue[1], Y. Lin[2], J. Wang[2], A. Aggarwal[1], S. Li[2], C.R. Reinhard[1], A.B. West[2], T.D. Barber[1]*. 1) Translational Therapeutics, Eli Lilly and Company, Indianapolis, IN; 2) Informatics, Eli Lilly and Company, Indianapolis, IN; 3) Statistics, Eli Lilly and Company, Indianapolis, IN.

Melanoma is a deadly form of skin cancer that results from the unregulated growth of melanocytes, and is an area of high unmet medical need. Although promising targeted therapies have recently emerged, it is clear that the high mutation rate and complex mutation spectrum of melanoma has contributed to the inconsistent improvements in overall survival rate. To further our understanding of the somatic mutation spectrum, we sequenced the exomes of 48 melanoma tumor-normal pairs. We identified mutations in well-established melanoma genes (*i.e.*, BRAF, NRAS, KIT), in genes recently described in melanoma (*i.e.*, PTK2B, GRM3, PREX2), and in genes whose role in melanoma progression remains to be determined. Additionally, utilizing our melanoma mutation data, as well as complementary datasets from recently published exome and whole-genome sequencing studies, we identified novel recurrent mutations that may play a role in driving melanoma tumorigenesis. Our comprehensive investigation expands the understanding of the mutation spectrum of melanoma and identifies mutation events that may underlie the etiology of this deadly disease.

1236W

RNA-Seq identifies differentially expressed genes and mutations in oligodendrogliomas. *E. Schrock[1], K. Szafranski[2], J.A. Campos Valenzuela[3], S. Schauer[1], D. Krex[4], A. Rump[1], K. Hackmann[1], G. Schackert[4], L. Kaderali[3], M. Platzer[2], B. Klink[1]*. 1) Institute for Clinical Genetics, Medical Faculty, University of Technology, Dresden, Germany; 2) Leibniz Institute for Age Research - Fritz Lipmann Institute (FLI), Jena, Germany; 3) Institut für Medizinische Informatik und Biometrie, Medizinische Fakultät Carl Gustav Carus, Technische Universität Dresden, Germany; 4) Klinik und Poliklinik für Neurochirurgie, Universitätsklinikum Carl Gustav Carus, Technische Universität Dresden, Germany.

Brain tumor patients have a very poor prognosis (survival time often below one year) and targeted therapies are not yet available. Therefore, we started an explorative study for the identification of therapeutic targets in 13 oligodendroglial tumors. Most oligodendrogliomas (O) and also some oligoastrocytomas (OA) are characterized by a unique and typical unbalanced translocation, der(1;19), resulting in a 1p/19q-codeletion. We studied nine Os/OAs with and four Os/OAs without the 1p/19q-codeletion in addition to three normal brain samples obtained commercially. We combined transcriptome next generation sequencing (RNA-Seq) using a 2×100 nt paired-end approach on the Illumina-HiSeq-platform, with high resolution array CGH using the 400K chip as well as miRNA array, 6×80k expression array and Exon array analyses (Agilent). Array CGH identified additional aberrations (e. g. -4, -9, -14, -18), which are known to be associated with an unfavorable prognosis. We could also detect additional smaller deletions and duplications, which have not been described so far, such as a gain on chromosome 2 (+2p22.1-pter) involving the MYCN oncogene. The comparison of the transcriptome data between tumors with and without the 1p/19q-codeletion as well as normal brain samples revealed significantly differentially expressed genes (adjusted p-value <0.05). The average expression level of genes on 1p and 19q was reduced by half in the 1p/19q-codeleted tumors compared to tumors without the codeletion. Consistent with this, most of the down-regulated genes were located on 1p. Interestingly, in normal brain samples, the average expression level of 1p-located genes was found to be placed in between the two tumor groups. Even more surprisingly, the average expression level of the genes on 19q in normal brain samples was as low as in the tumors showing the 19q deletion. These findings were confirmed by the RNA-expression data of the Agilent 8×60k Arrays. Using RNA-Seq we could also identify structural changes, like the known IDH1 c.395G>A mutation and mutations in CIC and FUBP1. Our ongoing integrative data analysis shows that our comprehensive approach is very promising for identifying the key molecular changes in oligodendrogliomas and we aim at identifying new candidate genes as molecular therapeutic targets in a larger cohort.

1237T

Identification and quantification of somatic mutations with the Ion AmpliSeq™ Cancer Panel. *M. Andersen[1], S. Roman[1], K. Rhodes[1], C. VanLoy[1], A. Broomer[1], D. Topacio[1], G. Roma[1], R. Bennett[1], T. Neff[2], C. Beadling[2], C. Corless[2]*. 1) Life Technologies, Carlsbad, CA; 2) OHSU Kinght Cancer Institute, Portland, OR.

Translational and clinical cancer research requires rapid approaches that are compatible with small input amounts of often challenging samples, such as archived FFPE tissue. Ion AmpliSeq™ technology is a new tool for enriching tens to thousands of genomic targets in a single tube from 10ng of input DNA. The purpose of this study was to validate the performance of the Ion AmpliSeq™ Cancer panel in identifying and quantifying somatic mutations in archived FFPE tumor tissue. The Ion AmpliSeq™ Cancer Panel consists of a pool of 190 primer pairs that are designed to amplify mutation hotspot regions (including 739 known somatic mutations) across 46 genes. Forty-five archived FFPE-derived samples of tumor DNA that were previously genotyped on a Sequenom MassARRAY® platform were amplified using this panel, and the products were then ligated with barcodes, subjected to emulsion PCR and sequenced on an Ion Torrent PGM using 316 chips (4 samples per chip). The average amplicon read length was 76 bp and the average read depth was 2000; more than 95% of the amplicons had a read depth >400. All 53 known point mutations were correctly identified by the Ion Torrent variant caller software, including mutations in two DNA samples prepared from tumor cells dissected by laser-capture microscopy (Arcturus XT, Life Technologies). The range of somatic mutation frequencies was 8% to 96% and correlated well with results from the MassARRAY® (R2= 0.84). There were 19 in/dels represented in the tumor samples, of which all were visible in the final sequence but only a subset were identified by the variant caller software. In addition to the known sequence variants, 27 new non-synonymous mutations were detected in gene regions not covered by the MassARRAY® panel. These included 24 single nucleotide substitutions and 3 deletions of 2 bp. All 27 were confirmed by Sanger sequence analysis, including one variant detected in both a tumor sample and a laser microdissected specimen prepared from the same tumor. The Ion AmpliSeq™ Cancer Panel represents a fast and easy approach to generating target sequence for next-generation sequencing. It requires very little input DNA, and high read depths can be generated to support good sensitivity. Custom panels based on this technology are now being tested.

1238F

Whole-genome and targeted sequencing analysis of early stage high-grade serous ovarian cancer. *M. Bibikova[1], S. Humphray[1], R. Grocock[1], J. Peden[1], F. Nielsen[1], Z. Kingsbury[1], J. Chien[2,3], E.L. Goode[2], V. Ho[1], C. April[1], S. Munchel[1], J. Cottrell[1], Y. Tarabishy[2], J.M. Cunningham[2], S. Kaufmann[2], L.C. Hartmann[2], K.R. Kalli[2], V. Shridhar[2], J.-B. Fan[1], G. Heath[1], D. Bentley[1]*. 1) Illumina, Inc., San Diego, CA; 2) Mayo Clinic, Rochester, MN; 3) University of Kansas Cancer Center, Kansas City, KS.

Ovarian cancer is an aggressive disease which is usually diagnosed at a late stage and has poor therapeutic outcome. There are currently no genetic tests available to screen for or diagnose ovarian cancer in its early stages. To identify potential biomarkers for the early detection of ovarian cancer, we designed an enrichment pool targeting exons from 260 candidate genes thought to be somatically altered in early stage ovarian cancer (~1.6 Mb). Design was based on whole genome sequencing of 25 Mayo Clinic fresh frozen tumors (17 early stage high grade serous carcinomas and 8 other histologic subtypes) with matching blood DNA and supplemented with genes identified from the literature and public databases for further biological validation. The candidate gene enrichment pool was screened in a large set of validation samples (N=230) that were sequenced to an average 400x coverage. Due to the lack of availability of high quality fresh-frozen ovarian cancer samples, the validation set was largely represented by archived formalin-fixed paraffin-embedded (FFPE) tissues. Therefore, we optimized our TruSeq® sequencing library preparation protocol for use with FFPE samples. Good concordance in variant calls was obtained between five matched FFPE and fresh-frozen samples, even though experimental noise was higher in FFPE samples. Discordant variant calls were mainly due to low depth of coverage in the regions where variant calls were made. Improvements to DNA sequencing methods for archived samples will significantly enhance cancer research and biomarker discovery, and will result in more reliable sequencing-based diagnostics.

1239W

Detection of somatic mutations in tumor genomes using *de novo* assembly with assembly to assembly mapping (DA-AM). *A.R. Carson[1], W. Pfeiffer[2], T. Schwartz[2], G. Oliveira[1], T. Nicholas[1], G. Zhang[1], M.A. Miller[2], E.J. Topol[1], S. Levy[1]*. 1) Scripps Translational Science Institute, Scripps Health, La Jolla, CA; 2) San Diego Supercomputer Center, University of California San Diego, La Jolla, CA.

Identification of somatic mutations in tumor genomes by standard variant detection strategies is currently not comprehensive. Typical sequencing approaches employ paired-end reads mapped against a reference genome and succeed in identifying a portion of all point mutations, indels, and structural variants in a sample. However, detection by such methods is limited by several factors, including increasing detection errors coupled with increasing mutation size. Here we propose a novel approach to contribute to the comprehensive detection of somatic mutations in tumors using *de novo* assembly, followed by assembly to assembly mapping (DA-AM). This strategy detects additional variants, including large indels, not found by traditional variant detection methods. We sequenced the exomes of a colon tumor-blood pair using the Illumina HiSeq platform, creating 100bp paired-end reads for *de novo* assembly using SOAPdenovo. Assembled contigs were then uniquely aligned to the human reference genome using ATAC, an assembly-to-assembly comparison tool. We then used unique alignments to identify indels in each exome. For comparison, we also mapped the reads using BWA and identified indels using the GATK variant detection strategy. Of the ~8,000 indels found in each tissue by DA-AM, 87% are also identified by GATK. Conversely, only 39% of the GATK variants are found by DA-AM. Interestingly, the size distribution of the DA-AM unique variants is significantly different from the DA-AM variants that match GATK. The DA-AM unique variants are 2–10x larger than their counterparts, and include a 927bp deletion found in both the blood and tumor. In contrast, GATK unique variants are typically smaller (2.5bp average versus 17.6bp for DA-AM unique variants). Additionally, DA-AM finds unique somatic mutations, including a 15bp tumor-specific insertion 5' of *SGK1*. Validation of these unique variants is currently underway, using multiple approaches including whole genome sequencing with Illumina and Ion Torrent platforms. In summary, the DA-AM methodology successfully identifies unique variants, including somatic mutations that often exceed the detection limits of traditional variant discovery approaches. The largest identified variants represent a size that, to date, has only been identified by arrays or paired-end mapping. As such, our strategy underscores the importance of *de novo* assembly in providing a more comprehensive set of somatic mutations in cancer genomes.

1240T

Identification of therapeutic targetable mutations in cancer by whole transcriptome and genome sequencing. *D.W. Craig, W. Liang, W. Tembe, A. Christoforides, J. Aldrich, T. Izatt, J.M. Trent, J.D. Carpten.* Dept Neurogenomics, TGen, Phoenix, AZ.

Recent technological advances in the form of Next-Generation Sequencing (NGS) technologies now provide us with platforms to interrogate entire human genomes at a fraction of the time and cost compared to more traditional sequencing technologies. Identifying targeting mutations or concepts is highly dependent on design of sequencing libraries, depending depth, regions sequenced, and type of material sequenced (RNA, DNA). In this work, we present a framework for integrated analysis of whole genome and transcriptome NGS data from matched tumor and normal cancer patients to identify genomic alterations occurring in advanced oncology settings. We compare methods for detection of actionable variants based on library preparation, such as between targeted sequencing and whole-genome sequencing. We show how use of multiple library preparation approaches can allow for greater resolution for detection of complex variants or low-frequency variants, such as use of through use of exomes and large-insert whole-genomes. For informing mutations, we show how use of transcriptomic data can assist in interpretation particularly in "N-of-1" cases and present an analysis pipeline for generating informative analyses for aiding interpretation of genomic events in the context of actionable targets.

1241F

Identification of Somatic Mutations in Parathyroid Tumors using Whole Exome Sequencing. *M.K. Cromer[1], L.F. Starker[2,3,5], M. Choi[1], R. Udelsman[2], C. Nelson-Williams[1], R.P. Lifton[1], T. Carling[2,3,4]*. 1) Genetics, Yale University, New Haven, CT; 2) Surgery, Yale University, New Haven, CT; 3) Endocrine Neoplasia Laboratory, Yale University, New Haven, CT; 4) Cancer Genetics and Genomics, Yale University, New Haven, CT; 5) Surgical Sciences, Uppsala University, Uppsala, Sweden.

The underlying molecular alterations causing sporadic parathyroid adenomas that drive primary hyperparathyroidism (pHPT) have not been thoroughly defined. Therefore, the aim of the study was to investigate the occurrence of somatic mutations driving tumor formation and progression in sporadic parathyroid adenoma using whole exome sequencing. Eight matched tumor-constitutional DNA pairs from patients with sporadic parathyroid adenomas underwent whole exome capture and high-throughput sequencing. Four of the eight tumors displayed a frameshift deletion or nonsense mutation in MEN1, which was accompanied by loss of heterozygosity (LOH) of the remaining wild type allele. No other mutated genes were shared among the eight tumors. One tumor harbored a Y641N mutation of the histone methyltransferase EZH2 gene, previously linked to myeloid and lymphoid malignancy formation. Targeted sequencing in an additional 185 parathyroid adenomas revealed a high rate of MEN1 mutations. Furthermore, this targeted sequencing identified an additional parathyroid adenoma that contained the identical, somatic EZH2 mutation that was found by exome sequencing. This study confirms the frequent role of LOH of chromosome 11 and MEN1 gene alterations in sporadic parathyroid adenomas and implicates a previously unassociated methyltransferase gene, EZH2, in endocrine tumorigenesis.

1242W

Exome sequencing of metastatic prostate tumors, GWAS and functional analysis of the methylation regulator TET2 in prostate cancer. *M. Dean[1], M. Nickerson[1], K.M. Im[1], K.J. Misner[1], W. Tan[2], H. Lou[2], D.W. Wells[2], K. Frederickson[3], T. Harkins[3], T. Naab[4], B. Gold[1], T. Andersson[2], B. Zbar[1], W.M. Linehan[5], G.S. Bova[6], H. Li[2], S. Anderson[1], M. Yeager[7]*. 1) Lab Experimental Immunology, NCI-FCRDC, Frederick, MD; 2) SAIC-Frederick, NCI-FCRDC, Frederick, MM; 3) Roche Diagnostics Corporation, Indianapolis, IN; 4) Department of Pathology, Howard University, Washington, DC; 5) Urologic Oncology Branch, NCI, Bethesda MD; 6) Department of Pathology, School of Medicine, Johns Hopkins University, Baltimore, MD; 7) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD.

Metastatic prostate cancer (mPCa) has highly morbidity with poor control using existing therapies. The molecular basis of lethal mPCa is incompletely defined and markers that distinguish indolent from aggressive cancer are needed. We performed exome sequencing on metastatic tumors from an Ashkenazi Jewish patient who died of mPCa to identify genetic changes in metastatic disease and validate an experimental approach that avoided complications due to primary tumor heterogeneity. We show a germline mutation in *BRCA1* and somatic, nonsynonymous alterations in 22 genes in the primary tumor. An additional 31 genes were altered in all metastatic tumors defining a metastatic progenitor distinct from the primary tumor. Multiple, known cancer driver genes were altered, including *BRCA1*, *TMPRSS2-ERG*, *PBRM1*, and *TET2*. We sequenced 19 genes altered in this subject in metastases from additional mPCa patients and observed additional somatic, nonsynonymous changes in *TET2*, encoding a methylcytosine dioxygenase previously linked to PCa risk by genome-wide association studies. We characterized *TET2* germline missense variants and confirmed expression of the gene and the protein in prostate samples. We further mapped the location of the GWAS loci in the *TET2* gene and demonstrated multiple linked associated variants that are present in the promoter and in the first non-coding exons of the gene, and characterized alternative transcripts. Mobility shift assays identified novel DNA binding proteins, at the site of the associated variants, interacting in an allele-specific manner. The experimental approach provided one of the most comprehensive analyses to date of metastatic cancer.

1243T

Identification of Novel Driver Mutation in EGFR/KRAS/ALK-Negative Lung Adenocarcinoma of Never Smokers by whole exome sequencing. *S. Han[1], J. Yoon[4], J. Ahn[3], H. Jang[3], M. Lee[1], H. Kim[2], B. Cho[2], J. Lee[1].* 1) Department of Phamacology, Brain Korea 21 Project for Medical Science, Yonsei University, Seoul, South Korea; 2) Division of Medical Oncology, Yonsei University College of Medicine, Seoul, South Korea; 3) Department of Chemistry, Yonsei Univeristy, Seoul, Korea; 4) Hwasung Public Health Center, Hwasung, Republic of Korea.

Lung cancer in never smokers (LCINS), known for distinct pathogenesis and prognosis from lung cancer in smokers, are not fully understood. To identify novel driver mutation in lung cancer in never smokers (LCINS), we performed whole-exome sequencing of 20 normal and matched tumor samples from never smoked lung adenocarcinoma patients without EGFR, KRAS, and ALK mutations ("triple-negative adenocarcinoma"). The data revealed that candidate driver mutations in MLL3, YTDHF1, PIK3CG, ARID3A, and EPSTI1. Recurrently and frequently mutated genes were re-sequenced in-depth with capture probes. Validated mutations were further analyzed to detect significantly affected pathways. The whole-exome sequencing analysis provides new insights in unrevealed mutation profiles as well as the underlying mechanism of developing LCINS.

1244F

Detection of low frequency tumorigenesis variants by ultra deep sequencing (>1000x) across 409 oncogenes. *T.T. Harkins[1], C.C. Lee[1], M. Andersen[2], E. Levandowsky[1], M. Dindinger[1], J. Spangler[1], T. Ross[1], S. McLaughlin[1], V. Sheth[1].* 1) Life Technologies, Beverly, MA. 01915; 2) Life Technologies, Carlsbad, CA. 92008.

Understanding the importance of low frequency somatic mutations has been a barrier to understanding how tumors evolve and which mutations drive progression of the disease and which mutations are passengers. Most sequencing techniques to date have either used whole genome sequencing or exome (via hybridization enrichment) to sequence tumors to 30 to 100x average coverage. This depth of sequencing does not allow the detection of variants that occur below the 10 to 20% level. In this study, we have developed a method that combines ultra deep sequencing of a collection of normal, primary tumor and metastatic tumors with hierarchical clustering using allele frequencies. We have sequenced a collection of archived samples from individuals with stage III to V ovarian cancer. Sampling 8 to 20 sites per individual, including multiple sites from the primary tumor along with several metastatic sites, has allowed us to create a model to look at the relationships between samples based upon mutation profiles. To perform this study we targeted 409 oncogenes using Ion Torrent's AmpliSeq™ Comprehensive Cancer Panel. This panel uses 16,000 unique amplicons that are multiplexed in a total of 4 tubes, requiring a total of 40 ng of genomic DNA. This technique generated average sequence depths greater than 1000x coverage across all amplicons for all samples. Using this ultra deep sequencing method has allowed the identification of low frequency mutations and their allele frequency changes across the sample collection. Phylogentic relationships based upon hierarchical clustering within the sample sets were established using the somatic mutation allele frequencies for each sample.

Targeted sequencing of clinically relevant genes using TargetRich™ Gene Panels. *K. Jansen Spayd[1], I.A. Vasenkova[1], T. Shvetsova[1], D.A. Kloske[1], R.C. Bachmeyer[1], D.T. Moore[1], K.E. Varley[1,2].* 1) Kailos Genetics Inc., Huntsville, AL; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL.

Next-generation sequencing (NGS) holds great promise for many clinical applications, including personalized therapy selection, fetal DNA screening, and the diagnosis of rare genetic diseases. Most NGS approaches target the whole genome or exome and, for studies that are focused on clinically relevant regions of the genome, this results in low coverage of target regions or inefficient use of sequencer capacity. The transition of NGS into the clinic will require the ability to deeply sequence hundreds to thousands of targeted genomic regions from a large number of DNA samples. The drawbacks of current targeted enrichment methods include wasted sequencing capacity occupied by off-target DNA, requirement for large quantities of template DNA, high cost of reagents, low sample throughput, the need for specialized equipment, and inflexible design parameters. We developed TargetRich gene panels, based on Nested PatchPCR, for investigators to perform targeted deep sequencing of hundreds of genomic regions in large numbers of patient samples, including formalin fixed paraffin embedded samples (FFPE), to fully and efficiently utilize NGS platforms. Here, we describe the use of two TargetRich cancer research panels: a ten gene panel and a sixty three gene panel. We simultaneously amplified over 750 target sequences in a single tube from only 250 ng of patient DNA. The TargetRich Nested PatchPCR protocol can be performed on many samples in parallel in standard 96-well plates, can be completed in less than 9 hours, and requires no specialized laboratory equipment. We sequenced the targeted genes on three NGS platforms: Illumina GAIIx, MiSeq and Ion Torrent PGM. The high percentage of on-target sequence data and focused content allowed us to achieve deep coverage across the loci (average of 400X read depth). The accuracy of germline variant detection was tested and confirmed on samples that were sequenced as part of the 1000 Genomes Project. In addition, we tested the sensitivity of the method for detecting sequence variants introduced at lower frequencies, and found that we could detect variants present in less than 1% of sample, demonstrating that the method is sufficiently sensitive for detecting somatic mutations in heterogeneous tumor samples or fetal DNA mutations in circulating maternal DNA. Together, these results demonstrate the potential utility for TargetRich Nested PatchPCR for targeted sequencing in a variety of clinical applications.

1246T

Rapid and economical re-sequencing of hundreds of genes from sample-limited specimens using the Ion AmpliSeq™ Comprehensive Cancer Panel and Ion PGM™ semiconductor sequencing. *D. Joun, SM. Chen, B. Kong, I. Causga, CY. Li, D. Ruff, R. Bennett, M. Shannon.* Ion Torrent, Life Technologies, South San Francisco, CA.

The Ion AmpliSeq™ Comprehensive Cancer Panel (CCP) interrogates a set of more than 400 genes that have been associated with a broad spectrum of human cancers. CCP leverages the transformative Ion AmpliSeq™ and Ion PGM™ semiconductor sequencing technologies to amplify the coding exons of 409 genes and enable detection of known and de novo mutations within these genes. The panel employs approximately 16,000 primer pairs that are distributed across 4 pools to selectively amplify target regions in parallel in highly multiplexed PCRs and requires only 40ng of DNA sample. In addition, with an amplicon length of 125–175bp, the panel is tailor-made for analysis of highly fragmented DNA samples such as those obtained from formalin-fixed paraffin-embedded (FFPE) specimens. In this study, we demonstrated the broad utility of the panel for robust detection of genetic variation in sample-limited archived fresh-frozen and FFPE specimens. We specifically assessed the genetic variation present in FFPE and fresh-frozen sample pairs, including normal (breast or liver) tissue versus primary tumor and primary tumor versus metastatic tumor. We established that the CCP performs equivalently with FFPE and high molecular weight DNA samples in terms of target coverage uniformity and reproducibility of single nucleotide variant detection. We also identified 3 known coding variants in TP53 (P72R), ARID2 (S587G), and HNF1A (I27L) in an archived normal liver tissue FFPE sample. In addition, we investigated TP53 as a global biomarker across various tumor types as well as several markers associated with breast cancer, including ERBB2, and GATA3. Although we found no differences in these genes between the tumor and normal samples tested, we uncovered variants in several other genes in the CCP, including both coding and non-coding variants, in the same samples. These findings underscore the benefits in terms of speed, simplicity, and target coverage of using the Ion AmpliSeq™ Comprehensive Cancer Panel with the Ion PGM™ sequencer to characterize hundreds of genes, especially for sample-limited specimens.

Bayes-MutSig: A novel approach to determine significantly mutated genes. *N.B. Larson, H. Sicotte, J. Sinnwell, K.R. Kalari, E. Wieben, L. Wang, J.C. Boughey, M. Goetz, R. Weinshilboum, B.L. Fridley.* Mayo Clinic, Rochester, MN.

Cancer is a complex genetic disease that is the result of multiple genetic mutations. One approach to identifying etiologically relevant genes is determining which genes are disproportionately mutated in tumor samples relative to the rest of the tumor genome. If we consider somatic mutation rates to differ based on the sequence context of the base-pair, as in the case of methylation-related mutation of CpG sites, it is necessary to estimate context-specific mutation rates to more accurately assess statistical significance. We propose a Bayesian approach, referred to as Bayes-MutSig, to estimate single- and multiple-sample background somatic mutation rates for various mutation categories using a logit-linear binomial model. This approach not only allows us to share information across genes, but incorporate prior knowledge about background mutation rates. Point estimates derived from the posterior distributions of the model are then used to identify significantly mutated genes for that individual relative to background mutation, obtaining gene-wise p-values and false discovery rate estimates. We applied this method to whole exome sequencing data of two paired tumor-normal samples from MC1137 (BEAUTY), a prospective neoadjuvant breast cancer study. Breast cancer biopsies (tumor) and matched patient blood samples (normal) were obtained from two patients with locally advanced breast cancer. We evaluated 18,394 non-overlapping genes using our Bayes-MutSig approach and identified significantly mutated genes for each sample.

1248W

The transcriptional landscape and mutational profile of lung adenocarcinoma. *W. Lee[1,3], Y. Ju[4], J. Shin[1,5], J. Lee[1,6], B. Thomas[1], J. Lee[1], Y. Jung[8], J. Kim[9], J. Shin[9], S. Understanding the molecular signatures of cancer is important to apply appropriate targeted therapies. Here we present the first large scale massively parallel RNA sequencing study of lung adenocarcinoma demonstrating its power to identify somatic point mutations as well as transcriptional variants such as gene fusions, alternative splicing events and expression outliers. Our results revealed the genetic basis of 200 lung adenocarcinomas in Koreans including deep characterization of 87 surgical specimens by transcriptome sequencing. We identified driver somatic mutations in cancer genes including EGFR, KRAS, NRAS, BRAF, PIK3CA, MET and CTNNB1. New cancer genes, such as LMTK2, ARID1A, NOTCH2 and SMARCA4, were also suggested as a candidate for novel driver mutation. We found 45 fusion genes, 8 of which were chimeric tyrosine kinases involving ALK, RET, ROS1, FGFR2, AXL and PDGFRA. Of 17 recurrent alternative splicing events, we identified exon 14 skipping of MET proto-oncogene as highly likely to be a cancer driver. The number of somatic mutations and expression outliers varied markedly between individual cancers and was strongly correlated with smoking history of cancer patients. Our findings broaden our understanding of lung adenocarcinoma and may also lead to new diagnostic and therapeutic approaches.

1249T

Genes with Single Nucleotide Variations in Early-onset Female Breast Cancer Patients Identified through Exome Sequencing. *C. Lee[1], N. Leng[2], W. Kuo[3], H. Yang[4], K. Nobuta[2], C. Lin[5], C. Chang[6], Y. Lu[5], K. Lo[1], L. Hu[7], H. Chu[7], W. Chou[7], C. Chen[7], W. Yao[7], K. Chiu[1], A. Cheng[5], C. Shen[7], K. Chang[3, 8], C. Haudenschild[2], C. Chen[1].* 1) Genomics Res Ctr, Academia Sinica, Taipei, Taiwan; 2) Genomic Services, Illumina Inc., Hayward, CA, US; 3) Department of Surgery, National Taiwan University Hospital, Taipei, Taiwan; 4) Molecular and Genomic Epidemiology Research Center, China Medical University Hospital, Taichung, Taiwan; 5) Department of Oncology, National Taiwan University Hospital, Taipei, Taiwan; 6) Department of Medical Research, National Taiwan University Hospital, Taipei, Taiwan; 7) Institute of BioMedical Sciences, Academia Sinica, Taipei, Taiwan; 8) Department of Surgery, Cheng Ching General Hospital, Taichung, Taiwan.

Female breast cancer patients diagnosed in young age showed different characteristics to patients diagnosed in old age. To investigate candidate cancer driver genes in early-onset female breast cancer, exome sequencing was performed by Illumina GAIIx system, which obtained using 2×75 bp pair-end sequencing. The average coverage in both blood and tissue samples were 127x, and the average on-target rate were 98%. Paired blood and tumor tissue samples were collected from 84 patients with breast cancer diagnosed at an age of 40 years or younger. Patients were classified into four subtypes according to the expression levels of ER, progesterone receptor (PR), human epidermal growth factor receptor 2 (HER2) and Ki67 antigen: luminal A [ER(+), PR(+/−), HER2(-), Ki67low] (36 cases), luminal B [ER(+), PR(+/−), HER2(-), Ki67high] (13 cases), HER2 positive [ER(+/−), PR(+/−), HER2(+)] (23 cases), and triple negative [ER(-), PR(-), HER2(-)] (12 cases). Using hg19 as a reference, single nucleotide variations (SNVs) in exons were identified by CASAVA1.7 and annotated by ANNOVAR software. With a cut-off value of 30x coverage, nonsynonymous SNVs and synonymous SNVs located in conserved regions of 46 species were included in the analysis. Comparing variations in all paired samples, SNVs only observed in tumor sample were defined as Pure Tumor only (PT) mutations, which were somatic mutations. SNVs observed in tumor samples and in both blood and tumor samples were defined as Tumor only and Same (TS) mutations, which were somatic mutations in some patients and might be germline mutations in other patients. A total of 2466 PT mutants in 2054 genes and 1601 TS mutants in 1340 genes were observed in 84 patients. After comparing with 47 controls to filter polymorphisms in normal population, there were 2326 PT or TS mutants demonstrated in 2323 sites of 1965 genes. Gene with the highest mutation number was observed in 20 (23.8%) patients, while 12 genes harboring mutation sites in more than 9 (10.7%) patients. Of 1965 mutated gene, only 19 (1.0%) genes showed significant distributions among four subtypes.

1250F

Pathway analysis of somatic mutations in the whole genome sequence of aggressive tumors in African American prostate cancer patients. *K. Lindquist[1], R. Kazma[1], J.A. Mefford[1], T.J. Hoffmann[1], N. Cardin[1], B.A. Rybicki[2], D.A. Chitale[2], A. Levin[2], J.S. Witte[1].* 1) University of California, San Francisco, San Francisco, CA; 2) Henry Ford Health System, Detroit, MI.

Prostate cancer is the most common cancer and the second leading cause of cancer mortality among men in the United States. African Americans have not been included in many cancer genome studies, though they are more likely to have aggressive tumors than other American men are. Previous studies have characterized the role of chromosomal rearrangements in aggressive prostatic tumors. However, the role of small (1–50 nucleotide) somatic substitutions or insertions/deletions (indels) in these tumors is poorly understood. Studying these mutations in a pathway context, rather than individually, may help to elucidate their role. In this study, we used whole genome sequence data generated by Complete Genomics from five African American patients with aggressive prostate cancer, and identified all genomic modifications that occurred only in the tumor cells. We selected potentially functional mutations that occurred in genes (including coding regions, introns, transcription start sites, and untranslated regions) for inclusion in pathway analyses. We excluded mutations in regions susceptible to false positive calls, such as regions overlapping known repetitive sequences. For each sample, we ranked the genes using a formula that took into account the confidence that each mutation is a true positive finding. Using the Kyoto Encyclopedia of Genes and Genomes (KEGG) and other pathway databases and tools, such as the Protein ANalysis THrough Evolutionary Relationships (PANTHER) classification system, we determined whether the top ranking mutated genes are overrepresented by particular pathways. Our preliminary results showed that these genes implicate several pathways, some of which were previously known to be involved in prostate cancer (such as p53 and growth factor signaling pathways), and others which may be worth further investigation. These results demonstrate that pathway analyses can be a powerful strategy for studying small mutations in aggressive prostate tumors. This approach may be also valuable for other cancers and complex diseases.

SeqWright's Next-Gen Sequencing of FFPE Tumor Tissue Allows for Analysis of Multiple Cancer Markers With High Sensitivity and Excellent Correlation to Other Validated Clinical Methods. *A.C. Pond[1], X.X. Tan[1], L.T. Szkotnicki[1], V. Venegas[1], E. Zhou[1], Y. Mou[1], K.B. Thomas[1], P. Choppa[2], K. Guekunst[2], F. Lu[1]*. 1) SeqWright, Inc. 2575 W. Bellfort St. Houston TX, 77054; 2) Clarient, Inc. 31 Columbia. Aliso Viejo CA, 92656.

Next-generation sequencing (NGS) is quickly becoming a proven and valuable tool in many clinical applications, including drug discovery, the development of companion diagnostics and patient screening. In light of this, we sought to demonstrate the clinical utility of NGS by sequencing key mutational hotspots within a number of oncogenes and tumor suppressors using two leading cancer sequencing panels; the Ion AmpliSeq™ from Life Technologies and the TruSeq™ Cancer Panel from Illumina. NGS on gene panels holds many advantages over other biomarker detection methodologies. Through deep, targeted sequencing, NGS can obtain similar sensitivity of proven methodologies, such as allele-specific PCR (AS-PCR), while interrogating thousands of loci in parallel. This, along with the ability of NGS to discern individual reads, allows for the quantification of allele frequency and gives these systems the power to resolve complex mutations otherwise undetectable by other leading methods. We were able to successfully sequence multiple genes in parallel, with nanogram quantities of formalin-fixed DNA from several clinical samples. The data demonstrate a high concordance between the two platforms' (MiSeq™ and Ion Torrent™) ability to quantitate allele frequency, an indication of their overall accuracy. In addition, NGS demonstrated one hundred percent concordance with clinical AS-PCR genotyping and Sanger sequencing results and proved exceptional in several key aspects, including the ability to calculate percent allele frequency and to resolve complex mutations otherwise undetectable by AS-PCR and Sanger sequencing. An overall analysis of the workflow and sample requirements illustrate the feasibility of applying NGS in a clinical setting with nanogram quantities of micro-dissected, formalin-fixed samples. Overall, these studies directly demonstrate the fundamental advantages of NGS in clinical mutational screening and illustrate SeqWright's proven ability to leverage the full potential of leading technologies to help our customers discover clinically-relevant biomarkers and successfully develop new diagnostic tools.

1252T

Amplicon sequencing of tumors from xenograft, FFPE and fresh frozen samples. *B. Riley-Gillis, C. Qiu, O. Puig, R. Benayed.* Genetics and Genomics Laboratory, Translational Reasearch Sciences(TRS), Pharma Research and Early Development, Hoffmann-La Roche, Nutley, NJ.

Formalin-fixed, paraffin-embedded (FFPE) tumor samples are an invaluable resource for cancer research, drug development, and diagnosis. However, utilizing these samples is complicated by the nucleic acid degradation and base modification that occurs during the fixation and storage processes. In this study, we use the TruSeq Amplicon Cancer Panel and the MiSeq platform to assess the feasibility of sequencing tumors from FFPE, fresh frozen (FF), and xenograft samples. The Cancer Panel is a pre-designed Illumina panel that targets >35kb of sequence with 212 amplicons in 48 tumor suppressor and oncogenes. The quick turnaround time, ability to detect low frequency mutations in FFPE samples, and coverage of critical cancer genes make this panel ideal for rapid, sequence analysis of DNA from different types of tumor tissue. As a pilot study, we initially sequenced 4 matched FF and FFPE samples, 2 xenograft samples, and 1 HapMap control. Including the Illumina control sample, we had a total of 8 pooled samples with mean depth coverage for FF samples 4687x, FFPE samples 2249x, and for xenograft samples 4257x. After filtering variants based on frequency and quality score, the 2 pairs of FF/FFPE samples had 48 and 53 overlapping variants, respectively. Of these overlapping variants, 2/48 and 1/53 are missense mutations reported in COSMIC, the remaining are dbSNPs or non-coding variants. In a follow-up experiment, we sequenced the matched FF/FFPE samples in a 6-plex format and observed deeper coverage, as expected, but also higher quality scores for the low frequency mutations. Additionally, we identified 48 and 42 variants in 2 separate xenograft samples and are currently comparing the data to exome sequencing data. The results indicate that DNA from FFPE tumor samples can be successfully sequenced and yield high quality data. We are currently sequencing 20 additional matched FF/FFPE samples to thoroughly investigate the quality of variants detected from FFPE samples and define the coverage needed to call low frequency variants with high confidence. The ability to capture the significant information available in FFPE samples will be critical to deepen disease understanding and enhance cancer therapy. Additionally, baseline assessment of tumors from patients in clinical trials using targeted sequencing platforms is necessary to define tumor mutations, stratify patient populations and evaluate/predict therapy response.

1253F

Loss of the canonical Notch mediator RBPJ is recurrent in oligoastrocytomas. *P. Salo[1], E.I. Gaál[1], O. Tynninen[2,3], M. Niemelä[4], A. Laakso[4], A. Karppinen[4], A. Paetau[2,3], H. Mäenpää[5], J. Hernesniemi[4], M. Perola[1,6,7]*. 1) Public Health Genomics, Natl Inst Health & Welfare, Helsinki, Finland; 2) Departmentof Pathology, Haartman Institute,University of Helsinki,Helsinki,Finland; 3) Helsinki University Central Hospital, Helsinki, Finland; 4) Department of Neurosurgery, Helsinki University Central Hospital, Helsinki, Finland; 5) Department of Oncology, Helsinki University Central Hospital, Helsinki, Finland; 6) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 7) University of Tartu, Estonian Genome Centre, Tartu, Estonia.

Gliomas are neoplasms of the central nervous system arising from cells of the glial lineage. WHO grade I gliomas are curable with surgical resection whereas grade II-IV gliomas cannot be completely resected, usually resulting in fatal recurrences. As a part of a personalized cancer care project, we sequenced the whole exome and transcriptome of a single oligoastrocytoma in order to gain insight into its genetic landscape. We detected and experimentally validated 34 nonsilent somatic mutations. Only one of these, R132H in IDH1, has a confirmed role in the pathogenesis of gliomas. However, intriguingly, the tumor had lost both alleles of the canonical Notch mediator RBPJ, one by a deletion of most of chromosome 4 and the other via a frameshift deletion. Notch signalling is a conserved pathway regulating apoptosis, proliferation and differentiation of cells in a variety of situations, including the differentiation of neural crest stem cells into glia. Several lines of evidence have suggested Notch signalling may contribute to the initiation or maintenance of gliomas but no conclusive data have been presented. Subsequently, we compared the tumor with a published series of 7 oligodendrogliomas and found another tumor which had lost the wild-type function of RBPJ, one allele via loss-of-heterozygosity (LOH) and the other by a somatic missense mutation. Based on these observations, we sequenced the protein-coding regions of RBPJ in an independent sample of seven oligodendrogliomas and three oligoastrocytomas. The tumors were selected to match the index case on the basis of carrying LOH at 1p/19q (a hallmark of oligodendrogliomas and oligoastrocytomas) and in the genomic region containing RBPJ on chromosome 4. Of these ten additional tumors, one carried a frameshift deletion and another one a nonsense mutation in the remaining copy of RBPJ. In effect, altogether 3 out of 11 or 27% of the gliomas we investigated had conclusively lost both alleles of RBPJ via a combination of LOH and nonsense or frameshift mutations. Furthermore, these three tumors had all been classified as oligoastrocytomas, so 3 out of 4 oligoastrocytomas had lost RBPJ. Our data add to the notion that Notch signalling is involved in the pathogenesis of malignant gliomas. They also suggest that the role played by Notch is most important in gliomas with an astrocytic component. This may aid molecular sub-classification of malignant gliomas and hence contribute to improved treatment.

1254W

Characterization of a Small Cell Prostate Cancer using Exome Sequencing. *A.F. Scott[1], D.W. Mohr[1], H. Ling[1], G.S. Liptak[2]*. 1) Inst Gen Med,Blalock 1034, Johns Hopkins Med Sch, Baltimore, MD; 2) Dept of Pediatrics, SUNY Upstate Medical Center, Golisano Children's Hospital, Syracuse, NY 13210.

We have performed genotyping and exome sequencing of a small cell prostate carcinoma (SCPC) and normal control. SCPC is a high-grade malignant tumor with neuroendrocrine differentiation. It accounts for fewer than 1% of all prostate cancers and has a poor prognosis. Unlike the more common prostatic adenocarcinomas, SCPC does not present with elevated PSA levels and is often discovered after the occurrence of metastases. No molecular characterization has been presented for this tumor type to our knowledge.

We isolated DNA from a metastatic Virchow node and used saliva (mouthwash) as the normal control sample. DNA was genotyped on a 1M Illumina array and exome sequenced on an Illumina HiSeq 2000 following library capture with an Agilent SureSelect All Exon v3 kit. Sequence data was processed using CIDRSeqsuite v2.3.0 and analyzed with interpretation software tools from Knome. The mean read depth for the tumor was 353 and 138 for the normal exome.

The genotyping array showed a large degree of apparent chromothripsis (copy number variation, loss of heterozygosity, etc.) with 17 of the 22 autosomes grossly affected. Although the number of nucleotide substitutions between tumor and normal were fewer than seen in many cancers we noted that the tumor contained a region of LOH affecting most of 17p including the tumor suppressor TP53. The retained allele contained a somatic substitution in the coding region not seen in the normal exome that was predicted to be damaging by SIFT and PolyPhen2 (H179R). A predicted “function changing” somatic nonsense mutation was also seen in RB1. Other potentially functional somatic mutations were observed in several genes including FOXA1, CNTD2, and ZNF8. Knome reported “phenotype-implicated” variants in the normal exome in the genes SRD5A2 and CREB3L1 although their role in this cancer remains to be determined. We conclude that the loss of a normal allele and the somatic mutation of TP53 are likely to be the major lesions in this tumor. Whether they occurred before or after chromothripsis remains unknown

Profiling mutations in circulating tumor cells from breast cancer patients by targeted sequencing. *Y. Shen[1,2], X. Xu[3], W. DeWitt[2], N. Xu[1], F.Z. Bischoff[4], K.D. Crew[3], D.L. Hershman[3], M.A. Maurer[3], R. Parsons[3], K. Kalinsky[3].* 1) Center for Computational Biol & Bioinformatics, Columbia Univ, New York, NY; 2) Columbia Genome Center, Columbia Univ, New York, NY; 3) New York Presbyterian Hospital, Columbia University Medical Center; 4) Biocept Inc, San Diago, CA.

The genomic signature of circulating tumor cells (CTCs) may serve as a surrogate marker for accurate description of the metastatic tumors of interest, especially in the setting of treatment response. Here we describe a method to profile mutations in CTCs from breast cancer patients with metastatic tumors. Method: First we enriched CTCs from blood samples in metastatic breast cancer patients using a microfluidic device that contains a cocktail of antibodies against both epithelial and mesenchymal markers. We then use emulsion-based multiplex-PCR to generate amplicons of genes that harbor known mutations, and then perform massive-parallel semiconductor-based sequencing (Ion Torrent) of the amplicons. We sequenced at very high depth of coverage (>1000x) in order to detect cancer somatic mutations present in CTCs that are only the 1–3% range. We recalibrated the quality score of mismatch bases based on the context of sequence including homopolymers. We inferred the somatic mutations by testing statistical significance using a beta-binomial distribution model. Results: we were able to enrich CTC samples in 9 of 17 samples (CTC range 1–1063, mean=134), with CTC purity ranging from 0.3% to 6%. We found known missense mutations at E545D on PIK3CA, F354L on STK11, and Q61R on NRAS; we also found novel mutations of L540F and Q1033K within the hot spot regions of PIK3CA. We analyzed a healthy female concurrently as a negative control, in which none of the aforementioned mutations were observed. Conclusions: We developed a new method to enrich CTCs in breast cancer patients and characterize somatic mutations in CTCs. This provides a foundation for the future studies to describe the clonal lineage of primary tumors, CTCs and metastatic lesions.

1256F

Exome and Whole Genome Mutational Landscape in Pancreatic Ductal Adenocarcinoma. *L. Timms, A. Panchal, L. Mullen, J. Johns, R. Denroche, R. De Borja, F. Yousif, Z. Zha, M. Sam, A.M.K. Brown, T. Beck, J.D. McPherson.* Genome Technologies, Ontario Inst Cancer Research, Toronto, Ontario, Canada.

Pancreatic cancer is the fifth leading cause of cancer deaths with a poor prognosis and 5-year survival rates of ~2%, a result of late diagnosis, tumor resistance to current therapies and high metastatic potential. As a contributing member of the International Cancer Genome Consortium (ICGC), the Ontario Institute for Cancer Research (OICR) has committed to sequence 375 independent pancreatic adenocarcinoma tumors and their matched controls, in an effort to catalogue genomic abnormalities with the goal of identifying diagnostic and prognostic biomarkers and therapeutic targets. To date, whole exome sequencing has been performed on over 85 matched pancreatic primary tumor-normal and or xenograft-normal pairs using the Illumina Genome Analyzer IIX and HiSeq 2000 sequencers with a minimum of 100x target coverage. Sequence alignment and variant calling were performed using Novoalign and GATK, respectively. On average, 33 somatic non-synonymous single nucleotide variants (SNV) and 13 somatic small insertion or deletions (indels) (up to 15bp) were identified in each tumor sample. Verification of somatic coding, non-synonymous SNV and indels was performed using PCR amplification followed by sequencing on the Ion Torrent Personal Genome Machine (PGM). Our results confirm several known genomics abnormalities in PDAC, such as KRAS, p53 and SMAD4. In addition, ultra-deep KRAS (exons 2 & 3) sequencing of over 140 primary tumors was performed using the Ion PGM as a method of tumor cellularity estimation, as this is a near universal driver in PDAC. Whole genome sequencing (WGS) of primary tumors with cellularity over 20% and matched normal controls is underway, with over 25 pairs sequenced to complement the exome data; verification of variants identified from WGS is in progress. All somatic variant data are being released thorough the ICGC portal (www.icgc.org).

1257W

De novo germline mosaic BRCA1 exon deletion associated with bilateral breast cancer. *M. Tischkowitz[1,2], I. Delon[2], A. Taylor[2], A. Molenda[2], J. Drummond[2], K. Oakhill[2], A. Girling[4], H. Liu[3], J. Whittaker[2], R. Treacy[2].* 1) Department of Medical Genetics, University of Cambridge, Cambridge, UK; 2) East Anglian Medical Genetics Service, Addenbrooke's Hospital, Cambridge, UK; 3) Molecular Malignancy Laboratory and Department of Histopathology, Addenbrooke's Hospital, Cambridge, UK; 4) Department of Histopathology, Norfolk and Norwich University Hospital, Norwich, UK.

De novo BRCA1/BRCA2 mutations are very rare and to date only eight such cases have been reported. Here we present a case of a de novo BRCA1 mosaic deletion for exon 16. A 48-year-old woman with no family history presented with two synchronous right-sided grade III ER- PR- breast cancers at age 39 and a left sided grade III triple negative breast cancer with basal features at age 47. Complete sequencing of and MLPA analysis of BRCA1/BRCA2 revealed a low level heterozygous BRCA1 deletion detected by MLPA. This was confirmed independently by the presence of the p.Ser1613Gly polymorphism present at 30% compared to a heterozygous control (50%). The deletion was not present in either parent. Long-range PCR was used to identify the breakpoints of the deleted fragment and we propose a possible molecular mechanism for the deletion by recombination via a 38 nucleotides repeat present on both sides of the breakpoint. Further analysis of p.Ser1613Gly in both normal breast tissue and the cancers showed loss of BRCA1 heterozygosity in the right sided cancer but not the left cancer. Interestingly LOH status correlated with lymph node metastases (2/18 positive on the right, 0/17 on the left). In conclusion we believe that this is the first reported case of a proven de novo germline mosaic BRCA1 mutation and this can cause a similarly strong phenotype to a full heterozygote.

1258T

Single-nucleotide variant calling from low-coverage single-cell sequence data using tumor population structure. *S. Vattathil[1,2], N. Navin[3], P. Scheet[2,1].* 1) Human & Molecular Genetics Program, Graduate School of Biomedical Sciences, Univ. of Texas at Houston, Houston, TX; 2) Dept. of Epidemiology, Univ. of Texas MD Anderson Cancer Center, Houston, TX; 3) Dept. of Genetics, Univ. of Texas MD Anderson Cancer Center, Houston, TX.

Advances in single-nucleus sequencing (SNS) have created an unprecedented opportunity to study somatic mutations and clonal diversity at high resolution. Analysis of different types of mutations, such as single-nucleotide variants (SNVs), copy number variants, and indels, may provide complementary views of tumor progression. The SNS method uses next-generation sequencing technology, but requires additional whole-genome amplification which makes it more error-prone than traditional tissue sequencing. Further, a comprehensive survey of the tumor requires sequencing of many cells, making the experiments expensive. Statistical methods to improve the accuracy of mutation calling at realistic low sequencing depths allow the analysis to be applied to more samples, increasing power to define relevant mutations and describe the tumor genomic landscape.

Here we investigate how structure within the tumor cell population can be used to improve SNV calls from low-coverage single-cell sequence data. Multisample genotype calling methods have been popularly applied to low-coverage data in emerging large-scale surveys of human population genetics. However, tumor cell populations have a unique feature that may be exploited, namely that the natural history of a tumor cell population can be defined at the level of the entire genome, instead of at the local haplotype level as is the case for samples of germline genomes. That is, a much larger set of observed data from a sample of tumor cells may be used to inform the genotype calls at a given site in an individual cell.

In our method, which we call Single-Nucleus Genotype Likelihood-based Estimation (SiNGLE), we first define initial genotype estimates for each cell given the observed allele-specific read counts and the somatic mutation allele frequency at each site, estimated from the SNS data or from high-coverage sequencing of a matched tumor tissue sample. We use the genotype estimates to make inference on the structure underlying the sampled cells, and then redefine the genotype probabilities conditional on the inferred population structure. We apply the approach to experimentally-obtained single-cell and tissue sequence data from a breast tumor and a breast tumor cell line, and also evaluate the robustness of the method by testing genotype inference from simulated tumor sequence data generated under several models of tumor evolution.

1259F

Initial genomic analysis of a pure erythroid leukemia developing in association with hydroxyurea treatment for sickle cell anemia. *Z. Wang[1], D. Darbari[1,2], Z. McIver[1], I. Maric[3], L. Diaw[1], Y. Song[4], P. Johansson[4], J.B. He[4], J. Wei[4], A.J. Barrett[1], J. Khan[4], J.G. Taylor[1]*. 1) Hematology Branch, NHLBI, NIH, Bethesda, MD; 2) Children's National Medical Center, Washington, DC; 3) Laboratory Medicine, Clinical Center, NIH, Bethesda, MD; 4) Pediatric Oncology Branch, CCR, NCI, Bethesda, MD.

The antimetabolite hydroxyurea (HU) is the only widely available therapy for reducing complications of sickle cell anemia (SCA). It is not widely prescribed due to concerns about adverse effects, including cancer. Insufficient data currently exist regarding its leukemogenic potential. HU associated leukemia in SCA is rare, with only 6 literature reports. Whether such cases are coincidental or related to HU remains unanswered. We identified a 33 year old male with pure erythroid leukemia (formerly M6 AML) and a unique combination of SCA, HU treatment, and a short 4 year treatment latency. Cytogenetics showed a 5q rearrangement, 7q deletion, losses of chromosomes 15–22 and Y, suggesting a therapy related etiology. To date, no SCA AML cases have undergone in-depth genomic analysis to determine if HU has an etiologic role in therapy related leukemogenesis. High density SNP genotyping was performed to understand progressive disease changes. Analysis of germline DNA prior to HU and tumor DNA identified 10 mosaic aneuploidy events at diagnosis including losses at 5q, 7q and 17p and gains at 19p. High throughput parallel sequencing was also performed across a 38 megabase exome from the patient's germline, tumor and relapsed tumor DNA. We reasoned that somatic mutations in M6 AML might occur more frequently in genes regulating erythroid differentiation and proliferation. Somatic mutations were not present in commonly mutated AML genes like *NPM1*, *RUNX1* or *IDH1*, although 33 putative somatic missense mutations were detected including a validated somatic *TP53* mutation. Genome-wide cytogenetic band enrichment analysis of exome sequence data suggests the presence of a significant cluster of mutations along chromosome 19p. Together, the mosaic aneuploidy and exome sequence analysis suggest a region of 19p is potentially important to the pathogenesis of pure erythroid leukemia. This region extends at least 1.9 Mb and includes 58 genes. We are validating mutations in this region and exploring the role of 19p during stress erythropoiesis to further determine the significance of this finding. Investigation of this rare leukemia case offers a unique opportunity to elucidate the pathogenesis of erythroleukemia and possibly to determine if HU therapy is associated with leukemogenesis.

1260W

Novel L1 and Alu Retrotransposon Insertions in Cancer Related Gene Loci in the NCI-60 Cancer Cell Lines. *J. Zampella[1, 2], K. Burns[1]*. 1) Johns Hopkins, Baltimore, MD; 2) Howard Hughes Medical Institute, Chevy Chase, MD.

Long Interspersed Elements (L1 LINE) and Alu family Short Interspersed Element (SINE) are active Transposable Elements (TEs) in the human genome which have been implicated in oncogenesis. The functional roles of TEs remain under-explored due to the inability of current methods to locate these high copy number repeats in the genome-a barier recently overcome. Using a new genomic method, this study aims to discover cancer-specific L1 LINE and Alu SINEs in the NCI-60 panel.Using transposon insertion profiling microarray (TIP-chip) on genomic DNA from the NCI-60 tumor cell lines, vectorette PCR selectively amplified the 3' end of TEs to yield unique DNA fragments. These unique PCR amplicons were fluorescently labeled and hybridized to a custom genomic tiling microarray. Contiguous positive probes were detected as peaks. Data analysis included filtering peaks for `true' insertions and annotating their locations with respect to known TEs and cancer-related genes. We report 853 candidate L1 insertions (199 known and 654 novel) and 2,889 candidate Alu insertions (1,249 known and 1,640 novel) across the NCI-60 panel. There were 506 cancer genes within 5kb of the predicted L1 insertion intervals and 224 putative L1s within 500 bps of an exon. Relevant genes included RB1, ALK, IGF1R and BCL2. 1,027 cancer genes including BRAF, KRAS, BRCA2 and EGF were identified within 5kb of the predicted Alu insertions. 4 of the candidate Alu insertions were within 500 bps of an exon and 377 Alu insertion intervals mapped to the first intron of a gene. This is the first study to use a high through-put method to discover novel TE insertions in the NCI-60 tumor cell lines. L1 and Alu TEs may affect gene expression, alter genomic stability or act as insertional mutagens in neoplastic cells. Discovering L1 and Alu locations within the genome is the first step to understanding these TEs and their roles in oncogenesis. This study affirms that TIP-chip provides an effective high through-put method by which novel L1 and Alu insertions may be discovered. The discovery of these novel L1 and Alu insertions in proximity to known cancer genes provides specific targets to help elucidate the relationship between TEs and the development of different neoplasias. Ongoing work will evaluate the functional significance of these insertions.

1261T

Exome sequencing approach for identification of causative mutations in neurofibromatosis type 1 (NF1)-associated plexiform neurofibromas. *A. Pemov[1], H. Li[2], M. Wallace[2], D.R. Stewart[1], NISC Comparative Sequencing Program, NIH Intramural Sequencing Center, NHGRI, NIH, Bethesda, MD.* 1) NCI, NIH, Bethesda, MD; 2) University of Florida, Gainesville, FL.

Background. NF1 is an autosomal dominant tumor pre-disposition genetic disorder, caused by constitutive inactivation of one of two copies of the tumor suppressor *NF1*. Individuals with NF1 are prone to the development of both benign and malignant tumors including skin and plexiform neurofibromas (PNF). Although it is accepted that somatic inactivation of *NF1* is a necessary step in PNF development, little is known what other genes/pathways are disrupted/affected in the tumor. In this study, we performed whole-exome sequencing of 11 tumor samples matched with germline DNA obtained from 11 unrelated NF1 patients. **Methods.** Germline DNA was extracted from peripheral white blood cells and tumor DNA was obtained from primary Schwann cell (SC) cultures established from dissected plexiform neurofibromas. All cell cultures were of low passage and contained at least 70% SC. We used a capture kit from Illumina ("TruSeq") that targets roughly 60 million bases consisting of the CCDS annotated gene set. We sequenced the captured DNA on the Illumina HiSeq platform until we had sufficient coverage to call genotypes with an arbitrary quality score ("MPG") of 10 for at least 85% of targeted bases. We analyzed the data using an R-based statistical software designed to identify "driver" genes from "passengers." **Results.** First, we analyzed the *NF1* locus in both germline and tumor DNA. We identified pathogenic mutations in the *NF1* gene in all but one germline sample. All germline mutations were also confirmed in the tumor DNA. In addition, we identified somatic inactivation of *NF1* in nine out of 11 tumors. Second, we evaluated concordance of the exome sequencing data with genotyping data obtained from Illumina 2.5M SNP-arrays. Out of ~45,000 SNPs genotyped in both platforms, 97% were concordant. Finally, we analyzed the data to identify genes that could play an important role in PNF tumorigenesis. After correcting P-values for multiple testing we identified eight frequently mutated statistically significant genes with false discovery rate (FDR) below 0.05. Evaluation of biological functions of the genes revealed that such processes as cell cycle, nonsense-mediated mRNA decay and Notch pathway signaling might play an important role in PNF tumorigenesis. **Conclusions and further steps.** To our knowledge, this is the first attempt to identify "driver" mutations in NF1-associated PNF via exome sequencing. We are validating select mutations with the classic Sanger approach.

1262F

***DICER1* RNaseIIIb domain is mutated at two different sites in two different lesions in the same patient.** *M. Wu[1,2,3], N. Sabbaghian[1,3], N. Hamel[1,2], C. Choong[4], A. Charles[5], W. Foulkes[1,2,3]*. 1) Lady Davis Institute, McGill University, Montreal, Canada; 2) The Research Institute, McGill University Health Center, Montreal, Canada; 3) Program in Cancer Genetics, Departments of Oncology and Human Genetics, McGill University, Montreal, Canada; 4) School of Paediatrics and Child Health, University of Western Australia, Department of Endocrinology, Princess Margaret Hospital, Perth, Western Australia; 5) Dept Paediatric Pathology, Princess Margaret Hospital for Children, Perth, Western Australia.

DICER1 is an endoribonuclease responsible for the generation of microRNAs (miRNAs). miRNAs are responsible for the repression of many genes. *DICER1* has been found to be mutated in pleiotropic tumour predisposition syndrome (OMIM 601200). Families with germline mutations in *DICER1* are at increased risk of developing a variety of tumours associated with pleiotropic tumour predisposition syndrome. Here we present a patient who presented with a Wilms tumour and multinodular goiter. We discovered that the proband inherited one germline *DICER1* mutation (c.2117–1G>A) and acquired different somatic mutations in *DICER1* in her Wilms tumour (c.5429A>G) and in her multinodular goiter (c.5438A>G). We suggest that the acquired point mutations do not cause missense mutations but instead introduce exonic splice silencer (ESS) motifs which promote an alternative splicing event by which exon 25 is excluded from the resultant transcripts. If DICER1 protein is produced from such transcripts, the RNaseIIIb domain is almost entirely missing. We hypothesize that lack of RNaseIIIb domain would severely affect the variety and abundance of miRNAs in both the Wilms Tumour and multinodular goiter as compared to normal kidney and thyroid respectively to contribute to pathogenesis. These data are consistent with a variant of the classical two-hit model of tumour formation, in that the first hit is likely inactivating whereas the second hit is highly specific.

1263W

Multiplex PCR-based targeted deep sequencing of the comprehensive human lung cancer gene panel for the detection of KRAS and EGFR mutations. *Q. Peng, R. Gardner, N. Slepushkina, V. Devgan.* QIAGEN, Center of Excellence in Biological Research Content, Frederick, MD, USA.

Next-generation sequencing (NGS) technologies are revolutionizing cancer genomics research. The genetic spectrum of mutations in cancers, however, appears to be highly complex, with numerous low frequency somatic variations in a limited number of genes. Therefore, the deep sequencing (more than 1000X coverage) of selected cancer-related genes offers an effective solution for detecting somatic variants in heterogeneous samples and cancer cell subpopulations. A multiplex PCR target enrichment method for human disease-specific genes was developed and integrated with next-generation sequencing to provide an improved technique to identify biologically relevant mutations. In this study, a set of 20 lung cancer-related genes was deep-sequenced using genomic DNA isolated from formalin-fixed paraffin-embedded (FFPE) lung adenocarcinoma samples. The results showed more than 85% coverage for protein coding and UTR regions for all genes, with approximately 95% uniformity (>0.1X of median sequencing depth) and 90% specificity (on-target reads). Sequencing analysis revealed a number of mutations on various cancer-related genes, including previously unknown mutations in KRAS and EGFR. These mutations were confirmed by qPCR somatic mutation and pyrosequencing assays. The results demonstrate that the multiplex PCR target enrichment method provides a highly sensitive and specific solution for comprehensive sequence analysis of a limited number (tens) of potentially clinically relevant cancer genes in FFPE samples. The applications presented here are for research use only. Not for use in diagnostic procedures.

1264T

Highly sensitive detection of rare somatic mutations in tissue and plasma. *A. Marziali[1,2].* 1) Boreal Genomics, Vancouver, BC, Canada; 2) Engineering Physics, University of British Columbia, Vancouver, BC, Canada.

DNA sequence analysis is routinely used for detection of clinically actionable somatic mutations in tumor tissue. Current methods are limited to profiling tissues with mutation abundances above a few percent, particularly when detecting many mutations simultaneously. Since samples may only contain a small fraction of tumor content, and only a fraction of tumor cells may contain relevant mutations, false negatives and ambiguous results are common.

There is also a need for less invasive tumor profiling in diseases such as lung cancer where emergence of mutations such as EGFR T790M result in resistance to targeted therapies and necessitate the need for re-biopsies. Traditional biopsies are invasive and carry risks, preventing their use a monitoring tool. Profiling mutation status by analysis of circulating nucleic acids in plasma would be preferable, but poses the challenge that tumor DNA is present in low abundance in a large amount of normal “wild-type” sequence. Current methods are not sensitive enough to allow such detection reliably, primarily due to the high false positive error rates induced by DNA amplification on the high abundance of wild-type alleles.

We have developed a novel method of detecting up to 100 somatic mutations in tumor samples containing as little as 0.01% mutant DNA. The enabling feature of our method is removal of wild type DNA sequences prior to amplification and detection; thereby reducing false positive rates that result from PCR induced errors on wild type DNA.

Our method is capable of detecting a handful of mutant molecules in a background of millions of wild-type genomes and allows for the detection of low abundance somatic mutations in tissue and plasma samples.

We present validation data in FFPE and plasma samples, demonstrating 0.01% sensitivity. We also report on concordance between mutation incidence in tissue and matched plasma in human samples.

1265F

Integrative investigation on breast cancer by ER, PR and HE2-defined subgroups using mRNA and microRNA expression profiling and cancer core pathway analysis. *X. Dai[1], S. Khan[1], T. Heikkinen[1], P. Heikkilä[4], K. Aittomäki[2], C. Blomgvist[3], D. Greco[1,5], H. Nevanlinna[1].* 1) Department of Obstetrics and Gynecology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 2) Department of Clinical Genetics, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Oncology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 4) Department of Pathology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 5) Department of Bioscience and Nutrition, Karolinska Institute, Stockholm, Sweden.

Breast cancer is a heterogeneous disease and understanding the core functional differences driving this heterogeneity is also of crucial clinical importance in seeking effective breast cancer treatment. Several layers of information, including immunohistochemical markers, mRNA and microRNA expression profiles and pathway analysis have been used for such purpose previously. However, an integrative approach of these is currently missing. We have studied here mRNA and microRNA expression profiles of breast cancer subgroups defined by immunohistochemical expression (IHC) of the major receptors defining breast cancer biology i.e. the hormone receptors ER and PR as well as human epidermal growth factor receptor 2 (HER2). The defined sets of features were validated in two independent data sets at multiple levels, including unsupervised clustering and supervised classification. A core basal group was further defined by epidermal growth factor receptor EGFR and cytokeratin 5/6 IHC expression and compared to triple negative [ER-/PR-]HER2- group. Moreover, the gene expression signatures of the tumor subgroups were screened by in-depth analysis of 12 cancer core pathways. We identified and validated a novel breast cancer gene expression signature composed of 976 mRNAs and 69 microRNAs. [ER+/PR+]HER2- and [ER+/PR+]HER2+ vs. [ER-/PR-]HER2+ tumors are shown to significantly differ both at the mRNA and microRNA levels. HER2 positive tumors are more closely related to triple negative tumors by mRNA profiling than by microRNA expression. Closely related microRNAs sharing the same targets may exert opposite roles in different subgroups. Besides the core cancer pathways, other pathways such as those controlling biomass synthesis are shown to be involved in the core basal group which may enable additional progressive nature compared to the other triple negative tumors. Some therapeutic strategies are proposed for breast cancer treatment, and the pathway analysis also reveals that the clinical strategy and pivotal targets need to be tuned according to different tumor subgroups. This study is the first attempt to elucidate mRNA and microRNA expression and cancer core pathways in breast cancer subgroups defined by ER, PR and HER2 expression. The results can avail functional studies of breast cancer with further translational potential for clinical use.

1266W

Novel Oligoheterocycles and potential ability as anti cancer therapy. *S. Al-Aqeel.* Department of Chemistry, Faculty of Science, King Saud University, Riyadh, PO Box 22452, Riyadh, Saudi Arabia.

There has been interest in heteocyclic systems as sequence-selective DNA minor groove binding agents (and some as RNA binding agents), such as dimeric benzimidazoles related to Hoechst33258 (and trimeric equivalents), and oligopyrroles (and benzimidazole-imidazole chimeras). More recently, some examples of symmetrical dimers or linked dimers, have been reported with similar targets, and at least some evidence of structures with potential for targeting G-quadruplexes. Developing new methods to generate novel bis- and oligobenzimidazoles and evaluation as nucleic acid binding agents is thus of interest. This contribution will describe synthesis of several families of novel oligoheterocyclic systems, designed to provide a modular approach to provide a range of new ligands types, categorized based on heterocyclic orientation, separation and various functionality of linkers incorporated, for example including compounds of the generic types shown. Additionally, other series of dimers, trimers and tetramers will be described. Data on evaluation of binding for an array of structures in the above classes to a series of target DNA sequences (containing various length (AT)n sections) will be presented, leading to identification of novel DNA-binding ligands in several structural families with sub-micromolar affinities and potential ability as anti cancer therapy.

1267T

Relative telomere length differs according to DNA extraction method. *L. Boardman[1], K. Litzelman[2], R. Johnson[3], M. Devine[1], R. Firl[1], A. Johnson[1], M. Vincent[1], J. Cunningham[3], C. Engelman[2], S. Seo[4], R. Gangnon[3, 4], D. Rider[5], G. Petersen[6], S. Thibodeau[3], H. Skinner[2]*. 1) Internal Medicine, Mayo Clinic,College of Medicine Rochester, MN; 2) Population Health Sciences, University of Wisconsin, Madison, WI Laboratory Medicine and Pathology, Mayo Clinic College of Medicine, Rochester, MN; 3) Laboratory Medicine and Pathology, Mayo Clinic College of Medicine, Rochester, MN; 4) Biostatistics and Medical Informatics, University of Wisconsin, Madison, WI; 5) Information Technology, Mayo Clinic College of Medicine, Rochester, MN; 6) Health Sciences Research, Mayo Clinic College of Medicine, Rochester, Mn.

Telomere length has been identified as a marker of biological aging. Both shorter and longer telomeres in peripheral blood leukocyte (PBL) DNA have been associated with diseases of aging, including multiple types of cancer and cardiovascular disease. However, associations have not been consistent across studies — even among studies of the same cancer type. In a study to assess the role of telomere length in colorectal cancer (CRC) patients, we examined PBL relative telomere length (RTL) measured by quantitative PCR (qPCR) in 1096 CRC patients and 1972 healthy controls ascertained through the Colon Cancer family registry (Colon CFR) recruitment locations (Hawaii, Australia, Toronto, Seattle, San Diego and the upper Midwest of the US). The centers used differing DNA extraction methods, including Phenol/Chloroform, PureGene and QiaAmp. We observed significant differences in RTL by DNA extraction method. PureGene extracted DNA had a mean RTL = 6219 base pairs (bp) with a range of 4548 -11050 bp compared to phenol/chloroform extracted DNA which had a mean RTL = 5593 bp with a range = 4184-16662 bp. DNA extracted by QiaAmp had a mean RTL= 4832 and a range = 4186-10544 bp. We subsequently compared RTL measured by qPCR from 25 CRC cases and 25 normal controls in PBL DNA extracted by each of the three DNA extraction methods used by the Colon CFR centers. The range of telomere length measured by qPCR from PBL DNA extracted by the QiaAmp column method was smaller than that which could be detected by either the Puregene or Phenol/Chloroform extraction methods (ranges: 4477-5266 bp, 4230-9259 bp, and 4761-9540 bp, respectively). Within-individual differences in RTL by extraction method supported this finding, with QiaAmp measuring telomeres as significantly shorter than PureGene (mean difference: 749.5 bp; 95% confidence interval (CI): [411.6, 1087.4]) or Phenol/Chloroform (mean difference: 908.3; 95% CI: [574.5, 1242.0]). These significant differences in PBL RTL based on DNA extraction method may contribute to the discrepancies between studies seeking to find an association between cancer or other diseases and RTL.

1268F

Hereditary breast/ovarian cancer in Algerian population: Molecular analysis of *BRCA1* and *BRCA2* genes. *F. Cherbal[1], R. Bakour[1], S. Adane[2], K. Boualga[3], N. Salhi[1], A. Chikh[1], P. Maillet[4]*. 1) Unit of Genetics, LBCM, Faculty of Biological Sciences, USTHB, Algiers, Algeria; 2) Central Hospital of Algiers, Algiers, Algeria; 3) Anti Cancer Center, Blida, Algeria; 4) SwissCheckup Laboratory, Yverdon Les Bains, Switzerland.

Background: Breast cancer is the leading cause of cancer death in women in Algeria. From year 2005 to 2010, we screened *BRCA1* and *BRCA2* genes in 121 individuals from an Algerian cohort with a personal and family history suggestive of genetic predisposition to breast/ovarian cancer. Methods: We analyzed 121 DNA samples from 90 breast/ovarian cancer families. 86 individuals from 70 families have been tested for complete *BRCA1* and *BRCA2* germline mutations screening. The approach used is based on *BRCA1* and *BRCA2* sequence variants screening by DGGE, SSCP or High-Resolution Melting (HRM) curve analysis followed by direct sequencing. Samples for which no pathogenic mutation was found were analyzed by MLPA. *In silico* analyses have been performed using different bioinformatics programs to individualize genetics variations that can disrupt the *BRCA1* and *BRCA2* genes function. Results: Three distinct pathogenic mutations c.83_84delTG, c.181T>G, c.798_799delTT and two new large genomic rearrangements involving deletion of exon 2 and exon 8 respectively, were detected in *BRCA1* gene. Interestingly, the *BRCA1* mutation c.798_799delTT was identified in two unrelated families. Two pathogenic mutations c.1310_1313delAAGA and c.5722_5723delCT were identified in *BRCA2* gene. In addition, 84 UVs and SNPs were detected in *BRCA1/2* genes (33 *BRCA1* and 51 *BRCA2*), 35 were new UVs (10 *BRCA1* and 25 *BRCA2*), 7 were rare UVs (4 *BRCA1* and 3 *BRCA2*) and 42 were SNPs (19 *BRCA1* and 23 *BRCA2*). Moreover, 9 new missense UVs identified in this study: two *BRCA1* (Q1356K and R1634M) and seven *BRCA2* (D367N, S879Y, S1013T, C1290S, V1810F, H2116D and G3086R) show a damaging PSIC score yielded by PolyPhen2 program and could be pathogenic. In addition, 6 new *BRCA2* missense UVs out of seven that were found to be damaging by PolyPhen2 program, also were deleterious according to SIFT program. Several SNPs of *BRCA1* P871L, K1183R, S1613G and *BRCA2* N289H, N372H, N991D, G2384K, have been identified with high frequency in patients who were tested negative for *BRCA1* and *BRCA2* mutations.These missense polymorphisms could have a role as susceptibility breast cancer markers in Algerian breast/ovarian cancer families where pathological *BRCA1* and *BRCA2* mutations were not present. Conclusions: The accumulating knowledge about the prevalence and nature of *BRCA1* and *BRCA2* variants in Algerian population will contribute in the future to the implementation of genetic testing and counseling for Algerian families at risk.

1269W

GENECAPP: Sequence-Specific *in vivo* Analysis of Protein-DNA Interactions in Human Cancer Cell Lines. *H. Guillen Ahlers[1], A. Ludwig-Kubinski[1], S. Tian[3], C. Anderson[1], A.M. Greene[1], J. Kennedy-Darling[2], M. Levenstein[2], R. Knoener[2], M. Chesnik[1], M. Scalf[2], Y. Yuan[2], R. Cole[1], M. Shortreed[2], L. Cirillo[1], R. Stewart[3], L.M. Smith[2], M. Olivier[1]*. 1) Wisconsin CEGS, Medical College of Wisconsin, Milwaukee, WI; 2) Wisconsin CEGS, University of Wisconsin, Madison, WI; 3) Morgridge Institute for Research at the University of Wisconsin, Madison, WI.

DNA-protein interactions are responsible for chromatin stability, activity, and transcription modulation of the encoded genetic information. Currently, no technologies exist to examine these protein-DNA interactions in a comprehensive genome-wide manner. To overcome this challenge, we developed **G**lobal **E**xo**N**uclease-based **E**nrichment of **C**hromatin-**A**ssociated **P**roteins for **P**roteomics (GENECAPP) which utilizes oligonucleotide capture to isolate selected chromatin regions in a sequence-specific manner and analyzes captured DNA-associated proteins using mass spectrometry.

We have used the GENECAPP technology in *S. cerevisiae*, targeting the Gal upstream activator sequence (UAS_{Gal}). In this study, GENCAPP is being used to target genomic regions in breast and ovarian cancer cell lines. Gene expression profiles of drug resistant cell lines (MCF-7_ADR, NCI_ADR) and their drug sensitive counterparts (MCF-7, OVCAR-8) were used to identify highly differentially expressed genes. We developed GENECAPP capture approaches to examine selected promoter regions of these genes to understand the underlying chromatin-proteome interactions that alter gene expression.

Our initial efforts focused on the promoter region of *ABCB1*, a gene implicated in multidrug resistance. Chromatin was extracted from cross-linked cells and fragmented using common restriction enzymes. Total capture efficiencies surpassed 10%, and the target region was enriched 15 fold compared to a negative control. Mass spectral characterization of protein binding before and after drug treatment is currently under way to identify DNA-binding proteins that may mediate the cell line-specific gene expression effect. Our initial data suggest that GENECAPP at the capture level works well in mammalian cells and has the potential to become a powerful tool to identify DNA-binding proteins bound to specific DNA regions of interest *in vivo*.Funded by the Wisconsin CEGS through NIH/NHGRI grant 1P50HG004952.

Examination of UVR-Induced DNA damage and repair and its association with apoptosis in human keratinocytes and fibroblasts. *M. Karbaschi[1], M.D. Evans[1], S. Macip[2], M.S. Cooke[1]*. 1) Department of Cancer Studies and Molecular Medicine, University of Leicester, Leicester, Leicestershire, United Kingdom; 2) Department of Biochemistry, University of Leicester, Leicester, Leicestershire, United Kingdom.

Skin cancer has an increasing incidence in countries with large populations of white skinned individuals. UVR, by initiating the DNA damage, can lead to mutagenesis and is regarded as the prime cause of most skin cancers. As a result, UVR protection is of primary importance to prevent UVR-induced skin cancers. Cyclobutane pyrimidine dimers (CPD) are an important form of DNA damage induced by both UVA and UVB and removed by nucleotide excision repair. The persistence of CPDs, compared to other forms of DNA damage, is understood to be a major contributory factor to their mutagenicity. Using the T4endonuclease V-modified comet assay on human keratinocytes and fibroblasts, we noted that there was rapid initial repair of CPDs over the first 6h post-irradiation, following either UVA or UVB treatments, but whilst this slowed significantly in the UVB-irradiated cells, it continued to be rapid in the UVA-treated cells with levels approaching baseline within 36h. This confirmed the widely accepted slow repair of UVB-induced cyclobutane thymine dimers, but we uniquely noted far more rapid repair of UVA-induced cyclobutane thymine dimers. There were no significant differences in cell viability between the two treatments over the first 6h post-irradiation, but at 24h post-irradiation viability had decreased significantly only in the UVB-irradiated cells. These data suggest that for at least the first six hours following UVB irradiation, the majority of cells were viable and capable of repair, after that time increasing numbers of cells enter apoptosis, and therefore fail to repair the DNA damage.

1271F

The IRS1 rs2943641 genetic variant and the protection against cancer. *S. Romeo, C. Maglio, J. Andersson Assarsson, K. Sjöholm, L. Sjöström, L.M. Carlsson.* University of Gothenburg, Gothenburg, Sweden.

INTRODUCTION: Obesity and insulin resistance are associated with an increased risk of cancer. Bariatric surgery and drugs that reduce insulin resistance have been shown to decrease cancer risk. The insulin receptor substrate 1 (IRS1) gene encodes the primary mediator of the insulin receptor. A single nucleotide polymorphism (rs2943641) in a non-coding region downstream of the IRS1 gene has been associated with insulin resistance in a genome-wide association study and this result has been widely replicated thereafter. However, the long term effect of this genetic variant on insulin-related comorbidities, such as cancer, remains unknown. The aim of this study was to determine whether the IRS1 rs2943641 T allele results in reduced insulin resistance and protects against cancer in the Swedish obese subjects (SOS) study cohort. METHODS: The SOS study is a prospective, controlled, intervention study involving 4,047 obese individuals; 2,010 individuals have undergone bariatric surgery and 2,037 conventional treatment (matched control group). A total of 2,988 non diabetic obese subjects (body-mass index, BMI=41±5) from the SOS study have been genotyped. Insulin resistance was measured by the homeostasis model assessment for insulin resistance (HOMA-IR). Data on the incidence of solid cancers were available from all individuals (median follow up: 15 years). SUMMARY OF RESULTS: At baseline, HOMA-IR levels were lower in T allele carriers from the SOS study cohort. However, at 2- and 10- year follow up, the association between the IRS1 T allele and HOMA-IR was blunted in surgery group. An interaction was observed between IRS1 genotypes and the surgical treatment on cancer incidence. In the control group, T-allele carriers had a significantly lower cancer incidence while there was no effect of IRS1 genotype on cancer incidence in the surgery group. CONCLUSION: the IRS1 rs2943641 T allele associates with protection against insulin resistance and cancer development in severely obese individuals. However, these associations are lost after bariatric surgery, suggesting that body weight modulates the effect of IRS1 genotype.

Lynch syndrome: Awareness among medical students at a United States medical school. *J. S. Taylor[1], M. K. Frey[1], M. Biewald[1], M. Worley, Jr.[2], S. Lin[1], K. Holcomb[1]*. 1) Obstetrics and Gynecology, New York Presbyterian Hospital Weill Cornell Medical Center, New York, NY; 2) Department of Gynecologic Oncology, Brigham and Women's Hospital, Boston, MA.

Objectives: Lynch syndrome was first described in the 1950s however until recently it was rarely included in medical school curricula. As a result, many practicing physicians have limited exposure, potentially contributing to significant under diagnosis. As identification of Lynch syndrome prior to malignancy allows for intensified screening, prophylactic surgery and improved patient outcomes, all physicians should be aware of the characteristics of affected families. We aim to determine the overall level of awareness of Lynch Syndrome among medical students at an American medical school Methods: A voluntary and anonymous questionnaire was delivered to students at an American medical school. The survey instrument assessed the respondent's perceived knowledge regarding the genetics and recommended screening for carriers of Lynch Syndrome mutations. Results: The questionnaire was distributed to the entire student body (405 students) with a response rate of 50%. Fifty-nine percent of students reported that they had learned about Lynch syndrome; 27% of first year students, 44% of second year students; 90% of third year students and 100% of fourth year students. Of the students familiar with Lynch syndrome, the reported knowledge of the underlying genetics was 46%, available genetic screening, 18%, criteria used to screen for the syndrome, 24%, recommendations for colon screening, 31% and recommendations for endometrial cancer screening, 17%. Conclusions: The majority of medical students surveyed had been exposed to Lynch syndrome and awareness increased over each year of education. Significantly more students were aware of recommendations for colon cancer screening than endometrial cancer screening (32% versus 17%, p = 0.01). Studies of the natural history of Lynch syndrome indicate that affected women are more likely to present with endometrial cancer than colon cancer and while there are no prospective data proving the efficacy of endometrial cancer screening in this high-risk population, the endometrium is easily accessible and can be sampled using simple office techniques. In addition, prophylactic hysterectomy and bilateral salpingo-oophorectomy are reasonable risk reducing interventions for the prevention of both uterine and ovarian cancer. Our findings suggest that increased emphasis must be placed on teaching the gynecologic manifestations of Lynch Syndrome in order to avoid the misconception that it is simply a colon cancer syndrome.

Characterization of active chromatin signatures in testicular germ cell tumour cell lines. *S.J. White[1], Y. van de Zwan[1,2], C.M. de Boer[1], F. Rossello[1], L.H.J. Looijenga[2], A.J. Notini[1]*. 1) Centre for Reproduction and Development, Monash Institute of Medical Research, Clayton, Victoria, Australia; 2) Erasmus MC, University Medical Center Rotterdam, Josephine Nefkens Institute, The Netherlands.

A fundamental goal of modern biology is understanding how genes are regulated both temporally and spatially. This control is not only dependent on DNA sequence; epigenetic factors such as CpG methylation and histone modifications also play a major role. A range of histone modifications are associated with different characteristics of transcriptional regulation, and techniques such as chromatin immunoprecipitation (ChIP) have started to reveal the complexity underlying this regulation. We have applied ChIP-seq to explore the epigenetic differences between the two major subtypes of testicular germ cell tumours (TGCTs), namely seminoma (SE) and non-seminoma/embryonal carcinoma (NS). SE consist of embryonic germ cells that are not overtly pluripotent, whereas NS are cancer cells that have reactivated pluripotency. Our initial studies focused on cell lines, with TCam-2 representative of SE and NCCIT of NS, especially the stem cell component; embryonal carcinoma (EC). Using antibodies specific for histone modifications such as H3K4me1, H3K4me3 and H3K27ac, we were able to identify active regions within the genome, including promoters and enhancers. Initial analysis matched the classification of the cell lines e.g. SOX17, a marker for SE, was strongly enriched for these modifications in TCam-2 compared to NCCIT, whereas the opposite was seen for SOX2, an EC marker. We are currently confirming the most significant differences between the two cell lines, and plan to expand this study into primary TGCTs. These findings will identify epigenetic differences between SE and NS, and will improve our understanding of pluripotency.

Single Nucleotide Polymorphisms (SNPs) and cancer risk in individuals with Costello Syndrome. *B.A. Thompson[1], G. Desachy[2], J. Quinn[2], A.E. Toland[3], L.A. Weiss[2], K.A. Rauen[1].* 1) Pediatrics, University of California San Francisco, San Francisco, CA; 2) Psychiatry, University of California San Francisco, San Francisco, CA; 3) Molecular Virology, Immunology and Medical Genetics, Ohio State University, Columbus, OH.

Background. The Ras/mitogen-activated protein kinase (MAPK) signal transduction pathway plays an important role in cell proliferation, embryonic development and tumorigenesis. Abnormal germline regulation of this pathway results in overlapping yet very distinct syndromes known as RASopathies, which are a class of human genetic syndromes caused by germline mutations in genes encoding components of the Ras/MAPK pathway. One feature observed in many RASopathies is an increased incidence of cancer. The type of cancer varies between each syndrome. Costello syndrome (CS), caused by germline mutations in *HRAS*, is one RASopathy whereby ~17% of individuals develop cancer including rhabdomyosarcoma, neuroblastoma and bladder cancer. It is unclear why some individuals with CS develop cancer and others do not. In population studies, SNPs in key oncogenes and tumor suppressor genes (TSGs) have been reported to be associated with an increased cancer risk. However, the association between these SNPs and cancer risk in CS individuals has not previously been described. **Methods.** Demographic information including ethnicity, sex and history of cancer was collected from 52 CS individuals. DNA was extracted from blood, fibroblasts or buccal swabs obtained from each patient. DNA was also extracted from a tumor obtained from one of the patients that was previously reported to exhibit loss of heterozygosity (LOH) for the wt *HRAS* allele. CS diagnoses were confirmed by sequencing *HRAS*. Eight SNPs previously reported to be associated with increased cancer risk were sequenced. These SNPs are located in the following genes: *MYC, AURKA*, *TP53*, *KRAS, MDM2* and *CDKN1A*. A statistical analysis of the allele frequencies was performed using a classic Fisher's exact test comparing cases and controls. **Results & Conclusion.** Of the 52 individuals with CS, 8 had a history of cancer (15%). Statistical analysis of the SNP allele frequencies of the cases (CS with cancer) vs controls (CS without cancer) yielded p-values >0.05 for all 8 SNPs. Sequencing of the tumor sample confirmed the LOH and presence of two copies of the HRAS G12S mutation, but did not show LOH at any of the 8 SNPs sequenced in this study. Although preliminary analysis of the data obtained from this study did not find evidence for association between these SNPs and cancer risk in this population, further analysis of other SNPs in TSGs or oncogenes may reveal an association impacting cancer risk assessment and future patient care.

Assessment of Individuals with BRCA1 and BRCA2 Large Genomic Rearrangements in High-Risk Breast Cancer and Ovarian Cancer Families. *L. Zhang[1], A. Arnold[2], M. Harlan[2], M. Robson[2].* 1) Molecular Diagnostics Service, Department of Pathology, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY.

Background Standard BRCA1/2 genetic testing (BRACAnalysis) has consisted of full gene sequencing and a BRCA1 gene 5-site rearrangement panel (Myriad Genetics Laboratories). Detection of other large rearrangements (LRs) in both BRCA1 and BRCA2 has been available since 2006. Although it has been reported that LRs comprise a significant component of identifiable mutations in BRCA1 and BRCA2, the prevalence of these mutations has not been fully established. Testing for LRs in BRCA1/2 is often not covered by many insurance companies. Methods Our cohort consisted of 3301 probands seen for genetic counseling and BRCA1/2 genetic testing at Memorial Sloan-Kettering Cancer Center from September 2006 to September 2011. A proportion of individuals (1279) without deleterious point mutations were screened for LRs in BRCA1/2. The cancer family history and ethnicity of patients having LRs were reviewed. The pre-test probability each proband had for carrying a BRCA1/2 gene mutation was retrospectively calculated by applying the BRCAPRO, Penn II and Myriad II models. Patients were excluded from this review if they presented for testing for a known familial BRCA1/2 LRs. Results 150 probands carry a deleterious BRCA1/2 mutation (probands with Ashkenazi Jewish founder mutations were excluded). 19 patients were found to have LRs. 2 probands had LRs detectable by standard BRCA1/2 testing. 17 probands (17/150=11.3%) had LRs not detectable by standard BRCA1/2 testing. 7/19 (36.8%) patients with LRs had a less than a 10% pre-test probability of carrying a BRCA1/2 mutation using BRCAPRO, which outperformed the other two models. 13/19 (68.4%) of patients were diagnosed with breast cancer at an average age of 36.4 years. 5/19 of patients (26.3%) had a diagnosis of high-grade serous ovarian/fallopian tube cancer with an average age of 46.6 years. One patient was unaffected. 13/19 (68.4%) of patients were from Europe. 4/19 (21%) LR positive patients carried a deletion of exon 20 in BRCA1. One patient who is 1/8 non-Jewish carried a LR mutation (BRCA1*del ex20). Conclusions The sensitivity of risk assessment models of a priori risk of harboring a BRCA1/2 large rearrangement mutation is relatively low. Our data support the recently published NCCN guidelines that LRs should be part of BRCA1/2 testing for all patients that meet testing criteria for the BRCA1 and BRCA2 genes.

1276T

Genetic background of familial colorectal cancer type X. *TT. Nieminen[1], J-P. Mecklin[2], HJ. Järvinen[3], P. Peltomäki[1].* 1) Med Gen, Univ Helsinki, Helsinki, Finland; 2) Deparment of Surgery, Jyväskylä Central Hospital, Jyväskylä, Finland; 3) Second Dapartment of Surgery, Helsinki University Central Hospital, Helsinki, Finland.

BACKGROUND Hereditary non-polyposis colorectal cancer (HNPCC) consists of two separate categories, namely Lynch syndrome (LS), in which mismatch repair (MMR) gene mutations are present, and familial colorectal cancer type X (FCCX) which clinically resembles LS, but MMR gene mutations are absent. FCCX patients have an increased risk of colorectal cancer (CRC), but extracolonic cancers are relatively uncommon. The average age at onset is around 60 years. Despite intensive research efforts, the predisposing genes for FCCX have remained unknown. AIM, MATERIALS AND METHODS This study aims to dissect the genetic background of FCCX taking advantage of 19 FCCX families from a nation-wide registry. The age at onset for CRC varies between 36 and 72 years in these families. Predisposing genes are sought for by genetic linkage analysis, exome sequencing and Sanger sequencing of candidate genes. We have also attempted to explore the genetic background of FCCX by tumor investigations. RESULTS In 2 out of 19 FCCX families, the BMPR1A gene revealed novel mutations which affected the extracellular part of the BMPR1A protein. The mutation in family 20 was an in-frame deletion of three nucleotides (AGA) at position 264 (c.264–266del) and in family 68 a 24-bp deletion at a splice site involving the 3'portion of intron 1 and the 5'portion of exon 2 (c.68-10_68+14del). Family members at-risk were tested for the presence vs. absence of the mutation in question and there were 24/48 (50%) mutation positive members in family 20 and 2/9 (22%) mutation positive members in family 68. All the other FCCX families were negative for BMPR1A mutation. BMPR1A has previously been connected to juvenile polyposis syndrome (JPS), but in our FCCX patients none of the adenomas or polyps showed JPS- like findings. The remaining families have been subjected to exome sequencing and analysis of the results is in progress. CONCLUSION Our finding is a landmark observation considering the role of BMPR1A mutations in FCCX. Now it will be important to investigate whether FCCX families from other parts of the world have BMPR1A mutations as well and if so, to generate more information of mutation types and locations and the associated clinical phenotypes. Our results also suggest that FCCX families are genetically heterogeneous and additional susceptibility genes are likely to be found by available high-throughput methods.

Development of a robust method for establishing B cell lines using Epstein-Barr Virus. *I. Danjoh, R. Shirota, Y. Nakamura.* Cell Engineering Division, RIKEN BioResouce Center, Tsukuba, Ibaraki, Japan.

B lymphoblastoid cell lines (B-LCLs) are established from B lymphocytes by infection with Epstein-Barr virus (EBV). As their genomic structure is stable in culture, B-LCLs are a valuable resource for genome analysis. Although the efficiency of establishing B-LCLs from freshly obtained blood samples from healthy individuals is almost 100%, if blood samples were handled inappropriately after collection or peripheral blood mononuclear cells (PBMCs) were stored in liquid nitrogen for a long time, the efficiency gets considerably lower. We have established more than 550 B-LCLs from PBMCs that have been collected from indigenous peoples living in closed societies in South America and stored in liquid nitrogen for over 20 years (Detailed description of this B-LCL collection was reported in the reference below*). As some of these populations no longer exist, the collection is a unique repository of the human genome. B-LCL establishment from such samples are difficult and failure means the waste of valuable and rare samples.

Although the methodology for establishing B-LCLs was developed at the end of 1970s, surprisingly little attention has been given over the years to identifying the factors that determine the success rate of generating cell lines. It was therefore essential that the methodology used for establishing B-LCLs from these was improved in order to create a resource that would not be rapidly depleted. For this purpose, we sought to improve our success rate for establishing B-LCLs from the difficult and irreplaceable samples by a detailed examination of each step of the process.

The analysis showed that two parameters were particularly critical: the density of the PBMCs plated after EBV infection, and the EBV titer. These observations shed light on cases where establishment of B-LCLs was hard due to the small number and/or damaged PBMCs.* Danjoh et al.; (2011) The Sonoda-Tajima Cell Collection, a human genetics research resource with emphasis on South American indigenous populations. Genome Biol. Evol. 3: 272-283.

Association of single nucleotide polymorphisms in ERα, ERβ, CYP17A1 and CYP19A1 with breast cancer risk: A case control study from North India. *S. Chattopadhyay[1], SVS. Deo[2], NK. Shukla[2], SA. Husain[1].* 1) Human Genetics Lab, Department of Biotechnology, Jamia Millia Islamia, New Delhi, Delhi, IndiaHuman Genetics Lab, Department of Biotechnology, Jamia Millia Islamia, New Delhi 110025 Delhi, India; 2) DR. BRA- IRCH, All India Institute of Medical Sciences, New Delhi 110029 INDIA.

A complex microenvironment exists in breast cancer that affects the dynamic signaling in cancer cells. Estrogen is important in promoting the proliferation of both normal and neoplastic breast epithelium. Biosynthesis and metabolism of estrogen play a pivotal role in initiation, promotion and progression of breast cancer. Estrogen acts by binding to one of the two specific estrogen receptors (ERs), ERα (ESR1) and ERβ (ESR2) (both belonging to nuclear receptor superfamily). CYP17A1 and CYP19A1 (also known as aromatase), are the key genes involved in biosynthesis of estrogen and thus to its exposure. Single nucleotide polymorphisms (SNPs) in these genes are possible risk factors implicated in breast cancer. The present study explores the role of estrogen biosynthesis pathway related gene polymorphisms in susceptibility to breast cancer in North Indian population. Estrogen receptors, ESR1 (rs2234693) and ESR2 (rs2987983); CYP17A1 (rs743572) and CYP19A1 (rs700519) polymorphisms were selected for the present study. Genomic DNA was isolated from 290 sporadic breast cancer patients and 290 sex matched healthy controls according to the standard phenol/chloroform method. Genotyping of rs2234693 was done by Polymerase Chain Reaction-Restriction Fragment Length Polymorphism (PCR-RFLP); genotyping of rs2987983 by tetra-primer amplification refractory mutation system (ARMS) PCR and of rs743572 and rs700519 by direct sequencing. Hardy-Weinberg equilibrium testing of all SNPs ($\chi 2$ test, $P>0.05$) was consistent with the distribution. 3×2 $\chi 2$ test was used to compare the overall distribution of genotypes between patients and controls, achieving significance for all SNPs ($P<0.05$). ESR1 Intron 1 (rs2234693; TT vs TC+CC, P=0.005); ESR2 Promoter (rs2987983; CC vs CT+TT, P= 0.002); CYP17A1 5' UTR (rs743572; CC vs CT+TT, P=0.009) and CYP19A1 Exon7 (rs700519; TT vs TC+CC, P=0.016) were all significantly associated with breast cancer after correction with age. Our study signifies the role of these SNPs in affecting the risk of breast cancer. The enhanced risks imparted by these variants suggest the potential role of these low penetrance genes in the development and progression of breast cancer. This study provides an insight into the role of estrogen in hormone dependent breast cancer. Efficacy of Sequenom Sample ID Plus® SNP genotyping in identification of FFPE tumour samples. *J.K. Miller, N. Buchner, D. Pasternack, J.D. McPherson.* Ontario Institute for Cancer Research, MaRS Centre South Tower, Toronto, Ontario, Canada.

Misidentification of cell line and tissue DNA intended for next-generation sequencing (NGS) can be costly if not detected early. For this reason, it is necessary to have quality control measures in place for source DNA identification and authentication of matching tumor and normal pairs at the beginning of sequencing pipelines. Short tandem repeat (STR) analysis, such as AmpFISTR Identifiler®, is a standard, PCR-based human genotyping method used in the field of forensics. This genotyping method has also been effectively applied as an early quality control step for NGS to prevent processing of misidentified samples. A major issue in large-scale cancer research studies involving archival formalin fixed paraffin embedded (FFPE) tissues is that varying levels of DNA degradation can result in failure to correctly identify samples using STR genotyping. PCR amplification of STRs of several hundred base pairs is not always possible when DNA is degraded. The Sample ID Plus® panel from Sequenom allows for human DNA identification and authentication using SNP genotyping. In comparison to lengthy STR amplicons, this multiplexing PCR assay requires amplification of only 80–120 base pairs, and utilizes 47 SNPs to discriminate between individual samples. In this study, we evaluated both STR and SNP genotyping methods of sample identification, with a focus on paired FFPE tumour/normal DNA samples. The ability to successfully validate the identity of degraded samples can enable cost savings by reducing NGS rework.

Gene-specific accelerated transcriptional aging in Type 2 diabetes. *J. Kent[1], M. Almeida[1], J. Peralta[1], H. Goring[1], J. Curran[1], M. Johnson[1], T. Dyer[1], S. Cole[1], J. Jowett[2], A. Comuzzie[1], M. Mahaney[1], L. Almasy[1], J. MacCluer[1], E. Moses[1], R. Duggirala[1], J. Blangero[1], S. Williams-Blangero[1].* 1) Dept Gen, Tx Biomed Res Inst, San Antonio, TX; 2) Baker IDI Heart and Diabetes Inst, Melbourne, Australia.

Patients with long-duration Type 2 diabetes mellitus (T2DM) exhibit some of the physiological changes associated with normal biological aging, including increased risk for atherosclerotic cardiovascular disease and osteoarthritis. Using transcriptional profiles of primary peripheral blood mononuclear cells from 1218 Mexican American participants in the San Antonio Family Heart Study for whom age and T2DM status were available, we identified 4,034 of 22,413 detectable transcripts whose expression levels were correlated with age at a 5% false discovery rate (FDR). We then tested whether the age-related change in gene expression was the same in individuals with and without T2DM, using a mixed linear regression model, implemented in SOLAR, that included the random effect of kinship. Of 402 age-correlated transcripts that were also nominally ($p<0.05$) correlated with DM, 153 (38%) also showed at least nominal evidence of age by diabetes interaction. Thus, for specific genes, individuals with diabetes showed an "older" transcriptional profile than unaffecteds, even accounting for the overall change in gene expression with age. The set of differentially expressed genes was enriched for mitochondrial function, lipid transport, and immune response. Cohort characteristics - combined: 59.1% female, mean(SEM) age=39.3(0.48)y, median age(range)=37.6(15–92)y; with T2DM: N=188, 37.2% female, mean(SEM) age=54.9(1.05)y, median age(range)=52.5(20–92)y; without T2DM: N=1,030, 58.4% female, mean(SEM) age=36.4(0.48)y, median age(range)=33.9(15–88)y.

Integrating Metabolomic Information in Genome-Wide Association Studies. *R. Rueedi[1,6], M. Ledda[2], T. Corre[1,6], R. Salek[3], V. Mooser[4], P. Vollenweider[5], G. Waeber[5], U.K. Genick[2], Z. Kutalik[1,6], S. Bergmann[1,6].* 1) Department of Medical Genetics, Université de Lausanne, Lausanne, Switzerland; 2) Department of Food-Consumer Interaction, Nestlé Research Center, Lausanne, Switzerland; 3) European Bioinformatics Institute, Cambridge, United Kingdom; 4) Department of Pathology and Laboratory Medicine, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 5) Department of Internal Medicine, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 6) Swiss Institute of Bioinformatics, Lausanne, Switzerland.

Genome-wide association studies (GWAS) have played an instrumental role in discovering robust genetic associations with dozens of clinically relevant phenotypes. The discovered genetic determinants of complex traits, however, explain a disappointingly small fraction of the heritability estimated by twin studies. Clearly, a substantial part of the genetic architecture underlying diseases is propagated through the metabolome. The aim of our study is to establish these cascades of causal links from genotypes to phenotypes via metabotypes. Close to 1'000 participants from the Cohorte Lausannoise (CoLaus) study provided urine samples for unspiked urine NMR assessment. We found 37 significantly associated SNP to metabotype feature (i.e. NMR shift) pairs. Several associations involve SNPs which have been shown to associate to metabolites in previous, usually serum-based, GWA studies. Moreover, the majority of the genotype-metabotype associations have been confirmed by an equal-sized replication study. Interestingly, many of these features are in turn associated to phenotypes, such as blood-lipids, obesity, and lifestyle factors, suggesting the role metabolites may have as intermediate phenotypes in genotype to phenotype GWA studies. The associated NMR shifts require annotation to reveal the metabolites which produce them. To simplify the identification of the metabolites involved in the SNP to feature associations, we developed a statistical lookup procedure which ranks metabolites according to the coherence between their known spectrum and their association spectrum. While this lookup procedure cannot uniquely identify the metabolite involved in the association, it produces a list of candidates, from which biologically sound metabolites can possibly be inferred with the help of metabolomics experts. After this initial study, we will now focus on the use of metabotypes as intermediate phenotypes in GWA studies, and how such an intermediate phenotype can increase the statistical power to detect genotype-phenotype association. If valid, such an approach would be a far more cost-effective method of increasing GWA output than resorting to ever larger cohorts, and would make metabotyping a very attractive component of future genotyping projects.

1282F

Application of principal components analysis to the investigation of expression profile data. *H.H.H. Göring[1], A.R. Sanders[2], E.I. Drigalenko[1], W. Moy[2], J. Duan[2], J.E. Curran[1], M.P. Johnson[1], E.K. Moses[3], J. Blangero[1], P.V. Gejman[2].* 1) Dept. of Genetics, Texas Biomedical Research Institute, San Antonio, TX, USA; 2) Dept. of Psychiatry and Behavioral Sciences, NorthShore University HealthSystem Research Institute, and University of Chicago, Evanston, IL, USA; 3) Centre for Genetic Epidemiology and Biostatistics, University of Western Australia, Perth, Western Australia, Australia.

Gene expression profiling is becoming a widely used approach in human genetic research. We have performed a detailed investigation of the utility of principal components analysis (PCA) for analyzing transcriptional profile data. Microarray-based gene expression profile data were available for 885 lymphoblastoid cell lines (LCLs) from the Molecular Genetics of Schizophrenia Study and 1244 lymphocyte samples from the San Antonio Family Heart Study. Gene expression profile data was found to have substantial underlying structure, with the top 1, 2, 5, and 10 principal components (PC) explaining ~9, 17, 25m and 35 of transcriptomic variation in LCLs, respectively, with similar proportions in lymphocytes. We investigated the relationship of expression PCs to putative confounder variables in gene expression profile studies, including sex and age as well as various LCL characteristics (including transformation site, cell growth rate, energy status, and viral copy load). By regressing out PCs, the influence of these variables on gene expression levels can be largely eliminated, reducing both the risk to identify false positive findings and the power to detect true expression signatures characteristic of a condition of interest. We developed an empirical approach to decide how many PCs should be regressed out to maximize power to detect expression quantitative trait nucleotides (eQTNs), while maintaining proper false positive rates. Regressing out PCs accounting for 50% of gene expression variation is nearly optimal for detection of putatively *cis*-acting eQTNs, nearly doubling the number of significant associations. While regressing out expression PCs lowers residual heritability (which presumably comprises trans-regulatory variation), it nonetheless increases power to detect significant *trans*-acting eQTNs, and enables detection of several weak, putative master regulators. Our investigation shows that PCA has great utility and wide applicability for investigations of transcriptional profile data.

1283W

Prioritization of SNPs identified in microRNAs and their targeted genes by integrated analysis of high throughput datasets. *X. Chen[1], H. Zhao[1,2,3].* 1) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT, USA; 2) Department of Genetics, Yale University School of Medicine, New Haven, CT, USA; 3) Department of Biostatistics, Yale School of Public Health, New Haven, CT, USA.

Tens of millions of genetic variants have been identified from the sequencing of the human genomes, and many of these variants may play a role in disease etiology of various common diseases. Great efforts have been made to annotate these variants for their functional relevance. These annotations may provide useful information to prioritize candidates from genome wide association studies for replications and/or functional studies. A number of annotation tools, such as SIFT, Polyphen and ANNOVAR, have been developed, but they mostly focus on protein coding regions, since finding the relationship of diseases and non-coding regions are usually harder due to lack of enough knowledge. However, recent studies have shown that alterations in microRNAs (miRNAs) and their binding sites (3'UTRs) may play a crucial role in affecting disease susceptibility. Therefore, accurate annotations of variants in these regions are important. In this presentation, we describe our approach to annotating variants in miRNAs and their target regions through an integrated analysis of different types of high throughput datasets. A hierarchical Bayesian model is proposed to rank the variants (either novel or known) by their potential relevance to the disease development with various prior information in these non-coding regions. One of the most important priors is the miRNA-gene interaction network inferred from paired expression profilings of different diseases and then weighted by the disease similarities, which enables us to find the disease-specific interaction and meanwhile incorporate the information over all other types of diseases. Other priors include cross-species conservation scores, sequence context for miRNA targeting, minor allele frequency (especially for novel or rare SNPs) and other features available for miRNA and targeted regions. Our methods and results may facilitate the interpretation and utilization of genetic variants identified through next generation sequencing technologies, especially those variants in the non-coding regions to the human genome.

Genome-wide association studies have so-far revealed over 4,500 SNPs that are associated with complex traits. However, due to linkage disequilibrium, it is often hard to identify the causal variant and gene, making it difficult to elucidate downstream molecular consequences. To resolve this, we performed expression quantitative trait locus (eQTL) mapping on 34,000 Illumina-based gene expression probes to identify *cis*-eQTLs (SNP and mid-probe distance < 250kb) and *trans*-eQTLs (SNP and mid-probe distance > 5Mb) in 5,311 peripheral blood samples across seven independent cohorts.

We confined our *trans*-eQTL analysis to 4,500 SNPs, associated with complex traits and detected over 350 SNPs with a *trans*-eQTL effect (FDR ≤ 0.05), reflecting 500 probes and 431 genes. 250 SNPs had both a *cis* and a *trans*-eQTL effect. In the genome-wide *cis*-eQTL analysis, we identified *cis*-effects for 15,376 unique SNPs, reflecting 16,076 probes and 10,129 genes. We observed that 38% of the 4,500 trait-associated SNPs have *cis*-effects.

Since the top 1000 *cis*-eQTLs showed a strong signal of association (having a P-value < 10^{-100}), we hypothesized that these *cis*-eQTLs may be enriched in causal variants. By comparing the top *cis*-eQTL SNPs with small-effect *cis*-eQTL SNPs, we observed a highly significant enrichment of SNPs that map to splice sites, introns, UTRs, miRNA binding sites and transcription factor binding sites. We furthermore observed that fewer than 6% of the top *cis*-eQTL SNPs were coding while 3% were non-synonymous, indicating that genetic gene expression regulation in peripheral blood is predominantly due to non-coding variation. Even though we studied peripheral blood, significant and biologically plausible *trans*-eQTLs were detected for SNPs that are associated with non-hematological traits. For example, rs174550 in *FADS1*, a SNP known to be associated with lipid and glucose levels, showed significant association in *trans* with *LDLR* gene expression levels (P-value = $4.27*10^{-14}$). We subsequently observed a significant correlation between *LDLR* gene expression and lipid levels.

Our results indicate that the analysis of *trans*-eQTLs in peripheral blood is applicable to identify downstream effects of trait-associated SNPs and that *cis*-eQTL analyses may aid in the identification of causal variants.

Ridge Regression for Genetic Data: A semi-automatic method to guide the choice of ridge parameter. *E. Cule[1], M. De Iorio[2].* 1) Imperial College London, London, United Kingdom; 2) Department of Statistical Science, University College London, London, United Kingdom.

We address the challenge of predicting disease risk using data obtained in a genome-wide association study (GWAS). Because genotypes are fixed at birth, but disease symptoms may not present until later in life, risk prediction using genetic data could suggest lifestyle or pharmaceutical interventions in higher risk individuals, which may reduce future disease susceptibility. In a GWAS, data are collected at hundreds of thousands or millions of genetic variants in hundreds or thousands of individuals. These data are typically analyzed one at a time (SNP-by-SNP). However, such an approach does not take into account the possible combined effect of multiple variants, a plausible hypothesis for complex diseases. Analyzing all SNPs simultaneously presents statistical challenges due to the high dimensions of the data and correlation among nearby SNPs. Traditional multiple regression fails under these circumstances. Current studies that incorporate genetic factors into risk prediction models use a small number of genetic variants most strongly associated with disease risk. However, the resultant risk prediction models offer little or no improved predictive ability compared to risk prediction models using clinical risk factors alone. Here we develop a method to fit a prediction model that incorporates all the variants in a GWAS simultaneously, with the aim of good predictive performance for complex diseases. Ridge regression (RR) is a penalized regression method that gives rise to stable coefficient estimates even when the number of predictors exceeds the number of observations. One challenge in the use of RR is the choice of the ridge parameter, which affects the model fit. A number of methods have been proposed in the literature to choose this parameter based on the data, but no consensus method provides a universally optimum choice. In this study we investigate a means of choosing the ridge parameter such that the degrees of freedom for variance is the same as that of a principal components regression with a specified number of principal components (PCs). We discuss ways to choose the number of PCs to use, and demonstrate that when the number of causal variables is large and effect sizes are small our method offers improved predictive performance over other regression methods. We apply our method to out-of-sample prediction using two Bipolar Disorder GWAS. We present an R package, ridge, which implements the method for genome-wide SNP data.

Defining the Functional Significance of Genes Using Natural Human Knockouts. *J.D. Hoffman, K.O. Polzin, A.E. Fish, P. Mayo, N.C. Schnetz-Boutad, J.L. Haines.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

BioVU is Vanderbilt University's biorepository that was developed with the goal of linking DNA to de-identified data from electronic medical records to allow assessment of how genetic variation impacts clinical phenotypes. BioVU currently contains DNA samples on over 140,000 individuals and de-identified clinical data from over 2,000,000 records. Samples and data are available to Vanderbilt researchers with a primary requirement that the genetic data be redeposited into the BioVU genotyping database. Using the wealth of clinical and genetic data stored in BioVU we studied the role of whole gene-knockouts on the burden of disease within this population. Our study included 2,856 Caucasian subjects that were previously genotyped on the Illumina 660w chip and re-deposited in the BioVU database. Using PennCNV as our algorithm for assessing gene copy number, we examined homozygous gene deletions and their association with ICD-9 clinical diagnosis codes. To be categorized as a gene-knockout, the copy number variation (CNV) called by PennCNV needed to fully overlap any gene in that region and be called as a zero copy. Of the original 2,856 samples, 2,387 passed quality filtering and were included in downstream analysis. 1,704 of these subjects had at least one homozygous gene deletion, with the late cornified envelope 3B (LCE3B) gene being the most commonly homozygous deleted gene (frequency = 0.40). LCE3B has previously been confirmed to be a common deletion in the Caucasian population. Association analysis was carried out for 26 genes (with homozygous deletion frequencies ≥ 0.006) and 201 ICD-9 codes (with frequencies ≥ 0.05). Genes were tested against ICD-9 codes with age at time of diagnosis as a covariate in our regression analysis. Our most significant findings included the association of the human major histocompatibility complex HLA-DRB5 with the ICD-9 code for rheumatoid arthritis and other inflammatory polyarthropathies (p=0.0026, OR= 3.98 [1.61–9.79]). This locus also was found to be significant with the ICD-9 code representing type 2 diabetes (p=0.0045, OR=3.06 [1.41–6.61]. Although refinement of analysis methods and more sensitive grouping of ICD-9 codes will be necessary, our preliminary analysis suggests that there are common clinical implications for fully deleted genes.

Intronic single nucleotide polymorphism of CALM-1 gene is significantly associated with osteoarthritis knee. *S. Raj, R. Srivastava, D. Sanghi, S. Awasthi, A. Mishra.* Orthopaedic Surgery, KG Medical College, CSM Medical University, Lucknow, UP, India.

Objectives: Genetic exploration of genome has resulted in several susceptibility loci isolation confirming the genetic association of osteoarthritis. The Japanese population has shown higher incidence of osteoarthritis in patients having intronic and core promoter SNP in CALM-1 gene. At the same, Caucasian and Greek population showed absence of any such predisposition in their population with the CALM-1 gene SNP. Methods: We planned a case control study in osteoarthritis knee to study the presence of CALM-1 gene SNP, correlation of its presence with osteoarthritis and its correlation with clinico-radiological stage of the disease. 120 cases and 120 controls were enrolled. Clinicoradiological features were noted and symptomatic clinical scoring was done. Genetic polymorphism in relation to intronic region of Calm-1 gene was studied by DNA extraction, PCR and RFLP method. Statistical analysis was done using Stata software Results: 39 (32.50%) cases and 18 (15%) controls showed the presence of SNP which was significant (P value = 0.0022). Among SNP positive cases and controls, 5 (8.7%) cases and none controls were heterozygosis for the occurrence of SNP. On regression of affecting variables against SNP, taking the presence of osteoarthritis as dependent variable, we calculated the adjusted odds ratio of all the significant variables. Thereafter, on logistic regression to see the effect of variables on the occurrence of disease, we found age, sex, and presence of SNP affecting the occurrence of disease significantly (p value < .05). Conclusions: CALM-1 gene intronic SNP (rs3213718) is present in Indian Population. The target SNP is significantly affecting the disease as the difference between cases and controls is highly significant (p value = .0022). Females are more predisposed for OA. Mean age of presentation in cases was 53.31+/-9.5 years. Age is a significant factor in causation of disease. However it is not influenced by existence of SNP. Between cases and controls, height, weight and BMI did not show any significant difference.

1288F

Genetic risk factor in development and progression of osteoarthritis knee. *R.N. Srivastava, A. Mishra, S. Raj, D. Sanghi.* Orthopaedic Surgery, KG Medical College, CSM Medical University, Lucknow, UP, India.

Overview: Background: Genome sequencing resulted in identification of several susceptibility loci confirming the genetic association of disease. Objective: Investigate the association of SNP in GDF- 5(BSiE1) and ESR á (BtgI) gene with osteoarthritis knee (KOA). Methodology: A case-control study, 300 cases with knee osteoarthritis and an equal number of age, sex matched healthy controls were included. Cases were diagnosed using the ACR Guidelines of knee osteoarthritis (KOA). Clinical symptoms were assessed with the knee specific WOMAC index and VAS for knee pain. The severity of disease was determined by radiological KL grades (Kellgren-Lawrence). Blood was drawn from patients genomic DNA isolated from blood polymerase chain reaction coupled restriction fragments length polymorphism (PCR-RFLP) was carried out to identify the SNPs. Results: The variant genotype of GDF-5 were found to be present at significantly higher frequency in cases than in controls, resulting in about 1.62 fold increase of KOA risk (P Value=0.040). Likewise increase in frequency of heterozygous genotypes of ESR-á increased the risk to KOA (O.R. 1.49; 95% C.I. 1.06–2.08). Risk was also found to be increased in the cases that carried combination of variant genotypes of ESR á and GDF-5 (O.R.5.62; 95% C.I. 1.57–20.05). OA knee was found to be significantly associated with BMI (P Value= 0.00). A significant association was found with clinical score of knee OA (VAS, WOMAC). Cases with variant genotype of GDF-5 and ESR- á shows significant association with clinical score of knee OA, though no significant association of these SNPs was observed with radiological score. Conclusions: The results suggest that GDF-5 (BSiE1) and ESR-á (BtgI) gene polymorphisms are associated with osteoarthritis knee and gene-gene interaction may influence the development of KOA. Likewise association of these SNPs with clinical score have again demonstrated the role of genetic polymorphism on GDF-5 and ESR- á in the development and progression of KOA .

Functional variant within vitamin D metabolism gene *ACADSB* is associated with a more severe disease in multiple sclerosis. *M.F. George[1], F.B.S. Briggs[1], P.P. Ramsay[1], H. Quach[1], A. Bernstein[2], B. Acuna[2], L. Shen[2], E. Mowry[3], C. Schaefer[2], L.F. Barcellos[1].* 1) Epidemiology, University of California, Berkeley, Berkeley, CA; 2) Division of Research, Kaiser Permanente, Oakland, CA; 3) Johns Hopkins Hospital, Baltimore, MD.

Multiple sclerosis (MS) is an autoimmune disease affecting the central nervous system with genetic and environmental hypothesized predictors of disease progression. The progression of MS is heterogeneous, with varying manifestations in cognitive and physical systems. Vitamin D has been shown to have a protective effect on both disease onset and progression. We investigated the effect of functional variants within vitamin D metabolism genes on cognitive status and MS severity score (MSSS), as important clinical phenotypes in 1008 white non-Hispanic MS patients identified from a large MS registry within Kaiser Permanente Northern California. A total of 15 candidate genes involved in vitamin D metabolism were studied (total 65 SNPs with putative function derived from whole genome profiles, Illumina 660K BeadChip). Cognitive score for each MS case was determined using a validated telephone interview cognitive status assessment tool. MSSS was calculated for each case using the expanded disability status score (EDSS) at study entry and disease duration, which was defined as the elapsed time (in years) between the first symptom and EDSS assessment. Within *ACADSB*, rs1131430 was associated with increased risk of disease progression. The crude association with MSSS, as measured continuously, was significant (β=0.46; p=0.043). Results remained significant after adjusting for age, gender, history of smoking, history of infectious mononucleosis, education, age of onset, history vitamin D supplementation, disease course, family history of MS, cognitive score, use of disease modifying therapy, weighted genetic risk score, and *HLA-DRB1*15:01* status. MSSS was also analyzed as a dichotomous variable (<5 [low] vs. ≥5 [severe]). Rs1131430 was significantly associated with severe MSSS (OR=1.69; p=0.002), even when adjusting for above covariates. No vitamin D metabolism gene variants were associated with cognitive status. In our population of white non-Hispanic MS cases living in Northern California, cases with the missense change (rs1131430) within *ACADSB* on chromosome 10 at codon 316 Ile->Val, were more likely to have a more severe disease. Our results support a role for vitamin D metabolism in MS disease progression. Replication and functional studies are currently under way in our laboratory.

Homozygous c.14576G>A Variant of *RNF213* Predicts Early-Onset and Severe Form of Moyamoya Disease. *S. Miyatake[1], N. Miyake[1], H. Touho[2], H. Doi[1], H. Saitsu[1], K. Shimojima[3], T. Yamamoto[3], N. Okamoto[4], N. Kawahara[5], Y. Kuroiwa[6], M. Taguri[7], S. Morita[7], Y. Matsubara[8], S. Kure[9], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University, Yokohama, Japan; 2) Touho Neurosurgical Clinic, Osaka, Japan; 3) Tokyo Women's Medical University Institute for Integrated Medical Sciences, Tokyo, Japan; 4) Division of Medical Genetics, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 5) Department of Neurosurgery, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 6) Department of Clinical Neurology and Stroke Medicine, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 7) Department of Biostatistics and Epidemiology, Yokohama City University Medical Center, Yokohama, Japan; 8) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 9) Department of Pediatrics, Tohoku University School of Medicine, Sendai, Japan.

Moyamoya disease (MMD) is a cerebrovascular disease which is now a relatively common cause of pediatric strokes. MMD can lead to devastating neurological deficits and intellectual impairments if left untreated. Preoperative infarctions, early age of onset, intellectual impairment, seizure and progressive posterior cerebral artery stenosis are known prognostic factors. Surgical revascularization can improve the cerebrovascular hemodynamics, and prevent subsequent attacks for the ischemic type of MMD. Thus, early diagnosis and surgical intervention are very important. Recently *RNF213* was reported as a susceptibility gene for MMD. However its clinical relevance remained unknown. Our aim was to clarify the correlation between *RNF213* genotype and MMD phenotype. The entire coding region of the *RNF213* gene was sequenced in 204 MMD cases, and corresponding variants were checked in 62 pairs of parents, 13 mothers and 4 fathers of the cases, and 283 normal controls. Clinical information was collected from clinicians. Genotype-phenotype correlations were statistically analyzed. The c.14576G>A variant was identified in 95.1% of familial MMD, 79.2% of sporadic MMD, and in 1.8% of controls, thus confirming its association with MMD, with an odds ratio of 259 and P<0.001 for either heterozygotes or homozygotes. Homozygous c.14576G>A was observed in 15 cases, but not in the controls and unaffected parents. The incidence rate for homozygotes was calculated to be >78%. Homozygotes had significantly earlier age of onset compared with heterozygotes or wild-types (median age of onset=3, 7, 8 years, respectively). Sixty-percent of homozygotes were diagnosed with MMD before age 4, comparing 15% of heterozygotes, and 14.3% of wild-types, respectively, and all had infarctions as the first symptom. Furthermore, infarctions at initial presentation and involvement of posterior cerebral arteries were of significantly higher frequency in homozygotes than heterozygotes and wild-types. These features indicate that c.14576G>A homozygotes have more severe and wider vasculopathy in the brain. Variants other than c.14576G>A were not associated with clinical phenotypes. In conclusion, the homozygous c.14576G>A variant could be a good DNA biomarker for predicting the severe type of MMD, in which early medical/surgical intervention is recommended, and may provide a better monitoring and preventing strategy.

1291F

C reactive protein as a prognostic marker in melanoma progression. *S. Fang[1], Y. Wang[2], D. Sui[3], H. Liu[2], C. Schacherer[2], J. Gardner[2], M. Ross[2], J. Gershenwald[2], J. Reveille[4], L. Wang[5], Q. Wei[5], C. Amos[1], J. Lee[2].* 1) Genetics, UT M.D Anderson Cancer Ctr, Houston, TX; 2) Department of Surgical Oncology, UT M.D Anderson Cancer Ctr, Houston, TX; 3) Department of Biostatistics, UT M.D Anderson Cancer Ctr, Houston, TX; 4) Division of Rheumatology and Clinical Immunogenetics, The University of Texas Health Science Center at Houston; 5) Department of Epidemiology, UT M.D Anderson Cancer Ctr, Houston, TX.

CRP has been proposed as a prognostic marker in melanoma patients, but the relationship of serial CRP levels to patient outcomes during longitudinal follow-up has not been evaluated. This study aimed to investigate whether increased CRP levels are associated with melanoma stage of disease, recurrence (DFS) and overall survival (OS), and whether changes in CRP levels among patients undergoing serial blood draw are related to dynamic changes in disease status during follow-up. Blood samples were obtained from 1,804 melanoma patients at MD Anderson Cancer Center from 1997 to 2009. 587 initial and 557 confirmatory patients underwent plasma CRP tests. Kaplan-Meier methods and Cox regression models were used to evaluate the association of CRP with stage and disease progression. 115 patients underwent sequential blood draws for CRP; in these patients we evaluated the relationship between change in disease status and change in CRP level using non-parametric tests. Finally, using a genome-wide scan of the entire patient population, we examined the relationship of significant and candidate SNPs with CRP blood levels and melanoma susceptibility, DFS and OS. An elevated plasma CRP level was associated with a poorer OS in both the initial and confirmatory datasets. CRP contributed to the risk death by a factor of 1.40 (95% confidence interval, 1.25–1.57) per unit increase of logarithmic CRP in the combined dataset. As compared with CRP<10 mg/l, CRP>= 10 mg/l conferred an elevated risk of death in patients with all stages of melanoma, as well as in the subsets of patients with stage I/II or stage III/IV disease, and an elevated risk of cancer recurrence among stage I/II patients. Investigation of serial CRP levels with disease status demonstrated strong correlation between an increase in CRP level and melanoma progression. Finally, we detected evidence of association between CRP-region genetic polymorphisms, plasma CRP level and melanoma development and progression. Our study confirms that the elevated CRP levels are independently associated with a poorer survival duration in both early- and advanced-stage patients. Elevated CRP levels predict recurrence in patients without measurable disease, and are also dynamically associated with disease response in patients with metastasis. These results suggest that CRP may be a valuable prognostic marker in melanoma patients, and that targeting CRP-associated inflammation in melanoma patients may have therapeutic value.

1292W

***TGFBR1* variant associated with constitutively decreased TGF-β signaling and risk for colorectal cancer.** *M.J. Pennison[1], N. Bellam[1], J. Zimmerman[1], Q. Zeng[1], M. Wang[1], M. Sadim[2], V. Kaklamani[2], N. Yi[1], K. Zhang[1], J. Baron[3], D.O. Stram[4], B. Pasche[1], CCFR Investigators, Colon Cancer Family Registry, National Cancer Institute.* 1) Medicine, Hematology/Oncology, University of Alabama at Birmingham, Birmingham, AL; 2) Medicine, Hematology/Oncology, Northwestern University, Chicago, IL; 3) Medicine, Dartmouth School of Medicine, Hanover, NH; 4) Preventative Medicine, University of Southern California, Los Angeles, CA.

Purpose: Twin cohort studies show approximately one third of all colorectal cancer (CRC) cases are inherited, but the genetic cause for the majority of these cases is unknown. Germline variants within the TGF-β signaling pathway serve as strong candidates for CRC risk modifiers due to TGF-β's early anti-tumor signaling activation of SMAD proteins. We have previously shown that constitutively decreased *Tgfbr1* expression in mice leads to reduced SMAD activation and increased CRC development. These findings were validated in humans and we found that constitutively decreased *TGFBR1* signaling was associated with CRC risk. In this family-based study, we aimed at determining the association of *TGFBR1* and *SMAD7* with CRC risk. **Methods:** The study included 1,558 colorectal cancer cases and 2,640 healthy controls recruited by the Colorectal Cancer Family Registry (CCFR). A total of 14 *TGFBR1* haplotype tagging SNPs were genotyped using ABI's TaqMan SNP genotyping platform, as well as a *SMAD7* SNP identified in GWA studies and validated in several case control studies. Results were analyzed using logistical regression analysis utilizing the Cockerham genetic model (determines additive and/or dominant genetic effect) and a codominant model (determines relative risk of the rare homozygous and heterozygous genotypes for each SNP). Risk prediction accuracy (receiver operating characteristic curves) of the dataset was also determined. Differential *TGFBR1* gene expression and downstream protein expression was assessed between high and low-risk genotypes using groups of patient-derived lymphoblastoid cell lines (LCLs). **Results:** *TGFBR1* rs7034462 (OR, 2.85; CI, 2.02–4.01, P value, 5.62×10^{-13}) and *SMAD7* rs4939827 (OR, 0.80; CI, 0.70–0.91, P value, 7.0×10^{-4}) were both strongly associated with CRC risk. Gene expression profiling showed a significant reduction in *TGFBR1* gene expression in 8 LCLs carrying high-risk genotypes versus a group of 8 low-risk LCLs (P = 0.042). Protein expression analysis performed with 3 matched LCL pairs showed significantly reduced TGF-β mediated SMAD signaling in cells carrying the high-risk alleles of these two SNPs. **Conclusion:** Our study shows that the *TGFBR1* SNP, rs7034462, is strongly associated with constitutively decreased TGF-β signaling and risk for colorectal cancer. This is also the first evidence provided that links rs7034462 to decreased expression of *TGFBR1*.

1293T

Limited survival of MEN1 patients with mutations in the JunD interacting domain and first elements for intrafamilial correlation in MEN1 syndrome. A study from the GTE cohort (Groupe d'étude des Tumeurs Endocrines). *J. Thevenon[1, 2], A. Bourredjem[3], L. Faivre[1, 2], A. Costa[4], E. Gautier[3], C. Bonithon-Kopp[3], A. Calender[5], C. Binquet[3], P. Goudet[4, 6], the Members of the GTE.* 1) Centre de Génétique et Centre de Référence (Anomalies du Développement et Syndromes Malformatifs), Hôpital d'Enfants, CHU Dijon, France; 2) Equipe émergente GAD EA-4271, IFR Santé STIC, Université de Bourgogne, Dijon, France; 3) Centre d'investigation clinique -épidémiologie clinique/essais cliniques, CHU, Dijon, France; 4) Centre d'épidémiologie des populations, EA 4184, Faculté de médecine de Dijon, Université de Bourgogne, Dijon, France; 5) Laboratoire de génétique moléculaire et médicale, hôpital Édouard-Herriot, 5, place Arsonval, 69437 Lyon cedex 03, France; 6) Centre Hospitalier Universitaire de Dijon, Service de Chirurgie Endocrinienne, Dijon, France.

Background: Multiple Endocrine Neoplasia syndrome type 1 (MEN1) is an autosomal dominant rare affection predisposing to endocrine tumours. The disease is secondary to mutations in the tumour suppressive *MEN1* gene. Although genotype-phenotype studies failed to identify a statistical correlation, some families harbour recurrent tumoral patterns. The MENIN protein function was elucidated through the discovery of its interacting partners. Point mutations were shown to alter MENIN interaction with its partners leading to inappropriate transcriptional regulation and tumorigenesis. This is the first genotype-phenotype correlation study in MEN1 disease considering a time dependant statistical analysis, testing intra-familial correlation and evaluating the impact of the mutation localization in MENIN interacting domains in a large cohort of MEN1 patients.

Methods: We report on the cohort of MEN1 patients, issued from the GTE network. Patients with *MEN1* mutation and clinical follow up were included, i.e. 262 families, 806 patients. Mutations type, localization and 9 interacting factors of the MENIN protein were compared to occurring tumour types and death ages. Assessment of the intra-familial correlation and genotype-phenotype correlation was performed using a frailty Cox model.

Results: Significant interfamilial variability was evidenced in this cohort. There was no significant correlation between mutation type and the different phenotypes. Overall survival was significantly reduced when mutations affected the JunD interacting domain (HR=2.13 (CI-95%[1.26; 3.60]). Patients had a higher risk of death from cancer of the MEN1 spectrum (HR= 2.44 (CI-95%[1.25; 4.77]).

Conclusion: This large genotype-phenotype correlation study with a time to event analysis highlighted the intrafamilial correlation of the MEN1 syndrome. As previously known, there was no direct genotype phenotype correlation but the higher risk of death in the patients carrying mutations affecting the JunD interacting domain is the first argument for a genotype-phenotype correlation in MEN1 syndrome. This result suggests that loss of interaction between JunD and MENIN might result in the development of more aggressive tumors. Modifying factors might be the comprehensive key of MEN1 syndrome variable expressivity.

1294F

Association of vitamin D receptor gene polymorphism and vitamin D status in knee osteoarthritis. *D. Sanghi, R. Srivastava, S. Raj.* Orthopaedic Surgery, KG Medical College, CSM Medical University, Lucknow, UP, India.

INTRODUCTION: Evidence suggests that low serum levels of vitamin D may increase the severity of Osteoarthritis (OA). VDR gene polymorphism is known for its association with osteoporosis. The inverse relationship between osteoporosis and OA suggests that VDR gene polymorphism is a candidate gene to be associated with OA. OBJECTIVES: This study was done to analyze the association of vitamin D receptor gene polymorphism (Taq1 and Apa I) and serum vitamin D levels in knee osteoarthritis METHODS: This case control study consisted of 180 Osteoarthritis Knee patients and 150 controls. Cases were clinically diagnosed according to ACR criteria. Gradation of the disease was done by using KL grading system on the basis of radiological findings. The serum levels of vitamin D were assessed by using kit of Enzyme Linked Immunosorbent Assay. Detection of VDR gene polymorphisms (Taq1 and Apa I) were done by PCR-RFLP technique RESULTS: We observed an insignificant association for genotypes of TaqI(p=0.086) and ApaI(p=0.60) polymorphism between cases and controls.However, for TaqI marginal significant association (p=0.053, OR 1.4, 95% CI 1.008–1.945) was observed between wild type(T) allele and mutant type(t) allele, but for Apa I, there was no significant difference (p=0.334, OR 1.17, CI 1.367–1.867) between wild type(A) allele and mutant type(a) allele.We observed a significant association of low level of serum vitamin D levels in homozygous mutant(tt) genotypes as compared to heterozygous(Tt) and wild type(TT) genotypes. But In case of ApaI, we found higher serum vitamin D levels in homozygous mutant(aa) genotype in comparison to heterozygous(Aa) and wild type(AA) genotype but this difference was not statistically significant CONCLUSION: Though insignificant association was found between osteoarthritis and the genotypes of TaqI and ApaI polymorphism, a significant association with mutant allele of TaqI(t) was observed. Additionally, the association of mutant allele with reduced level of vitamin D was noted.

Association between neural genes DRD2, AVPR1a, and ASPM and Endophenotypes of Speech Sound Disorder. *C.M. Stein[1], F. Qiu[1], B. Truitt[1], R. Raghavendra[1], P. Joseph[1], A.A. Avrich[1], R.P. Igo, Jr.[1], J. Tag[2], L. Freebairn[2], H.G. Taylor[2], B.A. Lewis[2], S.K. Iyengar[1,3].* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Psychological Sciences, Case Western Reserve University, Cleveland, OH; 3) Genetics, Case Western Reserve University, Cleveland, OH.

Speech sound disorder (SSD) is one of the most common types of communication disorders, with prevalence rates of 16% at 3 years of age, and an estimated 3.8% of children continuing to present speech delay at 6 years of age. Several studies have identified promising candidate gene associations between communication disorders and genes in brain and neuronal pathways. In this study, we focused on three genes related to brain and central nervous system functioning: dopamine D2 receptor (DRD2), arginine-vasopressin receptor 1a (AVPR1a), and microcephaly gene ASPM. We genotyped tag SNPs in these genes in 490 children from 178 families ascertained through a proband with SSD. TagSNPs were selected with an R-squared threshold of 80% and 5% MAF for a Caucasian population; there were 4 SNPs in ASPM, 7 in AVPR1a, and 27 in DRD2. Our phenotypes of interest included measures of phonological memory (nonsense word [NSW] and multisyllabic word [MSW] repetition), vocabulary (PPVT and EOWPVT), and reading decoding (WRMT-AT and WRMT-ID); these traits are highly correlated (20–40%). We analyzed the data using GenABEL in order to model familial structure and polygenic variance. In DRD2, we found several SNPs that were statistically significant after correction for multiple comparisons: for reading decoding (rs10891552 $p=8\times10^{-5}$ and rs2734831 $p=1\times10^{-4}$), and both measures of phonological memory (rs12805897 $p=2\times10^{-6}$, rs17529477 $p=8\times10^{-7}$, and rs7125415 $p=4\times10^{-6}$). In AVPR1a, we observed statistically significant associations with both reading decoding measures (rs11174811 $p=3\times10^{-6}$ and rs1587097 $p=6\times10^{-7}$). Other SNPs within DRD2 and AVPR1a were associated with these traits, as well as vocabulary, at an uncorrected α=0.05. Finally, SNPs in ASPM were associated with vocabulary, reading decoding, and speech sound disorder, though these associations were not statistically significant after multiple testing correction. These results show that neural genes are associated with key domains of SSD, including phonological processing, vocabulary, and reading decoding.

1296T

Parent-of-origin effects and gender differences influence age-at-onset variation in FAP ATTRV30M kindreds. *C. Lemos[1, 2], T. Coelho[3], A. Martins-da-Silva[3], J. Sequeiros[1, 2], A. Sousa[1, 2].* 1) UnIGENe, IBMC, Porto, Portugal; 2) ICBAS, Instituto Ciências Biomédicas Abel Salazar, Univ. Porto, Portugal; 3) Unidade Clínica de Paramiloidose (UCP), Centro Hospitalar do Porto (CHP), Porto, Portugal.

Familial amyloid polyneuropathy (FAP) ATTRV30M is an autosomal dominant systemic amyloidosis, due to a point mutation in the transthyretin (TTR) gene. More than 100 mutations have been found in the TTR gene but V30M is by far the most common. A wide variability in age-at-onset (AO) has been uncovered, including among Portuguese patients [17–82 yrs]. Early (≤40) and late-onset (≥50) cases are not separate entities, often coexisting in the same family, with offspring showing anticipation - a much earlier AO than their affected parent. Historically, anticipation was mostly ascribed to ascertainment biases. Previous studies with Portuguese, Swedish and Japanese families have shown the presence of a true marked anticipation. Our aim was to study anticipation in a larger number of kindreds than assessed before, removing possible biases and to gain more insight into parent-of-origin effects. From the UCP-registry, we analysed 926 parent-offspring pairs, both clinically observed and with well-established AO. Women had a statistically significant higher AO than men, either for daughters (mean, SD - 33.7, 6.84) vs. sons (29.43, 6.08) or mothers (39.57, 11.75) vs. fathers (35.62, 11.62). Also, 291 parent-offspring pairs showed marked anticipation (≥10 years) and the transmitting parent was the mother in 203 pairs. Conversely, among the 22 offspring showing a 10 years higher AO, 19 had a transmitting father. Mother-son pairs showed larger anticipation (10.43, 9.34) while the father-daughter pairs showed only residual anticipation (1.23, 9.77). To remove possible biases, we repeated these analyses: 1) excluding the proband, 2) removing pairs with simultaneous onset and 3) excluding offspring born after 1960. Anticipation was found in all subsamples and the same trend of parent-of-origin effects was observed. Noteworthy, no parent with AO ≤ 40 had an offspring with AO ≥50. These findings confirm anticipation as true biological phenomenon. Furthermore, both parents and offspring's gender were found to be highly significant factors for anticipation. We also found that mother-son pairs showed higher anticipation. The study of genetic modifiers should focus on families, aiming to unravel mechanisms of anticipation that may have important clinical implications.

Genome-wide analysis of germline copy number aberrations and association with breast cancer susceptibility. *Y. Sapkota[1, 5], B.S. Sehrawat[1], S. Ghosh[2, 5], P.J. Robson[3, 4], C.E. Cass[2, 5], J.R. Mackey[2, 5], S. Damaraju[1, 5].* 1) Department of Lab Medicine and Pathology, University of Alberta, Edmonton, Alberta, Canada; 2) Department of Oncology, University of Alberta, Edmonton, Alberta, Canada; 3) Department of Agricultural, Food and Nutritional Sciences, University of Alberta, Edmonton, Alberta, Canada; 4) Alberta Health Services - Cancer Care, Edmonton, Alberta, Canada; 5) Cross Cancer Institute, Edmonton, Alberta, Canada.

Background Breast cancer susceptibility determinants include both genetic and non-genetic factors. DNA variations identified thus far in the germline account for less than 30% of genetic risk, and additional unidentified variants likely contribute to breast cancer predisposition. Recent studies have shown that copy number aberrations (CNAs) are the most common type of structural variation in human genomes and may be associated with complex diseases, including familial breast and BRCA1-associated ovarian cancers. Our interest is in the role of germline CNAs as genetic determinants in sporadic breast cancers (late age at onset of disease). Methods We accessed hybridization intensity files (Affymetrix SNP 6.0 array) for 302 sporadic breast cancer cases and 321 apparently healthy individuals from our previous studies. All subjects were women, predominantly of Caucasian origin. CNAs were identified using Single Nucleotide Polymorphism-Fast Adaptive States Segmentation Technique 2 (SNP-FASST2) algorithm (a hidden markov model-based approach) implemented in Nexus Copy Number 6.0. Frequencies of CNAs between cases and controls were compared using Fisher's exact test (association test, two-sided). P values were adjusted for multiple hypotheses testing using false discovery rate (Q value). Results SNP-FASST2 algorithm identified 21,257 germline CNAs in 623 subjects with an average of 149 copy number events (gains/losses) and 302 allelic events (copy-neutral loss of heterozygosities) per sample. Frequency comparisons between cases and controls indicated that 162 copy number events (62 gains and 100 losses) were significantly associated with breast cancer (Q<0.05), and a majority of these CNAs were reported in the Database for Genomic Variants. Of these, copy number losses at Xp22.33 (Q=9.7E-15) and 19q13.2 (Q= 2.7E-10) and a copy number gain at 14q32.33 (Q=2.3E-05) exhibited the largest differences in frequencies between cases and controls (>20%). Gene ontology analysis for genes within 162 copy number events revealed “regulation of epidermal growth factor receptor signalling pathway” as the most significant pathway. Genes identified in this pathway were rhomboid 5 homolog 1 (Drosophila) and cadherin 13, H-cadherin (heart). Conclusions We have identified candidate germline copy number events strongly associated with breast cancer susceptibility. Technical validation of the highly significant CNAs and independent replication of these findings is warranted.

Whole-Genome Detection of Disease-Associated Deletions or Homozygosity in a Case-Control Study of Rheumatoid Arthritis. *C.C. Wu[1], S. Shete[2], E.J. Jo[3], Y.E. Lu[4], Y. Xu[5], W.V. Chen[4], C.I. Amos[4]*. 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Dept Biostatistics, Univ Texas MD Anderson CA Ctr, Houston, TX; 3) Duncan Cancer Center, Baylor College of Medicine, Houston, TX; 4) Dept Genetics, Univ Texas MD Anderson CA Ctr, Houston, TX; 5) Biostatistics, School of Public Health, Yale University, New Haven, Connecticut.

Compared with genome-wide association studies, comprehensive studies of the contribution of copy number variations to complex human disease susceptibility are generally lacking. Deletion copy number variations have been known to cause microdeletion syndromes and are frequently observed in patients with neuron-developmental disorders. Because genomic deletions are abundant in humans and represent one of the least well studied classes of genetic variants and because known rheumatoid arthritis susceptibility loci explain only a small portion of familial clustering, we performed a genome-wide study of association between deletion or excess homozygosity and rheumatoid arthritis using high-density 550K SNP genotype data from a genome-wide association study. We applied a genome-wide statistical method that we recently developed to test each contiguous SNP locus between the 868 cases and 1197 controls from the North American Rheumatoid Arthritis Consortium for detecting deletion variants or excess homozygosity that influence susceptibility. Our method is designed to detect statistically significant evidence of deletions or excess homozygosity at individual SNPs for SNP-by-SNP analyses and to combine the information among neighboring significant SNPs for cluster analyses. In addition to successfully detecting the known deletion variants on HLA-DRB1 and C4 in HMC, we identified the respective 4.3-kb and 28-kb clusters on chromosomes 10p and 13q, which were significant at a corrected 0.05 nominal significance level, adjusted for multiple comparison procedure. Independently, we ran PennCNV, an algorithm for identifying and cataloging copy numbers for individuals based on hidden Markov model, to identify cases and controls that had chromosomal segments with copy number < 2. Using Fisher's exact test for comparing the numbers of cases and controls per SNP, we identified 26 significant SNPs (protective; more controls than cases) aggregating on chromosome 14 with p-values < 10-8 and 49 SNPs on chromosomes 2, 14, and 20 with p-values between 10-5 and 10-8. In addition, we found that 12 cases and 1 control commonly shared a 6.6-kb segment with copy number = 1, which lay between 2 adjacent significant SNPs on chromosome 19p (2,054,962-2,165,057) detected by our cluster method. The Fisher's one-sided exact test for comparing 12 cases and 1 control gives a p-value of 0.0117. The PennCNV method did not successfully detect the known deleterious genetic variants in MHC.

1299T

T1D risk score modeling using dense genotypes in autoimmune associated genomic regions in 6,670 cases and 9,416 controls and validation in 2,601 affected sibpair families and 69 trio families. *W.-M. Chen[1,2], S. Onengut-Gumuscu[1,3], P. Concannon[1,4], S.S. Rich[1,2], T1DGC*. 1) Center for Pubic Health Genomics, University of Virginia, Charlottesville, VA; 2) Department of Public Health Sciences, University of Virginia, Charlottesville, VA; 3) Department of Medicine Division of Endocrinology, University of Virginia, Charlottesville, VA; 4) Department of Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA.

Type 1 diabetes (T1D) is the third most prevalent chronic disease of childhood and results from the autoimmune destruction of the pancreatic β cells. Although genome-wide association studies (GWAS) have identified ~41 distinct chromosomal regions associated with T1D, the effect on T1D from each individual SNP is small, and their joint effect on T1D and clinical relevance have not been extensively investigated. In a recent study, 196,524 variants in 186 distinct autoimmune associated genomic regions were genotyped using the ImmunoChip SNP panel in 6,670 T1D cases, 9,416 controls and 10,796 individuals from 2,601 affected sibpair (ASP) families and 69 trio families. The dense genotypes and the large sample size provided a unique opportunity to estimate the joint effect of currently known T1D candidate genes and to predict the T1D risk using a risk score model.

A SNP-based risk score may be used to predict the T1D status of an individual. We carried out a logistic regression analysis in the case-control data, modeling all statistically significant variants that were identified from the genome scan and the conditional analyses in associated regions, including 27 SNPs from the MHC region and 31 SNPs from non-MHC regions. A risk score for each individual was then derived as a linear combination of the associated SNPs with the weights being the regression coefficients. In this model, the MHC SNPs explained 5.7-fold more T1D variation than non-MHC SNPs. This risk score was able to predict the T1D status in the 6,670 and 9,416 controls with AUC=0.924. Due to the severely inflated risk scores among unaffected parents of the affected sibpairs, the prediction accuracy in the family data is underestimated as AUC=0.755. We developed a novel algorithm to estimate the effect size of risk scores in family data. After normalization to the observed distribution in the controls, the mean risk score in controls and cases was 0 and 1.538 respectively, with a difference 1.538 (se=0.014). The difference in risk scores between cases and controls in the random population was estimated using the family data as 1.446 (se=0.023) and the mean in cases was 1.592. The consistency of our MHC risk score estimate between the case-control and family data further validates the accuracy and utility of our risk score model in the prediction of T1D.

Variants in/near *DNER* are Reproducibly Associated with Type 2 Diabetes in Pima Indians. *Y.L. Muller, M. AbdusSamad, R. Hanson, W.C. Knowler, C. Bogardus, L. Baier*. Diabetes Molecular Genetics Section, Phoenix Epidemiology and Clinical Research Branch, National Institutes of Health, Phoenix, AZ., USA.

A prior genome-wide association study (GWAS) in 1149 Pima Indians using the Affymetrix 1-million SNP chip identified variants in/near *DNER* that were associated with type 2 diabetes (e.g. rs1861612, odds ratio=1.64 per copy of the risk allele, p=0.0002, adjusted for age, sex and birth-year). *DNER*, positioned on human chr.2:230222345-230579286, encodes a Delta/Notch like EGF-related receptor. Recent studies have shown that DNER mediates notch signaling via cell-cell interaction. DNER is expressed in human pancreatic islets, and the Notch signaling pathway plays a critical role in pancreatic development and β-cell fate. To follow-up on our GWAS findings, exons and exon-intron boundaries of *DNER* were sequenced in 180 Pima Indians to identify potentially functional novel variants. Additional tag SNPs (AF≥0.05, r^2≥0.8) were selected from the 1M GWAS to provide coverage in un-sequenced intronic and flanking regions (~25kb flanking each end of the gene). These 55 SNPs spanning *DNER* were genotyped in a population based sample of 3501 full-heritage Pima Indians for association analysis. Selected tag SNPs were further genotyped in a replication sample of 3723 Native Americans. Rs1861612, with a risk allele frequency of 0.64, was associated with type 2 diabetes in the full-heritage Pima Indian sample ($p=4.8\times10^{-5}$, OR=1.29, adjusted for age, sex, birth-year and family membership) and the association replicated in the separate Native American sample ($p=4.0\times10^{-4}$, OR=1.28, adjusted for age, sex, birth-year and heritage). Combining the full-heritage and replication samples (n=7224) provided the strongest evidence for association with diabetes for rs1861612 that achieved the statistical threshold typically required for genome-wide significance (adjusted $p=6.6\times10^{-8}$, OR=1.29). This SNP was also genotyped in 415 non-diabetic full-heritage Pima subjects who had been metabolically phenotyped for quantitative traits predicting T2D. The diabetes risk allele was associated with increased fasting plasma insulin levels (p=0.002, adjusted for age, sex, family membership and % body fat). Our data suggest that *DNER* may play a role in diabetes susceptibility in Native Americans.

1301W

Two multiple sclerosis risk variants from a large genome-wide association study are associated with disease progression in a population-based case cohort. *H. Quach[1], M.F. George[1], F.B.S. Briggs[1], P.P. Ramsay[1], B. Acuna[2], L. Shen[2], E. Mowry[3], A. Bernstein[2], C. Schaefer[2], L.F. Barcellos[3].* 1) Sch Pub Hlth, Univ California, Berkeley, Berkeley, CA; 2) Division of Research, Kaiser Permanente, Oakland, CA; 3) Johns Hopkins Hospital, Baltimore, MD.

Multiple sclerosis (MS) is an autoimmune disease affecting the central nervous system with genetic and environmental hypothesized predictors of disease progression. MS progression is heterogeneous, with varying manifestations in cognitive and physical systems. We investigated the effect of 52 risk loci from the largest genome-wide association study (GWAS) in MS (IMSGC and WTCCC, Nature 2011) and the combined weighted genetic risk score (wGRS) on three clinical phenotypes: cognitive status, MS severity score (MSSS), and age of onset in 1008 white MS patients identified from a large MS registry within Kaiser Permanente Northern California. We calculated wGRS by combining the weighted odds ratios from the 52 risk loci. The weight for each variant was the natural log of the odds ratio for each allele determined through GWAS (N≈30,000, Nature 2011). All samples were genotyped using the Illumina 660K platform. Cognitive score for each case was determined using a validated telephone interview cognitive status assessment tool. MSSS was calculated for each case using the expanded disability status score (EDSS) at study entry and disease duration. Age of onset was defined as the age at which first neurologic symptoms manifested. We investigated each of the 52 loci that comprise the wGRS with all clinical outcomes. Results show rs2303759, located in the promoter region of *DKKL1*, was significantly associated with cognitive score (β=-0.71; p=0.001). After adjusting for age, gender, history of smoking, history of infectious mononucleosis, disease course, use of disease modifying therapy, disease duration, and *HLA-DRB1*15:01* status, this association remained significant (β=-0.69; p=0.001). Rs2119704, located in the promoter region of *GALC*, was associated with MSSS when comparing the extreme phenotypes (<2.5 vs. ≥7.5; OR=0.42; p=0.001). After adjusting for the above covariates, results did not change. Both associations persisted after correction for multiple tests. The wGRS based on MS risk loci was not associated with cognitive status, MSSS, or age of onset. In our population of white non-Hispanic MS cases living in Northern California, two individual risk variants from the largest MS GWAS were more frequent among cases with a less severe disease presentation, in both cognitive and physical systems. This is among the first studies to investigate the effect of wGRS and individual established MS risk loci on important MS phenotypes.

1302T

Unraveling Phenotype Heterogeneity in Prostate Cancer Susceptibility in Finland Utilizing Covariate-Based Analysis. *C.D. Cropp[1], C.L. Simpson[1], T. Wahlfors[3,4], A. George[1,5], M.P.S. Jones[2], U. Harper[2], D. Ponciano-Jackson[2], T. Tammela[6], J. Schleutker[3,4], J.E. Bailey-Wilson[1].* 1) Inherited Disease Research Branch, National Human Genome Research Institute/ National Institutes of Health, Baltimore, MD; 2) Genomics Core/Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Rockville, Maryland; 3) Institute of Biomedical Technology/BioMediTech, University of Tampere and Fimlab Laboratories, Tampere, Finland; 4) Department of Medical Biochemistry and Genetics, University of Turku, Turku, Finland; 5) Fox Chase Cancer Center, Philadelphia, Pennsylvania; 6) Department of Urology, Tampere University Hospital, University of Tampere, Tampere, Finland.

Prostate cancer is the most common male cancer in developed countries. Previously, we reported a genome-wide linkage scan in 69 Finnish Hereditary Prostate Cancer (HPC) families, which replicated the *HPC9* locus on 17q21-q22 and identified a locus on 2q37. We used ordered subset analysis (OSA) to detect other loci linked to HPC in subsets of families to identify and detect other loci linked to HPC incorporating age of onset as a trait-related covariate to address genetic heterogeneity and strengthen the linkage findings previously reported. The overall mean age of onset across the families was 66.2±8.8 years while the range of individual onset ages ranged from 46 to 98 years. Although the highest OSA LOD score with a ΔLOD (p=0.02) was 2.876 on 15q26.2-q26.3 in a subset of 40 families ascending by age at onset, no other ΔLOD scores were significant after permutation testing. Since OSA uses a single covariate value per family, we used mean age of onset for each pedigree. To better capture the effect of age on the linkage signal, we used LODPAL to perform a linkage analysis in affected relative pairs, while adjusting for the age of each individual family member as a single covariate. Preliminary results revealed strong evidence of linkage to HPC on chromosome 15q was (LOD=4.9, 132cM) and 8q (LOD=3.1, 157cM). Permutations are ongoing to determine empirical p-values for these LOD scores.

1303F

A search for genetic variants predisposing to radiation induced meningioma. *R. Bruchim[1], B. Oberman[1], R. Milgram[1], I. Novikov[2], S. Sadetzki[1,3].* 1) The Cancer & Radiation Epidemiology Unit, The Gertner Institute, Chaim Sheba Medical Center, Tel-Hashomer, 52621 Israel; 2) The Biostatistics Unit, The Gertner Institute, Chaim Sheba Medical Center, Tel-Hashomer, 52621 Israel; 3) Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel.

Ionizing radiation is the only environmental exposure that has been shown to be a causative risk factor for meninigioma formation. However, only a fraction of previously exposed individuals develop the tumor. This supports the idea that an interaction between radiation and genetic susceptibility conferred by low penetrance genes could converge to facilitate tumor formation. The aim of this study was to test interaction between ionizing radiation and selected candidate genes in the development of radiation induced meningioma. Methods: The study population was taken from the Tinea Capitis (TC) cohort which includes a group of 10,842 individuals treated during the 1950's with radiation therapy for TC and 2 matched population and sibling non-irradiated comparison groups. This unique population has been followed for approximately 50 years for radiation sequelae in our institute. The project was designed as a 4 group nested case control study balanced for irradiation, and included meningioma patients (n=154), healthy controls irradiated for TC in childhood (n=189), sporadic meningioma patients (n=79) and healthy non irradiated controls (n=149). Data was collected by personal interview and blood samples were collected for genotyping of selected SNPs in 2 candidate genes involved in the DNA repair pathway: ATM and BRIP1. Results: One SNP in the ATM gene, rs1800057, showed indication for an association with borderline significance for meningioma formation (OR= 1.60, CI 0.93–2.75; p=0.09). The presence of the G allele in this SNP increased the risk for meningioma among the non-irradiated population by 5 fold (p=0.0063). Of 13 haplotypes constructed, 3 were associated with decreased meningioma risk in irradiated individuals and with increased meningioma risk in non-irradiated individuals. The BRIP1 gene analysis included 23 intragenic SNPs and yielded an association with meningioma for 3 of them (rs4986763, rs11871785, rs1157720). Although the results were not significant after adjustment for multiple comparisons, these SNPs are all located at the 5' of the BRIP1 gene within 72 KB. In addition, 2 haplotypes out of 24 were found to be associated with disease development and indicated a possible interaction between irradiation and meningioma. These results support the role of these genes in the formation of meningioma, and suggest a possible modification effect of the risk by irradiation status.

1304W

Variants in one-carbon metabolism and blood folate, homocysteine and B12 deficiency in a population-based study. *K. S. Crider[1], D. R. Maneval[2], N. F. Dowling[1], L. B. Bailey[3], G. Kaudwell[2], L. Hao[4], Z. Li[4], R. J. Berry[1].* 1) National Center on Birth Defects and Developmental Disabilites, CDC, Atlanta, GA; 2) University of Florida, Ganiesville, FL; 3) University of Gerogia, Athenes, GA; 4) Peking University, National Center of Maternal and Infant Health, Bejing, China.

One-carbon metabolism is critical to basic biological processes including DNA and protein methylation, as well as DNA replication. Genetic variation in this pathway has been associated with changes in disease risk, both for individuals (e.g. cancer, heart disease, mental health) and pregnancy outcomes (e.g. birth defect risk) although some of the reported associations are inconsistent across populations. In order to establish the impact of genetic variation on one-carbon metabolism we examined the association of 18 one-carbon metabolism polymorphisms with blood biomarkers—plasma and RBC folate, homocysteine and B12 concentrations—in a population-based study of reproductive age women from Northern China (n = 1019). This population has a high prevalence of the *MTHFR* 677 C to T polymorphism (rs1801133 TT frequency 36%) and is known to be at high risk for neural tube defect-affected pregnancies. Although each of the one-carbon biomarkers included in this study are significantly correlated with each other (r2 range 0.11–0.33; inverse for homocysteine range −0.25 to −0.28; all p <0.001) each has the potential to be differentially impacted by genetic variation and co-factors in the one-carbon pathway. Folate deficiency (plasma folate < 7>7;mol/L) was associated with two polymorphisms in *MTHFR* (rs1801133, rs535107 both chi square p < 0.001). Red blood cell folate deficiency (<317 >7;mol/L) was associated with variation in *MTHFR* (rs1801133 p<0.001) as well as *TCN2* (rs1801198p<0.01). B12 deficiency (<148 >7;mol/L) was associated with variation in *MTHFR* (rs1801133p<0.01) and marginally with TCN2 (rs1801198 p = 0.05). High levels of homocysteine (>10.4 >7;mol/L) were associated both *MTHFR* variants (rs1801133, rs535107; both p<0.001) as well as *CBS* (rs6586282; p<0.03). Individuals with 3 or more (vs. 2 or fewer) homozygous non-ancestral genotypes were significantly more likely to have high homocysteine (OR 3.7 95% CI 2.5–5.3) and have plasma folate deficiency (OR 1.6 95% CI 1.2–2.2). The *MTHFR* 677 C to T polymorphism critically affects each of the analyzed one-carbon metabolism biomarkers, which is not surprising given its unique unidirectional role in one-carbon metabolism; however, other variants had differential impacts on the clinical biomarkers assessed and should be taken into consideration when modeling one-carbon metabolism and disease risk.

Farrer[8].* 1) Assoc Prof, Ophthalmology & Visual Sci, Univ Utah, Salt Lake City, UT, USA; 2) Centre for Vision and Vascular Science, Queen's University, Belfast, UK; 3) Division of Preventive Medicine, Brigham and Women's Hospital and the Department of Ophthalmology, Harvard Medical School, Boston, MA, USA; 4) Department of Ophthalmology, University of Thessaly School of Medicine, Larissa, Greece; 5) Retina Service, Harvard Medical School, Massachusetts Eye and Ear, Boston, MA, USA; 6) The Fred Hollows Foundation New Zealand, Private Bag 99909, Newmarket, Auckland 1023, New Zealand and Population Health Eye Research Network, Auckland, New Zealand; 7) Department of Ophthalmology, Seoul National University Bundang Hospital, Seoul, Korea; 8) Departments of Medicine (Section of Biomedical Genetics), Ophthalmology and Biostatistics, Neurology, Epidemiology, Boston University Schools of Medicine and Public Health, Boston, MA, USA.

Age-related macular degeneration (AMD) is the most common cause of legal blindness in the United States. Significant work in AMD genetics has established alleles and haplotypes having large influences on AMD risk. While these findings have begun to provide insights into AMD etiology, there are still many questions about AMD risk that cannot be explained by the known AMD-related genes. For this reason, we genotyped 17 previously reported AMD-associated SNPs to examine the allele frequencies in populations of different ethnicities. Six SNPs from the CFH region (1q32), six SNPs from ARMS2/HTRA1 (10q26), three SNPs from ROBO1 (3p12) and two RORA (15q22) SNPs were genotyped in four populations from throughout the world that are well characterized and phenotyped for AMD status: a family-based cohort from New England (n=657), a case-control cohort from Central Greece (n=436), a case-control cohort recruited from Seoul National University Bundang Hospital (n=818), and a population-based cohort from Timor-Leste (n=535), a population with low documented frequency of AMD. Genotype and allele frequencies were calculated for each cohort. For normal subjects (average age > 55 years), genotype and allele frequencies were similar between all ethnicities for the ROBO1 and RORA SNPs, SNPs previously shown to have a modest effect on AMD risk. Frequencies were also similar at 10q26, the region most significantly associated overall with AMD risk, for the SNPs rs10490924, rs10664316, rs2672598, rs1049331 and rs2293870. Interestingly, the risk allele, A, of the HTRA1 promoter SNP rs11200638 was found at a higher frequency in the Timorese (63.5%) than in the other groups examined (23–40%). Of the six CFH region SNPs examined (rs800292, rs16840422, rs1061170, rs12144939, rs2284664 and rs12066959), 3 of the 5 SNPs previously shown to have a protective effect on AMD were found at a higher frequency in the Timor cohort. Specifically, rs800292, rs2284664, and rs12066959 were shown to have nearly three times the frequency in the Timorese than in the Korean or Caucasian populations. Additionally, the most commonly associated AMD-risk SNP, CFH rs1061170 (Y402H), was also seen at a much lower frequency in the Korean and Timor populations than in the Caucasian populations (C ~7% vs. ~40%, respectively). The low prevalence of AMD in the Timor population (2 subjects out of 535) may be due to the enrichment of protective alleles in this population.

Hidden heritability and risk prediction based on genome-wide association studies. *N. Chatterjee[1], B. Wheeler[2], J. Sampson[1], P. Hartge[1], S. Chanock[1], J. Park[1].* 1) National Institute of Health, Rockville, MD, USA; 2) Information management system, Rockville, MD.

Known discoveries from genome-wide association studies have limited predictive ability for individual traits, but recent estimates of "hidden heritability" suggest that in the future performance of predictive models can be potentially enhanced by incorporation of a large number of SNPs each with individually small effects. We use a novel theoretical model, discoveries from the largest genome-wide association studies and recent estimates of hidden heritability to project the predictive performance of polygenic models for ten complex traits as a function of the number and distribution of effect sizes for the underlying susceptibility SNPs, the sample size of the training dataset and the balance of true and false positives associated with the SNP selection criterion. We project, for example, that while 45% of the total variance of adult height has been attributed to common variants, a predictive model built based on as many as one million people may only explain 33.4% of variance of the trait in an independent sample. For rare highly familial conditions, such as Type 1 diabetes and Crohn's disease, risk models including family history and optimal polygenic scores built based on current GWAS can identify a large proportion (e.g 80–90%) of cases by targeting a small group of high-risk individuals (e.g subjects with top 20% risk). In contrast, for more common conditions with modest familial components, such as Type 2 diabetes (T2D), coronary heart disease (CAD) and prostate cancer (PrCA), risk models built based on GWAS with current or foreseeable sample sizes (e.g triple in size) can miss large proportion (>50%) of cases by targeting a small group of high-risk individuals. For these common disease, the proportion of the population that can be identified to have 2-fold or higher risk than an average person in the population ranged between 1.1% (CAD) and 7.0% (PrCA) for polygenic models built based on current GWAS. If the sample size for future studies could be tripled, these proportions could range between 6.1% (CAD) and 18.8% (T2D). Our analyses suggest that the predictive utility of polygenic models depends not only on heritability, but also on achievable sample sizes, effect-size distribution and information on other risk-factors, including family history.

Obesity susceptibility loci and associations across the pediatric body mass index distribution. *S.F.A. Grant[1,2], H. Hakonarson[1,2], T.R. Rebbeck[3], J.A. Mitchell[3].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Center for Genetics and Complex Traits, Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA.

Most studies investigating childhood obesity have leveraged mean BMI z-score to define the trait. We aimed to determine if previously identified obesity susceptibility loci are associated uniformly with pediatric BMI across the BMI distribution. Children and adolescents were recruited from the Children's Hospital of Philadelphia (n=7,225). In this population *FTO* (rs3751812), *MC4R* (rs12970134), *TMEM18* (rs2867125), *BDNF* (rs6265), *TNNI3K* (rs1514175), *NRXN3* (rs10146997), *SEC16B* (rs10913469), and *GNPDA2* (rs13130484) have been previously associated with BMI using linear and logistic regression. In the present study these associations were re-assessed using quantile regression. BMI z-score was modeled as the dependent variable, and genotype risk score (sum of risk alleles carried at the 8 loci) was modeled as the independent variable. Each additional increase in genotype risk score was associated with an increase in BMI z-score at the 5th, 15th, 25th, 50th, 75th, 85th and 95th BMI z-score percentiles by 0.04 (+/−0.02, P=0.08), 0.07 (+/−0.01, P=9.58 × 10^{-7}), 0.07 (+/−0.01, P=1.10 × 10^{-8}), 0.09 (+/−0.01, P=3.13 × 10–22), 0.11 (+/−0.01, P=1.35 × 10^{-25}), 0.11 (+/−0.01, P=1.98 × 10^{-20}), and 0.06 (+/−0.01, P=2.44 × 10^{-6}), respectively. Each additional increase in genotype risk score was associated with an increase in mean BMI z-score by 0.08 (+/−0.01, P=4.27 × 10^{-20}). In conclusion, obesity risk alleles were more strongly associated with increases in pediatric BMI z-score at the upper tail compared to the lower tail of the distribution. As such, previous studies may have underestimated the strength of the association between these obesity-susceptibility loci and pediatric BMI in the context of obesity.

Genome-wide association studies (GWAS) have succeeded in detecting numerous loci associated with BMI and waist-hip-ratio (WHR). To find additional loci and to identify potential causal variants by fine-mapping already known loci, we performed imputation using the 1000 Genomes panel with 2188 haplotypes (June 2011 release) in 18 European cohorts with GWA data from ENGAGE, followed by fixed-effects inverse variance meta-analysis in 78,131 (44,301) individuals for BMI (and WHR adjusted for BMI) respectively. Imputation with the larger 1000G reference data set revealed several features not observed in earlier rounds of GWA meta-analysis with HapMap2 imputation. These include: (a) genome-wide significant associations for BMI at 19 loci, of which 5 were novel including *GALNT10* (p=7.8×10^{-10}), *ZHX2* (p=4.5×10^{-8}), *AKAP6* (p=7.7×10^{-9}) and *PAX2-HIF1AN* (p=2.0×10^{-8}); (b) lead SNPs with stronger associations and larger effect sizes than previous signal, e.g. *RSPO3* for WHR (new β=0.12, p=4.4×10^{-14}, minor allele frequency (MAF)=0.08 vs old β=0.039, p=1.0×10^{-8}, MAF=0.49) and at *FAIM2*, *MAP2K5* and *NRXN3* for BMI; (c) novel associations with low MAF variants in the vicinity of 14 known BMI loci, with larger effect sizes than previous GWAS hits, for which conditional analyses will help to define whether these represent independent signals or are driving the GWA signal (e.g. *BDNF* β=0.21, p=9.0×10^{-4}, MAF=0.018 vs lead β=0.048, p=5.1×10^{-11}, MAF=0.18, CEU r^2=0.001); (d) four additional previously unreported association signals from sex-differentiated analysis including *TMEM56* for BMI (female-specific, p=1.1×10^{-8}, MAF=0.08, $P_{sex\text{-}het}$=0.0050) and *COL11A1* for WHR (female-specific, p=4.5×10^{-8}, MAF=0.19, $P_{sex\text{-}het}$=2.5×10^{-4}); (e) evidence of substantial overlap in trait associations: of 20 loci significantly associated with either BMI or WHR, 8 were associated with HDL cholesterol and 5 with triglyceride levels within parallel ENGAGE analyses. Our results highlight the potential of using existing GWAS genotyping data, supplemented by imputation from the high-density reference panel of the 1000 Genomes Project for the identification of associations with anthropometric traits.

A Two-Stage Genome-Wide Association Study to Identify Single Nucleotide Polymorphisms Associated with Development of Erectile Dysfunction Following Radiotherapy for Prostate Cancer. *S. Kerns[1,4], R. Stock[1], N. Stone[1,2], M. Buckstein[1], Y. Shao[3], C. Campbell[4], L. Rath[1], R. Hixson[5], J. Cesaretti[5], M. Terk[5], H. Ostrer[4], B. Rosenstein[1,6,7], *Collaboration developed under the framework of the Radiogenomics Consortium.* 1) Department of Radiation Oncology, Mount Sinai School of Medicine, New York, NY; 2) Department of Urology, Mount Sinai School of Medicine, New York, NY; 3) Division of Biostatistics, New York University School of Medicine, New York, NY; 4) Departments of Pathology and Genetics, Albert Einstein College of Medicine, Bronx, NY; 5) Florida Radiation Oncology Group, Jacksonville, FL, United States; 6) Department of Radiation Oncology, New York University School of Medicine, New York, NY; 7) Departments of Dermatology and Preventive Medicine, Mount Sinai School of Medicine, New York, NY.

Purpose: To identify single nucleotide polymorphisms (SNPs) predictive of erectile dysfunction (ED) among prostate cancer patients treated with radiotherapy. Methods and Materials: A two-stage genome-wide association study (GWAS) was performed to identify SNPs associated with development of ED following radiation therapy. Patients were split randomly into a stage I discovery cohort (132 cases, 103 controls) and a stage II replication cohort (128 cases, 102 controls). The discovery cohort was genotyped using Affymetrix 6.0 genome-wide arrays and, after QC filtering, association between 614,453 SNPs and radiation proctitis was assessed using logistic regression controlling for non-genetic risk factors and the first five principle components from principle components analysis (to control for potential population stratification). The 940 top ranking SNPs selected from the discovery cohort were genotyped in the replication cohort using Illumina iSelect custom SNP arrays, and association with ED was similarly assessed using multivariable logistic regression. Fisher's method was used to combine p-values from the discovery and replication studies. Results: 12 SNPs identified in the discovery cohort and validated in the replication cohort were associated with development of ED following radiotherapy (Fisher combined p-values 2.1×10^{-5} to 6.2×10^{-4}). In a multivariable model including non-genetic risk factors, the odds ratios for these SNPs ranged from 1.6 to 5.6 in the pooled cohort. There was a striking relationship between the cumulative number of SNP risk alleles an individual possessed and ED status (Sommers' D p-value = 1.7×10^{-29}). A one-allele increase in cumulative SNP score increased the odds for developing ED by a factor of 2.2 (p-value = 2.1×10^{-19}). The cumulative SNP score model had a sensitivity of 84% and specificity of 75% for prediction of developing ED at the radiotherapy planning stage. Conclusions: This GWAS identified a set of SNPs that have utility for predicting which men are likely to develop ED following radiotherapy. Notably, these 12 SNPs lie in or near genes involved in erectile function or other normal cellular functions (adhesion and signaling) rather than DNA damage repair, the focus of earlier candidate gene studies.

Genetic variation and vitamin D sufficiency in the U.S. population (NHANES III). *C. O. S. Neal, J. M. Jackson, K. S. Crider.* Pediatric Genetics Team/NCBDDD, Centers for Diseases Control and Prevention, Atlanta, GA.

Studies have linked vitamin D (VitD) insufficiency to adverse outcomes including skeletal, cardiovascular, autoimmune and metabolic disease. Over 20% of the US population are VitD insufficient (serum 25-hydroxyvitamin D below 20ng/mL - Institute Of Medicine guidelines) and significant variation in VitD sufficiency exists between subpopulations. The National Health and Nutrition Examination Surveys (NHANES) are population based studies designed to assess the health and nutritional status of US residents using interviews and physical examinations. NHANES III (1988–1994) contains single nucleotide polymorphism (SNP) data for 7,159 participants, age 12 years and older. Among NHANES III participants, VitD insufficiency was present in 12% of non-Hispanic whites (NHW), nearly 63% of non-Hispanic blacks (NHB) and 27% of Mexican Americans. Differences in VitD intake did not sufficiently account for the variation in serum levels of VitD. VitD metabolism involves multiple organ systems and myriad enzyme and transcriptional components, any of which might affect serum VitD levels. The Cytochrome p450 (CYP) family of approximately 60 genes is known to function in the synthesis and metabolism of various lipid soluble cellular molecules and chemicals, including VitD. Among genotyped NHANES III participants we explored genetic variation in CYP (33 SNPs in 9 genes) and VitD receptor genes (2 SNPs) in addition to covariates linked to sufficiency in previous studies such as season of sample collection (SSC), body-mass index (BMI), sex, supplementation habit, income, and age for associations with VitD sufficiency. We used chi square tests and multiple logistic regression in stratified [by racial/ethnic (RE) group] and single stratum models to assess associations with VitD sufficiency. Significant associations were found between VitD sufficiency and SSC, BMI, sex and age across RE strata. Several CYP SNPs were associated with VitD sufficiency in overall models. CYP2A6 (rs1801272) was significantly associated ($p<0.05$) with VitD sufficiency in multiple RE groups in both crude and adjusted models [odds ratio (95% confidence interval)=1.9(1.03–3.53) in NHW and 4.24(1.7–10.6) in NHB]. Although this is the first report of CYP2A6 association with VitD sufficiency, there is biological plausibility because of its wide range of potential metabolic targets. The role of the CYP family of genes and CYP2A6 in particular in VitD metabolism and sufficiency warrants further investigation.

1311T

The Genome-Wide Association Study of Phenotypic Robustness in Human-a Canalization Study. *R. Li[1], T.D. Spector[2], J.B. Richards[1,2].* 1) Lady Davis Institute, Jewish General Hospital, Montreal, Quebec, Canada; 2) Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom.

Human phenotypes exhibit significant levels of variation among individuals. Recently, genome-wide association studies (GWAS) have been performed to identify the genetic loci that control these variations. Despite the success of GWAS to identify a set of genetic loci, it has become widely recognized that these loci cannot fully explain the variance of a phenotype. One possible explaination is that there is phenotypic stochastic noise which has not been taken into account in typical GWASs. Normally, only one measurement of phenotype from each individual has been used in the typical GWAS which can introduce significant stochasticity, since many phenotypes, such as glucose show high intra-individual variability. However, if a phenotype is measured several times in the same individual, there is also considerable variation in the intra-individual stability of the phenotypic measurement, such that in some people the phenotype is relatively stable while in other people the phenotype is relatively variable. In other words, people show different levels of phenotypic robustness (canalization). The genetic control on phenotypic robustness has been reported in plants, yeast and mice. However, there is still scarce data in human. We hypothesized that genetic components controlling phenotype robustness may exist in humans. Since typical GWASs focus on the genetic variation impact upon average phenotypes, the findings from genetic control on phenotype stochastic noise would improve our understanding on the genotype-phenotype relationship. In TwinsUK cohort, we observed different levels of phenotypic robustness on glucose across multiple measures on each individual. We undertook GWA analysis on repeated glucose levels in 2,594 individuals from TwinsUK cohort, and we observed a trend of association on several genetic loci across the genome ($P < 5 \times 10e{-}6$). The identified loci are at chromosome 1q43 (rs12568231, *PLD5*), choromosome 6p21 (rs16871837, *SPATS1*), chromosome 6q24.2 (rs722755, *PHACTR2*), chromosome 7q22.1 (rs12539614, *EMID2*), chromosome 13q14 (rs7339165, *GTF2F2*), and chromosome 18q11.2 (rs17593321, *IMPA2*). While these loci are being replicated currently this studies identifies potential genetic determinants of canalization in humans.

Platelets are enucleated cell fragments derived from megakaryocytes that play key roles in hemostasis and in the pathogenesis of atherothrombosis and cancer. We conducted an electronic medical record (EMR)-based study to: 1) identify the variants that influence inter-individual variation in the number of circulating platelets (PLT) and mean platelet volume (MPV) by performing a genome-wide association study (GWAS) and 2) assess pleiotropic effects of such variants by performing a phenome-wide association study (PheWAS) with a wide range of EMR derived phenotypes. The study was performed in 13,582 participants of European ancestry in the electronic MEdical Records and GEnomic (eMERGE) network. We identified five chromosome regions associated with PLT and eight associated with MPV respectively ($P < 5 \times 10^{-8}$). In addition, we replicated 20 SNPs influencing PLT (out of 56 SNPs (α: 0.05/56 = 9E−04)) and 22 SNPs influencing (out of 29 SNPs (α: 0.05/29 = 2E-03)) MPV from among 69 SNPs identified in a recent meta-analysis of PLT and MPV. Genes in these regions influence thrombopoiesis and encode kinases (*AK3, DSTYK, PIK3CG, TAOK1*), membrane proteins (*BET1L, COPZ1, REEP3, TMCC2, TMEM81, TMEM120B*), proteins involved in cellular trafficking (*DNM3, NRBF2, REEP3*), transcription factors (*JMJD1C, MYB, NFE2, NRBF2, RBBP5*), proteasome complex subunit (*PSMD13*), proteins involved in signal transduction pathways (*ARHGEF3, SH2B3*), proteins involved in megakaryocyte development and platelet production (*AK3, CABLES1, EHD3, JMJD1C, MYB, NFE2, SH2B3*) and hemostasis (*SH2B3, JMJD1C, MYB, EHD3, PIK3CG, F2R, SIRPA, PTPN11, CABLES1, AK3, THPO, NFE2*). PheWAS analysis using a single-SNP Bonferroni correction (0.05/1368 = 3.6E−5) revealed that several variants in these genes have pleiotropic effects and are associated with diverse phenotypes including autoimmune diseases (inflammatory spondylopathies; P = 5.7E−08), hematologic disorders(B12-deficiency anemia; P = 6.1E−05), hypothyroidism(P = 1.7E−06) and myocardial infarction (P = 1.7E−04). Our results demonstrate the utility of EMR-based GWAS and PheWAS to identify genetic variants influencing traits of medical relevance and the pleiotropic effects of these variants.

1313W

Heterogeneity in Polygenic Contribution to Ischaemic Stroke subtypes by Age at Onset. *M. Traylor[1], HS. Markus[1], S. Bevan[1], M. Dichgans[2], R. Malik[2], H. Segal[3], PM. Rothwell[3], CL. Sudlow[4], CM. Lewis[5], Wellcome Trust Case Control Consortium (WTCCC2).* 1) Research Centre for Stroke & Dementia, St. George's University of London, London, United Kingdom; 2) Institute for Stroke and Dementia Research, Klinikum der Universität München, Ludwig-Maximilians-Universität, Munich, Germany; 3) Stroke Prevention Research Unit, University Department of Clinical Neurology, Oxford, UK; 4) Division of Clinical Neurosciences, University of Edinburgh, Edinburgh, UK; 5) Medical & Molecular Genetics, King's College London, UK.

Stroke is one of the three most common causes of death, the second most common cause of dementia and the major cause of adult chronic disability. It is a complex phenotype involving many pathological processes, and is generally classified into three subphenotypes: cardioembolic (CE), large vessel (LVD) and small vessel disease (SVD). Genome-wide association analysis of ischaemic stroke has identified a handful of variants in CE and LVD subtypes. We investigated the relationship between the polygenic contribution to disease and age-at-onset of stroke using the WTCCC2 ischaemic stroke cohort of 3,548 cases (790 CE, 844 LVD, 580 SVD) and 5,972 controls. We used the GCTA software to perform “sliding window” analyses of heritability within subsets of cases ranked by age-at-onset. We also explored the variance of heritability estimates within the subsets by bootstrap simulations, testing whether variance in age-at-onset-restricted subsets was equal to that in all cases, using Levene's test. Our heritability estimates for the subtypes using the GCTA software showed that a moderate proportion of variance can be explained by the common variants on GWAS chips for the CE (32.6%) and LVD (40.3%) subtypes, but a smaller proportion of the variance (16.1%) is explained for SVD. When considering age at onset, the proportion of variance explained was greatly reduced for subsets of older individuals in the CE subtype (16.5%), consistent with a stronger environmental contribution to disease for older individuals. Conversely, in SVD we found greatly reduced heritability estimates for younger subsets of the cases (5.3%). This may indicate a Mendelian inheritance for a subset of young onset SVD stroke cases. We found strong evidence in all subtypes of greater variance in the age-at-onset subsets of cases (compared to bootstrap samples from all cases), indicating significantly reduced heterogeneity in the polygenic component to disease when cases are stratified by age-at-onset. This was observed for all subtypes (p<10-3), with considerably stronger evidence in SVD (p<10-6). The results indicate significant heterogeneity in polygenic contribution to the ischaemic stroke phenotypes by age at onset, particularly for SVD. They may be used to guide case inclusion for further GWAS analysis and aid selection for exome sequencing.

1314T

Strategies for developing prediction models with increased discriminatory accuracy from genome-wide association studies. *J. Wu, R.M. Pfeiffer, M.H. Gail.* Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD.

Recent genome-wide association studies (GWAS) have identified hundreds of single nucleotide polymorphisms (SNPs) associated with complex human diseases. However, in most diseases, these risk loci have limited predictive value. Larger GWAS and improved technology will lead to the discovery of additional risk-associated SNPs, but it is likely they will have smaller odds ratios than those previously detected. It is possible that predictive value can be improved by including many such SNPs in models. Here we investigate various aspects of model building to improve prediction, as measured by the area under the receiving operating characteristic curve (AUC). In particular, we investigate: (1) how the training data should be allocated between SNP selection and estimation of genetic effect sizes; (2) how SNP selection based on p-value thresholding compares with selection based on ranking p-values, and how liberal one should be in setting thresholds or the number of top-ranked SNPs; (3) whether multivariate estimation of SNP effects is preferred to univariate estimation in the presence of linkage disequilibrium (LD); (4) whether design guidelines developed in the absence of LD also apply in the presence of LD; and (5) whether our findings for AUC hold for other figures of merit, such as the probability of correct classification. We used realistic estimates of the distributions of genetic effects and allele frequencies based on GWAS data, and we included analyses in the presence of LD by re-sampling chromosomes from GWAS controls. Broadly speaking, we found that much of the training data should be used for SNP selection, that univariate (marginal) estimation performs as well or better than multivariate estimation, and that one should not include too many SNPs in the prediction model.

Concurrent Modeling of Multiple Phenotypes and Genotypes in Family Data: Implications for Cleft Gene Discovery. *M. Govil[1], N. Mukhopadhyay[1], R.M. Silva[2], A.R. Vieira[1], S.M. Weinberg[1], K. Neiswanger[1], M.L. Marazita[1].* 1) Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, PA; 2) Department of Endodontics, School of Dentistry, University of Texas Health Science Center at Houston.

Non-syndromic clefting, one of the most common birth defects worldwide, has been demonstrated to be a heterogeneous trait with a multifactorial etiology. Substantial work has been done in the past several years to further characterize this birth anomaly by exploring sub-clinical and extended phenotypes. Genetic studies accumulating evidence for the role of genes in cleft etiology have primarily incorporated this additional phenotypic information in analyses by applying three different approaches: creating potentially homogenous subsets of the data for categorical values of the phenotype(s), recoding the affection status of individuals based on their cumulative phenotypic information, or analyzing each phenotype individually. Here, we include multiple phenotypes concurrently as predictors while regressing them against individual SNP genotypes in a candidate gene inverse regression analysis, as implemented in the R package MultiPhen (O'Reilly et. al., 2011), utilizing data from 79 families collected as a part of the Pittsburgh Orofacial Cleft Project. In the current study, 43 probands with clefts of the lip and/or palate have been selected such that each individual has complete information for three additional phenotypes — lip muscle discontinuities (binary, 21 affected), velopharyngeal insufficiency (binary, 33 affected), and handedness preference (measured quantitatively by a laterality quotient, mean = 59.5). Further, all 43 subjects have been genotyped for a candidate gene panel with 1040 SNPs. Preliminary results from this analysis provide potential evidence for association (p-value = 0.0007) with SNPs in the SKI gene (1p36.33), a component in the TGFB1 signaling pathway. To provide a contrast, we added 78 unaffected individuals, one randomly selected from each family. The top hit (p-value = 0.0004) was an association with GABABR2 (9q22.33), a gene associated with smoking behavior, where maternal smoking is known to be a risk factor for clefts. These initial results indicate the utility of the method to not only model potential inter-relationships between the phenotypes but to also provide evidence for genes which may be involved in complex pathways influencing multiple phenotypes. We continue to expand and refine the approach to incorporate existing family data from multiple populations, genotyped on whole genome linkage and GWAS panels, thereby further increasing the power of this method. Support: DE018085, DE016148.

1316W

A Phenome-Wide Association Study (PheWAS) using multiple National Health and Nutrition Examination Surveys (NHANES) to identify pleiotropy. *M.A. Hall[1], A. Verma[1], K.D. Brown-Gentry[2], R. Goodloe[2], J. Boston[2], S. Wilson[2], B. McClellan[2], C. Sutcliffe[2], H.H. Dilks[2,3], N.B. Gillani[2], H. Jin[2], P. Mayo[2], M. Allen[2], N. Schnetz-Boutaud[2], S.A. Pendergrass[1], D.C. Crawford[2,3], M.D. Ritchie[1].* 1) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, The Huck Institutes of the Life Sciences, The Pennsylvania State University, University Park, PA, USA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA; 3) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN.

Phenome-wide association studies (PheWAS) are a novel approach for discovering the complex mechanisms involved in human disease, through testing SNPs for association with a large and extensive set of phenotypes. The Epidemiological Architecture for Genes Linked to Environment (EAGLE) project uses the diverse genotypic and phenotypic data across race-ethnicity available from the National Health and Nutrition Examination Surveys (NHANES) conducted by the Centers for Disease Control and Prevention (CDC). Three NHANES surveys were used for our PheWAS: NHANES III phase 2 (1991–1994) and continuous NHANES (1999–2000 and 2001–2002). Comprehensive unadjusted tests of association were performed for 575 SNPs with 1009 phenotypes, stratified by race-ethnicity. We found 232 PheWAS results showing replication across the two surveys for the same SNP, phenotype-class, and race-ethnicity with $p < 0.01$ (allele freq > 0.01, sample size range n: 200–3974). Of these PheWAS associations, 20 replicated reported SNP-phenotype associations, 44 were related to reported associations, and 168 were novel associations. An intriguing novel result was for intronic FADS1 rs174547, previously associated with HDL cholesterol levels, associated here with total iron binding capacity (TIBC) in both non-Hispanic whites (W) and Mexican-Americans (MA). The p-values for ln(TIBC) in combined NHANES datasets were $p=1.91\times10\text{-}7$ in W ($\beta = 0.016$; n=6,368) and p=0.00021 in MA ($\beta = 0.015$; n=3,685). A total of 36 SNPs were associated with multiple phenotypes, indicative of pleiotropy. We found the missense SNP rs1260326 (within GCKR), associated across multiple classes in multiple race-ethnicities. Pleiotropic associations for rs1260326 include: for non-Hispanic blacks, the phenotype class of cell blood count (eosinophil %: $p=5.5\times10\text{-}4$; red blood cell count: p=0.007); for MA, the phenotype classes of cardiac/lipids (triglycerides: $p=4.05\times10\text{-}7$; QT interval: p=0.008), measures of nutrition (calories: p=0.009; thiamin: p=0.007), and diabetes (glucose: p=0.004; insulin: p=0.003); and for W, the phenotypes classes of diabetes (mother had diabetes: p=0.004; glucose: p=0.001) and serum vitamin levels (vitamin E: $p=9.14\times10\text{-}6$; vitamin B12: p=0.006). Previous associations for this SNP in W include phenotypes of platelet count, triglycerides, and glucose. These results demonstrate the utility of phenome-wide association studies for generating hypotheses about pleiotropic interactions for future research.

Genetic variants in pigmentation genes, skin color, and risk of skin cancer in Japanese. *T. Suzuki[1], Y. Abe[1], J. Yoshizawa[1], Y. Hozumi[1], T. Nakamura[2], G. Tamiya[2].* 1) Dept Dermatology, Yamagata Univ Sch Med, Yamagata, Japan; 2) Advanced Molecular Epidemiology Research Institute, Yamagata Univ Sch Med, Yamagata, Japan.

Melanin pigmentation plays an important role in shielding the body from ultraviolet (UV) radiation and may serve as a scavenger for reactive oxygen species. More than 150 genes have been implicated in determining in mice, and include transcription factors, membrane and structural proteins, enzymes, and several kinds of receptors and their legands, most of which have human orthologues. Although many molecular mechanisms involved in melanin pigmentation are being determined, relatively little is understood about the genetic component responsible for variations in skin color within or between human populations. First, in order to reveal their genetic contribution to skin color, we examined the association of pigmentation-related genes variants and variations in the melanin index in members of the general Japanese population whose skin color was objectively measured by reflectometry. The multiple regression showed that *OCA2* A481T rs74653330 (p = 6.18e-8) and, *OCA2* H615R rs1800414 (p = 5.72e-6) were strongly associated with the mean of the melanin index in the female population. Three variants (*SLC45A2* T500P rs11568737 p = 0.048, *OCA2* T387M p = 0.015, *TYR* D125Y rs13312741 p = 0.022) were also significantly associated with melanin index. However, no significant associations were found between age and melanin index for variants of *MC1R*. Second, we evaluated the associations of the pigmentation-related genes variants and the risk of skin cancer. The statistical analysis revealed that only *OCA2* H615R was associated with the risk of all skin cancers, especially malignant melanoma. We could not find any statistical significance in the associations of other variants, including *OCA2* A481T, or melanin index with the risk of skin cancer. This is the first report on the association between the genetic variants in pigmentation genes and the risk of skin cancer in East Asian population.

Validity of the Mendelian Randomization Approach: do the principles really hold? *M. Taylor, NJ. Timpson, JP. Kemp, B. St. Pourcain, DM. Evans, SM. Ring, DA. Lawlor, G. Davey Smith.* School of Social and Community Medicine, Bristol University, Oakfield House, Oakfield Grove, Bristol, BS8 2BN United Kingdom.

A clear focus of epidemiology is to attempt to establish causality. Mendelian randomization is an established approach, which uses genetic variants as instrumental variables to assess causality of associations between potentially modifiable risk factors and disease related outcomes. A key assumption of this approach is that genetic variants are independent of environmental characteristics and of other genetic variants that would result in a pathway between the variant being used as an instrumental variable to the disease outcome, other than through the risk factor of interest. One previous study found that 45% of pairwise associations between 96 unrelated non-genetic traits were statistically significant at the 1% level, whereas pairwise the expected 1% of pairwise associations between 23 independent SNPs and between these 23 SNPs and the 96 non-genetic traits were significant at 1%. The aim of this study was to further examine the Mendelian randomization assumption of independence by repeating the earlier study in a different dataset and with a much larger number of genetic variants. Patterns of association within a large collection of non-genetic variants between these and all single nucleotide polymorphisms with established genomewide association study (GWAS) results (Hindorff LA et al., www.genome.gov/gwasstudies) and with these genetic variants were assessed. Amongst 7260 possible pairwise associations between 121 phenotypic measures 1281 (18%) were statistically significant at a 1% level. From total of 13552 possible pairwise associations between 112 independent loci (pruned down from 4985 genetic variants) and phenotypic measures 167 (1%) were statistically significant at the 1% level. These results provide additional evidence supporting the assumption that genetic variants are largely unrelated to the large number of non-genetic characteristics or to each other. By contrast non-genetic characteristics are correlated with a wide-range of other non-genetic characteristics even when established associations have been removed from the characteristics tested. Mendelian randomization studies are therefore much less likely than conventional observational association approaches to be biased by residual confounding.

Polygenic modeling of healthy aging. *N.E. Wineinger[1], G. Atzmon[2], N. Barzilai[2], N.J. Schork[1].* 1) Scripps Translational Science Institute, La Jolla, CA; 2) Albert Einstein College of Medicine of Yeshiva University, Bronx, NY.

Past studies have shown that the manifestation of most common, heritable human diseases cannot be entirely attributed to one, or even a handful of segregating genetic variants. More recent statistical approaches which leverage numerous genetic markers, including entire genomes, have shown promising results. However, these methods have only been explored in a small subset of diseases and their clinical utility remains unclear. Healthy aging - that is, extended longevity and the absence of disease - is, perhaps, the ideal polygenic trait. One might expect that the genetic components contributing to this trait include the absence of risk variants associated with human diseases, the presence of beneficial variants specific to longevity, or some combination of both. We examined this in the Wellderly study, a cohort consisting of 397 healthy, elderly subjects and 386 matched controls. Wellderly cases had a median age of 87 and had remained free from major diseases and the need for long-term medications over the course of life. We found that 50.9% of the phenotypic variation could be explained by genetic variants genotyped on the Illumina 1M array and imputed from 1000 Genomes haplotypes, and that 18.4% of the genetic variation was due to variants recognized in the Catalog of Published Genome-Wide Association Studies or the Human Genome Mutation Database. We have begun attempts to replicate these findings in an advanced aging cohort from a dissimilar population (Ashkenazi Jews). Our preliminary results estimate 11.3% of the phenotypic variation can be explained by genotyped variants in this cohort, but we expect this figure to rise with the inclusion of imputed markers. We have explored alternative whole-genome approaches which allow for the estimation of individual marker effects and assessment of prediction within each cohort via cross-validation and between cohorts. Our findings highlight the utility of polygenic modeling, and the challenges when forming inference across populations.

1320T

Extended haplotype association study in Crohn's disease identifies a novel Ashkenazi Jewish-specific missense mutation in the *NF-kB* pathway gene, *HEATR3*. *K.Y. Hui[1], W. Zhang[1], A. Gusev[2], N. Warner[3], G. Nuñez[3], I. Pe'er[2], I. Peter[4], J.H. Cho[1].* 1) Departments of Internal Medicine and Genetics, Yale University School of Medicine, New Haven, CT; 2) Department of Computer Science, Columbia University, New York, NY; 3) Department of Pathology, University of Michigan School of Medicine, Ann Arbor, MI; 4) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY.

The Ashkenazi Jewish population has a unique genetic history, characterized by population bottlenecks, expansions, and endogamy, resulting in LD blocks of greater length and stronger correlation, compared to non-Jewish European ancestry populations. We present a study to uncover novel extended haplotypes associated to Crohn's disease and discover constituent genetic variants contributing to the several-fold higher prevalence of the disease in the Ashkenazim. Haplotype association has long played an important role in Crohn's disease in the Ashkenazi Jewish population, most notably at *NOD2*, in which three causal, uncommon, and conditionally independent variants (Arg702Trp, Gly908Arg, Leu1007fsinsC) reside on a shared background haplotype tagged by the common SNP rs2076756. In case-control cohorts of 828 Ashkenazi and 896 non-Jewish individuals, we detected shared haplotypes of length greater than 3 Mb, using the program GERMLINE; these showed significantly greater genome-wide association to Crohn's disease in the Ashkenazi Jewish population compared to a non-Jewish population (145 Jewish haplotypes with P-value < 10^{-3}; no significant non-Jewish haplotypes). Two haplotype regions, one each on chromosomes 16 and 21, conferred increased disease risk within established Crohn's disease loci. To detect novel variants within these regions, we performed exome sequencing of 55 Ashkenazi Jewish individuals, including carriers of these two haplotypes. In follow-up genotyping of chromosome 21 variants, we observed Ashkenazi Jewish-specific nominal association at R755C in *TRPM2*. Genotyping data within the chromosome 16 region showed genome-wide significance at rs9922362 of *BRD7* and R642S of *HEATR3*. We performed siRNA knockdown and over-expression studies of *HEATR3* demonstrating a positive role in *NOD2*-mediated *NF-κB* signaling. In logistical regression, the *BRD7* signal showed conditional dependence with only the rare causal variants in *NOD2*, but not with rs2076756, which elaborates this region as a key illustration of synthetic association's role in disease genetics. Notably, it illustrates conditional dependence of the cluster of *NOD2* functional polymorphisms on a secondary common background SNP across a span of 0.4 Mb.

1321F

Association analysis of CYP2A6 polymorphism in SIDS. *Y. Inaoka[1], M. Nakatome[2], F. Satoh[1], I. Hasegawa[1], M.Q. Fujita[3], M. Osawa[1].* 1) Department of Forensic Medicine, Tokai University School of Medicine, Isehara, Kanagawa 259-1193, Japan; 2) Department of Legal Medicine, Fujita Health University School of Medicine, Aichi 470-1192, Japan; 3) Department of Legal Medicine (Forensic Medicine), Keio University School of Medicine, Shinanomachi 35, Shinjuku-ku, Tokyo 160-8582, Japan.

The exposure to tobacco smoke is the major risk factor for the occurrence of sudden infant death syndrome (SIDS). A variety of components are present in the smoke, but nicotine is of particular concern in relation to SIDS because of penetrance in the placenta and effects on fetal development. The majority of intake nicotine is metabolized to the inactive forms, cotinine and 3'-hyroxycotinine by CYP2A6 in the liver. A large interindividual difference in the metabolism is evident, which is mainly attributed to CYP2A6 polymorphism. Three major alleles of *1A, *1B and *4, are present in the East Asia populations. In particular, CYP2A6*4 is the deficient allele with deletion of two exons, and clearly affects the nicotine metabolism. In this study, we performed an association study of CYP2A6 polymorphism with SIDS. A total of 71 specimens from SIDS subjects, diagnosed after full autopsy and subsequent examinations, were available. For the control, 225 samples of DNA from healthy adult individuals who had no relatedness were used. The present study has been approved by the institutional ethic committee. The genotype was determined by PCR-RFLP method to the DNA samples of SIDS and the control group. Allele frequencies of *1A, *1B and *4A were 0.436, 0.364 and 0.200, respectively. In the Japanese individuals, genotype frequencies were consistent with those expected under Hardy-Weinberg equilibrium ($\chi 2 = 4.40$, $P = 0.90$). Relative to the allele frequency of CYP2A6*1A, the odds ratio (OR) of *1B and *4A in the SIDS group was 1.20 (95% confidence intervals; 0.79–1.80) and 0.71 (95% CI; 0.41–1.25) respectively. In the homozygote-based analysis to *1A/*1A, the OR of *1B/*1B and *4A/*4A in healthy controls and SIDS samples were 1.50 (95% CI; 0.69–3.24) and 0.55 (95% CI; 0.11–2.78), respectively. These results suggest that CYP2A6 genetic polymorphism is not significant determinants affecting SIDS. We are planning to examine the effect onto sudden death of adult subjects.

Do severity of early lung disease and meconium ileus in cystic fibrosis have common genetic contributors? *W. Li[1, 2], D. Su[2], T. Chiang[2], X. Li[2], MR. Miller[2], K. Keenan[3], H. Corvol[4], FA. Wright[5], S. Blackman[6], ML. Drumm[7], GR. Cutting[6, 8], MR. Knowles[9], PR. Durie[3, 10], JM. Rommens[11, 12], L. Sun[1, 13], LJ. Strug[2, 1]*. 1) Biostatistics Division, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 2) Program in Child Health Evaluative Sciences, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Program in Physiology and Experimental Medicine, Research Institute, Hospital for Sick Children, Toronto, Ontario, Canada; 4) AP-HP, Hospital Trousseau, Pediatric Pulmonary Department, Paris, France; 5) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA; 6) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 7) Departments of Pediatrics and Genetics, Case Western Reserve University, Cleveland, Ohio, USA; 8) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 9) Cystic Fibrosis-Pulmonary Research and Treatment Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA; 10) Department of Pediatrics, University of Toronto, Toronto, Ontario, Canada; 11) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 12) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 13) Department of Statistics, University of Toronto, Toronto, Ontario, Canada.

Motivation We have established that common variation in multiple constituents of the apical plasma membrane are associated with meconium ileus (MI) in cystic fibrosis (CF) patients, as revealed by SNPs in *SLC26A9*, *SLC9A3*, and *SLC6A14* (Sun et al. 2012). MI is an intestinal obstruction seen in ~15% of CF patients at birth, and we sought to determine whether these 3 genes are pleiotropic for other CF traits, notably early CF lung disease, as all three genes are expressed in lung epithelia. Pleiotropy is a phenomenon whereby a single gene influences multiple phenotypic traits. Although conceptually straightforward, it is difficult to define and analyze pleiotropy statistically because, for example, the alternative hypothesis of interest is that the variant is associated with *all* phenotypes under study, in contrast to the conventional definition of *at least one*. **Methods** We used a cross-sectional measure of lung disease severity (SaKnorm, Taylor et al. 2011) that averages Forced Expiratory Volume in one second (FEV1) over a 3-year period of time, adjusting for age, sex and mortality. Unrelated individuals and sibling pairs from the North American CF Gene Modifier Consortium, for whom MI status was known and whose average age at FEV1 measurement was ≤ 18, were included for analysis (n=1,609). Four SNPs in *SLC26A9*, one in *SLC9A3* and three in *SLC6A14*, were analyzed for pleiotropy. To detect the pleiotropic effects of a SNP, we tested for its association with SaKnorm after accounting for its significant effect on MI. Specifically, we fit two nested mixed-effects proportional odds models at each SNP for which the ordinal response variable is the number of minor alleles of the SNP (0, 1 or 2), with a random intercept accounting for sibling correlations. The full model included both SaKnorm and MI, as well as top principal components and a recruitment site covariate; the reduced model omitted SaKnorm. We then used a likelihood ratio test to evaluate the statistical significance of the pleiotropic effects at the SNP. **Results** rs17563161 in *SLC9A3* had $p = 0.0005$ and rs3788766 in *SLC6A14* had $p = 0.02$. No SNPs in *SLC26A9* provided $p < 0.05$. **Conclusion** Evidence of pleiotropic effects for *SLC9A3* and *SLC6A14* were observed for two early CF traits, the increased risk of MI and decreased lung function in pediatric patients. The proportional odds and nested mixed modeling approach can assess evidence for pleiotropy among categorical and quantitative phenotypes in related samples.

Influence of Host Genetics and Environment on Nasal Carriage of Staphylococcus aureus in Danish Middle-Aged and Elderly Twins. *PS. Andersen[1], JK. Pedersen[2], P. Fode[1], RL. Skov[1], VG. Fowler JR[3], M. Stegger[1], K. Christensen[2]*. 1) Dept of Public Health Microbiology, Statens Serum Inst, Copenhagen, Denmark; 2) Danish Aging Research Center, Epidemiology, University of Southern Denmark, Odense, Denmark; 3) Department of Medicine, Duke University Medical Center, Durham, North Carolina, USA.

Background. Nasal carriage is a major risk factor for Staphylococcus aureus infection. Approximately, one-quarter of adults carry S. aureus. However, the role of host genetics on S. aureus nasal carriage is unknown. Methods. Nasal swabs were obtained from a national cohort of middle-aged and elderly Danish twins. Subjects colonized with S. aureus were identified by growth on selective plates and spa typing. A second sample was obtained from twins initially concordant for carriage. Twins found to again be colonized with S. aureus were defined as persistent carriers. Results. The prevalence of S. aureus carriage among 617 twin pairs (monozygotic/dizygotic pairs: 112/505) was 26.3% (95%-CI 32.2–29.9%). The concordance rate for carriage did not differ significantly between pairs of monozygotic (37.5%; 95%-CI 22.3–53.8), same sex (24.2%; 95%-CI 15.4–34.5%), and opposite sex (21.4%; 95% CI-12.0–33.4%) dizygotic twins. Despite shared childhood only 1/ 617 pairs was concordant with respect to lineage. Although heritability increased for S. aureus and lineage persistency, no significant heritability was detected. Conclusion. In this study, host genetic factors exhibited only a modest influence on the S. aureus carrier state of middle-aged and elderly individuals.

1324F

Polygenes and Estimated Heritability of Prostate Cancer in an African American Sample Using GWAS Data. *J. He, G. Chen, B. Henderson, C. Haiman, D. Stram, Genome-Wide Association Studies of Prostate Cancer in African Americans.* Preventive Medicine, University of Southern California, Los Angeles, CA.

Purpose: There is a gap between the phenotypic variance explained by genome-wide association study (GWAS) hits and those estimated from classical heritability methods. Here we utilize a more comprehensive evaluation of genetic variation trying to find the “missing” heritability in GWAS data. Methods: We adopted score analysis (Purcell et al) and linear mixed effects model (Yang et al) to estimate narrow sense heritability of prostate cancer using all SNPs in an African American Prostate Cancer (AAPC) GWAS simultaneously. In score analysis, two independent populations were used as discovery and target samples; each locus is tested in the discovery sample, and then the variation across nominally associated loci is summarized into quantitative scores that manifest a combined effect of many SNPs, and the scores are related to disease in the target sample. Linear mixed model is an alternative approach to fit all the GWAS SNPs where the effects of the SNPs are treated statistically as random, and the variance explained by all the SNPs together is estimated. In order to determine the sensitivity of both methods to long-range hidden relatedness, we simulated phenotypes and genotypes that have low pairwise correlation to see whether small correlations between individuals have a major effect on the estimate. Results: In the score analysis, both the statistical significance and phenotypic variance explained increased as a greater number of SNPs were considered; on a liability scale 29.5% of variance of AAPC can be explained by considering 873,644 SNPs simultaneously in linear mixed model. However, we concluded that the estimates from both methods may be biased upward due to unmeasured causal alleles and confounding effects of distant relatedness.

Using identity-by-descent information to detect *de novo* and recent mutations in population-based exome-sequencing studies. *N. Solovieff[1,2,3], M. Fromer[1,3,4], D. Ruderfer[4], J. Moran[3], K. Chambert[3], C. Hultman[5], P. Sullivan[6], H. Williams[7], E. Rees[7], P. Gormley[8], A. Palotie[8], G. Kirov[7], M. Owen[7], M. O'Donovan[7], P. Sklar[4], S. McCarroll[3], S. Purcell[1,2,3,4].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Department of Psychiatry, Harvard Medical School, Boston, MA; 3) Stanley Center for Psychiatric Research, the Broad Institute of Harvard and MIT, Cambridge, MA; 4) Division of Psychiatric Genomics, Mount Sinai School of Medicine, New York, NY; 5) Department of Medical Epidemiology, Karolinska Institutet, Stockholm, Sweden; 6) Departments of Genetics, Psychiatry, and Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 7) MRC Centre for Neuropsychiatric Genetics & Genomics, Cardiff University School of Medicine, Cardiff; 8) Wellcome Trust Sanger Institute, Hinxton, UK.

De novo copy number variation and point mutations have been implicated in a number of psychiatric disorders. To detect *de novo* variation, a trio design is typically used in which the proband is sequenced with both parents, although trios are more difficult to collect. We developed a method that utilizes identity by descent (IBD) information from exome sequencing in large population-based samples of unrelated samples to identify mutations that are more likely to be relatively recent, “private” mutations. These prioritized mutations will be enriched for *de novo* events, as well as mutations arising within the past several generations. For each singleton mutation in a population-based sequencing study, we search for other subjects who share the surrounding region IBD, by use of a hidden Markov model. If we observe data consistent with the index subject's maternal and paternal haplotypes each being shared by at least one other person (none of whom also share the index's singleton mutation), we can conclude that the mutation must post-date their most recent common ancestor. By focusing only on sharing of multi-megabase segments (indicative of more recent co-ancestry), we can effectively reduce the large number of rare variants each individual carries to a shortlist of truly rare alleles, more likely to contain large effect disease alleles. *De novo* variants represent a special case of this class. To evaluate this approach, we applied the method to a set of Bulgarian schizophrenia trios from an ongoing exome sequencing study. For validated *de novo* mutations, we asked whether we could flag these mutations without using any parental data, but instead using genome-wide IBD data from ~2000 unrelated, Bulgarian individuals. We were able to recover approximately 10% of the validated *de novo* mutations: this proportion will increase with larger sample sizes. For each proband, our approach flagged a small fraction of the hundreds of neutral, novel singleton variants each case carries. We posit that this fraction will be enriched for private mutations of large effect on disease as well as *de novo* variants and we are currently testing this hypothesis in a large cohort of ~12,000 unrelated Swedish samples (schizophrenia cases and controls), of which 5,000 have exome sequence data. We predict that singletons flagged by our approach will be more likely to be novel, loss-of-function and enriched in cases, compared to the much larger class of all singleton variants.

1326T

Mitochondrial DNA (mt DNA) Polymorphism 13704 (C/T) might Induce Hematologic Malignancy Predisposition in Turkish Population. *N. Duzkale, A. Tatar.* Medical Genetics, Ataturk University Medical Faculty, Erzurum, Erzurum, Turkey.

Hematologic malignancies are a group of heterogeneous neoplasia which consist of myeloid and lymphoid stem cell mass in the blood and bone marrow. Mitochondrial genome has been under investigation for various cancer types including hematologic malignancies to determine whether common polymorphisms of mtDNA can be considered as new moleculer markers of DNA damage and individual sensitivity to carcinogenic agents. It has been shown that mtDNA polymorhism can not only predict the risk of predisposition to cancer development but also tumor progression, prognosis and response to treatment. In this study, we evaluated mitochondrial (mtDNA) polymorphisms to understand the role they may have in hematologic cancer predisposition and/or pathogenesis. We have investigated 80 patients diagnosed with hematologic malignancy (30 CML, 18 CLL, 20 AML, 12 ALL) and 80 healthy controls assessing DNA samples from their peripheral blood white blood cells. Thirteen single nucleotide polymorphisms (SNPs) encompassing 6 mitochondrial regions that were evaluated were as follows: cytochrome b-15315 (C/T), NADH dehydrogenase subunit 5- 13704 (C/T), 12S rRNA -740 (G/A), 12S rRNA -680 (T/C), cytochrome c oxidase I- 7319 (T/C), cytochrome c oxidase I- 7444 (G/A), cytochrome c oxidase II- 7660 (G/A), cytochrome c oxidase II- 7975 (A/G), tRNA lysine- 8310 (T/C), cytochrome c oxidase II- 8014 (A/G, A/T), cytochrome c oxidase II- 8252 (C/G, C/T), cytochrome c oxidase II-8113 (C/A) ve cytochrome c oxidase II- 8152 (G/A). Polymorphisms were identified by the polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) analysis. Chi-square test was used to compare the study groups for their association with polymorphisms and the statistical significant level was accepted as $p<0.05$. One single SNP identified in the ND5-13704 region, 13704 (C/T), in 12 patients (3 CML, 1 CLL, 6 AML, 2 ALL) and one healthy control was statistically significant when compared to control group ($p=0.001$). We hypothesize that mtDNA 13704 (C/T) SNP can play a role in carcinogenesis process by creating susceptibility to cancer development. Further studies to elucidate the mechanism by which it does that, such as increased production of reactive oxygen species which damage the mitochondrial genome, is warranted.

1327F

Significant association of *LPL* polymorphisms with HDL- cholesterol level in Tongan adults. *I. Naka[1], R. Kimura[2], T. Inaoka[3], Y. Matsumura[4], J. Ohashi[1].* 1) Faculty of Medicine, University of Tsukuba, Ibaraki, Japan; 2) Transdisciplinary Research Organization for Subtropics and Island Studies, University of the Ryukyus, Okinawa, Japan; 3) Department of Environmental Sociology, Faculty of Agriculture, Saga University, Saga, Japan; 4) Faculty of Health and Nutrition, Bunkyo University, Kanagawa, Japan.

Lipoprotein lipase gene (*LPL*) is located at 8p22 and encodes lipoprotein lipase, which is primarily expressed in fatty (adipose) tissue and in muscle. The main function of lipoprotein lipase is to hydrolyze triglycerides in circulating chylomicrons and in very low density lipoproteins into free fatty acids and glycerol. Lipoprotein lipase also promotes the cellular uptake of chylomicron remnants, cholesterol-rich lipoproteins, and free fatty acids. Several single nucleotide polymorphisms (SNPs), including S447X (rs328), of LPL have been shown to be associated with levels of lipid fractions, hypertension, and coronary disease. Recently, genome wide association study of metabolic syndrome reported the significant associations of rs13702 at the 3' UTR of LPL with HDL-cholesterol and triglyceride levels. In this study the associations of these LPL SNPs, S447X and rs13702, with total-cholesterol, HDL-cholesterol, LDL-cholesterol, and triglyceride levels were evaluated in 127 adult subjects living in Tonga. A multiple regression analysis adjusted for age, sex, and body mass index (BMI) revealed that a copy of 477X significantly increased serum HDL-cholesterol by 8.6 mg/dl (*P*-value = 0.0151) and a copy of rs13702-T allele significantly decreased serum HDL-cholesterol by 2.9 mg/dl (*P*-value = 0.0363). No other significant associations were observed. Although rs328 and rs13702 were in linkage disequilibrium each other (D'= 1 and r^2 = 0.09), these SNPs were simultaneously included in regression analysis as independent variables. The results revealed that rs17302-T allele was significantly associated with the decrease in serum HDL-cholesterol (*P*-value = 0.025), but 477X did not show the significant association. Our results suggest that rs17302 affects the level of serum HDL-cholesterol independent of 477X and BMI in Tongan adults.

Personalized Risk Prediction for Prostate Cancer According to Specific Family History. *L. Cannon-Albright[1], F. Albright[2], W. Lowrance[3], R. Stephenson[3].* 1) Genetic Epidemiology, University of Utah School of Med., Salt Lake City, UT; 2) Pharmacotherapy Outcomes Research Center, Department of Pharmacotherapy, College of Pharmacy, University of Utah, Salt Lake City, UT; 3) Department of Surgery, Division of Urology, Huntsman Cancer Institute, University of Utah, Salt Lake City, UT.

Objective: Family history of prostate cancer (PC) is a key risk factor for the disease and may inform screening strategies. The impact on risk of PC by the number and degree of affected relatives is uncertain. We provide risk estimates for PC based on specific family history data obtained from a statewide cancer registry linked to detailed genealogy data. Methods: We analyzed the Utah Population Data Base (UPDB), a computerized genealogical resource linked to a statewide SEER cancer registry. Over 1 million individuals were analyzed. All males with specific patterns of PC family history were identified and the observed number of prostate cancer cases was compared to the expected number of prostate cancer cases using internal cohort-specific rates to estimate relative risk (RR). We considered family history out to 3rd degree relatives, number of relatives affected, paternal versus maternal family history, and age at diagnosis. Results: We analyzed a total of 611,799 males in the UPDB, of which 17,207 male subjects were diagnosed with histologically confirmed prostate cancer. Risk for prostate cancer was significantly elevated with each additional first-degree relative (FDR) affected, ranging from RR=1.85*, [95% CI: 1.80–1.89] for at least 1 FDR to RR=4.93*, [95% CI: 4.11–5.87] for at least 4 FDRs affected. In the absence of FDR family history, increased risk for PC was only observed in the presence of at least 2 second-degree relatives (SDR) affected (RR=1.18*, [95% CI: 1.12–1.25]). In the absence of positive FDR and SDR family history, there was no increased risk for PC for up to 5 or more third-degree relatives affected (RR=1.06, [95% CI: 0.92–1.21]). Earlier age at diagnosis of the affected relative was associated with higher estimates of PC risk, with RR= 4.06*, [95% CI: 3.27–4.98] for at least one FDR diagnosed before age 50 years and RR = 2.14*, [95% CI: 2.05–2.23] for at least one FDR diagnosed between age 60–69 years. We did not detect a significant risk difference based on whether the family history of PC was paternal or maternal. Conclusions: This study provides unbiased, population-based estimates of PC risk based on a man's specific PC family history constellation. The results of this study can be used to provide more informative and personalized risk estimates for PC in an individual clinical setting and on a population basis. These data should help guide PC screening policies targeting those at highest risk of the disease.

Estimating disease risk from environmental and genetic factors to motivate behavioural changes. *C.M. Lewis, J.M. Yarnall, G.H.M. Goddard, D.J.M. Crouch.* Med & Molec Genetics, King's College London, London, United Kingdom.

The identification of genetic variants predisposing to disease has raised the prospect of predicting individual-level disease risk. However, prospective studies have indicated that genetic profiling with SNPs of modest effect size provides little information of value. Here, we develop a mathematical model for joint modelling of genetic and environmental risk factors for disease to calculate a relative risk. An empiric confidence interval (CI) for the relative risk is simulated from sources of variation (genotype frequencies, odds ratios for environmental risk factors, coefficient of variation for disease prevalence). Using these CIs allows the population to be classified into risk groups, where genetic-environmental profiles of low, elevated and high risk have a level of risk that is statistically different from individuals of average risk. Applying this model to common, complex disorders using REGENT (open source software written in R) shows the following. 1) The addition of many SNPs for risk prediction is counterproductive with low risk SNPs having a low signal-noise ratio, producing wider CIs and reducing discrimination into risk categories. 2) For SNP alleles and environmental risk factors of similar risk level and frequency, the genetic component contributes more information to the risk model. 3) CIs and risk classifications become stable with estimates extracted from case-control studies with total sample sizes of >= 20,000. 4) Application of the model to common complex diseases with risk factor estimates from published studies enables a reasonable proportion of the population to be classified as at elevated or high risk, for example 19% in age-related macular degeneration (AMD), 17% for colorectal cancer, 18% for Crohn's disease. These individuals have a risk that is statistically elevated above an average member of the population and may be targeted for behavioural modification programmes or regular screening. The model also enables users to identify subgroups of the population, or specific individuals, where environmental changes (e.g. smoking cessation, BMI reduction) could reclassify their risk from high to elevated, or elevated to average, thus motivating adherence to healthy lifestyle. Simulating individuals representative of the population shows that, for example, 6.75% of obese individuals (BMI >=30 kg/m^2) classified as high or elevated risk for AMD would be reclassified to lower levels of risk if they reduced their BMI.

Background: At present, the majority of coeliac disease (CD) patients are not being properly diagnosed and therefore remain untreated, leading to a greater risk of developing CD-associated complications. Identifying high-risk individuals could help prioritize those to target for closer follow-up. The major genetic risk for CD, HLA-DQ2 and DQ8, is already used in clinical practice to exclude the disease. However, approximately 40% of the population carry these alleles and never develop CD. We recently identified 57 non-HLA single nucleotide polymorphisms (SNPs) that contribute to CD development. Here, we explore if CD risk prediction can be improved by adding non-HLA susceptible variants to the common HLA testing, and we assess how well our risk models can be transferred to other cohorts. Methods: We developed an average weighted genetic risk score (GRS) with 10, 26 and 57 SNPs in 2,675 cases and 2,815 controls and assessed the improvement in risk prediction provided by the non-HLA SNPs. Moreover, we assessed the transferability of the genetic risk model with 26 non-HLA variants to a nested case-control population (n=1,709) and a prospective cohort (n=1,245) and then tested how well this model predicted CD outcome for 985 independent individuals. Findings: Adding 57 non-HLA variants to HLA testing showed a statistically significant improvement compared to scores from models based on HLA only, HLA+10 SNPs, and HLA+26 SNPs. The area under the ROC curve reached 0·854 and 11·1% of individuals were reclassified to a more accurate risk group. Moreover, we show that the risk model with HLA+26 SNPs is useful in independent populations, mainly for HLA-DQ2- and DQ8-positive individuals. Interpretation: Predicting risk with 57 additional non-HLA variants improved the identification of potential CD patients. This demonstrates a possible role for combined HLA and non-HLA genetic testing in diagnostic work for CD.

Bayesian polygenic prediction of myocardial infarction risk and lipid levels. *B.J. Vilhjalmsson[1], R. Do[2], E.A. Stahl[3], B. Pasaniuc[1], S. Pollack[1], N. Zaitlen[1], J. Yang[4], M.E. Goddard[4], P.M. Visscher[5], P. Kraft[1], N. Patterson[2], S. Kathiresan[2], A.L. Price[1].* 1) Harvard School of Public Health, Boston, MA, USA; 2) Broad Institute, Cambridge, MA, USA; 3) Harvard Medical School, Boston, MA, USA; 4) Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 5) The University of Melbourne, Parkville, Victoria, Australia.

Despite the success of GWAS, associated loci generally explain only a small fraction of total heritability and provide poor predictive accuracy. Although polygenic scores using less stringent P-value thresholds have been shown to yield greater predictive accuracy, we show here that under realistic genetic architectures the standard thresholding approach can be improved. Assuming that only summary statistics are available from the training data set, our approach is to estimate posterior mean effect sizes while explicitly modeling the prior mixture distribution of underlying causal effect sizes, the impact of linkage disequilibrium (LD) on indirect associations at non-causal markers, and the effects of sampling noise. We adjust estimated effect sizes for local LD as estimated from an external reference sample (Yang *et al.* 2012), and further impose a nonlinear Bayesian shrink, generalizing the standard thresholding approach that applies a shrinkage factor of 0 or 1 to each marker.

In simulations of unlinked markers with causal effect sizes drawn from a Gaussian mixture or exponential mixture distribution with $h^2=0.5$, we observed a relative increase in prediction r^2 of up to 20% for the Bayesian scheme, as compared to the standard thresholding approach with optimal threshold. When simulating phenotypes using real genotypes from the Wellcome-Trust Case Control Consortium, we observed a similar improvement in prediction r^2 when accounting for LD.

We applied our method to predict myocardial infarction (MI) phenotypes in 6,000 test samples using summary statistics from 80,000 training samples, obtaining a prediction r^2 of 3%, which is lower than predicted by theory. Results may be limited by discordance between MI training samples and early-stage MI test samples, as our method produced superior results for height (see Speliotes *et al.* abstract). Our study demonstrates the efficient use of genetic data for prediction of clinically important diseases and traits when only summary statistics are available. As training sample size increases, the prediction accuracy will further increase.

1332T

Testing for the Presence of Liability Models. *C. Herold[1, 2], T. Vaitsiakhovich[3], T. Becker[2, 3].* 1) Harvard School of Public Health, Boston, USA; 2) German Center for Neurodegenerative Diseases, Bonn, Germany; 3) Institute for Medical Biometry, Informatics and Epidemiology, Bonn, Germany.

It has recently been suggested that so-called liability models may define the architecture of the genetics of complex diseases [Zuk et al., 2012]. For individuals with less than k risk alleles a moderate baseline penetrance f0 <=5% applies, whereas for individuals with an allele load above the threshold the penetrance f>k can be as high as 50%–80%. Such models in general do not lead to a type of epistasis that is detectable by pair-wise testing but exhibit interaction of all higher orders. For a phenotype with m confirmed SNPs from the GWAS catalogue, it is an important question whether these SNPs follow a threshold model. To this purpose, we present a simple 1 d.f. regression test for the presence of a liability threshold. The test is based on the evaluation of the significance of a simple indicator parameter and allows the analysis of covariates and quantitative trait data. We conducted an extensive simulation for the threshold models with $n \in \{5, 10, 20, 50\}$ and liability threshold corresponding to a critical portion of 70%–85% causal alleles. Our models lead to marginal effects that are compatible with typical GWAS effect sizes and pair-wise interaction effects that typically are not detectable. However, with moderate sample size (3000 individuals) the power to detect the presence of a threshold model is effectively 100%, given that all SNPs of the threshold model are known. For the more realistic situation, in which the number of already detected SNPs m is smaller than the number n of SNPs in the unknown model, we can show that for m > 2/3 n there is decent power to proof the involvement in a threshold model. We present results to Alzheimer's and Type II Diabetes GWAS data sets.

Alcohol and aldehyde dehydrogenase polymorphisms and blood pressure elevation in Japanese over 20 years. *M. Isomura, T. Wang, Y. Yoshida, T. Nabika.* Functional Pathology, Shimane University, Shimane, Shimane, Japan.

Purpose: Effects of the genetic polymorphisms in the alcohol dehydrogenase-2 (ADH1B) and aldehyde dehydrogenase-2 (ALDH2) on the blood pressure (BP) were investigated in a 20-year follow-up study involving Japanese rural residents. Methods: 570 individuals attending both health examinations held in 1987 and 2006 were participated in this study. BP and demographic factors of interest were recorded on site at both time. Genomic DNAs of participants were extracted form blood and genotypes were determined by the TaqMan method. Multivariate regression analyses were performed to examine association between BP and genetic polymorphisms of those genes. Results: In the 20-year follow-up study, systolic and diastolic BP at baseline and follow-up were comparable among the ADH2 and the ALDH2 genotypes. Multivariate quantitative analyses showed that homozygote of ALDH2*2 exhibit significantly lower SBP and DBP than carrier of ALDH2*1. By contrast, ADH2 genotype did not influenced blood presser. Genetic variation in the both genes apparently influenced the drinking behavior that the number of the drinkers was significantly reduced in the homzygote of ALDH2*2. Genetic variations in either gene confer the risk of blood presser change in 20-yerars. Conclusion: These observations clarified the conflicting results regarding the effects of the ALDH2 on BP and exemplified gene-gene and gene-environment interaction influencing BP.

The *PPP6R3/LRP5* locus influences lean mass in children of different ethnic background and highlights pleiotropic effects on muscle-bone interactions. *M.C. Medina Gomez[1,2,3], D.H.M. Heppe[2], K. Estrada[1], J. Van Meurs[1], A. Hofman[3], Y.H. Hsu[4], D. Karasik[4], V.W.V. Jaddoe[2], M.C. Zillikens[1], A.G. Uitterlinden[1,2,3], F. Rivadeneira[1,2,3], GEFOS consortium.* 1) Internal Medicine, Erasmus MC University, Rotterdam, The Netherlands; 2) The Generation R Study Group, Erasmus Medical Center, Rotterdam, The Netherlands; 3) Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 4) Hebrew SeniorLife and Harvard Medical School, Boston, MA.

Aim: Lean and bone mass have considerably high phenotypic and genetic correlations with a shared heritability estimate ranging between 30–40% in adults. A genome-wide association study (GWAS) on total body lean mass and a bivariate GWAS on lean mass & BMD were ran in a cohort of children to identify genes with pleiotropic effects on muscle mass and peak bone mass attainment. **Methods:** Subjects are part of the Generation R study, a prospective multiethnic birth cohort in Rotterdam, The Netherlands; we included 4,096 children (mean age=6.2,SD=0.50 years) with total body DXA measurements (GE-Lunar iDXA) and genomewide genotyping (Illumina 660K). The univariate and bivariate GWAS were adjusted for age, sex, height, fat percent and 20 genomic principal components using bivariate PLINK. A $P<5\times10^{-8}$ was considered genome-wide significant (GWS). **Results:** Genomic inflation factors were close to unity indicating adequate correction for stratification. In the univariate analysis we identified a GWS association with lean mass ($\beta=0.13$, $P=2.9\times10^{-8}$) for a SNP mapping to 11q13.2, in the *PPP6R3/LRP5* locus. The SNP explained 0.8% of the variation in lean mass and was nominally significantly associated with BMD ($\beta=0.10$, P=7.6×10-5) explaining 0.4% of BMD variation. The association with lean mass was reduced after additional correction for bone mineral content ($\beta=0.08$, P=0.001), explaining 0.2% of the phenotypic variance. In the bivariate GWAS this SNP was also associated at GWS level ($P=4.8\times10^{-8}$) showing positive correlations of the bivariate trait with both lean mass (0.96) and BMD (0.68). **Conclusion:** While *LRP5* (an ubiquitously expressed gene member of the Wnt signaling pathway) is known to play a key role in bone mechanosensing with GWAS showing association with BMD and fracture in elderly adults; we showed that genetic variation in the *PPP6R3/LRP5* locus exerts pleitropic effects on muscle mass and peak bone mass acquisition of children. Given the high regional LD it is difficult to establish from which gene the GWAS signal is arising. *PPP6R3* is a gene of unknown function ubiquitously expressed across tissues among others in bone and muscle. Replication in additional children cohorts is underway while the exact same SNP has been found associated at genome significant level in a bivariate GWAS of bone strength and lean mass in two large consortia of adult individuals. Such pleiotropic effects on muscle mass and BMD observed in children are still evident later in life.

Examining the Interaction Effect of SNPs Associated with Urinary Bladder Cancer. *H. Schwender[1,2], S. Selinski[3], T. Stöcker[1,2], M. Blaszkewicz[3], R. Marchan[3], K. Ickstadt[1], K. Golka[3], J. Hengstler[3].* 1) Faculty of Statistics, TU Dortmund University, Dortmund, Germany; 2) Heinrich-Heine University Duesseldorf, Duesseldorf, Germany; 3) Leibniz Research Center for Working Environment and Human Factors (IfADo), Dortmund, Germany.

Genetic association studies aim to detect single nucleotide polymorphisms (SNPs) and combinations of SNPs associated with a disease, where it is hypothesized that the effect of individual SNPs on the disease risk increases when they are considered in combination. In genome-wide association studies concerned with urinary bladder cancer (UBC), e.g., a handful of SNPs has been detected to be associated with UBC (e.g., Kiemeney et al., 2008; Rothman et al., 2010) and was confirmed in other independent cohorts, e.g., in the case-control data collected by the Leibniz Research Center for Working Environment and Human Factors (IfADo), consisting of 1,595 Caucasian UBC cases and 1,760 Caucasian controls. It, however, has not been investigated yet if the high-risk alleles of these SNPs interact with one another, leading to an even higher disease risk. We therefore considered the most influential SNPs (rs1014971, rs9642880, rs710521, rs8102137, rs11892031, rs1495741) as well as GSTM1 (Glutathione S-Transferase M1), a detoxifying phase II metabolizing enzyme for which it is well established that a deletion variant is associated with an increased UBC risk (e.g., Bell et al., 1993), and investigated whether combinations of these polymorphisms increase the individual UBC risks. Moreover, we compared the resulting UBC risks with the ones of cigarette smoking and occupational exposure. In our presentation, we summarize the results of this examination. We found that for combinations of up to three polymorphisms the UBC risk increases with the number of polymorphisms, where the most important three-way interactions substantially differed between smokers and non-smokers. All the important interactions showed stable results, as a bootstrap analysis revealed. Nonetheless, the most influential three-way interaction still had a UBC risk smaller than the one of smoking and comparable to occupational carcinogen exposure risks. References: Bell, D.A., et al. (1993). Genetic risk and carcinogen exposure: a common inherited defect of the carcinogen-metabolism gene glutathione S-transferase M1 (GSTM1) that increases susceptibility to bladder cancer. J. Multivariate modeling for a more powerful genetic association analysis. *S. Eyheramendy[1], C. Meza[2].* 1) Statistics, Pontificia Univ Catolic, Santiago, Chile; 2) CIMFAV, Universidad de Valparaiso, Valparaiso, Chile.

Hundreds of genome-wide association studies (GWAS) have been performed leading to the identification of many genetic variants associated with common and complex diseases. Usually, these studies are performed on several phenotypes, but the association analysis is performed separately at each one. Statistical correlations have been observed between many traits and also pleiotropy in not uncommon among these studies. Our purpose in this work is to show that genetic association studies can benefit by jointly modeling correlated pheno- types. We developed a multivariate model and software that jointly assess the association between a genetic variant and two correlated phenotypes. We compare our approach with the univariate standard methodology and show that an increased power is achieved to detect genetic associations. Our methods is also able to detect pleiotropic loci. We show our results on real data from two large German cohorts.

Random-effects model for massive meta analysis in Genome wide association study with structured populations. *E. Kang[1], N. Furlotte[1], B. Han[2,3,4], J. Joo[5], R. Davis[6], A. Lusis[6,7], E. Eskin[1,7].* 1) Department of Computer Science, University of California, Los Angeles, CA, USA; 2) Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, MA, USA; 3) Partners HealthCare Center for Personalized Genetic Medicine, Boston, MA, USA; 4) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 5) Interdepartmental Program in Bioinformatics, University of California Los Angeles, CA, USA; 6) Department of Medicine, University of California, Los Angeles, CA, USA; 7) Department of Human Genetics, University of California, Los Angeles, CA, USA.

Meta-analysis is an effective approach to achieve higher power in genome-wide association studies (GWAS) by combining results from multiple different studies when there is not enough power to detect the very small effect size of the SNP to target phenotype. Previously we proposed optimal meta-analysis method based on mixed model for structured populations such as mouse model organism to achieve higher power while correcting population structure which cause a large number of spurious association and inflates the significance of true associations. One promising main application of this proposed meta-analysis method is applying it to a large number of publicly available data set such as mouse phenome database. These publicly available large number of data sets are very promising sources to discover causal SNPs with small effect size through combining these studies using meta-analysis approach. However one possible challenge to performing meta-analysis with these data set is the heterogeneity in the effect size of the causal SNP to the target phenotype due to the various different conditions such as diets and sex when the data is collected. Previous studies shows that the heterogeneity in the effect size can result in the lost of statistical power in the association study when fixed effects model is applied. In this paper, we propose the random-effects model which accounts for the heterogeneity in the effect size between studies in the meta-analysis procedure, which extends our mixed model based meta-analysis approach. In the simulation experiments, we show that the new method achieves higher statistical power than previously proposed fixed effects model when there is heterogeneity, while correcting the population structure in the association procedure under the condition that there exists a population structure in the data. We show the practical utility of the proposed method by applying it to 19 HDL studies containing 4000 individuals, some of which are from publicly available mouse phenome database and 3 different atherosclerosis studies.

1338T

Comparison of rare variant tests. *J. Lihm[1,5], E. J. Yoon[1], H. Wu[1], T. Harris[1], C. Wong[1], J. Ceris[1], J. Weisburd[1], N. R. Mendell[1], W. Kim[2], K. Ahn[3], D. Gordon[4], S. J. Finch[1].* 1) Department of Applied Mathematics and Statistics, Stony Brook University, Stony Brook, NY; 2) Department of Mathematics and Statistics, University of South Florida, Tampa, FL; 3) Division of Biostatistics, Department of Public Health Sciences, Penn State College of Medicine, Hershey, PA; 4) Department of Genetics, Rutgers University, Piscataway, NJ; 5) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

We study the null rejection rate and power of two classes of statistical procedures proposed to detect rare variants. The first class includes two multivariate tests using Hotelling's T-squared test without collapsing and with collapsing into a number of indicator variables within a gene. Collapsing all variants into a single indicator variable is studied as well. The second class of methods studied sums allele frequencies across the variants. We implement the weighted-sum method of Madsen and Browning which weights each variant by its estimated variance as well as a fixed and variable threshold methods that sum the frequencies of variants with minor allele frequencies less than a threshold. The fixed threshold methods using 1% and 5% and the collapsing method have rejection rates for non-causal genes closest to the nominal 0.05 level. Although the power of detecting causal genes for each method varies across the genes, the sum statistic of minor allele frequencies less than 5% fixed threshold consistently shows the greatest power for causal genes.

Artificial Intelligence Analysis of Prostate Cancer Susceptibility Using a Pareto-Optimized Computational Evolution System. *J.H. Moore[1], D.P. Hill[1], A. Sulovari[1], L. Kidd[2].* 1) Department of Genetics, Institute for Quantitative Biomedical Sciences, The Geisel School of Medicine, Dartmouth College, Lebanon, NH; 2) University of Louisville, KY.

Given infinite time, humans would progress through modeling complex data in a manner that is dependent on prior knowledge of their domain, computer science and statistics as well as their prior experience working with other data. For example, a human modeler interested in identifying genetic risk factors for type II diabetes might start by examining insulin metabolism genes. The goal of the present study is make extensions and enhancements to a computational evolution system (CES) that has the ultimate objective of tinkering with data as a human would (i.e. artificial intelligence). This is accomplished by providing flexibility in the model-building process and a meta-layer that learns how to generate better models. The key to the CES system is the ability to identify and exploit expert knowledge from biological databases or prior analytical results. Our prior results have demonstrated that CES is capable of efficiently navigating these large and rugged fitness landscapes toward the discovery of biologically meaningful genetic models of disease predisposition. Further, we have shown that the efficacy of CES is improved dramatically when the system is provided with statistical expert knowledge, derived from a family of machine learning techniques known as Relief, or biological expert knowledge, derived from sources such as protein-protein interaction databases. The goal of the present study was to apply CES to the genetic analysis of prostate cancer aggressiveness in a large sample of European Americans. We introduce here the use of Pareto-optimization to help address overfitting in the learning system. We further introduce a post-processing step that uses hierarchical cluster analysis to generate expert knowledge from the landscape of best models and their predictions across patients. We find that the combination of Pareto-optimization and post-processing of results greatly improves the genetic analysis of prostate cancer. This works takes a step closer to the development of genetic analysis software that approaches modeling as a human would.

1340W

A simple Bayesian method for modeling effect heterogenity across genetic studies. *C.C.A. Spencer[1], P.J. Donnelly[1,2], M. Pirinen[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Statistics, University of Oxford, Oxford, United Kingdom.

There is now a wealth of successful genome-wide association studies for hundreds of phenotypes. An exciting opportunity is to compare and contrast observations across studies and to combine studies to discover new associations. Most standard statistical methods assume a genetic variant to have the same effect on risk across studies. As an increasing amount of genetic data becomes available from different populations and/or related phenotypes it is beneficial to relax the fixed effects assumption for the purpose of identifying new associations. Moreover, it is often of interest to compare statistical models directly in order to quantify the evidence for similarities and differences in effect between studies. We introduce a novel Bayesian framework to answer questions like:

- Is there evidence for association in all studies?
- What is the combined evidence assuming the effect to be similar?
- Is the effect the same across studies?
- Is there an effect in only one study?
- How similar are the effects across studies?

An appealing property of the approach is its computational simplicity which makes it widely accessible to the genetics research community. We illustrate the utility of the proposed methodology with two applications: a study into genetic determinants of malaria susceptibility across three African populations, and combining existing studies of auto-immune disease.

Effectively identifying and characterizing eQTLs from multiple tissues using a meta-analytic approach. *J. Sul[1], B. Han[1], C. Ye[2], T. Choi[3], E. Eskin[1,4].* 1) Computer Sci, Univ California, Los Angeles, Los Angeles, CA; 2) Broad Institute of MIT and Harvard, Cambridge, Massachusetts, 02142, USA; 3) Predictive Biology, Inc., San Diego, CA; 4) Department of Human Genetics, University of California, Los Angeles, California 90095, USA.

Gene expression data, in conjunction with information on genetic variants, have enabled studies to identify expression quantitative trait loci (eQTLs) or locations in the genome that affect gene expression. Moreover, technological developments and cost decreases enable studies to collect expression data in multiple tissues. One advantage of multi-tissue datasets is that studies can combine results from different tissues to identify eQTLs more accurately than examining each tissue separately. The idea of aggregating results of multiple tissues is closely related to the idea of meta-analysis which aggregates results of multiple genome-wide association studies. In principal, meta-analysis methods can be used to combine results from multiple tissues. However, a key challenge is that genetic variants may have different effects in different tissues, a phenomenon known as heterogeneity. In this paper, we propose a novel approach leveraging a recently developed meta-analysis method that incorporates heterogeneity. We first show by simulations that our method is more powerful than a meta-analysis method that does not consider heterogeneity in detecting eQTLs from multiple tissues when heterogeneity exists. We then apply our method to multi-tissue dataset from mouse. This dataset contains expression from many different tissues and different numbers of samples for tissues allowing us to observe power to detect eQTLs under various scenarios. We analyze four tissues from 50 samples per tissue and ten tissues from 22 samples. We demonstrate that our method detects 95% and 23% more eQTLs than a traditional eQTL method or the meta-analysis method that does not consider heterogeneity, respectively, in the four tissues. In the ten tissues, we detect 520% and 11% more eQTLs. Additionally, our method provides an interpretation framework that accurately predicts whether an eQTL has an effect in a specific tissue. Our method computes the posterior probability of the presence of an effect building on recent work in interpretation of meta-analysis. Simulations show that this probability predicts effects more accurately than an approach using p-values. Applying the framework to the mouse dataset, we try to detect eQTLs having effects in all tissues since they can help us understand tissue-independent regulatory mechanisms. We show that our approach detects 221 and 45 more such eQTLs than the approach using p-values in the four and ten tissues, respectively.

PEDF gene Polymorphism (p.Met72Thr) Analysis in Diabetic Retinopathy Cases. *S. Passan, V. Vanita.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: To study the association of Pigment Epithelium Derived Factor (PEDF) gene polymorphism (p.Met72Thr) in type 1 and type 2 diabetic retinopathy cases. Material and Methods: The present case control association study included 777 type 2 diabetes patients and 42 type 1 diabetes patients. All the patients were unrelated and of Indian origin. These patients were recruited from Dr. Daljit Singh Eye Hospital, Amritsar. 507 diabetic patients had different types of retinopathies. Of these 128 had Back-ground Diabetic Retinopathy (BDR), 299 patients were suffering from Proliferative Diabetic Retinopathy (PDR), 80 patients had Pre Proliferative Diabetic Retinopathy (PPDR), and 312 diabetic patients with no sign of retinopathy were collected as controls. The genotyping was carried out by bi-directional sequence analysis of the amplified products. Statistical analysis was performed using SPSS for windows (Version. 16.0). One way ANOVA test was applied to find any association for various clinical parameters (age, age of onset of diabetes, duration of diabetes, basal metabolic index (BMI), systolic and diastolic blood pressure) with diabetic retinopathy. Genotype distributions and allele frequencies were evaluated using statistical calculator (StatPac V. 3. 0). MedCalc (V 9. 3. 9. 0) was used to determine the odds ratios (OR) and 95% confidence intervals (CI). Results: The present study, revealed statistical significant differences between age, age of onset, duration of diabetes, and BMI when DR patients (BDR, PPDR, and PDR) were compared with controls. For *PEDF* p.Met72Thr polymorphism the allele frequencies (p=0.9266) and genotype frequencies (p=0.5373) in DR patients showed no statistical difference when compared with controls. However, OR analysis revealed a significant relationship with (TC) heterozygote genotype of the *PEDF* polymorphism in DR cases in comparison to controls (OR=1.32). Conclusions: To our Knowledge, the present study is the first report of case control association study of *PEDF* polymorphism (p.Met72Thr) with diabetic retinopathy in North Indian type 1 and type 2 diabetic patients. Present findings suggest no association of PEDF gene polymorphism (p.Met72Thr) with DR. However, TC heterozygote genotype showed 1.3 times increased risk of diabetic retinopathy indicating that TC genotype of *PEDF* is associated with increased risk of diabetic retinopathy.

Chromosome 10 gene may be associated to response to Leishmania antigens. *L. Pereira, J. Pescarini, R. Ferreira, L.M. Camargo, H. Krieger, L.M. Garrido.* Dept Parasitology, Univ Sao Paulo, São Paulo, Brazil.

Leishmania is a protozoan that causes an endemic disease at the Amazonian region, affecting about 2,000 individuals every year, with a mortality ratio close to 10%. In Brazil, there are two forms of leishmaniasis: cutaneous and visceral, both transmitted by an insect of the subfamily Phlebotominae. The test of Montenegro (MN), is an immunological technique of delayed skin hypersensitivity with specificity between 86% around 100%. It is performed by inoculating a small amount of leishmania antigen in the arm and after 48 hours it is possible to observe a papule. This papule is measured and if its size is equal or larger than 5mm, the individual is assumed to be positive to leishmania infection. The sample is composed by two subsamples one of 80 individuals from Monte Negro (10° 15' S, 63° 18' W) collected in the late 90s and 34 individuals from the same locality collected in the late 2000. This last sample was ascertained in order to verify the association of some genetic markers and Montenegro phenotypes. Two Taqman (rs11251056 and rs11251062) from chromosome 10 (Applied Biosystems) SNP genotyping probes were chosen based on suggestions of association disclosed by genomic scanning with the Genechip Affymetrix 250 Nsp I. Joint-analysis uses statistical techniques to combine into one summary measurement the results of independent studies aimed at a single issue. The meta-analysis, using small samples such as these are relevant since it reveals important characteristics of complex traits such as the response to infection and may show possible relationship to infection and therefore display mechanisms of susceptibility/resistance. The meta-analysis disclosed an association for rs11251062 (p=0.03) with MN reaction while the analysis for SNP rs11251056 showed a borderline significance value (p= 0.07). These two SNPs are located near lincRNA which is an important regulatory factor and shows differential expression patterns in a wide variety of cells and tissues (LI, et al., 2012; NIE, et al., 2012). This regulatory region showed promising results indicative associations with our phenotype, which can be re-evaluated in future samples and thus actually confirm this strong suggestion (CNPq).

1344T

Genetic associations with essential amino acids in infants with patent ductus arteriosus. *K.K. Ryckman[1], J.M. Dagle[1], O.A. Shchelochkov[1], S.L. Berberich[2], J.C. Murray[1].* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) State Hygienic Laboratory, Univ Iowa, Iowa City, IA.

Patent ductus arteriosus (PDA) is a significant complication of prematurity where the ductus arteriosus fails to close normally after birth. If left untreated the infant can experience difficulty breathing, poor growth and eventually heart failure. The risk for PDA is directly correlated with gestational age (GA), where the earlier an infant is born the more risk there is for PDA; however not all infants born early experience a PDA. In addition to the GA risk for PDA we have previously demonstrated an associations with alleles of the genes transcription factor AP-2 beta (TFAP2B) and tumor necrosis factor receptor-associated factor 1 (TRAF1). We have also observed that infants with PDA on day of life 5–7 have higher levels (compared to infants without PDA adjusted for GA) of essential amino acids leucine (P=1.0×10-3), methionine (P=1.2×10-3), phenylalanine (P=4.7×10-4) and valine (P= 3.2×10-4) measured from newborn screening samples at 24 hours of age. To explore these associations further we examined 20 SNPs in 8 candidate genes for PDA (including TFAP2B and TRAF1) for association with ten amino acid concentrations captured from the Iowa Neonatal Metabolic Screening Program on 199 infants. Infants included in the study were born less than 32 weeks GA and not on total parenteral nutrition at the time of newborn screening. Non-parametric Kruskal-Wallis tests were used to test for associations between each SNP and amino acid levels in all infants, infants with a PDA and infants without a PDA. The strongest associations were with rs7267595 in the jagged 1 gene (JAG1) and alanine (P=0.03), leucine (P= 3.5×10-3), methionine (P=4.7×10-3) and valine (5.1×10-3) in all infants. When examining associations further the association was only present in the absence of a PDA. Jag1 knockout mice die in early postnatal period secondary to PDA. In addition, rare mutations in JAG1 are associated with Alagille syndrome, a rare genetic disorder of the liver, heart (including PDA) and kidney. Preterm infants have higher essential amino acid levels likely due to liver and kidney immaturity. Genetic associations with JAG1 and the essential amino acids may represent a genetic predisposition to the liver dysfunction observed in extremely preterm infants.

1345F

Low frequency SNPs are associated with congenital and severe clinical phenotypes in an Electronic Medical Record. *J.D. Mosley[1,2], D.M. Roden[1,2], J.D. Denny[1,3].* 1) Department of Medicine, Vanderbilt University, Nashville, TN; 2) Clinical Pharmacology, Vanderbilt University, Nashville, TN; 3) Biomedical Informatics, Vanderbilt University, Nashville, TN.

The human genome harbors numerous SNPs with low minor allele frequencies (MAF). Their low frequency has been attributed to both recent rapid population expansion and negative selection pressure due to the deleterious effects of the resultant gene products. We hypothesized that subjects who were homozygous for the minor alleles of relatively rare SNPs would have an increased burden of human disease. To test this hypothesis, we analyzed a set of 8,659 Vanderbilt University Medical Center patients (6012 whites, 1743 blacks, 911 other races) who had been previously genotyped in GWAS studies. Phenotype data for these subjects were generated from ICD-9, CPT and physician-maintained problem lists contained in the electronic medical record (EMR). 4220 SNPs with a MAF less than 0.10 in both whites and blacks were tested against 1670 phenotypes representing individual or aggregate clinical problems. The median number of homozygotes for the minor allele of a SNP was 20 subjects (s.d. 14). Bonferroni-corrected p-values were obtained using exact multivariable logistic regression analyses comparing minor-allele homozygotes to the common-allele homozygotes and the number of significantly associated ($p<0.05$) phenotypes was tallied for each SNP. 224 SNPs were significantly associated with 1 to 4 phenotypes after Bonferroni adjustment. Among SNPs causing missense mutations, higher polyphen scores were associated with more phenotypic associations (p=0.04). A review of the SNPs with multiple phenotype associations demonstrated a number of diverse biologically plausible genotype-phenotype associations. For instance, 6 of 12 subjects homozygous for a BRCA1 missense variant (MAF=0.04) were diagnosed with leukemia (p=0.00001). The associations fell across a number of domains including developmental conditions (renal agenesis, coarctation of the aorta, congenital heart disease), acquired conditions (ulcerative colitis, osteomyelitis), tumors (leukemia, pheochromocytoma) as well possible syndromic phenotypes (such as adrenal and thyroid cancers). In summary, our analytical approach supports the idea of leveraging EMR data to identify clinical phenotypes associated with rare minor alleles in a diagnosis-agnostic fashion.

Rare variant testing for meta-analysis and survival analysis. *H. Chen[1], T. Lumley[2], J. Dupuis[1, 3], J. Brody[4], A. Morrison[5], B. Cornes[6, 7], D.J. Lybarger[3], B. Davis[5], C. Sitlani[4], D. Siscovick[4], J.B. Meigs[6, 7], L.A. Cupples[1, 3].* 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 2) Department of Statistics, University of Auckland, Auckland, New Zealand; 3) The National Heart, Lung and Blood Institute's Framingham Heart Study, Framingham, MA; 4) Cardiovascular Health Research Unit, Departments of Medicine and Epidemiology, University of Washington, Seattle, WA; 5) Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX; 6) General Medicine Division, Massachusetts General Hospital, Boston, MA; 7) Department of Medicine, Harvard Medical School, Boston, MA.

The Sequence Kernel Association Test (SKAT) (Wu et al 2011, Am. J. Hum. Gen) is an omnidirectional test for association between a set of possibly-rare genetic variants and a binary or continuous phenotype. We propose two extensions to the test that increase its applicability in the context of a consortium of cohort studies. The first is an approach to meta-analysis for settings where individual data cannot be shared, and the second is a version for survival phenotypes. Both extensions are based on the characterization of the SKAT test as a weighted sum of squared z-statistics for association between phenotype and individual variants. The meta-analysis requires each participating study to share the cohort-specific minor allele frequencies, genotype covariance matrix and the z-statistics for score tests of each variant in a generalized linear model. The score tests may optionally be adjusted for population structure or other factors, and may involve sampling weights to adjust for phenotype-based sampling. The score test statistics are then meta-analyzed with weights based on the statistical information provided by each study (or simply on sample size), and combined in a weighted sum to give the overall SKAT test statistic. The non-standard sampling distribution for the test statistic is estimated using the eigenvalues of a sample-size-weighted average of the per-study genotype covariance matrices. With no adjustment variables the meta-analysis test statistic is identical to the SKAT test statistic using individual data and adjusting for study; with adjustment variables the agreement is still very close. Generalizing the test to survival phenotypes using the score test in a Cox model (logrank test) does not work. The logrank test is anticonservative for rare variants, and leads to a seriously anticonservative overall test. Replacing the score z-statistic with the signed square root of the log partial likelihood ratio test statistic gives a test with accurate control of Type I error. Meta-analysis of this test involves weighted meta-analysis of the signed likelihood root test statistics in exactly the same way that score z-statistics statistics are meta-analyzed for linear and binary phenotypes. To illustrate the method we will present the meta-analysis SKAT results for associations with fasting insulin in the CHARGE-S targeted resequencing study.

Selection of sequence variants for quantitative traits using penalized regression: using LASSO, LARS and Elastic Net in the Tiled Regression framework. *Y. Kim[1], B. Suktitipat[1,2], A.J.M Sorant[1], A.F. Wilson[1].* 1) IDRB/ Genometrics Sec, NHGRI/NIH, Baltimore, MD; 2) Biochemistry Dept, Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand.

Selecting the set of independent genetic variants that contribute to the variation of quantitative traits can be challenging because of the multicollinearity caused by highly correlated sequence variants either in linkage or gametic disequilibrium; and the use of regression methods that ignore multicollinearity can be problematic. Penalized regression methods are known to be robust to the multicollinearity of variables — shrinking the coefficients of less informative variables close to or equal to zero until the regression model is optimized. In this study we investigate the performance of penalized regression methods and compare these results to those from stepwise regression as currently implemented in the Tiled Regression Analysis Program (TRAP v1.0). We compared the performance of three penalized regression methods: LASSO, Elastic Net (EN) and LARS, to results from stepwise regression (STEP). We simulated 4000 individuals with 300,000 variants based on HapMap data, and 100 replicates of quantitative traits from seven independent causal loci with the same effect size but with various locus-heritability (h^2) ranging from 0.00045 to 0.01 based on an additive genetic model. We examined the detection rates (% per 100 replicates) of each causal locus, precision (true positive/true positive + false positive) and sensitivity (true positive/ true positive + false negative) of all causal loci in the final subset under two scenarios: including and excluding causal variants. In the presence of causal variants, LASSO, EN, and STEP showed high detection rates (76–100%) for causal variants with locus-specific $h^2 > 0.005$, but LARS and STEP were higher than LASSO and EN for detecting causal variants of $h^2 < 0.005$. However, LARS showed the least precision (0.004) and sensitivity (0.42) for the final subsets. After excluding causal variants in causal loci, the penalized regression methods showed slightly higher detection rates (1–28%) than STEP (0–15%) — doing a somewhat better job at detecting variants that were correlated to the excluded causal variants. Overall sensitivity and precision were decreased compared to the results including causal variants. LARS showed the least precision (0.002), but observed similar sensitivity (0.18) with LASSO (0.16) and EN (0.16). In conclusion, LASSO and EN may be an effect tool in detecting variants that are correlated with causal variants when the causal variants are not among the variants considered.

1348F

Identification of genome-wide SNPs that are informative for individual genetic heritage in the family investigation of nephropathy and diabetes. *R. C. Williams, FIND Research Group.* Phoenix Epidemiology and Clinical Research Branch, NIDDK, NIH, Phoenix, AZ.

Assessment of IGH is potentially important in genome-wide association studies (GWAS) but evaluation of an American Indian component is limited because there is little information on parental frequencies from American Indians typed on a commercially available platform. We therefore searched the 22 autosomes for SNPs informative for contrasts between three parental populations: European Heritage (Eu) (represented by HAPMAP, CEU), African Heritage (Af) (HAPMAP, YRI and LWK, combined and averaged allele frequencies), and American Indian heritage (AI) (represented by a GWAS on the Affymetrix 6.0 SNP array in 964 full heritage Pima Indians). From among 719,109 SNPs with valid genotypic data in all parental samples, 1390 SNPs were identified according to the following criteria: 1) a difference in allele frequency (Δ) in at least one pair of parental groups ≥ 0.5, 2) a distance $\geq$ 500kb between syntenic loci, 3) a sample size ≥ 100 for estimating the allele frequencies, and 4) no A/T or G/C polymorphisms. The mean distance between adjacent syntenic loci was 729,148bp (range: 500,002–12,126,238bp). The mean of the maximum Δ value was 0.708 (range: 0.500–0.986). Maximum likelihood methods were used to calculate IGH using these markers. C.C. Li's method for estimating the information and variance was used to quantify precision of the estimates. In the parental populations, where the expected mean is 1.000 for the respective IGH, the agreement was very close: Eu, N=174, HapMap CEU (Mean=0.993 ± std.= 0.008); Af, N=209, HapMap YRI (0.999±0.003); Af, N=110, HapMap LWK (0.981± 0.014); AI, Pima, N=964 (0.990± 0.047). The method was then applied to data from the FIND GWAS for four ethnic groups: 1) American Indians, N= 869 (mean Eu=0.046, ±std.=0.090; mean AI=0.945 ± 0.110; mean Af=0.009 ± 0.048); 2) African Americans, N=1385 (Eu=0.151 ± 0.103; AI=0.016 ± 0.026; Af=0.832 ± 0.109); 3) Mexican Americans, N=1451 (Eu= 0.473 ± 0.134; AI=0.451 ± 0.139; Af=0.076 ± 0.048); 4) European Americans, N= 826 (Eu=0.958 ± 0.087; AI= 0.015 ± 0.021; Af=0.026, ± 0.083). In the combined FIND samples, N=4531, the mean standard errors for IGH are small (Eu, 0.014; AI, 0.010; Af, 0.017). We have identified a set of SNPs, included on the Affymetrix array, that provide precise estimates of IGH from 3 parental groups. This will facilitate assessment of IGH in studies that have used this array; genotyping these markers, or a subset, may also be useful in other studies.

1349W

Testing Copy Number Variant/Trait Associations Detected using Manhattan Plots. *G.A. Satten[1], D. Ramachandran[2], J.G. Mulle[2], A.S. Allen[3], L.J.H. Bean[2], C. Maslen[4], S.L. Sherman[2], R.H. Reeves[5], M.E. Zwick[2].* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) Emory University, Atlanta GA; 3) Duke University, Durham NC; 4) Oregon Health Sciences University, Portland OR; 5) Johns Hopkins University, Baltimore MD.

Background: Finding association between copy number variants (CNVs) and disease is hampered by poor detection of CNVs using log-intensity ratio (LIR) data from genotype arrays. Breheny et al. (Plos One 2012; 7(4):e34262) suggested directly comparing LIR values between cases and controls, rather than first inferring copy number states, obtaining a p-value at each locus. CNV-trait association is then found by using CNV-detection software on the Manhattan plot of -log(p) values. We sought to improve upon the methods of Breheny et al. by developing a method to assign a formal p-value to associations found in this way. We applied our approach to a GWAS of children with Down syndrome (DS), who are at greatly increased risk for congenital heart defects including atrioventricular septal defects (AVSDs).

Methods: DNA from children with DS and AVSDs (cases, n=238) and with DS but without heart defects (controls, n=267) was genotyped using the Affymetrix 6.0 array. We fit a linear regression model for LIR at each locus, testing the effect of case status on LIR in the presence of genotype principal components to control for population stratification. We used our CNV BEAST software (www.duke.edu/~asallen/Software.html) to find runs of large -log(p) values, and found several candidate associations. We tested significance with a bootstrap hypothesis test. We first calculated the residuals from our regression model. We then resampled from these residuals to generate 1000 bootstrap replicate datasets by that preserve population structure but have no other difference between cases and controls. We resampled residuals by individual to preserve spatial correlations. Because the CNV BEAST gives a scalar score to each CNV, we can calculate a p-value by comparing the distribution of largest scores assigned to any CNV in each replicate to the score observed in the actual data.

Results: Although our largest signal seemed robust, comprising over 100 adjacent loci on Chromosome 1 between 149041794 and 149246018, we found a 7.1% chance of seeing such a large signal under the null hypothesis.

1350T

A novel collapsing method for rare copy number variants (CNVs). *J.P. Szatkiewicz[1], P.F. Sullivan[1,2], J.Y. Tzeng[3].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC, 27599; 2) Department of Psychiatry, University of North Carolina, Chapel Hill, NC, 27599; 3) Department of Statistics and Bioinformatics Research Center, North Carolina State University, Raleigh, NC, 27607.

CNVs play an important role in the etiology of multiple psychiatric disorders. Multiple recent studies found that the genome-wide burden of rare CNVs is greater in cases with schizophrenia, autism, or bipolar disorder than in controls. Several specific and likely the most pathogentic CNVs have been discovered; however, the individual effects of most CNVs on disease risk remain unknown due to modest marginal effect size or rarity of the CNV. Collapsing approaches could be important to evaluate multigenic models to study how CNVs impact risk for psychiatric disorders. In contrast to sequence variants that affect single nucleotides, CNVs vary in size, type, dosage, and sequence level details of gene disruption. Because of its multifaceted nature, CNV analysis is more challenging and the most important consideration is allelic heterogeneity. For example, heterogeneous clusters of rare CNVs are often observed where CNVs with variable breakpoints and sizes disrupt genes in different ways. CNVs can also have heterogeneous effects by being a mixture of neutral, risk, and protective variants. Consequently, collapsing methods developed for rare sequence variants cannot be generalized directly to rare CNVs. Existing burden tests also do not fully explore CNV-specific challenges. Typically, rare CNVs are aggregated into discreet categories, such as deletion, duplication, exon, gene, or genome; and within each category the rates of events were compared between cases and controls, treating all events equivalently. This approach falls short in two counts: ignoring heterogeneity entails loss of power and testing one-category-at-a-time has suboptimal efficiency. We propose a novel collapsing method for CNVs that is robust to multiple types of heterogeneity. Our method is based on SimReg (Tzeng et al. PMID 21835306), a similarity collapsing approach, to collectively examine the effects of multiple CNV features (e.g. size, type, dosage, mixture effects) and weight CNVs by their frequencies and details of gene disruption. Multiple confounders can be simultaneously corrected. We conducted simulation to evaluate type I error and power in various scenarios and compared our method to the existing CNV burden test as implemented in PLINK. We then applied our method to multiple well-powered psychiatric GWAS studies where each included more than 10K subjects. Full results will be reported at the conference, but preliminary results suggest manifest improvement in performance.

1351F

A pseudo-score-based meta-analysis in genetic association studies: Application to Mayo Genome Consortia data. *E. Ryu[1], RE. Gullerud[1], PA. Decker[1], J. Pathak[1], PJ. Limburg[2], SJ. Bielinski[1].* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN.

Objective: The Mayo Genome Consortia (MayoGC) is a cohort of 6,307 Mayo Clinic patients who have electronic medical record (EMR) and genotype data. Among patients who have a record of colonoscopy, we identified 1048 cases with neoplastic colon polyps (adenoma, serrated, or cancer) and 2386 patients with normal colonoscopy results. We propose a new meta-analysis method that will be used to investigate less-common genetic variants that contribute to neoplastic colon polyps. **Method:** A pseudo-score confidence interval is obtained by inverting a test that uses a Pearson chi-square statistic to compare fitted values under two models: one under the null hypothesis that takes various fixed values, and the other model under the alternative hypothesis. For each study, midpoint and pseudo standard error will be obtained from the pseudo-score confidence interval. Borrowing an idea from inverse-variance weighting approach, the common parameter estimate and p-value will be calculated using a new meta-analysis method. As an example, SNP rs9532209 in chromosme 13 with MAF equal to 2.5% was randomly chosen for an association testing with being neoplastic. A simulation study was also performed to compare the new approach to two popular meta-analysis approaches (inverse-variance weighting method, and the weighted Z-score method) and a method based on profile likelihood. **Result:** P-values for testing an effect of rs9532209 on case status are 0.018, 0.020, 0.011, and 0.015 for inverse-variance weighting method, the weighted Z-score method, profile likelihood-based approach, and pseudo-score based approach, respectively. Common parameter estimates are -0.451, -0.486, and -0.457 for inverse weighting method, profile likelihood-based approach, and pseudo-score based approach, respectively. Assuming MAFs close to 0.05 for three studies and true odds ratio being 2, with sample sizes 400, 500, and 600, a simulation study showed that our new approach performed similar to profile likelihood based approach, and better than two popular existing methods. **Conclusion:** Our proposed method appears to perform better than existing popular meta-analysis methods for variants with MAF < 5%. Furthermore, this approach can be applied to the datasets that the popular methods do not work due to convergence failures in standard logistic regression. It is because pseudo-score-based method does not require the estimated variance of the effect size for each study.

1352W

Diacylglycerol kinase K variants impact hypospadias in a California study population. *S. L. Carmichael[1], N. Mohammed[2], C. Ma[1], D. Iovannisci[2], S. Choudhry[3], L. S. Baskin[3], J. S. Witte[4], G. M. Shaw[1], E. J. Lammer[2].* 1) Pediatrics, Stanford University School of Medicine, Stanford, CA; 2) Children's Hospital Oakland Research Institute, Oakland, CA; 3) Department of Urology, University of California, San Francisco, CA; 4) Department of Epidemiology and Biostatistics and Institute of Human Genetics, University of California, San Francisco, CA.

PURPOSE: Hypospadias occurs when the urethral meatus is on the underside of the penis. It is one of the most common birth defects, affecting 4–6 per 1000 male births. It can range from mild (coronal or glanular), moderate (penile shaft) or severe (at the peno-scrotal junction or perineal area). A recent genome-wide association study reported the novel finding that variants in diacylglycerol kinase kappa (DGKK) were associated with hypospadias. The discovery phase was based on pooled samples, and replication was restricted to two SNPs. Our objectives were to determine whether this finding could be replicated in a more racially-ethnically diverse study population of California births and to provide a more comprehensive investigation of variants. METHODS: We examined the association of 27 DGKK SNPs with hypospadias, relative to population-based non-malformed controls born in selected California counties from 1990–2003. Analyses included a maximum of 928 controls and 665 cases (91 mild, 336 moderate, 221 severe, 17 undetermined). Results for mild and moderate cases were similar so they were grouped together. RESULTS: For mild and moderate cases, odds ratios (OR) for 15 of the 27 SNPs had p-values <0.05; two of the ORs were <1, and the others ranged from 1.3 to 1.8. Among severe cases, ORs tended to be closer to one and none of the p-values were <0.05. Due to high LD across the SNPs, haplotype analyses were conducted, and two blocks were generated. These analyses identified a set of eight variants that was associated with a three- to four- fold increased risk, relative to the most common haplotype, regardless of severity of the phenotype (the OR was 4.1, p<10-4 for mild to moderate cases and 3.3, p=0.001 for severe cases). CONCLUSIONS: This study confirms that DGKK variants are associated with hypospadias. Further studies are needed to enable a more thorough investigation of DGKK variability and to delineate the mechanism by which DGKK contributes to urethral development.

GEEWAS: Family-based genome-wide association studies for non-normal responses. *C. Ekstrom.* Biostatistics, Univ Southern Denmark, Odense, Denmark.

Genome-wide association studies (GWAS) are widely used to identify genes influencing traits and diseases from data on unrelated individuals. However, the lack of success in explaining more than a fraction of the heritability has lead to increased focus on family-based GWAS studies - in partiular since family-based data are available back from linkage era. The linear mixed effect model has been the workhorse for GWAS of normally distributed traits for both unrelated and related individuals, but its generalizations to non-normal traits have been prohibitively slow.

We examine the use of generalized estimating equations (GEE) for family-based genome-wide association studies with unequal family structure. GEEs accommodate both normal and non-normal responses, provide robust standard errors against misspecification of the intra-family correlations, and are heteroscedasticity consistent, which is relevant when, for example, several rare variants are segregating in unidentified sub-populations. Correct modelling of the working correlation among individuals in a pedigree improves the efficiency but the kinship coefficient matrix used with linear mixed models needs to be adapted for use with GEEs.

Our implementation, GEEWAS, runs in R and simulations show that the GEEWAS implementation runs approximately 30–50 times faster than a corresponding linear mixed effect model and provides the same unbiased estimates. Our results show that correct modeling of the correlation matrix improves the efficiency of the estimates and approximately 10% smaller standard errors compared to an independent working model which in turn provides more powerful tests to detect genes associated with a qualitative or quantitative phenotype. The GEEWAS implementation handles families of varying structure and the simulations show that GEEWAS is able to identify genes influencing both binary and ordinal categorical scale responses that are used for example to classify mental disorders.

An multiple testing procedure for association studies appropriately incorporating admixture signals. *G. Gao, W. Chen.* Dept Biostatistics, Virginia Commonwealth Univ, Richmond, VA.

Admixed populations (such as African Americans) denote the populations formed by recent admixture of two or more ancestral populations. For gene mapping in admixed populations, admixture mapping tests use admixture linkage disequilibrium (LD) existing in large chromosomal segments inherited from an ancestral population and can only identify a causal variant in a large chromosomal region (several Mbs). To identify a causal variant in a small region (less than a few hundred Kbs), association tests that correct for local ancestry and therefore use background LD existing in the ancestral populations have been developed. However, these tests can have relatively low power. Recently, joint association tests that combine information from admixture mapping tests and association tests that correct for local ancestry have been proposed, but the joint methods may have inflated type I error rates when null single nucleotide polymorphisms (SNPs) are located in regions with admixture signals but far from causal variants (i.e., in admixture LD but not in background LD with the causal variants). A main reason for this is that these joint methods may use too much information from the admixture mapping at a test SNP. In this study, we adapt the generalized sequential Bonferroni procedure (GSB) to association studies to incorporate appropriate amount of information from admixture mapping into association tests that correct for ancestry. Our simulation studies indicate that the GSB procedure not only control family-wise error rates, but also can have improved power compared to the association tests that correct for local ancestry. We applied the GSB procedure to association studies in a data set from the Multi-Ethnic Study of Atherosclerosis project.

Correcting for population structure due to rare and common variants with an approximate Bayesian regression framework. *G.E. Hoffman[1], J.G. Mezey[1,2].* 1) Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) Department of Genetic Medicine, Weill Cornell Medical College, New York, NY.

With the growing interest in testing associations of rare variants, new problems of population structure are arising in exome and genome sequence datasets due to the more recent origin and more localized distribution of rare compared to common variants. Two widely used statistical approaches, namely including principal components as covariates in a regression or using a linear mixed model, have proven successful in correcting for structure due to common variants as such structure is well modeled by a linear gradient [1,2]. However, these methods are not able to account for the complexities unique to rare variants where population structure can be more localized due to spatially private alleles [3–5]. We propose a novel regression framework for testing associations of rare variants that incorporates nonlinear functions of principal components to explicitly model the localization of rare variants. Since only a small fraction of the principal components and nonlinear functions thereof will be biologically relevant, we use an approach akin to penalized splines to select a small subset of relevant basis vectors using a sparse Bayesian learning method for variable selection. Moreover, our method approximately integrates over parameter uncertainty using a variational Bayes technique. We consider linear and logistic regression models to test a single marker but our framework can incorporate collapsing or multiple-marker tests of association [6,7]. We conduct an extensive simulation study using simulated spatial population data and exomes sampled from the NHLBI Exome Sequencing Project to evaluate the conditions under which our novel method correctly accounts for population structure due to rare variants.

Unified association analysis of genes, regions or pathways containing multiple SNPs. *L.C. Lazzeroni, A. Ray.* Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA.

Candidate gene and genome-wide association studies typically examine several genetic polymorphisms within the same gene, genomic region or biological pathway. This comprehensive strategy increases the likelihood that genetic associations existing in the population will be represented by one or more functional or tagging SNPs in the data. Unfortunately, the numerous SNP-specific test results produced by this strategy are often difficult to interpret, especially given the stringent standards imposed by multiple testing corrections. If the gene, region or pathway is the target of scientific inquiry, inconsistent results across SNPs can lead to uncertainty in reaching an overall conclusion. As a consequence, several authors have recently proposed various methods for conducting unified gene-wide association tests using data from multiple SNPs that can also be applied to regions or pathways. We will consider the desirable properties of such tests, which include: (1) power and maintenance of nominal significance levels in various settings; (2) interpretability of results and accuracy of effect sizes at both the gene and SNP levels; and (3) potential for use in extended analyses of gene-gene (G×G) and gene-environment (G×E) interactions. The relative importance of these criteria depend on the goals of a particular study. We will introduce a novel empirical Bayes method for tests and estimates of gene-wide association and describe new ways to improve the interpretability of an alternative method using principal components. Our comparisons of these and competing methods, such as haplotype analysis, will focus on interpretability and include application to analysis of G×G interactions.

1357F

Genome-wide association study on the variation of quantitative trait as a tool to identify important genetic variants for related complex diseases, an example of CHD risk in T2D patients. *Z. Liu[1,3], Q. Qi[2], F. Hu[2], L. Qi[2], L. Liang[1,3].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Department of Nutrition, Harvard School of Public Health, Boston, MA; 3) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

Extreme levels of underlying quantitative traits may be important to the development of complex diseases. Genome-wide association studies for quantitative traits have been focusing on the comparison of the mean levels of the traits among individual with different genotypes. Genetic variants related to the increased variation of the trait also can lead to extreme level of the quantitative trait. In this study, we use mathematical derivation and simulation to show that novel genetic variants for complex disease may be identified by giving high priority to variants associated with different magnitude of the variation of related quantitative traits. We applied this approach and carried out a genome-wide association scan for the variation of HDL using the 700,000 SNPs on Affymetrix 6.0 array typed on 1461 T2D cases (505 with CHD and 745 without CHD, 66 stroke and 145 unknown) from a T2D study involving the Nurses' Health Study (NHS, n=660) and the Health Professionals Follow up Study (HPFS, n=801). After adjusting for age, BMI and eigenvectors obtained from genotype, we found a locus, SLC2A9, on chr4p16.1 significantly associated with the variation of HDL in both NHS and the HPFS samples (meta-analysis p-value=4.2×10^{-9}). The SLC2A9 locus we identified has been shown to be associated with uric acid level which is a risk factor for T2D and CHD and might imply important gene-environment interaction, gene-gene interaction or other mechanisms underlying the genetics of HDL. We further tested the association with CHD risk in T2D and found that the top SLC2A9 SNP associated to HDL variation was associated with CHD risk in diabetic men (OR [95%CI]: 0.52 [0.29–0.94], P=0.029) but not in diabetic women (1.24 [0.74–2.08], P=0.40). Among the top 50 SNPs that have significant interaction effect with the SLC2A9 locus on HDL level in diabetic men, we found a SNP at chr16q11.2 also has significant interaction with the SLC2A9 SNP on CHD risk (p-value for interaction effect on CHD risk = 0.006, pvalue for interaction effect on HDL level = 5.59×10^{-7}) in diabetic men. In summary, we show that genome-wide association study on the variation of quantitative trait provides a promising approach to identify new loci and improve the understanding of the genetic bases of complex diseases.

Power and sample size calculations for genetic association tests in the presence of pleiotropy. *D. Londono, D. Gordon.* Department of Genetics, Rutgers The State University of New Jersey, Piscataway, NJ.

Genetic pleiotropy is a common phenomenon in studies of complex diseases. Its effect on the ability to localize genes in association studies is not yet fully understood. In this work, we investigate what factors most significantly affect statistical power of some commonly used association tests, namely the Pearson chi-square genotype test, the Cochran-Armitage Trend Test and the Transmission Disequilibrium Test, when two different but clinically related diseases are associated with a common locus. We derive the non-centrality parameter (NCP) of these tests in the presence of pleiotropy. With the NCP formulae, sample size can be determined for a given power and significance level. We estimate empirical power and type-I error rates by simulating case-control and trio data using a factorial design for different settings of: (i) linkage disequilibrium; (ii) marker and disease allele frequencies; (iii) genotype relative risk; (iv) prevalence; and (v) the proportion of individuals in the observed sample expressing the second disease phenotype. Our results show that, for all tests, the heterozygote relative risk in the second disease is the most significant factor affecting difference in power between using only individuals affected with the first disease and using both types of affected individuals. Additionally, the heterozygote relative risk in the first disease and the frequency of the disease susceptibility allele are also important factors, although the significance of their effect is different across different tests. Also, we show under which circumstances power is gained/lost by adding individuals expressing the second disease when the two diseases have different inheritance models. Finally, our power results show high degree of correlation with a previously proposed decision rule for case-control data that determines whether two similar phenotypes should be combined to improve power.

Using regression residuals to map association between genetic variants and environmentally influenced longitudinal phenotypes. *A. Musolf[1], D. Londono[1], R. Wang[2], J. Brandon[3], J. A. Herring[4], C. A. Wise[3,5,6], H. Zou[7], M. Jin[7,8], L. Yu[1,9], S. J. Finch[2], T. C. Matise[1], D. Gordon[1]*. 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Department of Applied Mathematics and Statistics, Stony Brook University, Stony Brook, NY; 3) Seay Center for Musculoskeletal Research, Texas Scottish Rite Hospital for Children, Dallas, TX; 4) Department of Orthopedic Surgery, Texas Scottish Rite Hospital for Children, Dallas, TX; 5) Department of Orthopaedic Surgery, University of Texas Southwestern Medical Center, Dallas, TX; 6) McDermott Center, University of Texas Southwestern Medical Center, Dallas, TX; 7) Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, China; 8) Shanghai Bio Corp, Shanghai, China; 9) Center of Alcohol Studies, Rutgers University, Piscataway, NJ.

We have previously developed a method that tests for association between longitudinal phenotypes and genetic variants. This method uses growth mixture models to determine longitudinal trajectory curves. The method computes also the Bayesian posterior probability (BPP) of belonging to a specific curve as a quantitative phenotype in association analyses. The method was shown to maintain correct type I error rate. We observed high power for both single disease loci and multiple disease loci in numerous simulation studies. Here, we present two major extensions to this method. The first is a correction for population stratification. Our previous method showed inflated type I error in data sets that were known to be of mixed populations. Our correction involves a cluster analysis of the data set. The probability of being in a certain cluster was used as a predictor in a linear regression, with BPP as the response variable. Residuals were then used as a quantitative phenotype for association analysis. This correction reduced inflation while still maintaining high power. We conclude that using the residuals as a quantitative phenotype is more effective at detecting association because it allows for the correction of confounding factors without sacrificing power. Second, we tested our method with simulations involving environmental covariates. Our simulations had a factorial design, with factors including noise level (variance of trajectory curves), minor allele frequency of the disease variant, and a metric representing distance among trajectory curves. Various biological factors were also considered, such as inheritance modes (additive, dominant, and recessive). Single locus and multi-locus models were also considered, as were varying penetrance levels. Finally, data was simulated for all scenarios using equations from two distinct data sets. We report that throughout all simulations our method: 1) maintains the correct empirical type I error, and, 2) produces 95% power or higher for most simulations. We conclude that our method robustly detects allelic association with longitudinal phenotypes that are partially influenced by environmental variables. Overall, we conjecture that this method can be used in practice by fellow researchers that are interested in finding association between longitudinal phenotypes and genetic variants, even in the presence of confounders such as environment and population stratification.

Enabling mixed model association analysis for large case-control studies. *A. Price[1], N. Zaitlen[1], B. Vilhjalmsson[1], T. Hayeck[1], S. Pollack[1], J. Yang[2], G.B. Chen[2], M. Goddard[3], P. Visscher[2], N. Patterson[4]*. 1) Harvard Sch Pub Hlth, Boston, MA; 2) University of Queensland, Brisbane, Australia; 3) University of Melbourne, Melbourne, Australia; 4) Broad Institute, Cambridge, MA.

Mixed linear models (MLM) are an effective approach to eliminate confounding and increase power in association studies of quantitative traits. However, existing MLM methods are not applicable to large case-control studies, because case-control ascertainment (CCA) induces correlations between unlinked causal SNPs, leading to a loss in power. Our case-control simulations in unrelated individuals indicate that the power loss of MLM increases with the ratio of sample size (N) to effective number of independent SNPs (M), with liability-scale heritability explained by genotyped SNPs (h2g) and with lower disease prevalence (f). For N/M=1, h2g=0.5, we observed an average drop in test statistics at causal SNPs of -15% at f=0.01 (-36% at f=0.001) as compared to linear regression (LR), which is equivalent to MLM with genetic relationship matrix (GRM) = I. The observed-scale heritability explained by genotyped SNPs (h2g_obs) estimated by MLM was deflated relative to its correct value, but using the correct value did not improve the power of MLM. Analysis of WTCCC phenotypes (WTCCC 2007) using subsets of the genome to vary N/M led to MLM power loss consistent with simulations. The power loss caused by including SNPs in LD with the candidate SNP (due to CCA) in the GRM is analogous to the power loss of including the candidate SNP in the GRM (Listgarten 2012), but we excluded the candidate SNP from the GRM in our analyses. Our solution to the power loss of MLM is to estimate posterior mean liabilities (PML) of each sample conditional on case-control status and liability-scale phenotypic covariance h2g*GRM+(1-h2g)*I, to account for CCA-induced LD. h2g is estimated accurately by transforming (Lee 2011) h2g_obs from H-E regression. PML are estimated via MCMC with total running time O(N^3+ITER*N^2), with ITER<N via Rao-Blackwellization. The association between genotype and PML is then tested, accounting for genetic covariance based on GRM. This method (LTMLM) does not suffer a loss in power. For N/M=1, h2g=0.5, f=0.01, we observed an increase in test statistics of +4% vs. LR. The increase in power arises by implicitly conditioning on unknown causal variants. MLM and LTMLM both had correct false-positive rate in simulations with population stratification. N/M=1 corresponds to N=60,000, since effective M~60,000 in humans (Goddard 2009), but MLM suffers a proportionate loss in power for smaller N/M. We recommend using LTMLM instead of MLM for case-control GWAS with N>10,000.

Accounting for parent-of-origin effects detects association between 4q35 genetic variants and combined asthma-plus-rhinitis phenotype. *C. Sarnowski[1,2,3], G. Malerba[4], Q. Vincent[5], C. Laprise[6], K. Rohde[7], M. Moffatt[8], P. Margaritte-Jeannin[1,2,3], M-H. Dizier[1,2,3], P.F. Pignatti[4], W.O.C. Cookson[8], M. Lathrop[3], F. Demenais[1,2,3], E. Bouzigon[1,2,3], EGEA collaborative group.* 1) U946, INSERM, PARIS,75010, France; 2) Univ Paris Diderot, Sorbonne Paris Cité, Institut Universitaire d'Hématologie, France; 3) Fondation Jean Dausset-Centre d'Etude du Polymorphisme Humain (CEPH), France; 4) Section of Biology and Genetics, Department of Mother and Child and Biology-Genetics, University of Verona, Italy; 5) U550, INSERM, PARIS, France; 6) Université du Québec à Chicoutimi, Canada; 7) Max-Delbrück-Center for Molecular Medicine (MDC), Germany; 8) National Heart Lung Institute, Imperial College, UK.

A strong linkage signal was previously detected in the 4q35 region with the combined asthma-plus-rhinitis phenotype in 640 families from European ancestry (French (EGEA), British (MRCA) and Italian) when accounting for imprinting (LOD=3.14, $P=2.5\times10^{-5}$). We further investigated this region in 161 families (206 offspring) from the French EGEA study (Epidemiological study on the Genetics and Environment of Asthma) using a panel of 1300 SNPs (spanning 6Mb). Two different methods aiming to detect parent-of-origin and/or maternal genotype effects were used to test for association between these SNPs and asthma-plus-rhinitis phenotype: 1) the Monte-Carlo Pedigree Parent-Asymmetry-Test (MCPPAT) and 2) the Parent-of-origin-Likelihood ratio Test (PO-LRT). We identified 26 markers associated with asthma-plus-rhinitis ($P\leq0.005$) among which one reached the multiple testing-corrected threshold of $P\leq6.5\times10^{-5}$. Analyses conducted with imputed data (Hapmap2) strengthened the evidence for association with three genes. In order to replicate our findings, we conducted association analysis in 152 French Canadian families (Saguenay-Lac-Saint-Jean) under the same epigenetic model detected in the discovery set. The combination of EGEA and SLSJ results using a fixed-effect model evidenced association with two SNPs tagging two different genes ($P_{comb}=9\times10^{-5}$ and $P_{comb}=9\times10^{-4}$) under parent-of-origin effect model. Further linkage analyses performed in EGEA sibships stratified according to the genotypes at each of the two most significant SNPs showed that one SNP accounted for most of the linkage signal detected in the 4q35 region. Moreover, association analyses performed separately with each allergy-related phenotypes (asthma, rhinitis, atopy) suggested that the other SNP is more likely associated to atopy ($P=5\times10^{-5}$) than the combined asthma-plus-rhinitis phenotype. Further investigation is needed to confirm our findings and to better understand the role of these loci in asthma-plus-rhinitis and their relationships with respect to allergy. The combination of these results with expression and methylation data will help pinpointing towards the functional SNPs influencing asthma-plus-rhinitis and allergy phenotypes. This study highlights that taking into account complex mechanisms facilitates the identification of new genes. 1362T

Evaluation of classical multivariate methods for gene-based tests of association with multiple related traits. *Y. Shu, R. Watanabe, J. Lewinger.* Preventive Med, Univ Southern California, Los Angeles, CA.

Many statistical methods have been proposed for testing the global effect of a group of SNPs in a gene or pathway on a single trait. The premise behind these methods is that, if many SNPs in a gene have small effects, combining the evidence across them may enhance the power to detect associations. Similarly, if a complex disease exhibits a syndromic phenotype that is not fully captured by a single binary or quantitative trait, power maybe enhanced by combining the evidence across multiple related traits. However, we are unaware of any methodology specifically proposed for testing the association of a group of SNPs with multiple related traits. Here we explore a range of classical dimension reduction techniques such as principal component analysis (PCA), partial least squares (PLS), and canonical correlation analysis (CCA), coupled with multivariate regression-based methods such as MANOVA, to detect genetic association between multiple (possibly correlated) SNPs and multiple related traits. We completed an initial series of simulations in which we evaluated the power of these methods under a range of scenarios covering differing degrees of correlation among the SNPs and the traits, and also a range from high sparsity scenarios (few SNPs associated with few traits) to low sparsity scenarios (many SNPs associated with many traits). We assessed statistical significance using permutation tests, which ensures the type I error is maintained at the target level and provides objective comparison across methods. We find that applying MANOVA on latent variables for both SNPs and traits obtained from dimension reduction yields higher power to detect a global effect than raw variables in most scenarios. For a scenario (200 SNPs, 40 traits, 300 individuals) with 8% of the SNPs and traits are associated with a common linear effect of 0.8, MANOVA using latent variables from PLS has highest (90%) power, MANOVA on raw variables has 63% power, and univariate analysis on raw variables only has 16% power. Latent variables from PLS and CCA, which are derived from both SNPs and traits jointly, did not result in a significant advantage compared with latent variables derived from PCA, which are derived from SNPs and traits separately. Knowing biologic pathways are likely to involve complex non-linear relationship between genetic variants and traits, in a second set of simulations we explore performance of nonlinear kernel-based methods and compare to the linear methods above.

1363F

A two-stage random forest approach to identify genetic variants using recombination hotspot information. *S. Szymczak[1], Q. Li[1], Y. Kim[2], A. Dasgupta[3], J.D. Malley[4], J.E. Bailey-Wilson[1].* 1) Statistical Genetics Section, Inherited Disease Research Branch, National Human Genome Research Institute, NIH, Baltimore, MD; 2) Genometrics Section, Inherited Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, MD; 3) Clinical Sciences Section, National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, MD; 4) Center for Computational Bioscience, Center for Information Technology, National Institutes of Health, Bethesda, MD.

In genome-wide association studies (GWAS) each single-nucleotide polymorphism (SNP) is usually analyzed separately for association with a disease. However, it is expected that multiple genetic loci jointly contribute to disease risk. Recently, several machine learning algorithms have been used to study many or even all genome-wide genetic variants simultaneously. One promising approach is random forest (RF), an ensemble method based on a large number of classification and regression trees trained on bootstrap samples. RF provides variable importance measures that can be used to select the most relevant SNPs. However, identification of true risk SNPs that are in strong linkage disequilibrium (LD) with non-risk SNPs is challenging. Large regions of strong LD can lower the ranking of all SNPs in a causal region since they can serve as proxies for each other in different trees.

We propose a two-stage approach that uses information about recombination hotspots in the genome. In a first step, a random forest is trained for each region between two hotspots. SNPs within these regions are more likely to be in strong LD. Predicted case-control status or estimated probability of case/control status based on each region's SNPs then replaces the group of SNPs as a predictor variable. These new predictor variables for all hot spot blocks are used in a genome-wide random forest analysis in the second stage.

We compare our approach with a random forest analysis using all SNPs simultaneously based on simulated GWAS data mimicking local LD patterns observed in European samples of the 1,000 genomes project. Genotype data for 500K SNPs in 5,000 cases and 5,000 controls are generated using the software GWAsimulator. We compare the false-positive errors under a null model with no true genetic effects. For a power analysis several variants with different minor allele frequencies and in regions with different local LD structure are modeled as true risk SNPs with independent effects on the disease status.

Effect size distribution for prioritizing results of association studies. *D. Zaykin, C-L. Kuo.* Dept Biostatistics, NIEHS/NIH, Res Triangle Park, NC.

In large scale association studies, signals of detectable magnitude are rare, while majority of variants have tiny or essentially zero effect size. Because of this sparseness of effects, the proportion of false positives among most significant findings is difficult to estimate. A crucial component of such calculation is an accurate representation of the effect size distribution among variants examined in a study. We develop efficient methods for characterizing the effect size distribution. Knowledge of this distribution allows estimation of the proportion true positives in a specified number of top hits and leads to more rigorous study designs.

Modeling multivariate and correlated data in genetic association analysis. *J. H. Zhao[1], F. Xue[2], Q. Tan[3], S. Li[4], J. A. Luan[1].* 1) MRC Epidemiology Unit and Institute of Metabolic Science, Addenbrooke's Hospital Box 285, Hills Road, Cambridge CB2 0QQ, United Kingdom; 2) Department of Epidemiology and Health Statistics, School of Public Health, Shandong University, Jinan, PR China; 3) Epidemiology and Biostatistics, University of Southern Denmark, Denmark; 4) Department of Epidemiology, School of Public Health and Tropical Medicine, Tulane University, New Orleans, USA.

Background: Considering the numerous limitations with available methods in genetic association analysis, we focus on aspects related to multivariate and correlated data. Methods: We described a latent variable model to account for both multiple single nucleotide polymorphisms (SNPs) and multiple phenotypes, as with a mixed model to account for correlation among related individuals. The models were applied to simulated and real data. Results: The combination of dimension reduction and latent construct as in partial least squares path modelling offers a viable option to regional association involving genetic variant(s) as with correlated phenotypes for a latent variable. When applied to the EPIC-Norfolk study, stronger evidence of association with obesity in the FTO region was demonstrated compared to its single-SNP counterpart. Moreover, a latent score has been derived from body mass index, waist and hip circumferences as with a predisposition score from multiple SNPs. As for the mixed model, the great appeals lies in its ability to account for various sources of variations whose feasibility was demonstrated with Genetic Analysis Workshop 17 simulated data while the utility of whole genome data was shown with the Framingham data in deriving relationships among related individuals comparable to those defined by family structure. Some computational issues were also resolved in the process. Conclusion: Our work suggests that both models have many desirable properties and are preferably combined in a vigorous framework for both genetic and environmental factors involved with different types of data such as unrelated individuals from the population and relatives in families. In addition, R (http://www.r-project.org) could facilitate this greatly. References Xue F, et al. A novel spatial mapping method identifies shared genetic effects across immune-mediated diseases. *C. Cotsapas[1,2], J. Kasvin-Felton[3].* 1) Neurology, Yale School of Medicine, New Haven, CT; 2) Genetics, Yale School of Medicine, New Haven, CT; 3) Yale Combined Program in Biological and Biomedical Sciences, Yale School of Medicine, New Haven, CT.

Genome-wide association studies (GWAS) have identified hundreds of risk loci for autoimmune and inflammatory diseases. We have previously shown that almost half these appear to be shared across diseases and that they encode sets of interacting genes, suggesting that the architecture of pathogenesis is shared. However, comparisons of individual markers cannot conclusively distinguish between true pleiotropy, where the same genetic variant influences risk to multiple traits, and independent disease-specific variants located in the same genomic region. We can thus not formally identify the extent of disease overlap or underlying pathogenic mechanisms without resolving this question. We address this deficit with a novel spatial mapping approach, comparing association signals across two diseases. Using publicly available summary statistics, our method compares the pattern of association across an interval to determine whether it is the same in the two diseases. We define a fixed window around each marker and compute the correlation of association statistics between the two diseases in the window. We then use a wavelet-based peak-detection algorithm to find regions of the genome where correlation coefficients deviate from expectation, indicating simultaneous association. We show using simulation that the method can distinguish between cases of true pleiotropy and co-localization of independent signals. We also show that, in real GWAS data for Crohn's disease and ulcerative colitis, we detect simultaneous association at 60 loci known to harbor variants to both diseases; simple meta-analysis of these GWAS data across the two diseases only identifies 11 loci. We also identify a further 80 regions not previously known to harbor variants for both diseases, which we suggest are novel risk loci. We are currently comparing publicly available GWAS data for these and several other autoimmune/inflammatory diseases, including multiple sclerosis and type 1 diabetes, with preliminary results suggesting similar levels of overlap. The number of loci discovered suggests our method has more statistical power to detect overlaps simultaneous associations than simple meta-analysis by virtue of considering intervals rather than single markers. Our results also suggest that genetic factors for immune-mediated disease are indeed shared to a large extent; we are currently pursuing several validation and interpretation strategies to aid in identifying shared pathogenic pathways.

1367W

Adjust local ancestry to detect rare variants in next-generation sequencing data. *X. Wang, X. Zhao.* Zilber School of Public Health, University of Wisconsin-Milwaukee, Shorewood, WI.

Population stratification is a well-known issue in genome wide association studies (GWAS) in which the local ancestry at a test single nucleotide polymorphism (SNP) may confound with the association signal and ignoring it can lead to spurious association. Practical evidences and a report of Genetic Analysis Workshop 17 (GAW17) show that population stratification is expected to be a more severe issue with rare variants than with common variants in next-generation sequencing studies. In this study, we demonstrate theoretically that adjustment for local ancestry at the test collective rare variants is sufficient to remove the spurious association regardless of the mechanism of population stratification whether due to local or global ancestry differences among study subjects. We further develop a novel method to detect collective rare variants while adjusting for local ancestry. This method is based on a conditional likelihood framework which models the distribution of the collective rare variants in a considered region given disease status and flanking marker genotypes. We conducted extensive simulation studies using population genetic models. The population-specific levels of rare variation and driven stratification in association tests are affected by the cumulative effects of different sources such as growth, migration and selection. The type I error rates of our test are under control and it performs similarly or more powerful than existing methods in association tests when there exist different scenarios of stratification. The key advantage of the new method is that it is robust and very powerful when different directions of association exist in the ancestral populations.

Detecting association for low-frequency variants in case-control studies. *C. Xing, CY. Lin.* McDermott Ctr, Univ Texas SW Med Ctr, Dallas, TX.

In testing association between genetic variants and a disease, there exist popular metrics such as odds ratio and Phi coefficient to measure the strength of association, and there exist popular tests such as Pearson's chi-squared test, Fisher's exact test, and the likelihood ratio test to test the strength of association. However, these measures and tests are not sensitive to detect association for low-frequency exposures. In this study, we propose a new statistic for the purpose of detecting low-frequency variants associated with the disease. The association test based on the new statistic is more sensitive than existing methods in detecting association for low-frequency variants. We are able to numerically prove that the new statistic offers higher power while maintains the same type I error rate as Pearson's chi-squared test in a balanced study design. Application of the new method in genetic studies of detecting association of rare genetic variants with diseases is shown.

The Empirical Assessment of Statistical Power of Rare Variant Association Methods. *K. Hao[1], H. Chen[1], H. Zhou[1], Z. Kan[2], H. Zheng[3], X. Liu[3], S. Li[4], T. Barber[4], Z. Gong[3], H. Gao[3], M. Willard[4], J. Xu[2], R. Hauptschein[2], P. Rejto[2], G. Wang[3], Q. Zhang[3], R. Cheng[1], K. Sung[5,6], Z. Peng[3], C. Zhang[1], Q. Zhang[3], R. Poon[5], S. Fan[5], J. Wang[3,7,8], J. Hardwick[1,9], C. Reinhard[4], Y. Li[3], J. Luk[5], M. Mao[2,9], H. Dai[1].* 1) Merck Research Laboratories, Boston, MA; 2) Pfizer Oncology, San Diego, CA; 3) Beijing Genomics Institute, Shenzhen, China; 4) Eli Lilly and Company, Indianapolis, IN; 5) Department of Surgery, University of Hong Kong, Hong Kong; 6) School of Computing Science, National University of Singapore, Singapore; 7) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 8) The Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark; 9) Asian Cancer Research Group, Inc., Wilmington, DE.

Backgrounds The role of rare genetic variation in the etiology of complex disease remains as an active research field. The next-generation sequencing technologies were powerful in identifying genetic variants responsible to Mendelian disorders, but had limited success in dissecting complex diseases. Several novel statistical methodologies have been recently proposed to assess the contribution of rare variation to complex disease etiology. So far, their statistical power was assessed mainly on simulated phenotypes. **Methods** We quantified the statistical power of popular rare variants association methods empirically using the eQTL framework. That is the relative statistical power is proportional to the number of eQTLs captured at fixed FDR. **Results** On N=100 human non-tumor liver tissues, we measured gene expression trait with Affymetrix HU133-Plus2 chip, and conducted whole genome DNA sequencing (WGS) at 30X coverage. Also, we measured the genotype using Illumina 650Y array. Results of conventional single marker tests with 1000G imputation was compared to those of rare variants association methods, including cohort allelic sum test (CAST), weighted sum test (WST) and SKAT. When only focusing on SNVs of MAF<5%, none of the rare variants association methods have meaningful statistical power. When including all SNVs, rare variants association methods offer comparable power to single marker test (ie, GWAS methods) **Conclusion** WGS has no advantage in term of statistical power over SNP array in identifying eQTLs. Gene-level tests offer higher power due to less multiple testing penalties. SNVs on exons, splicing site or UTRs were more likely to control gene expression levels.

1370W

Rare Variant Burden Tests and Meta-Analysis Using Summary Level Statistics. *D. Liu, G. Abecasis.* Dept Biostatistics, University of Michigan, Ann Arbor, MI.

Studies of the contribution of rare functional variation to complex traits could elucidate the biology of many complex traits and diseases. Since most coding variation is very rare, achieving sufficient power will often require examining the average effect of multiple variants in a gene (through “gene burden tests”) and combining information across many samples. Here, we develop a framework for combining information across many studies that allows for the calculation of gene burden test statistics using summary statistics from each component study. First, we show that gene burden test statistics including the Collapsing of Rare Variants Test, the Variable Threshold Collapsing of Rare Variants Test, and Sequence Kernel Association Tests that allow variants in the same gene to have opposite directions of effect can be constructed by combining a linkage disequilibrium matrix with carefully selected single marker summary statistics. Second, we show that when information on linkage disequilibrium patterns and summary statistics are combined across several samples, our method results in “gene burden test” statistics that are equivalent to those obtained by merging raw genotype data across studies. Finally, we provide examples of the utility of our method with examples from ongoing studies of the genetics of blood lipid levels and other traits. Software implementing our methods is freely available and should facilitate analysis of rare variation that combine data across multiple sequenced or genotyped samples.

A geometric framework for the evaluation of rare variant tests of association. *N. Tintle[1], K. Liu[2], S. Fast[3], M. Zawistowski[4].* 1) Math, Stat and CS, Dordt College, Sioux Center, IA; 2) Dept. of Biostatistics, Harvard University, Cambridge, MA; 3) Massachusetts Institute of Technology, Cambridge, MA; 4) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

The tidal wave of next-generation sequencing (NGS) data has arrived, but more questions than answers exist about how to best analyze NGS data to investigate the potential contribution of rare genetic variants to human disease. Numerous rare variant association testing methods have been proposed which attempt to aggregate association signals across multiple variant sites in an effort to increase statistical power. While emerging simulation results suggest that some rare variant testing methods work better than others for particular genetic architectures, little concrete understanding of the tests is available. We propose a geometric framework which quickly classifies existing rare variant tests of association into two broad categories: length and joint tests. We then demonstrate how genetic architecture (relative risk distribution, allele frequency distribution and number of variants) directly relates to the behavior of length and joint tests. We go on to illustrate further implications of the geometric framework including the differential impact of variant weighting strategies, population stratification and genotype uncertainty on length and joint tests. We also describe how the geometric framework suggests a lack of diversity in current approaches for rare variant testing, along with numerous potential alternative rare variant association tests and how they will behave. The geometric framework articulates the connection between disease architecture and test behavior, providing a clear set of next steps for applied and theoretical researchers.

Subset-based Approach to Combined Genetic Association Analysis of Heterogeneous Phenotypes. *S. Bhattacharjee[1,2], S.M. Boca[2], P. Rajaraman[2], K.B. Jacobs[3], W.A. Wheeler[4], B.S. Melin[5], P. Hartge[2], M. Yeager[3], C.C. Chung[6], S.J. Chanock[6], N. Chatterjee[2], GliomaScan Consortium.* 1) National Institute of Biomedical Genomics, Kalyani, West Bengal, India; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD; 3) Core Genotyping Facility, National Cancer Institute, Gaithersburg, MD; 4) Information Management Services, Rockville, MD; 5) Department of Radiation Sciences, Oncology, Umeå University, Umeå, Sweden; 6) Laboratory of Translational Genomics, DCEG, National Cancer Institute, Bethesda, MD.

Combining GWAS of related traits can provide promising directions for the discovery of loci with small but common pleiotropic effects. Here, we study an agnostic, subset-based approach for conducting meta-analysis of heterogeneous genetic association studies. It involves exploring the subset space to identify the strongest association signal and then appropriately evaluating the statistical significance of the signal accounting for the multiple testing incurred due to subset search. We consider pooled case-control studies of heterogeneous traits as well as analysis of heterogeneous disease subtypes of a single case-control study. To avoid computationally intensive resampling-based procedures, we develop fast analytic approximations for the p-values of our proposed statistics. We demonstrate using simulations and real data applications that our methods retain substantial advantage in terms of power and interpretation over standard meta-analysis approaches. Further, we study extensions of subset-based methods to analyze SNP data across a gene or region. These methods can take into account the linkage disequilibrium structure among SNPs and detect overall gene-level pleiotropic association with multiple related traits.

Subset-based association analysis of some known cancer GWAS hits with 6 Cancers

SNP	Primary (Known)	Genes (Chr)	P-value	Secondary (Risk)	Secondary (Protective)

Genome wide significance thresholds for SNPs ascertained by sequencing. *T. Blackwell[1], A.K. Manning[2], GoT2D Investigators.* 1) Center for Statistical Genetics, Univ Michigan, Ann Arbor, MI; 2) Broad Institute, Cambridge MA.

Resequencing projects including 1000 Genomes have greatly expanded the number of SNPs and the range of allele frequencies available to genome wide association studies. Previously, the HapMap catalogue constituted the universe of SNPs one could hope to test for association, and one could set a p-value threshold for genome wide significance that was invariant to a study's sample size. Most newly identified SNPs have minor allele frequencies (MAF) well below those of HapMap sites, and linkage disequilibrium (LD) generally decreases with MAF. Low MAF also introduces a dependence on the study's overall sample size, since a minimum number of observations of the minor allele are needed before it is possible to reach genome wide significance using a case control test for a single variant.

We quantify both effects using the June 2011 whole genome data freeze from GoT2D as an example. Permuting case control status gives a valid 5% experiment wide significance threshold which accounts for LD. With 1510 cases and controls combined, a conventional 5×10^{-8} genome wide threshold is appropriate for testing all 4.3 M SNPs with 0.11 MAF and above in this study. A threshold of 2×10^{-8} is required for testing the 8.5 M SNPs down to 0.01 MAF. If the study sample size were expanded tenfold to 15,100 cases and controls, without ascertainment of additional variants, extrapolation using an analysis from Moskvina and Schmidt (2008) shows that a threshold of 1×10^{-8} would suffice for testing 12.5 M SNPs down to 0.001 MAF.

One can measure the redundant information due to LD using the ratio of the actual number of SNPs tested to the number of independent tests that would produce the same empirical threshold. The sites above 0.11 MAF show an average fold redundancy 4.3. This decreases linearly with log allele frequency to an average of 1.5 fold redundancy among the SNPs at 0.001 MAF. These results are restricted to single variant tests for case control outcomes and refer to an ethnically homogeneous sample from northern Europe. Added ethnic diversity will almost certainly increase the total number of SNPs at each MAF and reduce the average redundancy. This argues for using a study-specific threshold for genome wide significance. Gene level `burden' tests would show quite different behavior, since the number of tests is invariant to the number of SNPs and to a study's sample size.

1374T

On the analysis of imputed genotypes in family-based association studies. *A. Cobat[1,2], A. Alcais[3], E. Schurr[1,2].* 1) McGill Centre for the Study of Host Resistance, Montreal, QC, Canada; 2) Human Genetics Dept, McGill University, Montreal, QC, Canada; 3) Laboratory of Human Genetics of Infectious Diseases, INSERM U980, Paris, France.

Genotype imputation is an efficient statistical approach for inferring genotypes at ungenotyped variants. However, because of the probabilistic nature of imputed SNPs specific techniques are needed for their analysis to account for genotypic uncertainty. One of the most popular approach relies on the expected allele count E1=2P11+P12, also called allele dosage, to test for association1. In population-based designs, testing of association between the phenotype and expected allele count (instead of genotype) is straightforward using standard linear or logistic regression frameworks. By contrast, equivalent methods for family-based studies are missing. To close this gap, we developed a new analytical approach which is based on the methodology proposed for the analysis of copy-number variants2 to perform association testing of imputed SNPs in the family-based design (FBAT-dosage). We further extended our method to combine the family-based statistic with a paired test statistic for founders when parental phenotypes are available (FBAT-dosage_c). Simulation studies under the null hypotheses of “no linkage, no association” and “linkage, no association” showed that the FBAT-dosage and FBAT-dosage_c methods provide very consistent type I errors, whatever the sibship size and the level of certainty with which the marker under study was imputed. An alternative to our approach is the Best-guess genotype approach which does not allow testing for association between the phenotype and SNPs imputed with low certainty. Hence using FBAT-dosage will provide substantial increase in power for most scenarios. For SNPs imputed with certainty (or observed SNPs), the FBAT-dosage statistic is equal to the FBAT statistic for genotypes using the empirical variance3. Finally, the FBAT-dosage method and its extension have been implemented in C++ language and are suitable for genome-wide imputation analysis. 1. Marchini J, and Howie B. Sex-specific and X-chromosome Association Studies of Venous Thromboembolism (VTE). *M. de Andrade[1], S.M. Armasu[1], L.L. Chan[1], J.A. Heit[2].* 1) Div Biomed Statistics & Informatics, Mayo Clinic, Rochester, MN; 2) Div Cardiovascular Diseases, Mayo Clinic, Rochester, MN.

Background: VTE is a complex disease (h^2~0.6), and likely results from multigenic action as well as environmental exposures. **Objective:** To identify autosomal and X-chromosome VTE-susceptibility genes, both overall and by sex. **Methods:** Genome-wide scan (Illumina 660W Quad [530,865 SNPs]) genotypes from 1270 non-Hispanic adults of European ancestry with objectively-diagnosed VTE and 1302 controls (frequency-matched on case age, sex, race, MI/stroke status) were imputed to about 9.2 million SNPs with BEAGLE using EUR 1000G. Genome-wide association analyses were performed on autosomal and X-chromosome SNPs, both overall and by sex, using PLINK. **Results:** For the autosomal females analysis, after adjusting for age, state of residence and stroke/MI status, 3 SNPs on chromosome 1q24.2 (including *F5* rs6025 [Factor V Leiden], odds ratio [OR]=3.2, p=2.5E-9) and 38 on chromosome 9q34.2 (including *ABO* rs2519093, OR=1.7, p=3.7E-9; and rs495828, OR=1.7, p=3.5E-9) exceeded genome-wide significance. Similar results were observed for males (*F5* rs6025, OR=4.1, p=3.0E-12; *ABO* rs2519093, OR=1.9, p=1.4E-10; and rs495828, OR=1.7, p=2.7E-8). For the X-chromosome overall analyses, the most significant SNPs were near 4 pseudo-genes and *FAM46D* (rs12688059, OR=1.48, p=7.07E-5); for females only, near *FAM47A* (chrX:34138682, OR=0.048,p=2.54E-5) and *TEX11* (chrX:69992070, OR=2.81, p=6.20E-5); and for males only, near *SCML2* (rs58926087, OR=0.74, p=8.14E-5). **Conclusion:** Autosomal and X-chromosome VTE-susceptibility genes vary, overall and by sex, consistent with the hypothesized multigenic action.

Correcting for the effect of cryptic relatedness and population structure among cohorts in meta-analysis of GWAS. *T. Feng, N. Morris, X. Zhu.* Epidemiology & Biostat, Case Western Reserve Univ, Cleveland, OH.

Genome-wide association study (GWAS) is a main approach to detect genetic variants underlying complex traits, but is often conducted through meta-analysis of the summary statistics from multiple studies and assumes that the samples from different studies are independent. In practice, genome control procedure is often applied at both individual study level and meta-analyzed result in order to control the cryptic relatedness and population structure within and between studies. However, this procedure may fail to control type I error and reduce statistical power. Here, we present a new meta-analysis method to correct the effect of cryptic relatedness and population structure by estimating the correlation structure among cohorts using the GWAS summary statistics. We conducted a simulation study using the Welcome Trust Case control Consortium data (WTCCC). Our results showed that the proposed meta-analysis method can control the type I error and preserve statistical power well but the genome control procedure failed to control type I error. We will also present the results in the BP GWAS in Family Blood Pressure Program using the proposed method.

1377T

Genome-wide association study (GWAS)-identified genetic variants for lipid traits are associated with gallstone disease in the diverse Third National Health and Nutrition Examination Survey. *R. Goodloe[1], K. Brown-Gentry[1], N. Gillani[1], H. Jin[1], P. Mayo[1], M. Allen[1], B. McClellan[1], J. Boston[1], C. Sutcliffe[1], N. Schnetz-Boutaud[1], H. Dilks[1,2], D. Crawford[1,2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN.

Gallstone disease (GD) is one of the most common digestive disorders, affecting more than 30 million Americans. Previous twin studies suggest a heritability of 25% for gallstone formation. To date, one genome-wide association study (GWAS) has been performed in a population of European-descent. Several candidate gene studies have been performed in various populations, but most have been inconclusive. Given that gallstones consist of up to 80% cholesterol, we hypothesized that common genetic variants associated with high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), and triglycerides (TG) would also be associated with gallstone risk. To test this hypothesis, we as the Population Architecture using Genomics and Epidemiology (PAGE) study and Epidemiologic Architecture for Genes Linked to Environment (EAGLE) performed tests of association between 49 GWAS-identified lipid trait SNPs and GD in the Third National Health and Nutrition Examination Survey (NHANES III; n= 7,159). NHANES III is a population-based cross-sectional study of Americans ascertained regardless of health status by the National Center for Health Statistics at the Centers for Disease Control and Prevention. NHANES III is diverse with non-Hispanic whites (NHW; n=2631), non-Hispanic blacks (NHB; n=2,108), Mexican Americans (MA; n=2,073), and Asians (A; n=348). GD was defined by “yes” to the question “Has the doctor told you had gallstones?” or a positive ultrasound (defined as presence of scar tissue (surgical removal) or demonstration of gallstones present in the gallbladder). A total of 379 NHW, 137 NHB, 227 MA, and 28 A cases and 2251 NHW, 1971 NHB, 1846 MA, and 320 A controls were identified. Tests of association were performed using logistic regression, assuming an additive genetic model stratified by race/ethnicity and adjusted sex, age, and body mass index. Most associations were observed among NHB, with 2 HDL-C, 4 LDL-C, and 1 TG-identified SNPs associated with GD at p<0.05. Among all other groups, we identified at least one significant finding for each race-ethnicity (4 total associations: 2 NHW; 1 MA; 1 A). The most significant finding was rs6756629, previously associated with LDL-C, in NHW (odds ratio=1.518; 95% confidence interval= (1.137–2.026); p=0.0046; coded-allele frequency (CAF) =0.07). Overall, we demonstrate that lipid-identified genetic variants are associated with GD in this US representative population.

1378F

A unified framework for testing for genetic associations integrating environmental exposures. *S.S. Han, P.S. Rosenberg, N. Chatterjee.* National Cancer Institute, Bethesda, MD.

Recent genome-wide association studies (GWAS) have discovered over 6,000 susceptibility loci for more than 125 complex human traits. Despite this success, the common genetic variants detected through GWAS can explain only a small fraction of the heritability of these traits; this has led to challenges in dissecting the full genetic architecture of complex diseases. One major barrier to the current genetic association study using case-control data is the lack of statistical methods with full consideration of environmental exposure effects. A standard approach for incorporating exposures is to include them as covariates to a logistic regression. A major limitation of this approach is that it doesn't allow heterogeneous genetic effects across exposure levels—which is commonly observed. One existing approach that could potentially deal with this limitation is to introduce interaction terms to a logistic regression, and to jointly test for association and interaction. A drawback of this approach is that it inevitably increases degrees of freedom by testing additional interaction parameters, leading to loss of power. In addition, this method also often leads to association findings that lack biological interpretations in which the directions of genetic effects are reversed by exposure levels. Another fundamental barrier to genetic association studies is the lack of statistical methods capable of employing an appropriate disease risk model based on evidence from data. Current methods rely on a specific risk model, a multiplicative risk model via logistic regression, which is not based on evidence from data or biological explanations, but on statistical convention and convenience. In this study, we propose a novel framework for testing genetic associations that integrates the effects of environmental exposures; a class of score tests is constructed by imposing weights on genotypes by exposure levels, allowing heterogeneous genetic effects by exposures, and also leading to the detection of genetic associations whose directions are invariant with respect to exposure levels. The proposed method unifies a class of underlying disease risk models by maximizing suitable score statistics over a range of disease risk models including multiplicative, supra-multiplicative, additive and liability threshold risk models. We illustrate our method by applying it to National Cancer Institute lung cancer GWAS data in consideration of gene by smoking interactions.

1379W

Efficient association analysis for groups of genetic markers that avoids confounding by genetic structure. *D. Heckerman, C. Lippert, J. Listgarten.* Microsoft Res, Los Angeles, CA.

Approaches for testing groups of variants for association with complex traits are becoming critical. Examples of groups typically include a set of rare or common variants within a gene, but could also be variants within a pathway or any other set. These tests are important for aggregation of weak signal within a group, allow interplay among variants to be captured, and also reduce the problem of multiple hypothesis testing. Unfortunately, these approaches do not address confounding by, for example, family relatedness and population structure, a problem that is becoming more important as larger data sets are used to increase power. We introduce a new approach for group tests that can handle confounding, based on Bayesian linear regression, which is equivalent to the linear mixed model. The approach uses two sets of covariates (equivalently, two random effects), one to capture the group association signal and one to capture confounding. We also introduce a computational speedup for the two-random-effects model that makes this approach feasible even for extremely large cohorts, whereas it otherwise would not be. Application of our approach to richly structured GAW14 data, comprising over eight ethnicities and many related family members, demonstrates that our method successfully corrects for population structure, and application of our method to WTCCC Crohn's disease and hypertension data demonstrates that our method recovers genes not recoverable by univariate analysis, while still correcting for confounding structure.

1380T

A non-threshold region-specific method for detecting rare variants in common diseases. *A.R. Hsieh, C.C. Chang, C.S.J. Fann.* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

To date, rare variants (with MAF < 1% or 5 %) have a proven role in some complex diseases. Owing to the low frequency and large number of rare variants, many statistical methods proposed for the detection of common variants associated with diseases are not suitable and have low power in the case of rare variants. Furthermore, some limitations exist in previous developing collapsing-based methods for testing rare variants. Accordingly, we developed a region-specific method that do not use the threshold for defining rare variants and take the directions of effects into account. Our region-specific method used the concept of weighting variants according to their minor allele frequencies and odds ratios (OR) to combine effects of common and rare variants on disease occurrence into a single score, and provided a test statistic in assessing the significance of the score. To evaluate the performance of our method, we simulated extensively under different disease models and effect sizes according to Basu and Pan (2011). We found that the power of our method increased as the effect sizes increased. The power of our method (86.22% on average) was very good in dominant and additive models. The type I error of our method was controlled well in spite of the simultaneous variations. Moreover, we also compared the performance of detecting associated signals between our proposed method, and Combined Multivariate and Collapsing (CMC) proposed by Li and Leal (2008). Results from our method showed a 20% increase in power comparing with CMC (71.85% vs 53.18%) for recessive models. For other models, the two methods were compatible. We applied our method to a publicly available dataset of Diabetic Nephropathy disease downloaded from the database of Genotypes and Phenotypes (http://www.ncbi.nlm.nih.gov/gap). We confirmed previous findings. Furthermore, we identified the association between Diabetic Nephropathy disease and COL23A1 (collagen, type XXIII, alpha 1) which was originally implicated by bioinformatics studies using other diabetic related data sets. The COL23A1 gene included 194 SNPs and 9 of them were rare SNPs. Although these SNPs were not significant (p-value <10 -5) by using the Trend test, they were detected by our method. In this study, we showed that using rare variant analysis is possible to assist researchers in gaining more insight into identifying genetic risk factors for complex diseases.

Joint admixture and association test on African American inflammatory bowel disease identifies novel significant loci. *C. Huang[1,2], S. Kugathasan[3], D.P. McGovern[4], J.H. Cho[5], R.H. Duerr[6], J.D. Rioux[7,8,9], M.S. Silverberg[10,11], T. Dassopoulos[12], L.W. Datta[1], L.W.H. Kao[2], S.R. Brant[1,2].* 1) Lyn P. and Harvey M. Meyerhoff Inflammatory Bowel Disease Center, Dept of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Dept of Epidemiology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; 3) Dept of Pediatrics, Emory University, Emory, GA; 4) Inflammatory Bowel and Immunology Research Institute, and Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 5) Dept of Medicine and Genetics, Yale University, New Haven, CT; 6) Dept of Medicine, and Dept of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 7) Depts of Medicine, Surgery, Public Health Sciences, Immunology, and Molecular and Medical Genetics, University of Toronto, Toronto, Canada; 8) Samuel Lunenfeld Research Institute and Mount Sinai Hospital, Toronto, Canada; 9) Toronto General Hospital Research Institute, Toronto, Ontario, Canada; 10) Université de Montréal and the Montreal Heart Institute, Research Center, Montreal, Quebec, Canada; 11) Broad Institute of MIT and Harvard, Cambridge, MA; 12) Gastroenterology Division, Washington University School of Medicine, St. Louis, MO.

Inflammatory bowel disease (IBD) is a disorder of immune dysregulation causing chronic idiopathic inflammation of the gastrointestinal tract. More than 160 loci have been recently confirmed in white populations using the “Immunochip,” a custom Illumina array designed to fine map and deep replicate GWAS signals for 12 autoimmune and inflammatory diseases including IBD. The array also contains ancestry informative SNPs located throughout the genome. We initiated evaluation of IBD loci using the Immunochip in African Americans (AA), a recent admixed population with 80% West African and 20% European global ancestry. Information from local admixture mapping is rarely incorporated into genomewide evaluations to increase power. We examined a joint admixture and association test described by Shriner et al (2011) that uses admixture posterior probabilities as prior information in association mapping under generalized linear regression framework, enabling incorporation of other covariates. This method also capitalizes on the reduced test burden of admixture mapping relative to association mapping. We genotyped our initial study sample of 722 AA IBD cases and 317 healthy controls for 181,268 autosomal SNPs using the Immunochip. Local and global admixture was estimated using WINPOP (Pasaniuc et al 2009). No SNP reached significance of $p < 2e\text{-}6$ with traditional logistic regression after adjusting for global ancestry and significant principal components. We employed a routine to use the Shriner joint test and identified four significant SNPs on 3 loci: 2 SNPs on 1q23, 1 on 8q22, and 1 on 22q13. These four SNPs showed only modest association by logistic regression ($5e\text{-}5 < p < 1e\text{-}3$). The 1q23 and 8q22 loci are novel IBD loci, and the 22q13 locus was previously established in European IBD (Franke et al. 2010). Global West African ancestry differed little between cases (80.7%) and controls (81.6%). However, West African ancestry about the 22q13 locus was significantly lower for cases vs. controls (76.4% vs. 80.2%, respectively, p=3e-4). Our findings highlight the value of local admixture adjustment, use of Bayesian analytic approaches and evaluation for novel IBD loci in the understudied, admixed African American population.

Comparison of phylogenetic and haplotype methods for the study of genotype/phenotype association in genome-wide studies. *M.G. Johnson[1], D.L. Swofford[1], M.W. Lutz[2], D.G. Crenshaw[2], A.D. Roses[2].* 1) Duke University, Biology Department, Box 90338 Durham, NC. 27708; 2) Duke University, Neurology Department, Box 3503 Durham, NC 27705.

Numerous approaches have been proposed to test whether polymorphisms in a genomic region are associated with phenotypic variation. Some of these approaches are based on the principle that evolutionarily closely related haplotypes will share mutations that are important in the expression of phenotype. Assessment and comparison of these methods for detection power and specificity requires a computational framework that allows rapid inclusion of new methods and supports a spectrum of realistic genetic models. Datasets were generated by forward-time simulation, beginning with the HapMap genomes, followed by population expansion under slight negative selection. Case-control datasets were generated from these populations under an additive model with five levels of penetrance. Six analysis methods were analyzed: basic chi-squared tests, ancestral recombination graphs, perfect phylogenies, tree disequilibrium tests, haplotype clustering, and phylogenetic clustering. An analytical pipeline was developed to easily replicate simulation datasets under various test conditions, and generate input files for the analysis programs. Each method was assessed for power (ability to detect the causal marker) and specificity (number of false positives both near and far from the causal marker). All six methods were able to recover an association at the true causal marker in 95% of trials when the Genotype Relative Risk (GRR) was 2.0, even with the strictest score thresholds. The methods were less successful with lower GRR, although the tree-disequilibrium test and phylogenetic clustering were most successful at moderate risk levels. None of the methods were able to consistently recover the true marker at GRR = 1.25. No method found false associations far away from the causal locus, but many markers crossed even the strictest significance threshold for each program near the disease locus. Phylogenetic clustering had by far the fewest false positives, while the tree disequilibrium method had the most. Several methods were able to exceed basic chi-squared tests in detection power both with and without a typed causal marker. However, many of these methods suffered from low specificity; many markers near the true locus crossed a significance threshold. Therefore, use of any method requires a comprehensive understanding of the thresholds at which associations should be accepted. One method, phylogenetic clustering, outperforms the other methods in both power and specificity.

Benefits of using local whole exome reference panels for the imputation of rare variants in two European populations. *P. Joshi[1], R.M. Fraser[1], V. Vitart[2], C. Hayward[2], R. McQuillan[1], O. Polasek[1], S.H. Wild[1], N. Hastie[2], A.F. Wright[2], H. Campbell[1], I. Rudan[1], C. Haley[2], P. Navarro[2], J.F. Wilson[1].* 1) Centre for population health Sciences, University of Edinburgh, Edinburgh, United Kingdom; 2) MRC Human Genetics Unit, University of EdinburghWestern General Hospital, Crewe Road, Edinburgh, UK.

Increasing focus is being put on the potential for rare variants to explain a significant portion of the heritability of complex diseases, which are a substantial health burden in western countries. While whole genome sequencing remains expensive, imputation provides a cost effective method of inferring rare variants on the basis of existing high density genome-wide SNP genotyping. This study examines whether the use of a local reference panel of whole exome sequences can increase the accuracy of rare exonic variant imputation compared with the use of the 1000 Genomes reference panel alone, in the ORCADES and CROATIA-KORCULA genetic isolate studies. 90 Orcadian and 91 Korculan samples were whole exome sequenced and genotyped using the Illumina Hap300 or 370CNV arrays, and ~200k common autosomal array SNPs were used for imputation. A local reference panel was created from the exomes and the array genotypes together and this was phased using SHAPE-IT. The SNP panel genotypes were phased using SHAPE-IT and then each subject was imputed with the array genotypes only, using IMPUTE2. The imputations used (a) the 1000 Genomes reference panel only(500 Europeans and 1221 non-Europeans), and (b) the 1000 Genomes alongside the local panels of ~90 exomes in each population, however the subject being imputed was excluded from the reference panel used in their imputation, to avoid giving IMPUTE2 the actual genotypic values directly. The accuracy of the two imputations was measured against the rigorously Quality-Controlled exomes. We examine the differences in accuracy by allele frequency and population. This study gives an indication of the improvement in accuracy of using local genome sequences to supplement a general population reference panel, when imputing genotypes for rare variants using genome-wide SNP data.

1384F

Combined linkage and association analyses identify a novel locus for obesity near PROX1 in Asians. *H. Kim[1], Y. Yoo[2], Y. Ju[3], S. Lee[1], S. Cho[4], J. Sung[4], J. Kim[1], J. Seo[1].* 1) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul, Republic of Korea; 2) Department of Mathematics Education, Seoul National University, Seoul, Republic of Korea; 3) Genomic Medicine Institute (GMI), Medical Research Center, Seoul National University, Seoul, Republic of Korea; 4) Seoul National University School of Public Health, Seoul, Republic of Korea.

Although genome-wide association studies (GWAS) have substantially contributed to understanding the genetic architecture, unidentified variants for complex traits remains an issue. One of the efficient approaches is to improvement of the power of GWAS scan by weighting P-values with prior linkage signals. To identify new susceptibility loci for obesity, we performed a family-based GWAS combined with a genome-wide linkage study in an isolated Mongolian sample of 1,049 individuals from 74 families. We obtained linkage information for body mass index (BMI) and waist circumference (WC) via a multipoint genome-wide linkage scan. For both BMI (LOD = 3.3) and WC (LOD = 2.6), the highest linkage peak was discovered at chromosome 10q11.22. Next, a family-based GWAS, which integrates within- and between-family components, was performed using the genotype data of 756 individuals of the Mongolian sample, and P-values for association were weighted using linkage information obtained previously. Six single-nucleotide polymorphisms (SNPs) for BMI and five SNPs for WC reached a significant level of association (P-value<1^10-5). Of these, only one of the SNPs associated with WC (rs1704198) was replicated in 327 Korean families comprising 1,301 individuals; this SNP was located in the proximity of the prospero-related homeobox 1 (PROX1) gene, the function of which was validated previously in a mouse model. Our powerful strategic analysis enabled the discovery of a novel candidate gene, PROX1, associated with WC in an Asian population.

1385W

A more powerful burden tests to detect Rare Genetic Variants. *J. Kim[1], J. Lee[1], S. Choi[2], M.S. Kwon[2], T. Park[1].* 1) Department of Statistics, Seoul National University, Seoul, South Korea; 2) Interdisciplinary program in Bioinformatics, Seoul National University, Seoul, South Korea.

Analysis of rare variants, typically defined to have a minor allele frequency (MAF) less than 1%, is not straightforward due to data sparsity. To overcome this sparsity problem, a variety of burden tests have been proposed such as Sequence Kernel Association Test (SKAT) (Wu et al., 2011), Gene- or Region-based ANalysis of Variants of Intermediate and Low frequency (GRANVIL) (Morris and Zeggini, 2010), Hoffman's method (Hoffman et al., 2010) and so on. The objective of burden tests is to identify association with complex traits and genetic variants efficiently, not through traditional association analysis of single nucleotide polymorphisms (SNPs), but through condensed analysis of rare variants together combined into genes or regions in a reasonable manner. The main goal of our work is to propose a new burden test based on the mixed effects model which has a more flexible structure of random effects. The proposed test is compared to other burden tests via power and Type 1 error using the exome sequence data set of Genetic Analysis Workshop 17. Our comparison study shows that the burden tests based on the mixed effects models tend to perform better than other tests.

Efficiently Identifying Significant Associations in Genome-wide Association Studies. *E. KOSTEM, E. ESKIN.* Computer Science Dept., UCLA, LOS ANGELES, CA.

The genome-wide association study (GWAS) is a widely used method for locating genomic regions that are associated with complex disease traits. In a GWAS, single nucleotide polymorphisms (SNPs) are collected across the genome and tested individu- ally to identify significant associations, which may provide insight into the genetic basis of the disease. Association studies attempt to collect information on as many SNPs as possible to cover the whole genome. However, as the number of collected SNPs increases so does the computational burden to identify the significant associations. In expression quantitative trait loci (eQTL) studies, tens of thousands of gene expres- sion levels are measured and the GWAS approach is applied to each gene expression level. This leads to computing billions of tests and requires substantial computational resources. We introduce a novel two-stage testing procedure that identifies all of the significant associations more efficiently than testing all the SNPs. In the first-stage a small number of informative SNPs, or proxies, across the genome are tested. Based on their observed associations, our approach locates the regions which may contain significant SNPs and only tests additional SNPs from those regions. We show through simulations and analysis of real GWAS datasets that the proposed two-stage procedure identifies the significant associations approximately ten times faster than testing all the SNPs. Our method and software packages to perform rapid genome-wide association testing are available at http://genetics.cs.ucla.edu.

A multi-SNP locus-association method reveals a substantial fraction of the missing heritability. *Z. Kutalik[1,2], G. Ehret[3,4], D. Lamparter[1,2], C. Hoggart[5], J. Whittaker[6], J. Beckmann[1,7], GIANT consortium.* 1) Med Gen, Univ Lausanne, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Switzerland; 3) Division of Cardiology, Geneva University Hospital, Geneva, Switzerland; 4) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, Maryland, United States of America; 5) Department of Pediatrics, Imperial College London, London, United Kingdom; 6) Quantitative Sciences, GlaxoSmithKline, Stevenage, UK; 7) Service of Medical Genetics, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzer- land.

There are many known examples of multiple (semi-)independent associations at individual loci, which may arise either because of true allelic heterogeneity or imperfect tagging of an unobserved causal variant. This phenomenon is of great importance in monogenic traits but has not yet been systematically investigated and quantified in complex trait GWAS. We describe a multi-SNP association method that estimates the effect of loci harbouring multiple association signals using GWAS summary statistics. Applying the method to a large anthropometric GWAS meta-analysis (GIANT), we show that for height, BMI, and waist-hip-ratio (WHR) 10%, 9%, and 8% of additional phenotypic variance can be explained respectively on top of the previously reported 10%, 1.5%, 1%. The method also permitted to substantially increase the number of loci that replicate in a discovery-validation design. Specifically, we identified in total 263 loci at which the multi-SNP explains significantly more variance than the best individual SNP at the locus. A detailed analysis of multi-SNPs shows that most of the additional variability explained is derived from SNPs not in LD with the lead SNP suggesting a major contribution of allelic heterogeneity to the missing heritability.

1388W

Leveraging Input and Output Structures For Joint Association Mapping of Epistatic and Marginal eQTLs. *S. Lee, E. Xing.* School of Computer Science, Carnegie Mellon University, Pittsburgh, PA.

Interdependent genetic variations affect gene regulations, and they make the outcomes of many complex diseases and expression phenotypes. Thus, it is essential for association mapping to take into account both additive and epistatic (interaction) effects of multiple candidate genotypes. However, it poses computational challenges as it requires massive computations and a very large sample size. Fortunately, recent development of genetic interaction networks has generated prior knowledge about complex interactions between genotypes, and they can be used to reduce the computational complexity and increase the statistical power of association mapping. We propose a novel computational method called structured input-output lasso that uses prior information on structures on both genetic variations (input structure) and expression phenotypes (output structure). Our method makes use of a novel regularization scheme in a general regression setting, which enables us to find multiple related SNPs (e.g. SNPs in LD) which are jointly associated with multiple related expression traits (e.g. co-expressed genes). In addition, we generalize our model to detect SNPs having epistatic effects with manageable computational complexity by incorporating prior knowledge from genetic interaction networks. We show that our method can effectively use prior information for better search of association SNPs. We also present yeast eQTLs that we identified with the analysis of their biological functions.

Evaluating the power of single variant association tests for low frequency variants in joint and meta-analysis. *C. Ma, T. Blackwell, M. Boehnke, L.J. Scott, GoT2D investigators.* Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

The case-control association testing method for common genetic variants (minor allele frequency [MAF] $\geq$ 5%) is well established: test individual variants using logistic regression and combine results across multiple studies using fixed-effects meta-analysis to increase statistical power. For common variants, meta-analysis has comparable power to joint analysis of the combined individual-level data (Lin & Zeng, 2010). However for less common variants (MAF < 5%), it remains to determine: (1) the single variant test with the greatest power and best calibration (i.e. least conservative type I error rate below the nominal significance threshold), and (2) the relative power of joint and meta-analysis. In this study, we use analytic calculation and computer simulation to compare the type I error rate and power of four logistic regression tests (Wald, score, likelihood ratio, and Firth bias-reduced) in both joint and meta-analysis for less common variants. Using preliminary low-pass whole-genome sequencing data for 499 type 2 diabetes cases and 409 controls from the GoT2D study, we also compare joint analysis of the combined dataset, to meta-analysis of the three cohorts contributing to the study.

Analytic and simulation results demonstrate that for joint analysis of less common variants, the Firth test consistently has the best-calibrated type I error rate in both balanced (equal numbers of cases and controls) and unbalanced studies. For meta-analysis of less common variants in balanced studies, the score test is best-calibrated while the Firth test is conservative. However, for meta-analysis of unbalanced studies, all statistical tests can be anti-conservative. Power correlates roughly with the relative conservativeness of each test. The GoT2D data analysis results are consistent with the analytical and simulated type I error and power findings. In conclusion, if individual-level data are available, for association testing of less common variants in both balanced and unbalanced studies, we recommend joint analysis using the Firth test. If individual-level data are unavailable, for meta-analysis of balanced studies we recommend the score test. For meta-analysis of unbalanced studies, further work is required to identify a well-calibrated statistical test.

1390F

One Thousand Genomes Imputation in the NCI Breast and Prostate Cancer Cohort Consortium (BPC3) Aggressive Prostate Cancer Genome-wide Association Study. *M.J. Machiela[1], C. Chen[1], L. Liang[1], WR. Diver[2], VL. Stevens[2], KK. Tsilidis[3], SJ. Chanock[4], DJ. Hunter[1], P. Kraft[1], National Cancer Institute Breast and Prostate Cancer Cohort Consortium.* 1) Program in Molecular and Genetic Epidemiology, Harvard School of Public Health, Boston, MA; 2) Epidemiology Research Program, American Cancer Society, Atlanta, GA; 3) Cancer Epidemiology Unit, Nuffield Department of Clinical Medicine, University of Oxford, Oxford, UK; 4) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD.

Genotype imputation substantially increases the number of markers available for analysis in a genome-wide association study (GWAS) by leveraging information on linkage disequilibrium from a reference panel. We sought to (i) investigate the performance of imputation from the August 2010 release of the 1000 Genomes Project (1000GP) in a GWAS of aggressive prostate cancer (PCa), (ii) look for novel associations with PCa risk, (iii) fine-map known PCa susceptibility regions using two complementary approaches (an approximate Bayesian framework and stepwise regression), and (iv) compare power and efficiency of imputation and de novo sequencing designs for future genetic association studies of low-frequency and rare variants. We used a collection of 2,782 aggressive PCa cases and 4,458 controls from the NCI Breast and Prostate Cancer Cohort Consortium (BPC3) aggressive prostate cancer GWAS to infer 5.8 million well-imputed autosomal single nucleotide polymorphisms from the 1000GP reference panel. Imputation quality, as measured by correlation between imputed allele counts and true counts, varied widely from variant to variant, with common variants having higher correlations than rare variants. While our study systematically investigated associations of a subset of 1.2 million well-imputed common and low-frequency 1000GP variants with PCa risk, we found no novel associations. 1000GP imputation provided dense coverage of previously-identified PCa susceptibility regions, highlighting its potential as an inexpensive first-pass approach to fine-mapping. For example, we found a subset of highly probable potential causal variants for further analysis at 5p15 and were able to successfully replicate known multi-locus associations at 8q24 found using denser genotyping approaches. At a whole genome sequencing cost of $2,500, imputation from SNP arrays is a more powerful strategy for SNPs with minor allele frequencies (MAF) above 1%. As sequencing costs fall, whole genome sequencing will become more cost effective at higher MAF's, however; SNP arrays are likely to remain the most cost-effective strategy for common variants. Our study shows 1000GP imputation can accurately identify low frequency and rare variants in large cohorts and stresses the importance of large sample size when attempting to use imputation for association studies with low frequency and rare variants.

SHAVE - Shrinkage Estimator Measured for Multiple Visits Increases Power in GWAS of Quantitative Traits. *O. Meirelles[1], J. Ding[1], T. Tanaka[1], S. Sanna[2], H. Yang[1], D.B. Dudekula[1], F. Cucca[2], L. Ferrucci[1], G. Abecasis[3], D. Schlessinger[1].* 1) Laboratory of Genetics, National Institute on Aging, Baltimore, MD; 2) Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche, Monserrato, Cagliari, Italy; 3) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, Michigan.

Measurement error and biological variability generate distortions in quantitative phenotypic data. In longitudinal studies with repeated measurements, the multiple measurements provide a route to reduce noise and correspondingly increase the strength of signals in genome-wide association studies (GWAS). In order to optimize noise correction, we have developed Shrunken Average (SHAVE), an approach using a Bayesian Shrinkage estimator. This estimator uses regression towards the mean for every individual as a function of 1) their average across visits; 2) their number of visits; and 3) the correlation between visits. Computer simulations support an increase in power, with results very similar to those expected by the assumptions of the model. The method was applied to a real data set for 14 anthropomorphic traits in ~6,000 individuals enrolled in the SardiNIA project, with up to 3 visits (measurements) for each participant. Results show that additional measurements have a large impact on the strength of GWAS signals, especially when participants have different number of visits, with SHAVE showing a clear increase in power relative to single visits. In addition, we have derived a relation to assess the improvement in power as a function of number of visits and correlation between visits. It can also be applied in the optimization of experimental designs or usage of measuring devices. SHAVE is fast and easy to run, written in R and freely available online.

1392T

To adjust or not to adjust, how and when to incorporate covariates into GWA studies. *G.P. Page[1], N. Garge[2], E.O. Johnson[3].* 1) Statistics & Epidemiology, RTI International, Atlanta, GA; 2) Genomics, Statistical Genetics, and Environmental Research Program, Research Triangle Institute International, Research Triangle Park, NC; 3) Behavioral Health Epidemiology Program, Research Triangle Institute International, Research Triangle Park, NC.

Diseases and traits that are studied using genome wide association studies often have environmental risk factor in addition to the genetic ones. Motivated by a GWA study of HIV among IV drug users whose other significant risk factors include age, gender, number of sex partners, sex work, receptive anal sex, STIs, and needle sharing, and recruitment pre- or post- availability of antiretroviral therapy, we sought to understand how to incorporate covariates into our analysis with maximal power and minimal error. We studied the impact on type I error and power of various strategies for the incorporation of covariates into GWA studies, including: matching, reducing covariates using latent class and principle component analysis, fully adjusting for covariates in linear and logistics models, and ignoring covariate effects. In linear and logistic models, we explored the trade-off between using a single set of covariates for all SNPs in the GWA verses maximizing the model for each SNP individually. We found essentially the same performance whether we used AIC, BIC, MSE or p-values for selecting covariates. The incorporation of a false covariate only modestly decreased power to detect genetic effects. When genetic variance is 5% of total variance and environmental variance 0% of total variance, power without incorporating false covariate is 0.616 (versus 0.612 when false covariates were considered). However modeling a real covariate markedly increases power as the effect of real covariate increases. At 5% genetic variance, the power produced in the presence of 10% environment variance was 0.659 in comparison to 0.836 at 40% environment variance. The joint consideration of real and false covariates only modestly reduced power (power = 0.832). The addition of neither real (0% genetic, 40% real environmental effects, type 1 error = 0.050) nor false environmental covariates (0% genetic, 40% real environmental effects, plus false environmental effect, type 1 error = 0.050) had an effect on the type 1 error for the genetic studies. Our studies suggest that covariates can and should be incorporated into GWA studies even if there is worry that they will be false for the increase in power due to real covariates far outweighs the reduction in power due to false covariates, and that the incorporation of covariates in to GWA does not lead to type 1 biases. In addition, our studies indicate that models can be built per SNP rather than using a single model for all SNPs.

1393F

Refining association mapping in a heterogeneous population: An example in a Schizophrenia case-control study. *A. Ray[1], LC. Lazzeroni[1, 2].* 1) Psychiatry and Behavioral Sciences Department, Stanford University, Stanford, CA; 2) Pediatrics Department, Stanford University, Stanford, CA.

We propose a refined association mapping method to address the possibility of variable linkage disequilibrium (LD) structure within a heterogeneous population. Here we will consider the situation in which markers associated with a trait fall into different LD blocks although the trait frequency is the same across ancestral populations. In this setup, individuals are allowed to have mixed ancestry originating in more than one subpopulation and subpopulations are allowed to have different LD patterns. Our two-stage association statistic combines aspects of principal component adjusted analyses and stratified analyses in order to address two issues simultaneously. The ancestry proportions will be determined locally in each LD block and stratified regression will be performed with each subpopulation as strata. We will apply our method to a genome-wide study of schizophrenia (GAIN) containing phenotype and genotype data for 1 million SNPs in 2.8K European and 2.2K African American participants. We will use schizophrenia diagnosis and the total DSM score to analyze the two heterogeneous populations separately focusing on candidate genes previously characterized by the Consortium on the Genetics of Schizophrenia (COGS) for association with schizophrenia and related endophenotypes. We will compare the association signals from our proposed two-stage association method in the heterogeneous GAIN populations to the relatively homogeneous Caucasian population in COGS and to one-stage association methods that allow less complex patterns of admixture and LD.

1394W

Improved heritability estimation from genome-wide SNP data with application to epilepsy. *D. Speed[1], G. Hemani[2], M. Johnson[3], D. Balding[1].* 1) UCL Genetics Institute, University College London, London, WC1E 6BT, United Kingdom; 2) Diamantina Institute, University of Queensland, Brisbane, Queensland 4102, Australia; 3) Division of Brain Sciences, Imperial College London, London W6 8RF, United Kingdom.

There has recently been much interest in using genome-wide SNP data to estimate the heritability of complex traits (Yang et. al. Common SNPs explain a large proportion of the heritability for human height, Nat. Gen. 2010). The method has been used to investigate numerous disease and other traits, and yet many of the assumptions underpinning the mixed model on which it is based have not previously been rigorously estimated. Through extensive simulation studies, we found the method to be surprisingly robust to violations of underlying assumptions of three types: the effect size distribution, the relationship between effect size and minor allele fraction, and the number of causal variants. However, we found that the heritability estimates can be highly biased by uneven patterns of LD across the genome. In particular, the contribution of causal variants in areas of high LD (for example in the MHC region) are over-estimated, while the contribution of causal variants in areas of low LD are under-estimated. To address this problem, we propose the use of a novel kinship matrix, in which the contribution of each SNP is weighted according to local LD levels. This LD-adjusted kinship matrix almost entirely removes the biases observed in our simulation study using the standard allelic-correlation kinship matrix. Applying our method to WTCCC data, we find for certain traits the estimates of heritability can be altered by as much as 25% compared with the standard method. SNP-based heritability analysis has been used to investigate the genomic architecture of traits, by comparing the variance explained by particular subsets of SNPs, for example, genic vs inter-genic SNPs or low MAF vs high MAF SNPs. By improving its accuracy, the adjusted analysis gives a better insight into the nature of causal variants, which we illustrate with reference to epilepsy GWAS data. LD-adjusted kinship is likely to be beneficial in other application areas of kinship coefficients, such as mixed model association analysis and genomic selection.

GLOMS: A mixed model-score test based system for association studies of binary traits with risk covariates in populations of related individuals. *S. Stanhope, M. Abney.* Department of Human Genetics, The University of Chicago, Chicago, IL.

Although a variety of effective and tractable methods have been developed for performing association studies of quantitative traits with risk covariates in populations of related individuals, there are substantially fewer options for studies of binary traits. This is likely due to the comparative technical difficulty of developing methods in the mixed model regression frameworks that are typically used for such analyses, and is compounded with the fact that there is currently an increasing focus on performing not only marker-wise studies of association, but also analogous gene enrichment, gene x environment, or marker x marker studies. In this talk, we describe GLOMS (Genome-wide LOgistic mixed model / Multivariate Score test), a parallelized, computationally efficient and powerful system for performing a wide variety of types of association studies of binary traits with risk covariates in populations of related individuals. We demonstrate the application of GLOMS to several kinds of association studies of hypertension in the Hutterites, a population related though a dense 13-generation pedigree.

1396F

Tiled Regression Improves the False Discovery Rate in Genome-Wide Association Studies. *B. Suktitipat[1,2], Y. Kim[1], A.J.M. Sorant[1], H. Sung[1], A.F. Wilson[1].* 1) Genometrics Section, NHGRI/NIH, Baltimore, MD; 2) Department of Biochemistry, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand.

Most genome-wide association studies (GWAS) aim to identify causal genes based on single variant effects ignoring the effects of all other variants in the genome. Ideally, multiple regression of all the variants in the genome would identify the set of independent causal variants; however, the requirement of complete data makes this approach problematic. Tiled Regression combines simple linear or logistic regression models, stepwise selection of variables and a staged approach. User-defined regions ("tiles") of potentially correlated SNPs (e.g., based on hotspots or genes) are first considered separately and discarded if they show no evidence of association with a trait. Stepwise regression is then used to select independent significant SNPs from the remaining tiles, with higher order stepwise regression used at the chromosome and genome levels. We evaluated the performance of this approach with the Tiled Regression Analysis Program (TRAP v1.0) using simulated data. We simulated 4000 individuals with 306,097 markers spanning 53,060 tiles across the genome, based on phased data from the HapMap CEU population. To evaluate the false positive rate, we simulated 100 replicates of normally distributed random phenotypes. To evaluate the power, we simulated 100 replicates of quantitative traits from seven independent loci with the same effect size but with various locus specific heritability from 0.0005 to 0.01 assuming additive genetic model. A critical value of 0.0001 was used as the selection criteria for the stepwise regression for the tile, chromosome, and genome levels. We compared our results to conventional single marker analysis based on simple linear regression model testing one marker at a time. On average, the type I error for TRAP was 5E-05, about one-half of the nominal type I error rate. TRAP had a false discovery rate (FDR), calculated as a proportion of false positive signals divided by all positive signals, of 0.76, which was better than the FDR of 0.86 from single marker analysis using the same statistical significant level. Power estimated with TRAP was comparable to the power estimated from single marker analysis. In summary, in a GWAS setting, we found that TRAP has comparable power but with a lower FDR when compared to single marker analysis. Thus, the use of TRAP is beneficial in selecting independent markers contributing to quantitative trait and in reducing the false discovery rate in GWAS.

1397W

Gene-based association tests using dimension reduction methods and marker correlation structure. *D.M. Swanson, C. Lange.* Biostatistics, Harvard University, Boston, MA.

The advent of genome-wide association studies has led to many novel disease-SNP associations, opening the door to focused study on their biological underpinnings. Because of the importance and relative simplicity of analyzing these associations, many statistical methods have been devoted to them. However, fewer methods have attempted to associate entire genes or genomic regions with outcomes, which is potentially more useful knowledge from a biological perspective. We develop two methods for quantifying the degree of association between a genomic region and outcome, both of which adequately control for LD structure in the region. One method uses dimension reduction methods when significant LD exists in the region to "filter" redundant information and increase power, while the other controls for LD by scaling marker Z-statistics using knowledge of the correlation matrix of markers. We apply both methods to sequence data of oral cleft and compare our results to previously proposed methods, in particular permutation-based ones. We find a significant association in the sequence data between the 8q24 region and oral cleft using our dimension reduction approach and a borderline significant association using the Z-statistic-based approach.

1398T

Impact of hidden sample structure on meta- and joint-analysis in genome-wide association studies. *P.J. Walter, H.M. Kang.* Biostatistics, University of Michigan, Ann Arbor, MI.

Genome wide association studies (GWAS) have shown the ability to detect novel loci associated with many human diseases but issues of hidden relatedness and population structure continue to engender spurious associations and high Type I error. While joint-analysis across multiple studies may provide high power, meta-analysis is often used in practice for convenient and secure analysis with robust control against heterogeneity among studies. Under confounding effect from population structure, correcting for hidden sample structure via principal component analysis or linear mixed models is typically recommended for joint-analysis. However, it is not clearly understood how these strategies behave in the context of meta-analysis with unknown pairwise genetic relatedness between different study samples. Through simulated phenotypes under a variety of polygenic models across nearly ten thousand individuals, we evaluated the statistical power and Type I error across different strategies of joint- and meta-analyses. We find that meta-analysis provides comparable power to joint-analysis for detecting common causal variants. We also find that, while joint-analysis with mixed models is slightly better at prioritizing causal SNPs than principal component correction, they perform similarly in meta-analysis. Compared to uncorrected analysis, we find that correcting for hidden sample structure within studies is better at prioritizing causal SNPs, and accounting for sample structure across studies, if possible, provides even slightly better results. We also evaluate the impact of different strategies of applying genomic control in meta-analysis. Finally, we evaluate different meta- and joint- analysis strategies focusing on low frequency variants. We expect that our results will serve as a useful guidance in designing genetic analysis of complex traits across multiple studies.

1399F

Natural and Orthogonal association framework to detect parent-of-origin effects. *F. Xiao, J. Ma, C. Amos.* UT M.D Anderson Cancer Center, Houston, TX. 1515 Holcombe Blvd. Houston, TX 77030 1-877-MDA-6789.

Many human diseases, such as cancer, diabetes and obesity may be related to imprinted genes. Traditional association studies always assume equal contribution of the paternal and maternal alleles to the trait. Recently many studies have revealed that the power of GWAS could be improved when the parent-of-origin effect (POE) is considered in the analysis model, while searching for complex disorders related genes. In the natural and orthogonal interaction (NOIA) framework which was developed for the quantitative trait analysis by Alvarez-Castro and Carlborg [Genetics, 2007], the estimates of genetic effects are unrelated, also called orthogonal. Therefore I proposed that the power of NOIA could be improved when POE is considered in the analysis model while keeping its orthogonality. Thus we may detect some novel significant genes that associate with complex disease, which were masked before in usual models. We conducted simulations to evaluate the performance of the statistical models in comparison with the usual functional models. We also compared the power of NOIA models with and without POE considered. The results showed that the power for testing associations while allowing for POE considered using the statistical model is much higher than using usual functional models. And as expected, even with the POE considered, the statistical model is still orthogonal for detecting both overall genetic effect and POE effect. We also applied our approach to family data about oral cleft disorder.

Efficient calculation for multi-SNP genetic risk scores. *T. Johnson.* GlaxoSmithKline, Stevenage, United Kingdom.

Genetic risk scores based on genotypes at multiple single nucleotide polymorphisms (SNPs) have several applications in association studies for complex human phenotypes. However, for many human diseases and traits of clinical importance, identifying genetic associations has required large sample sizes, so single SNP associations typically use meta-analysis summary results obtained from multiple genotype-phenotype datasets held at different institutions. In such settings, testing association between a multi-SNP genetic risk score and a phenotype is prone to organisational difficulties and potential for analytic error. I have developed a convenient "summary statistic" method, which allows most powerful testing of association between a multi-SNP genetic risk score and a phenotype, when only single SNP summary association statistics are available. The method is thus both statistically and computationally efficient. The method has been applied to genetic risk scores for blood pressure, adiponectin, and lipid levels, in several recent publications (Ehret et al. Nature 478:103–109, Dastani et al. PLoS Genetics 8:e1002607, Voight et al. Lancet online early), but the method itself has hitherto not been described in detail. I show that the "summary statistic" method gives comparable results to direct analyses of subject-specific phenotype and genotype data, shows increased power in genetic risk score analyses compared to alternative methods that combine information across SNPs, and demonstrate a novel diagnostic plot and goodness of fit test for the genetic risk score model. The latter may help to identify SNPs with pleiotropic effects, and may indicate situations where a Mendelian randomisation interpretation is not appropriate. I illustrate the method by application to previously published GWAS meta-analysis results for serum lipid traits and for risk of coronary artery disease (CAD). The results suggest that both serum high density lipoprotein (HDL) cholesterol, and serum triglycerides, are not themselves valid therapeutic targets for primary prevention of CAD. These results complement recent similar results for HDL and myocardial infarction (Voight et al. Lancet online early).

Gene-gene co-association and pathway-based co-association studies for next generation sequencing. *L. Luo[1], M. Xiong[2].* 1) Division of Epidemiology and Biostatistics, Department of Internal Medicine, University of New Mexico, Albuquerque, NM; 2) Division of Biostatistics, Human Genetics Center, The University of Texas School of Public Health, Houston, TX.

Systematically investigating the genetic architecture of common diseases requires complete knowledge of the human DNA sequence variations including SNPs, CNVs and other structural variations across the entire allele frequency spectrum. It has been increasingly realized that gene-gene interactions and the contribution of rare variants could be two potential factors in finding the unexplained disease heritability. However, to develop powerful statistics for testing gene-gene interaction based on data generated from next-generation sequencing remains great challenges for genetic epidemiologists and biostatisticians: (1)rare variants will be difficult to distinguish from sequencing errors in NGS studies; (2) existing statistical methods are underpowered to detect the interaction; (3) taking single SNPs as the basic units of interaction analysis will encounter severe multiple testing problems and heavy computations. To meet the challenges in testing the interaction between genetic variants, we propose to develop a novel concept of gene-gene co-association in which a gene or a genomic region is taken as a unit of association analysis and employing the stochastic processes to develop a unified framework for testing the co-association with disease of two genes, and multiple genes constituting a pathway, that contain both common and rare variants. We also developed a modified co-association analysis method which takes population stratification into consideration. We performed extensive simulations to validate the null distribution, and results showed that the newly developed statistic has type I error rates not appreciably different from the expected nominal level. Application to two independent GWAS datasets of psoriasis identified a network of gene-gene co-association that can be replicated in both studies. Results also showed that a pair of genes, each with no marginal association, may be jointly associated with disease.

May consanguinity between parents be a risk factor for insulin resistance in childhood obesity? Role of Mitochondrial Uncoupling protein 2 (UCP2) gene polymorphism. *S. Oguzkan Balci[1], N. Col-Araz[2], M. Nacak[3], M. Araz[4], S. Halime[1], A. Balat[5], S. Pehlivan[1].* 1) University of Gaziantep, Faculty of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey; 2) University of Gaziantep, Faculty of Medicine, Department of Pediatrics, Gaziantep, Turkey; 3) University of Gaziantep, Faculty of Medicine, Department of Pharmacology, Gaziantep, Turkey; 4) University of Gaziantep, Faculty of Medicine, Department of Endocrinology and metabolism, Gaziantep, Turkey; 5) University of Gaziantep, Faculty of Medicine, Department of Pediatric Nephrology, Gaziantep, Turkey.

Objectives: Obesity is a global health problem, and frequently associated with metabolic complications such as type 2 diabetes mellitus. Childhood obesity will contribute to an increased prevalence of adult obesity. Uncoupling protein 2 (UCP2), a mitochondrial protein, plays an important role in thermogenesis and energy metabolism that might be related with the early onset of obesity or insulin resistance. The aim of this study was to investigate whether polymorphisms of-866 A/G UCP2 gene may be associated with childhood obesity and insulin resistance. **Methods:** A hundred obese children and adolescent and 100 age-and sex-matched healthy controls were tested for two polymorphisms which were -866 A/G promoter and exon 8 insertion/deletion (I/D) polymorphisms in UCP2 gene. Genotyping were performed by PCR and/or RFLP. Insulin resistance was determined as homeostasis model assessment >3.16 (HOMA). **Results:** Exon 8 I/D polymorphism in UCP2 gene showed an association with obesity. The distribution of DD, ID and II genotypes for the gene was 46.0 %,31.0 % and 23.0 % in obese subjects compared with 65.0 %, 30.0 % and 5.0 % in the controls. II genotype was higher in obese patients ($p=0.0001$), while DD genotype was higher in controls ($p=0.0034$). There were no statistically significant differences in the UCP2 gene -866 A/G promoter polymorphism between groups ($p>0.05$). There was also no statistically significant difference between -866 A/G promoter and exon 8 I/D polymorphisms in UCP2 gene and insulin resistance in childhood obesity ($p>0.05$). But if there was an consanguinity between parents GA genotype and A allele were associated with insulin resistance in chilhood obesity ($p<0.05$). Conclusion: Our results suggest that II genotype, of exon 8 of UCP2 gene was associated with childhood obesity, while -866 G/A poymorphism was not. However, GA genotype and A allele were associated with susceptibility to insulin resistance in case of an consanguineous marriage. However, further studies with larger sample size are needed in order to have a better understanding on the effect of this gene in childhood obesity and insulin resistance.

A Gene-based Association Statistic for Meta-Analysis. *P. Chanda[1,5], H. Huang[2,3], A. Alonso[4], J.S. Bader[1,5], D.E. Arking[6].* 1) Department of Biomedical Engineering, Johns Hopkins University, Baltimore, Maryland, USA; 2) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital, 185 Cambridge St., Boston, Massachusetts, USA; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, 7 Cambridge Center, Cambridge, Massachusetts, USA; 4) Division of Epidemiology and Community Health, School of Public Health, University of Minnesota, Minneapolis, Minnesota, USA; 5) High Throughput Biology Center, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 6) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA.

Gene-based association analysis has emerged as a powerful complement to identifying disease associated genes using traditional genome-wide single SNP association tests. In a gene-based analysis, one jointly analyzes all independent variants within a putative gene to obtain a single p-value representing the significance of association of the entire gene. When individual level genotype and phenotype data are not available, often due to restrictions on sharing data across cohorts, only the genotype-phenotype summary statistics are available for further analysis. We present a Bayesian method of greedy model selection combining multiple independent effects within a gene to generate a stronger association signal using summary data from a meta-analysis. Our method uses summary data (regression coefficients and standard errors) to perform efficient model selection (selecting a minimal subset of associated SNPs within a gene), parameter estimation and statistical testing (calculating gene-based p-values and genome-wide significance thresholds). The model selection procedure includes a model complexity penalty based on the number of effective SNPs within a gene and a Bayesian Information Criterion penalty that permits a fast estimate of the model likelihood through the sufficient statistics of the maximum likelihood estimator. In the absence of individual level genotype and phenotype data, the empirical p-values are computed by simulating z-scores under the null using random variates sampled from a multivariate normal distribution with covariance matrix computed from the linkage disequilibrium between the SNPs in an appropriate reference population (e.g. HapMap or 1000 Genomes Project). When applied to meta-analysis from genome-wide scans of Atherosclerosis Risk in Communities (ARIC) electrocardiographic traits, we recovered known associations (gold standard loci) with multi-SNP models with power similar to individual level genotype data. Our preliminary results indicate that the proposed method has the potential to identify additional novel disease-susceptibility genes for complex diseases using summary data from large GWAS datasets.

Joint testing of rare and common variants in admixed populations. *H. Qin, J. Li, H.-W. Deng.* Center for Bioinformatics and Genomics, Department of Biostatistics and Bioinformatics, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA.

An admixed population and its ancestral populations bear different burdens of a complex disease, partially due to different frequencies of deleterious alleles. Deleterious alleles and allele ancestries are dependently distributed among admixed subjects. Within a susceptible gene, the affected and unaffected groups in an admixed population may differ in the marginal distributions of mutation accounts and allele ancestries as well as in the correlations between genotypes and ancestries. The next-generation sequencing technologies are enabling us to discover nearly all rare and common variants. As evidenced by ample empirical findings, rare and common genetic variants as well as environmental factors may work together to influence complex diseases. We propose a novel gene-based framework to integrate local ancestries with rare and common genetic variants in next-generation sequence data of admixed subjects. In this framework, we combine ancestries, genotypes, ancestry-gene interactions across variant sites in a gene by informative weights (e.g., signal-to-noise ratios) to enrich genetic information. We link the enriched genetic information to disease status through a regression model to adjust for covariates (e.g., population structure and environmental factors) and construct a suitable test statistic. Under the null of no association, the test statistic asymptotically follows the chi-square distribution with one-degree-of-freedom (1-df). Our framework allows for genetic effects of diverse sizes and directions and corrects for arbitrary covariates. It properly controlled type I error rates under extensive high-replicate simulations. Under various modes of disease genetics, our framework proved uniformly more powerful than several popular sequence association tests, e.g., the CAST, the SDWSS and the EREC. We demonstrated the prevailing utility to integrate local ancestries, rare variants, common variants and ancestry-gene interactions. Our novel framework can be potentially applied in next-generation sequence association studies of admixed populations.

The role of KIR genes polymorphisms in Brazilian patients with rheumatoid arthritis and systemic lupus erythematosus. *A.R. Marrero[1], T.D.J. Farias[1], C.C. Coêlho[1], L.D. Hausmann[1], D.G. Augusto[2], M.L. Petzl-Erler[2], I.A. Pereira[3], A.F. Zimmermann[3], S.C.M.S. Fialho[3], Y.C.N Muniz[1], I.R. Souza[1].* 1) LAPOGE, Federal University of Santa Catarina, Florianopolis, Santa Catarina, Brazil; 2) Federal University of Paraná, Curitiba, Paraná, Brazil; 3) HU, Federal University of Santa Catarina, Florianopolis, Santa Catarina, Brazil.

Rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) are a common autoimmune diseases that affects worldwide population, with female prevalence and characterized by a complex disease and unknown etiology. RA disease affects mainly the joints but can also compromise heart, lung, and eyes functions, while SLE disease affects kidney, lungs and heart functions and development arthritis and rash. The role of immune system in autoimmune pathogenesis is unclear, but the Natural Killer (NK) cells and its cytokines production behave differently in RA and SLE patients. The Killer-cell Immunoglobulin like Receptors (KIRs) are NK cell surface proteins that play an important role modulating the cytotoxicity on innate and adaptive immune system cells. In this study the genotyping was carried out by PCR-SSP from peripheral blood leucocytes of 145 RA, 166 SLE and 270 controls unrelated donors from Universitary Hospital of Federal University of Santa Catarina (Brazil). To eight KIR's genes, the difference in the presence frequency of individual KIR genes in cases and control was tested for significance using Chi square test and Odd Ratios was calculated, and $p<0.05$ was considered significant. Gene frequencies found in the present study were: KIR3DL3 (1.0), KIR2DL3 (0.942), KIR2DS3 (0.373), KIR2DS5 (0.430), KIR2DL4 (0.957), KIR3DS1 (0.436), KIR2DS4 (0.704) and KIR3DL2 (0.996). These frequencies are very similar to frequencies found in another Brazilian population from a different region. The activating KIR genes KIR2DS5 (OR=4.75, $p<0.0001$), KIR2DS3 (OR=2.117, $p=0.003$), and KIR3DS1 (OR=2.242, $p<0.0001$) were associated only with SLE, and the inhibitory genes KIR2DL3, KIR3DL3, KIR2DL4, KIR3DL2 gene was not associated with RA and SLE ($p>0.05$). These results may be indicating a potential role for NK cells in SLE pathogenesis since KIRs interact through its alleles to enhance the inflammatory response (Financial support: PNPD CAPES, FAPESC, CNPq and UFSC).

Genome-wide linkage, association and gene expression analysis of antibody levels against 13 common infections. *R. Rubicz[1], R. Yolken[2], E. Drigalenko[1], M.A. Carless[1], T.D. Dyer[1], P.E. Melton[1,3], J.W. Kent, Jr.[1], R. Duggirala[1], J.E. Curran[1], M.P. Johnson[1], S.A. Cole[1], L. Almasy[1], E.K. Moses[1,3], N.V. Dhurandhar[4], E. Kraig[5], J. Blangero[1], C.T. Leach[6], H.H.H. Goring[1].* 1) Dept of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Stanley Division of Developmental Neurovirology, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Centre for Genetic Epidemiology and Biostatistics, The University of Western Australia, Perth, Australia; 4) Infections and Obesity Laboratory, Pennington Biomedical Research Center, Louisiana State University System, Baton Rouge, LA; 5) Department of Cellular and Structural Biology, University of Texas Health Science Center at San Antonio, San Antonio, TX; 6) Department of Pediatrics, University of Texas Health Science Center at San Antonio, San Antonio, TX.

There are individual differences in susceptibility to infectious diseases, which are attributable to a number of potential factors including host genetic variation. We previously demonstrated that differences in antibody titer, which reflect history of infection with a particular pathogen, are significantly heritable. Here we conduct genome-wide analyses using 3 genome-wide gene mapping technologies in order to identify genetic factors influencing variation in these serological phenotypes. Blood samples from >1300 Mexican Americans were quantified for IgG antibody titer to 13 common bacterial and viral infections: *Chlamydia pneumoniae*; *Helicobacter pylori*; *Toxoplasma gondii*; cytomegalovirus; Epstein-Barr virus (EBV); herpes simplex I virus; herpes simplex II virus; human herpesvirus 6; varicella zoster virus; adenovirus 36 (Ad-36); hepatitis A; influenza A; and influenza B. The quantitative antibody titer phenotypes were analyzed for each pathogen and for several measures of seroreactivity to multiple pathogens (i.e., all herpesviruses, all viruses, and all pathogens). Genome-wide variance components linkage yielded significant LOD scores for EBV (on chromosome 6), influenza A (on chromosome 6), and Ad-36 (on chromosome 18). Joint linkage and association analyses (using an additive measured genotype model and ~1 million SNPs) produced genome-wide significant results for EBV on chromosome 6 ($p = 1.1 \times 10^{-12}$). Results for measures of seroreactivity to multiple pathogens, however, were not significant. Microarray-based gene expression data (for >16,000 transcripts, generated from peripheral blood lymphocytes collected at the same time as the blood samples used for serological phenotyping) led to identification of significantly correlated transcripts for approximately half the pathogens. Further investigation of anti-EBV antibody variation indicates this trait is influenced by multiple genetic factors within the human leukocyte antigen (HLA) complex, which are specific to this pathogen and not infection in general. Our results demonstrate that individual loci regulating serological measures of these common infections do exist and can be localized by statistical gene mapping approaches.

Combining Affected Families, Independent Cases, and Controls to Obtain a Single, More Powerful Test of Association. *W. Stewart[1], J. Cerise[2].* 1) Battelle Center for Mathematical Medicine, The Research Institute, Nationwide Children's Hospital, Columbus, OH; 2) Dept Biostatistics, Columbia University, New York, NY.

Over the last few decades, investigators have begun to accumulate complicated data sets that contain affected families, independent cases, and controls. However, the statistical complexity of these data sets makes them difficult to analyze efficiently, and in effect, this has encouraged investigators to perform suboptimal analyses instead. Therefore, we propose a unified test that is the weighted average of a population-based (e.g. case-control) and a family-based (e.g. TDT) test of association. Since both tests are influenced by a common set of genotypes (namely, the genotypes of cases within affected families), the two tests are correlated. Our unified test accounts for this correlation; and for large samples, its distribution is approximately normal (with mean zero and variance one) under the null hypothesis of no association. To assess the power and the type I error of our unified test, which we have implemented in the program POPFAM, we simulated genotypic and phenotypic data across: different genetic models, minor allele frequencies, and levels of correlation between the test SNP and the trait locus. We compared POPFAM to existing methods, and we applied it to the analysis of a real hypertension study as well. Our simulations show that POPFAM is more powerful than individual case-control or family-based tests of association, and that, for some scenarios POPFAM is more powerful than other methods that combine population-based and family-based evidence of association. Finally, in our re-analysis of a familial arterial hypertension study, we integrated information from publicly available HapMap controls to reduce the p-value at a candidate SNP. Overall, in regions containing prior evidence for linkage, POPFAM provides increased power to detect an association. In addition, the software is user-friendly, well documented, and freely available from the web.

We propose a novel approximate inference methodology to identify the subset of rare variants within a gene that drives association with phenotype. While many burden tests have been proposed to identify genes with an aggregation of rare variants associated with phenotype, they generally lack the capability to identify which rare variants are responsible for the association with phenotype. This is both biologically and statistically relevant for mapping rare variation because previous work indicates that even among non-synonymous mutations, likely only 15–20% are functional. Our approach specifically models the presence of both functional and neutral variants with a discrete mixture distribution. We show through simulations that our approach has greater or comparable power to other popular burden tests such as the Combined Multivariate and Collapsing (CMC) method, the Sequence Kernel Association Test (SKAT), the Weighted Sum Statistic (WSS), the Variable Threshold (VT) method, and the Gene or Region-based Analysis of Variants of Intermediate and Low frequency (GRANVIL) method, while also identifying the subset of rare variants associated with phenotype. Our algorithm leverages a fast variational Bayes approximate inference methodology to scale to exome-wide analyses. To demonstrate the efficacy of our approach we analyze platelet count within the National Heart, Lung, and Blood Institute's Exome Sequencing Project. Platelet count is a potentially important intermediate phenotype for blood and thrombotic diseases and has a reported heritability in the range of 50–70%. Through a recent genome-wide association study with imputed exome data in African Americans, several common and lower-frequency variants associated with platelet count have been identified. Using our novel mixture modeling approach, as well as other popular burden methods including the SKAT, GRANVIL, VT, and WSS methods, we identify novel genes with nominally significant exome-wide associations. For these genes we demonstrate the advantage of our mixture method over competing methods by discriminating between putative functional and neutral variants based on the estimated posterior probability of association for each variant from the mixture model.

1409W

Detecting Association of Rare Variants by Testing an Optimally Weighted Combination of Variants in Family-based Designs. *Q. Sha, S. Fang, S. Zhang.* Mathematical Sciences, Michigan Technological University, Houghton, MI.

Although next-generation sequencing technology will soon allow sequencing the whole genome of large groups of individuals, the development of powerful statistical methods for rare variant association studies is still underway. Even though many statistical methods have been developed for mapping rare variants, most of these methods are for unrelated individuals only, whereas family data have been shown to improve power to detect rare variants. Most of the existing methods for unrelated individuals are essentially testing the effect of a weighted combination of variants with different weighting schemes. The performance of these methods depends on the weights being used. Recently, Sha et al. (Genetic Epi, 2012) proposed a Test to test the effect of an Optimally Weighted combination of variants (TOW) for unrelated individuals. It has been shown that TOW performs better than others, especially when both risk and protective variants are presence or there are a large number of neutral variants. In this article, we extend our previously developed TOW for unrelated individuals to family-based data and propose a novel Test to test the effect of an Optimally Weighted combination of variants for Family-based design (TOW-F). The optimal weights are analytically derived and can be calculated from children's genotypes and phenotypes. TOW-F is based on within-family information and thus is robust to population stratification. Using extensive simulation studies, we evaluate and compare our proposed method with the following three methods (1) Weighted Sum Family-Based Association Test (WS-FBAT) that is based on the weight suggested by Madsen and Browning (PLoS Genet 5:e1000384, 2009); (2) Tmax = max {Ti}, where Ti is the FBAT at the ith variant; (3) Adaptive Weighting FBAT (AW-FBAT) in which, we calculate adaptive weights using between-family information, then use FBAT to test for regional association based on the adaptive weighted combination of variants (Fang et al., Genetic Epi, DOI:10.1002/gepi.21646, 2012). Our results show that the proposed method is robust to population stratification, robust to the direction and magnitude of the effects of causal variants, and is more powerful than the other three methods, especially when both risk and protective variants are presence.

1410T

Haplotype-based methods for detecting uncommon causal variants with common SNPs. *N. Liu[1], W. Lin[2], N. Yi[1], D. Zhi[1], K. Zhang[1], G. Gao[3], H. Tiwari[1].* 1) Dept Biostatistics, Univ Alabama at Birmingham, Birmingham, AL; 2) Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 3) Department of Biostatistics, Virginia Commonwealth University, Richmond, Virginia.

Detecting uncommon causal variants (minor allele frequency (MAF) < 5%) is difficult with commercial single-nucleotide polymorphism (SNP) arrays that are designed to capture common variants (MAF > 5%). Haplotypes can provide insights into underlying linkage disequilibrium (LD) structure and can tag uncommon variants that are not well tagged by common variants. In this work, we propose a wei-SIMc-matching test that inversely weights haplotype similarities with the estimated standard deviation of haplotype counts, to boost the power of similarity-based approaches for detecting uncommon causal variants. We then compare the power of the wei-SIMc-matching test with that of several popular haplotype-based tests, including four other similarity-based tests, a global score test for haplotypes (global), a test based on the maximum score statistic over all haplotypes (max), and two newly proposed haplotype-based tests for rare variant detection. With systematic simulations under a wide range of LD patterns, the results show that wei-SIMc-matching and global are the two most powerful tests. Among these two tests, wei-SIMc-matching has reliable asymptotic P values, whereas global needs permutations to obtain reliable P values when the frequencies of some haplotype categories are low or when the trait is skewed. Therefore, we recommend wei-SIMc-matching for detecting uncommon causal variants with surrounding common SNPs, in light of its power and computational feasibility.

1411F

Multivariate Adjusted Sequence Kernel Association Test for Rare Variants Controlling for Cryptic and Family Relatedness. *K. Oualkacha[1,2], R. Li[2], B. Richards[2,3,4,6], A. Ciampi[4], C. Greenwood[2,4,5], UK10K cohorts group.* 1) Mathematics, Université de Québec à Montréal (UQÀM), Montreal, Québec, Canada; 2) Lady Davis Institut, Jewish General Hospital, Montreal, Québec, Canada; 3) Medicine, McGill University; 4) Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, Québec, Canada; 5) Oncology, McGill University, Montreal, Québec, Canada; 6) Human Genetics, McGill University, Montreal, Québec, Canada.

We have recently developed a framework for association testing of rare variants in family-based designs. This framework is an adaptation of the sequence kernel association test (SKAT) which allows us to control for family structure. Our adjusted SKAT (ASKAT) combines the SKAT approach and the factored spectrally transformed linear mixed models (FaST-LMM) algorithm to capture family effects based on a linear mixed model incorporating the realized proportion of the genome that is identical by descent between pairs of individuals. ASKAT is fast and can analyze hundreds of thousands of markers. Moreover, regardless the level of the trait heritability and the sample structure, the ASKAT framework has good control of type I and provides good power. Despite the performance of this method, power for rare-variant association tests is always a concern. Most currently used methods analyze a single phenotype at a time. However, often multiple correlated phenotypes are collected and the single-phenotype analyses do not exploit this correlation. Multivariate-phenotype analysis has been shown to provide greater statistical power than single trait analysis in linkage studies and in genome-wide association studies (GWAS) of complex diseases/traits, but has not received attention in rare variant association tests. We have developed a multivariate analytical method for rare variant association study in family-based or mixed designs, which is an extension of the ASKAT framework to high dimensions. Our approach, (MASKAT), controls the sample structure, the polygenic pleiotropy and the environmental effects based on a multivariate unbalanced mixed model. Performance is validated through extensive simulation studies. Under different simulation scenarios, the results show that our MASKAT approach outperforms rare-variant single-phenotype approaches in terms of power. In particular, MASKAT has substantial advantages when a positive phenotypic correlation between traits exists. Overall and learnt from this approach, to gain power when multiple correlated phenotypes are available, we would recommend in practice the use of MASKAT approach. We plan to apply our methodology to the bone density data from the UK10K consortium.

1412W

Robust and powerful tests for rare variants using Fisher's method to combine evidence of association from two or more complementary tests. *A. Derkach[1], J.F. Lawless[2,3], L. Sun[1,2].* 1) Statistics, University of Toronto, Toronto, Ontario, Canada; 2) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 3) Statistics and Actuarial Science, University of Waterloo, Waterloo, Ontario, Canada.

Many association tests have been proposed for rare variants, but there is uncertainty about the practical choice of a good test due to lack of insight concerning the underlying genetic models. Current methods use either linear statistics, which are powerful when almost all variants are causal and have the same direction of effect, or quadratic statistics which are more powerful in other scenarios. The differences in power, unfortunately, can be significant in many settings, e.g. 20% vs. 60% or vice versa To achieve robustness, we propose using Fisher's method to combine evidence from the complementary linear and quadratic statistics. We can also consider minimum-p as another robust statistic. Analytical results and extensive simulation studies of over 10,000 different models for studies of both binary and quantitative traits show that both Fisher's and minimum-p methods are robust across genetic models with varying proportions of causal, deleterious and protective rare variants, variant frequencies, effect sizes and the relationships between variant frequencies and effect sizes. Further, Fisher's method consistently outperforms the minimal-p approach and the individual linear and quadratic tests in several plausible scenarios, for example, when at least 75% of the causal effects are in the same direction (either deleterious or protective). When a linear or quadratic test has moderate power of 20% or more, Fisher's test has considerable better power than each test for 90% of the models considered, while the maximum absolute power loss is 8% for the remaining 10% of the models. An application to the Genetic Analysis Workshop (GAW) 17 quantitative trait Q2 data based on sequence data from the 1000 Genomes Project shows that, compared with the individual linear and quadratic tests, Fisher's test not only has comparable power for all 13 functional genes, but it also provides the best power for more than half of them. The general concept of using Fisher's method to borrow information from two or more existing but complementary methods applied to the same data, beyond the traditional setting of meta-analysis of multiple data resources, to provide robust and (in some scenarios) more powerful tests can be readily extended and useful to many other genetic and genomic studies.

Leveraging family history in genome-wide association studies. *A. Ghosh, S. Wacholder, P. Hartge, M. Purdue, S. Chanock, N. Chatterjee.* Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD.

Participants in many genome-wide association (GWA) studies provide information on history of cancers in family members, particularly first-degree relatives. Mendelian law implies that genotypes of susceptibility markers will be associated with participants' family history; nonetheless, information on association between genetic markers and family history is ignored in standard analyses aimed at gene discovery.

We propose a novel meta-analysis approach that combines association signals from both the primary case-control outcome and the family-history information. Weights used in standard meta-analysis typically accounts for precision of association parameter estimates. Our modification to standard meta-analysis weights also incorporates expected attenuation of strength of association between genotype and family history due to inference of distribution of relatives' genotypes from that of participants. To evaluate the method empirically we used genotype and family history data from 6,411 men and women from the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO) cohort included in previously conducted GWA studies. Specifically, we evaluate the performance of the proposed approach in studying associations with 30 single-nucleotide polymorphisms (SNPs) previously established as prostate cancer susceptibility markers. We report the median and the mean of the ratio of the chi-square statistics from case-control and meta-analysis over 30 SNPs to evaluate relative efficiency.

We show that meta-analysis further strengthens evidence for genetic association, at times by a few orders of magnitude. For rs4242382, the SNP most strongly associated with prostate cancer, the p-values are 1.1×10^{-7} and 4.8×10^{-10} from standard case-control and meta-analysis respectively. The mean and median of the ratio of chi-squares from meta-analysis and case-control analysis are 1.62 and 1.25 respectively, which matches with our expectation from theoretical calculation of asymptotic relative efficiency.

Routinely collected information about family history in studies used in GWA can increase the power of detecting association between a genetic variant and disease at no extra cost.

Identifying environmental exposures for gene-environment investigations using LASSO penalized regression methods. *E. Mowry[1], X. Shao[2], F.B.S. Briggs[2], B. Acuna[3], L. Shen[3], A. Bernstein[3], C. Schaefer[3], L.F. Barcellos[2].* 1) Department of Neurology, JOhn Hopkins Hospital, Baltimore, MD; 2) Genetic Epidemiology and Genomics Laboratory, Division of Epidemiology, School of Public Health, University of California, Berkeley, Berkeley, CA; 3) Division of Research, Kaiser Permanente, Oakland, CA.

In epidemiological studies with detailed genetic and environmental exposure data, determining key predictors for gene-environment (GxE) analyses is challenging, as the ordinary least squares model may become oversaturated. In addition to multiple testing concerns, the underlying correlation structure between predictors may introduce residual confounding. Thus, we are motivated to implement variable selection to identify trait-associated predictors for investigation. LASSO (least absolute shrinkage and selection operator regression) is a popular penalized statistical method that can address these challenges, and can be summarized as calculating the regression coefficients by minimizing the penalized sum of squares. Therefore, LASSO may be considered as a variable selection method for the OLS model, and there is high probability that the predictors selected contain the true set of effective variables. We applied LASSO to identify a subset of environmental exposures for GxE analyses in a large population-based multiple sclerosis (MS) case-control study. MS is a complex autoimmune disease of the central nervous system, with genetic and environmental components. More than 50 risk loci have been identified, however only a few environmental exposures have been confirmed, including tobacco smoke exposure, history of infectious mononucleosis, and vitamin D intake. LASSO was applied to a large data set of 1503 white female (914 MS cases and 589 controls) members of the Kaiser Permanente Northern California membership. Thirteen environmental exposures were studied, including several cosmetic, occupation, chemical and animal exposures. These predictors, known MS environmental risk factors, socioeconomic status (SES) and age were evaluated by LASSO. Ten-fold cross-validation determined the shrinkage parameter that minimized the variance. Six exposures had non-zero coefficients in LASSO regression. Logistic models, adjusted for known environmental risk factors, age, SES, *HLA-DRB1*15* and the weighted genetic risk score assessed the relationship between the selected predictors and MS risk. Our results did not show a strong effect on MS susceptibility for any of the environmental exposures investigated. Here, we demonstrate the application of LASSO to identify a subset of environmental exposures from a large dataset with reduced penalty for multiple statistical test.

1415W

Application of targeted maximum likelihood estimation using genome-wide association data reveals new genetic predictors of disease severity in multiple sclerosis. *X. Shao[1], M. van der Laan[1], F. Briggs[2], P. De Jager[3,4], L. Barcellos[2], The International Multiple Sclerosis Genetics Consortium.* 1) Division of Biostatistics, School of Public Health, University of California, Berkeley, CA 94720-7356, USA; 2) Division of Epidemiology, School of Public Health, University of California, Berkeley, CA 94720-7356, USA; 3) Program in NeuroPsychiatric Genomics, Center for Neurologic Diseases, Department of Neurology, Brigham & Women's Hospital and Harvard Medical School, Boston, MA 02115, USA; 4) Program in Medical & Population Genetics, Broad Institute of Harvard University and Massachusetts Institute of Technology, Cambridge, MA 02139, USA.

Genome-wide association studies (GWAS) have been widely used for identifying disease associated loci. With high-throughput genotyping technology, GWAS test millions of variants across the human genome. Multiple sclerosis (MS) is a chronic inflammatory disorder of the central nervous system with a strong genetic component which influences both disease onset and progression. Studies have shown that the genetic architecture of MS progression is likely polygenic and comprised of moderate effects. Due to insufficient power and lack of efficient methods to correct for multiple testing, GWAS have not been fruitful in identifying risk loci for disease severity. Therefore, rather than assessing the causal effect of SNPs based on GWAS, it is more reasonable to consider GWAS as a screening tool for disease gene discovery. This study aims to identify candidate genes that may influence disease severity, measured by MS Severity Score (MSSS). A two-stage analytical method was applied to a genome-wide SNP data which consisted of two million SNPs for 1,470 MS cases. The phenotype was less severe disease (MSSS≤5) vs. more severe disease (MSSS>5). In the first stage, univariate logistic regression was applied to the two millions SNPs. Lasso was applied to SNPs with marginal unadjusted p-value<0.05 from univariate tests and was reduced to 1,011 independent SNPs. In the second stage, targeted variable importance measures (tVIM) based on targeted maximum likelihood estimation (TMLE) were obtained for each SNP. tVIM is an updated TMLE estimate based on the initial estimator and the confounding mechanism between the targeted SNP and a set of related SNPs. P-values were computed for the marginal tVIM, and modified FDR control for multi-stage analysis was applied. The candidate loci were selected based on adjusted p-values (P<0.05). The most significant finding was a non-genic SNP: rs11765846 on 7q21.2 (P=1×10-17). The top genic results were *C1orf49* on 1q25.2 (rs12754916: P=2×10-11); *ABCA9* on 17q24.2 (rs17684521, a missense SNP: P=2×10-09); *AMPH* on 7p14-p13 (rs17171399: P=5×10-7); *PTPRD* on 9p23-p24.3 (rs10977017: P=2×10-5; rs1322133: P=0.04); and *PPARGC1A* on 4p15.1 (rs10938963: P=3×10-5). In this GWAS, TMLE based tVIM approach identified 36 variants within 35 genes that associate with MSSS; replication analyses are currently underway. Compared to other machine learning algorithms, this approach provides interpretable statistical inference with valid p-values (FDR adjusted).

1416T

Case-sibling studies that acknowledge unstudied parents and enroll unmatched individuals. *M. Shi, D.M. Umbach, C.R. Weinberg.* Biostatistics Br, NIEHS, Res Triangle Park, NC.

Family-based designs enable assessment of genetic associations without bias from population stratification. However, parents are not always available — especially for diseases with onset later in life and the case-sibling design, where each case is matched with one or more unaffected siblings, can be useful. Analysis typically accounts for within-family dependencies by using conditional logistic regression (CLR). We consider an alternative approach that treats each case-sibling set as a nuclear family with both parents missing by design. Under weak assumptions, one can carry out maximum likelihood analysis by using the Expectation-Maximization (EM) algorithm to account for missing parental genotypes. We show that this approach enables the investigator to incorporate supplemental cases who do not have a sibling available and supplemental controls whose case sibling is not available (e.g. due to death). We compare conditional logistic regression and the proposed missing parents approach under several risk scenarios. Our proposed method offers both improved statistical efficiency and asymptotically unbiased estimation for genotype relative risks and genotype-by-exposure interaction parameters.

A Variable-Selection-Based Novel Statistical Approach to Identify Susceptible Rare Variants Associated with Complex Diseases with Deep Sequencing Data. *H. Sun, S. Wang.* biostatistics, Columbia University, New York, NY., Select a Country.

Existing association methods on sequencing data have been focused on aggregating variants across a gene or a genetic region in the past two years due to the fact that analyzing individual rare variants is underpowered. However, to identify which rare variants in a gene or a genetic region out of all variants are associated with the outcomes (either quantitative or qualitative) is a natural next step. Here we proposed a variable-selection-based novel approach that is able to identify the locations of the susceptible rare variants that are associated with the outcomes with sequencing data. More specifically, with all *P* rare variants in a gene or a genetic region, we generated the power set of the *P* rare variants except the empty set, that is, subsets $S = 2^P - 1$ of the *P* rare variants. We then treated the *S* subsets of the *P* rare variants as the *S* "new variables" and applied the penalized likelihood estimation using L_1-norm regularization in a regression framework where outcomes were regressed on the *S* subsets. The proposed method only requires the regularization procedure to select the highest impact subset out of the *S* subsets on the outcome without worrying the selection of an optimal regularization parameter. After a subset of *P* rare variants is selected as the most associated subset with the outcome, we applied a permutation procedure specifically designed to assess the statistical significance of the selected subset. The selection performance and power of the proposed method were evaluated through intensive simulation studies where different effect sizes, sample sizes and directions of the effects of the individual rare variants were considered. The results demonstrated that the proposed method is able to select subsets with most of the outcome related rare variants in all simulation scenarios considered. The type I error and power of the subsequent permutation procedure demonstrated the validity and advantage of our selection method. The proposed method was also applied to sequence data on the ANGPTL family of genes from the Dallas Heart Study (DHS). Our proposed method was implemented in an **R** package *RVsel* which will be freely downloaded at *http://www.columbia.edu/~sw2206*.

Causal-Seek: A strategy for finding causal variants via trans-ethnic fine-mapping. *X. WANG[1], Y. Teo[1,2].* 1) School of Epidemiology and Public Health, National University of Singapore, SINGAPORE; 2) Department of Statistics and Applied Probability, National University of Singapore, SINGAPORE.

Genome-wide association studies (GWAS) have achieved remarkable success in identifying genomic variants that are associated with human traits and complex diseases. However, these variants are unlikely to be the real causal SNPs, but are markers that are in linkage disequilibrium (LD) with the functional variants. SNPs having high LD with the causal SNP often emerge from the analysis with strong association signals with the phenotype of interest. To identify the actual causal SNP, fine-mapping with denser genotyping or sequencing information is performed in the candidate regions identified by GWAS. This procedure is hampered by the extensive LD patterns around the causal SNP, which can yield numerous perfect surrogates that are indistinguishable from the real causal SNP. Trans-ethnic fine-mapping that leverages the diverse LD patterns across multiple ethnic populations can be used to address this difficulty. Here we introduce a novel statistical method to perform trans-ethnic fine-mapping, by calculating the probability that each SNP is the causal variant given the observed GWAS association results as well as the genetic variability in each population. Across multiple populations, Maximum likelihood method is adopted to assess the probability at each SNP position. After leveraging the diverse LD patterns across multiple ethnic populations, the SNP that is consistently in high correlation with the surrogates (SNPs emerged from GWAS with strong association signals) in separate GWAS is most likely to be the real causal SNP. We first implemented a series of simulations under different scenarios to assess the power and false positive rates. Subsequently, we applied this method to genome-wide association data of type 2 diabetes in Chinese, Malay and Asian Indian populations from Singapore as well as the diverse populations from European and Japan, to investigate for the real causal variant for the phenotype of interest.

Novel insights into the genetics of Parkinson's disease on chromosome 17. *W.WS. Lau.* RESEARCH DEPARTMENT O F GENETICS, EVOLUTION AND EN, UNIVERSITY COLLEGE LONDON, LONDON, United Kingdom.

Parkinson's disease (PD) is the second most common neurodegenerative disease. Several G enome Wide Association (G WA) studies have been preformed to date focusing primarily on sporadic PD. These studies have reported a relatively small number of susceptibility loci even though recent studies have indicated a large genetic contribution. Here w e show significant progress by using high-resolution metric linkage disequilibrium maps to identify new genes on chromosome 17 that harbours the MART gene (strongest replicated G WA signal on 17q). Our analysis of the NIN DS G WA data (Illumina 550, 677 cases and 538 controls) has identified the MAPT gene-region but with an estimated location of the casual variant downstream of MAPT. This localization was replicated with precision using an independent G WA on sporadic PD (Illumina 1 M, 2,000 cases and 1,986 controls). Here w e report several additional novel genes, including ALOX15, RABEP1, PER1, CENTA2, TH E M100, AXIN 2, CD300LE, LG ALS3BP. All these signals have been replicated with great precision and most of our location-estimates point to causal variants within regulatory regions. The use of metric linkage disequilibrium maps can bring a much greater resolution and hence they can accelerate progress in identifying the genetic factors to PD and other complex disorders.

1420F

Joint statistical modeling of multiple phenotypes in samples with related individuals. *Z. Wang.* Division of Biostatistics, Yale University, New Haven, CT.

Genetic association studies have routinely been conducted to search for variants associated with diseases and quantitative phenotypes. Clinical and epidemiological studies typically collect data on a set of correlated phenotypes that may share common environmental and/or genetic factors. Such phenotypes contain more information than univariate phenotypes. Thus joint modeling of multiple phenotypes can potentially have increased power to detect association and increased precision of parameter estimation than univariate analysis. In this study, we develop novel statistical methods for multivariate association mapping in samples that contain arbitrarily related individuals. We address both common and rare variants association. The proposed methods are based on retrospective analysis that is less dependent on model assumptions on phenotypes, thus they are robust to trait model misspecification. The new methods can accommodate the external biological information by integrating graphical models and multivariate analysis, and are computationally affordable. We comprehensively evaluate the proposed methods using simulation studies and compare with existing methods. The proposed methods are applied to analysis of blood lipid levels in a whole genome sequence study on the Sardinian population.

Association of three polymorphisms of IL-18 genes (137G/C, 607C/A,133C/G) in patients with allergic rhinitis in the Iranian population. *S. Ramazi[1], M. Motovalibashi[1], H. Khazraei[2], M. Hashemzade chaleshtori[2].* 1) Cellular and Molecular Research Center, Shahrekord University of Medical Science, Shahrekord,Iran; 2) Division of Genetics, Department of Biology, Faculty of Science, University of Isfahan, Isfahan.

Background: Allergic rhinitis (AR) is an inflammatory disease of the nasal mucosa induced by an IgE-mediated reaction, following exposure to an allergen. IL-18 is a member of the IL-1 family.It was originally described as IFN-γ -inducing factor (IGIF),and is known to influence the balance of Th1/Th2 immune response. This study aimed to examine the association of three different (SNPs) located in IL-18 gene (-607 C/A, -137 G/C and-133 C/G) on chromosome 11q22 with allergic rhinitis. Methods :to determine the role of IL-18 gene in Allergic rhinitis susceptibility, we conducted a case-control study and genotyped three different (SNPs) in promoter region(-137 G/C (rs 187238), -607 C/A (rs 1946518), -133C/G (rs360721)) in 300 patients with allergic rhinitis and 200 healthy controls frame Iranian population. Polymerase chain reaction-restriction fragment length polymorphism were used for genotyping. Results: The frequency of the GC genotype of the IL-18/-133 gene polymorphism was greater in allergic rhinitis patients than in control. Conclusions: This study suggests that IL-18 gene variants may participate as a risk factor in the pathogenesis of AR or in intermediary phenotypes.

Accounting for Population Stratification in DNA Methylation Studies. *R.T. Barfield[1,2], L.M. Almli[3], V. Kilaru[3], A.K. Smith[3], K.B. Mercer[3], T. Klengel[4], D. Mehta[4], E.B. Binder[3,4], K.J. Ressler[3], K.N. Conneely[1,5].* 1) Department of Biostatistics and Bioinformatics, Emory University, Atlanta, GA; 2) Department of Biostatistics, Harvard University, Boston, MA; 3) Department of Psychiatry and Behavioral Science, Emory University, Atlanta, GA; 4) Max-Planck Institute of Psychiatry, Munich, Germany; 5) Department of Human Genetics, Emory University, Atlanta, GA.

DNA methylation is an important epigenetic mechanism that has been linked to complex disease, and is thus of great interest to researchers as a potential link between genome, environment, and disease. As the scale of DNA methylation association studies approaches that of genome-wide association studies (GWAS), issues such as population stratification will need to be addressed. Failure to adjust for population stratification in genetic association studies can lead to false positives, but population stratification generally has not been accounted for in DNA methylation studies. Here, we devise and compare several approaches to correct for population stratification in DNA methylation studies. We first analyzed DNA methylation for association with race in 388 individuals (365 African American and 23 Caucasian) from a larger study of post-traumatic stress disorder. Whole blood DNA methylation for these individuals was assessed using the Infinium HumanMethylation450 BeadChip Assay, and genotype data was collected using Illumina Omni-Quad 1M and Omni-Express arrays. We identified widespread associations between methylation and race (12,800 associated CpG sites; FDR<0.05). We then compared three different principal-components-based approaches on their ability to adjust for population stratification, measured as the percent reduction in the number of sites significantly associated with race. We examined principal components computed from 1) genome-wide methylation data, which we first pruned to obtain a set of roughly independent sites, 2) sets of CpG sites within 0 bp, 1 bp, 2bp, 5bp, 10bp, 50bp, and 100bp of a known SNP ("informed pruning"), and 3) conventional principal component analysis based on the genome-wide SNP data (after the usual LD-based pruning). We found that by including principal components based on either GWAS data or informed pruning of methylation data, we reduced the number of sites significantly associated with race by nearly 100%. The informed pruning approach was also less computationally intensive than the other two approaches, which both require correlation-based pruning. We have therefore developed an effective method to account for population stratification in DNA methylation studies that does not require the additional collection of genome-wide SNP data.

1423F

Genetic case-control matching strategies for rare-variants analysis in genome-wide association studies. *A. Lacour[1], T. Becker[1,2].* 1) German Center for Neurodegenerative Deseases (DZNE), Bonn, Germany, Bonn, Germany; 2) Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany.

Population stratification in samples of genome wide association studies give rise to large obliterations in the results of statistical tests. In order to correct for stratification effects we have developed and implemented three structuring strategies for association testing. Taking the identity-by-state matrix as a measure for genetic kinship, we obtain pairwise case-control matchings, groupings with respectively at least one control and one case, and clusters. All strategies have in common that they are based on a `maximum weighted bipartite matching' by making use of the hungarian algorithm which solves the assignment problem in polynomial time. We also present a set of quality control strategies that make sure, that the structures found by the algorithm are not between distinct strata. The matching strategies can not only be performed genome-wide but also window-wise as a `localized matching'. Local window sizes of a few thousand SNPs are enough to guarantee identification of strata. This is of particular interest for the application to the analysis of rare variants since the amount of stratification is expected to vary according to the genomic location. Association P-values are obtained by within-structure case-control permutations. As it turns out from simulation studies, the empirical niveau becomes close to the confidence niveau for within-structure permutation becomes close to the nominal level. Thus, our method leads to an increase of power and simultaneously to a reduced false-positive rate in simulations compared to unstratified analyses. As a byproduct, our implementation strongly outperforms common covariate approaches based on principal component analysis or multidimensional scaling in runtime, and makes genome-wide application possible. Our method for stratified analyses is implemented in the genome-wide interaction analysis software INTERSNP.

1424W

Ancestry Informative Principal Components Analysis in Structured Samples with Known or Cryptic Relatedness. *T. Thornton, M. Conomos.* Biostatistics, University of Washington, Seattle, WA.

A problem that is often encountered in association studies of complex traits is that of identifying and adjusting for population stratification, as it is well known that failure to appropriately account for population structure can lead to spurious association. Principal components analysis (PCA) is a commonly used tool for the detection and correction of confounding due to population structure in association studies. For genetic studies that include related individuals, however, PCA can lead to principal components that do not adequately capture population structure due to the complex correlations among relatives. We consider the problem of PCA in related samples from structured populations. We propose a method, PC-AIR, for obtaining ancestry informative principal components in samples with related individuals. PC-AIR can be used across a variety of study designs, ranging from studies that have a combination of unrelated individuals and pedigrees with known genealogy to studies with partially known or completely unknown pedigrees. In simulations studies with related individuals and population structure, including admixture, we demonstrate that PC-AIR provides a substantial improvement over traditional PCA in a broad range of settings. We apply PC-AIR to the Mexican Americans in Los Angeles, California (MXL) population sample of release 3 of phase III of the International Haplotype Map Project (HapMap) where we demonstrate that the first principal component with PC-AIR captures population structure better than the top 30 principal components with traditional PCA.

1425T

Admixture and Association Mapping Identifies Marker in FAM19A2 Associated with FEV_1/FVC in African-Americans. *M.M. Parker[1], M.G Foreman[2], R.A. Mathias[3], T.H. Beaty[1], C.R. Gignoux[4], E.G. Burchard[4], J.B. Hetmanski[1], E.K. Silverman[5], J.D. Crapo[6], COPDGene Investigators.* 1) Epidemiology, Johns Hopkins University, Baltimore, MD; 2) Morehouse School of Medicine, Atlanta,GA; 3) Allergy and Clinical Immunology, Johns Hopkins Asthma and Allergy Center, Baltimore, MD; 4) Department of Medicine, University of San Francisco, San Francisco, CA; 5) Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 6) National Jewish Medical and Research Center, Denver, CO.

Background: The ratio of forced expiratory volume in 1 second (FEV_1) to forced vital capacity (FVC) is used to diagnose chronic obstructive pulmonary disease (COPD) severity. Racial differences in FEV_1/FVC ratio exist between non-Hispanic Whites and African-Americans and have not been fully explained. Methods: We performed admixture mapping to identify genetic variants associated with FEV_1/FVC ratio in 3260 unrelated African-American smokers in the COPDGene Study. FEV_1/FVC ratio was measured using an EasyOne Spirometer and participants were genotyped on the Illumina OMNI Express platform (728,648 SNPs). Local ancestry was estimated for each individual at each marker using LAMP, which infers local ancestry using a clustering algorithm on sliding windows of contiguous SNPs. Overlapping windows are then combined via majority vote to estimate the most likely ancestral population for each SNP. These estimators of local ancestry were included in a linear regression to identify genomic regions where local ancestry was a significant determinant of FEV_1/FVC ratio. Results: Global percent African ancestry among African-American COPDGene participants ranged from 29.5%–99.9% with a mean of 81.7%. This global measure of African ancestry was significantly associated with FEV_1/FVC ratio (β=-0.3412, p=0.033). The strongest association signal from the regression of FEV_1/FVC ratio on local ancestry at each genetic marker (controlling for age, gender, BMI, current smoking status, pack years smoked, and global ancestry) was on chromosome 12 ($p=6.77\times10^{-6}$). Single-SNP genotype association analysis in this region identified an associated SNP within the intronic region of FAM19A2 (rs11174267, $p=6.10\times10^{-9}$) that remained significant even after adjustment for local ancestry ($p=1.71\times10^{-6}$). FAM19A2 is a member of the TAFA gene family and is involved in immune and nerve cell regulation, but has not been reported to be associated with pulmonary function. Conclusion: Through a combination of admixture mapping and association analysis, we identified a marker (rs11174267) significantly associated with FEV_1/FVC ratio among African-American participants in the COPDGene study. This may partly explain of racial differences in spirometry, although the role of this marker in lung function remains unclear. Funding: U01HL089856 (EKS), U01HL089897 (JDC), HL092601 (MGF).

1426F

The Gamma Method for gene set analysis of RNA-Seq data: Simulation results and application to a smallpox vaccine study. *B.L. Fridley[1], G.D. Jenkins[1], D.E. Grill[1], J.M. Biernacka[1], R.B. Kennedy[2], G.A. Poland[2], A.L. Oberg[1].* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) General Internal Medicine, Mayo Clinic, Rochester, MN.

Many complex disorders may be controlled by the interplay of multiple genes within the same molecular pathway or gene set (GS). Thus, gene set analysis (GSA) has been widely used for mRNA data from microarrays. Aggregating the association signals for a set of genes within a GS incorporates biological knowledge, reduces the multiple-testing burden, and may increase the association signal, thus increasing the power to detect meaningful associations. With the advent of next-generation sequencing technologies, the use of GSA is even more relevant due to limited statistical power, as RNA-Seq studies are often conducted on a small number of subjects. However, RNA-Seq data analysis comes with some different challenges, as RNA-Seq experiments measure the gene expression levels from the total number of reads detected in a gene. Therefore, the analysis methods for RNA-Seq data are quite different than those for microarray-based data. In our GSA, we use generalized linear models to assess per-gene significance assuming the negative binomial distribution. Using these gene-level results, we propose the use of the Gamma Method (GM) for GSA. The GM is based on summing p-values transformed using an inverse Gamma(ω, 1) transformation (Zaykin et al., 2007). Application of different p-value transformations is achieved by changing the ω parameter which varies the emphasis given to particular p-values, and has been referred to as the soft truncation threshold (STT). When ω is 1, GM is equivalent to Fisher's Method. Due to dependency between genes in a GS, empirical GS p-values are determined using permutation testing. In a simulation study with more than 1,400 scenarios, we found the GM with STT < 0.20 outperforms other commonly used self-contained GSA methods such as Fisher's Method and the global model of Goeman et al. (2004), while maintaining control over the type I error rate. We have applied the GM for GSA to a RNA-seq smallpox study to identify GSs with differences in mRNA expression between high and low responders to smallpox vaccine. The top GSs (with good coverage) included: Biotin metabolism (p=0.0005); non-homologous end-joining (p=0.02); focal adhesion (p=0.04); D-Glutamine and D-glutamate metabolism (p=0.04); and ECM-receptor interaction (p=0.05). The results of this research will lead to a powerful method for GSA of RNA-Seq data and new insights into the genomic basis of individual variations in immune response to the smallpox vaccine.

1427W

Evaluation of SNP and indel imputation quality using reference haplotypes from the 1000 Genomes project. *Q. Duan[1], E.Y. Liu[1,3], K.L. Mohlke[1], D.C. Croteau-Chonka[1], Y. Li[1,2,3].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC 27599; 2) Department of Biostatistics, University of North Carolina, Chapel Hill, NC 27599; 3) Department of Computer Science, University of North Carolina, Chapel Hill, NC 27599.

Genotype imputation has become a routine in genome-wide association (GWA) studies. As imputation accuracy directly affects downstream analysis, there is an increasing need to better understand the quality of imputation, especially for rare genetic variants. Currently, one can only infer SNP and indel imputability information by conducting imputation, which can be computationally costly for a large number of markers of interest. To facilitate this inquiry, we sought to perform a detailed imputation quality assessment of SNPs and indels discovered in the 1000 Genomes project and to provide the imputability information through a publicly available database. Imputation was performed using MaCH-Admix with 2184 haplotypes from the 1000 Genomes project (version 3 March 2012 release). We mimicked imputation practice in typical GWA studies by treating markers absent from selected commercial genotyping platforms as untyped markers. We imputed the genotypes at these untyped markers one sample at a time using the rest of the samples as reference. Imputation accuracy of each marker was measured by the squared Pearson correlation coefficient between the imputed dosages and the actual (masked) genotypes. The accuracy was evaluated separately for each of four continental groups. Genotyping platforms currently available are Affymetrix 500K, Affymetrix 6.0, Affymetrix Axiom, Illumina Human1M, Illumina Omni5 and Illumina Omni ZhongHua. Our results show that imputation accuracy differs by the choice of genotyping platform. Within each genotyping platform, imputation quality increases with the minor allele frequency (MAF) in terms of number of SNPs passing quality control (QC) and the average of the squared Pearson correlation. Finally, we show that the imputation accuracy at each QC level is affected by both population group and MAF, indicating that to achieve similar imputation performance, different QC thresholds need to be applied by taking ancestry and MAF into consideration. The imputability of SNPs and indels is publicly available through our website (http://www.unc.edu/~yunmli/imputability.html).

1428T

An efficient design to detect transplant donor and recipient genetic interactions. *W. Guan[1], A.K. Israni[2].* 1) University of Minnesota, Minneapolis, MN; 2) Hennepin County Medical Center, Minneapolis, MN.

Long-term renal and liver allograft failure remains a major problem in transplantation. Besides recipient characteristics, donor-related factors also play important roles to predict allograft failure, accounting for up to 45% of the observed patient-to-patient variation in allograft function. In order to determine the role of donor and recipient genetic factors and potential interactions, we will design a genome-wide association study (GWAS) using the recipient-donor pairs. A deceased donor usually donates two kidneys and/or a liver, typically each to a different recipient. This unique design allows us to distinguish the relative contribution of the donor genetic factors from the recipient and environmental related factors. In the proposed analysis, we will conduct the association tests in two stages. We first identify recipient variants associated with allograft failure using recipient pairs by conditional logistic regression; and then test for association between donor variants and allograft failure, with the donor-recipient genetic interaction being modeled with each of the identified recipient variant. Through computer simulations, we will compare the statistical power using this recipient-donor pair design over traditional case-control design which exhaustively searches for interactions between every donor and recipient variants. We hope that our approach will help to identify the donor and recipient genetic factors for all solid organ transplants and lead to future development of novel immunosuppression therapies/treatments.

Dissecting features of causal variants. *S. Sengupta, X. Wen, G. Abecasis.* Biostatistics Dept, University of Michigan, Ann Arbor, MI.

Genome-wide association studies, which examine millions of genetic variants in thousands of individuals, have identified many complex trait associated loci. Most of these loci include many strongly associated variants and, often, variants which are not tested for association but are known to be in strong linkage disequilibrium with the variants exhibiting strongest evidence of association. The large number of variants actually or potentially showing evidence for association in each locus makes it challenging to prioritize likely functional variants at each locus.

We reasoned that causal variants for each trait might share certain genomic features. For example, causal variants for lipid traits might preferentially overlap transcription factor binding sites active in liver, where important steps in lipid metabolism take place. More generally, causal variants for many traits might be non-synonymous variants that alter protein coding sequences. We develop a hierarchical model that identifies genomic features enriched among associated many associated loci and uses this information to prioritize likely functional variants in each locus.

Our model can be fitted to summary statistics from individual studies, making it convenient to incorporate in ongoing genome-wide association study meta-analysis that can include 100,000s of individuals distributed across dozens of studies. We evaluate our method using simulations and application to genome-wide association study data for a variety of metabolic traits.

Genetic Programming for Detecting Interactions of SNPs with Fuzzy Genotypes in Association Studies. T. *Stöcker[1,2], H. Schwender[1,2]*. 1) Faculty of Statistics, TU Dortmund University, Dortmund, Germany; 2) Faculty of Mathematics and Natural Science, Heinrich Heine University, Düsseldorf, Germany.

In genetic association studies, combinations of single nucleotide polymorphisms (SNPs) are assumed to have a higher impact on the risk of developing a disease than individual SNPs. Therefore, several methods for detecting SNP interactions associated with disease have been proposed, reaching from multiple testing procedures and exhaustive search approaches to procedures such as logic regression (Ruczinski et al., 2004, J. Comput. Graph. Statist. 12, pp. 475–511) and GPAS (Genetic Programming for Association Studies; Nunkesser et al., 2008, Bioinformatics 23, pp. 3280–3288) that search the space of all possible SNP combinations for the interactions influencing the disease risk most substantially by employing a stochastic search algorithm, and therefore, avoid the need to consider all possible combinations. In these methods, the genotypes of the SNPs are typically considered as if they were deterministic. This, however, ignores that in microarray and sequencing studies the genotypes are estimated by a calling algorithm, and hence, specified with uncertainty. It is well-known that taking this uncertainty into account by, e.g., using fuzzy genotypes, i.e. sums over the three possible genotypes weighted by their probability of being the true genotype, can lead to an improved statistical power in association studies. Considering fuzzy genotype becomes even more important (if not mandatory) when imputed SNPs are included in the analysis, as the uncertainty in these genotype calls is even higher. We have therefore extended GPAS to the analysis of fuzzy genotype calls. This procedure called Fuzzy GPAS thus allows not only accounting for the confidence in the genotype calls when searching for SNP combinations associated with disease, but also enables the consideration of both typed and imputed SNPs. In our presentation, we describe Fuzzy GPAS and show how it can be applied to typed and imputed SNPs. Moreover, we propose a measure quantifying the importance of the found SNP interactions, and hence, allowing the ranking of these interactions by their impact on the disease risk. As applications to simulated and real data show, this measure is able to correctly order the interactions by their influence on the disease risk.

Rare variant analysis for family-based design. *W. Yip[1], G. De[1], I. Ionita-Lazza[2], N. Laird[1]*. 1) Dept of Biostatistics, Harvard School of Public Health, Boston, MA; 2) Dept of Biostatistics, Columbia University, New York, NY.

Many common diseases are now thought to be caused by rare as well as common variants. Genome-wide association studies (GWAS) are designed only to identify the common variants. Recently, a number of methods have been proposed to detect rare variants in population based designs. Here, we proposed a novel method to test for association of rare variants in family-based design by collapsing the standard family-based association test (FBAT) statistic over a region of interest. A weighting scheme based on allele frequency of the SNPs is used to upweigh rare variants compare to common variants. Using simulations, we show that our method performs at par with the population-based methods under no population stratification. By definition, family-based designs are completely robust to population stratification and hence our proposed method is valid even when population stratification is present. The proposed method has been incorporated as an option (-v) in the popular FBAT software. Manuscript submitted to PLos ONE and is currently under review.

1432F

BMI trajectory from early childhood associates with leukocyte telomere length in Northern Finnish women. *S. Das[1], J.L Buxton[2], A. Rodriguez[1,7,8], A. Couto[1], M. Kaakinen[3,4], S. Sebert[1], P. O'Reilly[1], L. Coin[1], A.I.F. Blakemore[2], M-R. Jarvelin[1,3,4,5,6]*. 1) Epidemiology and Biostatistics, Imperial college London, London, UK; 2) Section of Investigative Medicine, Division of Diabetes, Endocrinology and Metabolism, Imperial College London, UK; 3) Institute of Health Sciences, University of Oulu, Finland; 4) Biocenter Oulu, University of Oulu, Finland; 5) National Institute for Health and Welfare, Helsinki, Finland; 6) MRC Health Protection Agency (HPA) Centre for Environment and Health, Imperial College London, UK; 7) Social Genetic Developmental Psychiatry Centre, King's College London, UK; 8) Mid Sweden University, Östersund, Sweden.

Leukocyte telomere length (LTL) is a biomarker for healthy aging, and short telomeres are associated with several age-related conditions, including obesity, type 2 diabetes, cardiovascular diseases and some cancers. Telomeres generally shorten with each cell division, a process exacerbated by oxidative stress. Inverse associations between telomere length in adults and increased body mass index (BMI), waist-to-hip (WHR) ratio and excess visceral fat have been previously reported. There is also some evidence for association between adverse events in childhood and shorter adult LTL. However, there are no studies on the relationship between BMI trajectories from childhood to adulthood and LTL in adulthood. We examined the longitudinal variation in BMI trajectories from childhood (at 5y) to adulthood (at 31y) to identify associations with adult LTL in the Northern Finland 1966 Birth Cohort. Relative mean LTL measurements were obtained using multiplex qPCR in DNA taken from N=5620 participants aged 31 years. We calculated the variation in BMI trajectories as the difference between standardised BMI measurements taken at ~5 y and at 31 y, and tested for association with LTL using regression models adjusting for qPCR plate, and obesity in childhood and in adulthood in consecutive models. Separate analyses were conducted in males and females.We found that changes in BMI across early childhood and adulthood are associated with shorter mean relative LTL in women, independent of obesity status in either early childhood or concurrent at age 31 (P=0.01). We did not find any evidence for an association between BMI trajectories and LTL in men. We also found that the mean relative LTL in men is significantly shorter than that in women (P=1 × 10-4), consistent with previous studies, and with the known antioxidant effects of oestrogen. The identification of novel factors affecting both telomere length and rate of telomere shortening throughout life is important for the elucidation of mechanisms underlying healthy aging. We show here that the degree to which BMI increases after childhood is associated with shorter telomeres at age 31, irrespective of whether individuals are obese at either timepoint. Further longitudinal studies are required to assess the long term effects of weight gain after childhood on LTL and cardiovascular disease risk, and the gender difference observed.

1433W

A model for combining data on de novo mutations with case-control data to identify risk genes. *X. He[1], S. Sanders[2], L. Liu[3], M. State[2], B. Devlin[4], K. Roeder[1,3]*. 1) Lane Center of Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 2) Program on Neurogenetics, Child Study Center, Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 3) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA; 4) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Purpose: De novo mutations, which are not inherited from parents, affect risk for many diseases. An example is autism. Four recent whole-exome sequencing (WES) studies of 932 autism families (mother, father and affected offspring) identified five novel risk genes from a multiplicity of de novo loss-of-function (LOF) mutations and revealed that de novo LOF mutations occurred at a twofold higher rate than expected by chance. Not all WES studies, however, target families and in any case we would expect transmitted variation to also play a role in risk. Therefore an important research challenge is to develop statistical methods that increase the utility of de novo mutations by leveraging additional datasets of inherited or case-control variation. Methods: Our strategy is to model data on de novo mutations together with other forms of data. Case/control WES data, for example, are an unknown mixture of de novo and inherited variation. For simplicity, we focus on LOF mutations because they tend to have large effects on risk (e.g., autism). We develop a statistical model relating the number of de novo mutations to a set of genetic parameters such as mutation rate and relative risk; in addition, the statistical framework analyzes additional datasets, such as case-control data, in an integrated fashion. Inference is based on an empirical Bayes strategy that allows us to borrow information across all genes to infer parameters that would be difficult to estimate from individual genes. Results and Discussion: We validate our statistical strategy using simulations mimicking rare, large-effect mutations. We found that using either de novo mutations or case/control data alone is relatively inefficient. Moreover a naïve method of combining the two datasets using sum of log p-values (Fisher's method) has limited benefits. In contrast, our model substantially increases statistical power and dominates all other methods in almost all settings we examined. We will apply the model to WES data from autism to evaluate its performance on real data.

Variable Selection in High-dimensional Meta-Analysis for Genetic Data. *Q. He[1], H. Zhang[2], D.Y. Lin[1], C.L. Avery[3].* 1) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel hill, NC; 2) Department of Statistics, North Carolina State University, NC; 3) Department of Epidemiology, University of North Carolina at Chapel Hill, Chapel hill, NC.

Meta-analysis plays an important role in summarizing and synthesizing scientific evidence from multiple studies. When the dimensions of the data are high, such as in the genome-wide association studies or the sequencing studies, it is desirable to incorporate variable selection into meta-analysis to improve model interpretation and prediction. Existing variable selection methods require direct access to raw data, but in reality, it is often difficult to obtain the raw data from different resources. We propose a new approach, Sparse Meta-Analysis (SMA), which performs variable selection for meta-analysis based solely on summary statistics. This method is extremely useful when the information of many studies needs to be integrated in order to identify weak genetic variants. In addition, our method allows the effect sizes of each covariate to vary among studies, thus offering high flexibility for statistical modeling. Simulation studies and real data analysis demonstrate that the proposed methods perform well in both variable selection and prediction. Since summary statistics are far more accessible than raw data, our methods provide a powerful tool for selecting important variables from high-dimensional meta-analysis.

1435F

Integrative approaches for genetic association studies via Bayesian model uncertainty. *M.A. Quintana, D.V. Conti.* Dept of Preventive Medicine, Division of Biostatistics, University of Southern California, Los Angeles, CA.

Recent technological advances within the genetics community have lead to the collection of massive datasets involving numerous types of genomic data on a single set of individuals or across various levels of information. Traditional analyses concentrate on a single data type and relied heavily on an expert to build models for inference based on contextual knowledge. However, with the shear amount of factors available for evaluation it is often impracticable to build a model in this way. With this in mind, we are interested in developing integrative approaches for high-dimensional genetic association studies that incorporate multiple-levels of data, including functional information. In particular, we have developed iBMU, a Bayesian model uncertainty method that formally incorporates multiple sources of data via a multi-stage hierarchical probit model on the probability that each predictor is associated with the outcome of interest. Using simulations, we demonstrate that iBMU leads to a more efficient model search algorithm that yields an increase in power to detect true associations over more commonly used techniques. Finally, we demonstrate the power and flexibility of iBMU for several genome wide association studies involving: (1) the analysis of rare variants with incorporation of genetic annotation; (2) gene-set enrichment analysis for inference of gene- and pathway-level associations; (3) integrated genomic analysis incorporating functional information via biomarkers.

Meta-analysis of co-regulated subnetworks in transciptomics data: towards functional marker profiles of human ageing. *E.B. van den Akker[1,2], W.M. Passtoors[1], E.W. van Zwet[3], J.J. Goeman[3], M. Hulsman[2], V. Emilsson[4], M. Perola[5], B.T. Heijmans[1], A.B. Maier[6], J.N. Kok[1,7], P.E. Slagboom[1,8], M.J.T. Reinders[2], M. Beekman[1,8].* 1) Molecular Epidemiology, Leiden University Medical Center, Leiden, Zuid Holland, Netherlands; 2) The Delft Bioinformatics Lab, Delft University of Technology, Delft, Zuid Holland, Netherlands; 3) Medical Statistics, Leiden University Medical Center, Leiden, Zuid Holland, Netherlands; 4) Icelandic Heart Association, 201 Kopavogur, Iceland; 5) National Institute for Health and Welfare, Helsinki, Finland; 6) Gerontology and Geriatrics, Leiden University Medical Center, Leiden, Zuid Holland, Netherlands; 7) Algorithms, Leiden Institute of Advanced Computer Science, University of Leiden, Netherlands; 8) Netherlands Consortium for Healthy Ageing, Leiden, 2333 ZC, Netherlands.

Age associated modules within co-expression networks may provide a molecular basis for identification of mechanisms underlying age related diseases. However, age-changes in gene expression profiles typically have low signal-to-noise ratios that seriously hamper a solely data driven approach. We cope with this aspect in two ways. First, we employ a meta-analysis approach on multiple large-scale expression studies for constructing the co-expression network and detecting age associated modules therein. Second, we project the co-expression network onto the Protein-Protein Interaction (PPI) network spanned up by predicted or experimentally validated functional relations between genes to improve the confidence and interpretation of observed co-regulated subnetworks. For the analysis we created a gene expression compendium of 2,539 subjects in an age range of 15 to 95 years belonging to three published expression studies measured in peripheral blood or lymphocytes: SAFHS, IFB cohort and DILGOM. Single gene meta-analysis showed functional enrichment for N-linked glycosylation, besides a few other broadly defined terms. Our approach based on co-regulated subnetworks (CoRSuN), on the contrary, detected 70 age associated CoRSuNs, including a highly significant module containing T-cell differentiation markers (p = 1.3E-143). To investigate whether the detected CoRSuNs mark ageing up to the highest ages, we tested them for association with age in 50 middle-aged and 50 ninety-year-old participants from the Leiden Longevity Study. This confirmed age-changes in five CoRSunNs, including the T-cell CoRSuN, independent of lymphocyte and monocyte cell counts. Since the T-cell differentiation markers are established markers of T-cell lineages, their expression may point to proportions of T-cell subpopulations, rather than to a molecular mechanism. We therefore adjusted the age-associated CoRSuNs for the first principle component of the T-cell differentiation CoRSuN now revealing 15 out of the 70 subnetworks, including a ribosomal (p = 9.7E-4) and mitochondrial module (p = 4.1E-5). We conclude that age-changes in the blood transcriptome likely reflect changes in T-cell populations, potentially confounding the genomic analysis into ageing mechanisms. Furthermore, we demonstrate that de novo grouping of genes using co-expression networks in conjunction with a PPI network yields functional gene modules as relevant markers of human ageing up to very high ages.

Integrative Analysis of Sequencing and GWAS Data Improves Statistical Power in Detecting Rare Variants Associated With Complex Diseases. *Y.J. Hu[1], Y. Li[2,4], L.A. Lange[4], E.M. Lange[4], C. Bizon[6], P. Auer[5], G. Heiss[3], C. Kooperberg[5], N. Franceschini[3], U. Peters[5], A.P. Reiner[5], L. Hsu[5], S. Jiao[5], C.S. Carlson[5], K.E. North[3], D.Y. Lin[2], NHLBI GO Exome Sequencing Project.* 1) Department of Biostatistics and Bioinformatics, Emory University, Atlanta, GA; 2) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 3) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 4) Department of Genetics, University of North Carolina, Chapel Hill, NC; 5) Fred Huchinson Cancer Research Center, Seattle, WA; 6) Renaissance Computing Institute, University of North Carolina, Chapel, Hill, NC.

Biological evidence suggests that low-frequency and rare variants account for a large proportion of the genetic contributions to complex human diseases. Although next-generation sequencing has made it possible to conduct association studies on low-frequency and rare variants, it is still not economically feasible to sequence all subjects in a large cohort. A cost-effective sequencing strategy prioritizes subjects in the extremes of the quantitative trait distribution or those with diseases. In the NHLBI Exome Sequencing Project (ESP), subjects with the highest/lowest values of body mass index, low-density lipoprotein or blood pressures and those with early onset myocardial infarction or ischemic stroke were selected for whole-exome sequencing. The ESP samples were drawn from large well-established cohort studies which had collected GWAS data on most cohort members. By imputing the exome-sequencing data from the GWAS data for the cohort members who were not selected for sequencing, we can dramatically increase the number of subjects with information on low-frequency and rare variants. It is highly challenging to impute rare variants because only a very small proportion of subjects carry a rare mutation. In addition, treating the imputed genetic values as known quantities in downstream association analysis yields inflated type I error and biased estimates of genetic effects with under-estimated variances, especially when the sequenced subjects are not random samples from the underlying cohorts. We propose to impute burden scores (i.e., linear combinations of mutation counts over multiple variant sites within a gene) rather than individual variants and to integrate the imputation of burden scores and the inference of association into a single likelihood framework that properly reflects the actual sampling design. This approach produces the most powerful test among all valid tests and provides unbiased and efficient estimates of genetic effects. The advantages of the proposed methods are demonstrated through extensive simulation studies and applications to the NHLBI ESP.

1438F

Regionally-Smoothed Meta-analysis for GWAS studies. *F. Begum[1], E. Feingold[1,2].* 1) DEPARTMENT OF BIOSTATISTICS, UNIVERSITY OF PITTSBURGH, PITTSBURGH, PA; 2) DEPARTMENT OF HUMAN GENETICS, UNIVERSITY OF PITTSBURGH, PITTSBURGH, PA.

Over the last decade, genome-wide association studies (GWAS) have become a standard tool for gene discovery in human disease research. While debate continues about how to get the most out of these studies and on occasion about how much value these studies really provide, it is clear that many of the strongest results have come from large-scale mega-consortia and/or meta-analyses that combine data from up to dozens of studies and tens of thousands of subjects. While such analyses are becoming more and more common, statistical methods have lagged somewhat behind. There are good meta-analysis methods available, but even when they are carefully and optimally applied, there remain some unresolved statistical issues. Imputation availability and inaccuracy, heterogeneity in the study cohorts, and differences in data cleaning and statistical modeling among datasets are a few of the major unresolved issues. To address some of the current challenges, we propose a two-stage regionally smoothed meta-analysis (RSM) method for GWAS studies. In the first stage of RSM, we use a sliding window method to get a regional statistic. In the second stage, summarized window statistics for different studies are combined using an appropriate meta-analysis model and allowing for study heterogeneity. RSM is the first method that makes it possible to combine different studies with different sets of SNPs. We applied our method to combine several real GWAS data sets with known results. RSM was able to detect the known genes with increased power.

1439W

Phenotype Mapping using Information Explorer. *Y. Arens[1], J.L. Ambite[1], C.N. Hsu[1], L. Lange[2], S. Sharma[1], S. Voinea[1].* 1) Intelligent Systems Div, USC-ISI, Marina del Rey, CA; 2) Department of Genetics, University of North Carolina, NC.

Databases such as dbGaP represent extremely valuable resources of data that have been assembled across multiple cohorts. The increasing development of cost-effective high-throughput genotyping and sequencing technologies are resulting in vast amounts of genetic data. While such databases were formed in order to archive and distribute the results of previously performed genetic association analyses, an increasing number of studies have provided de-identified individual-level genotypic and phenotypic data that are made available to outside researchers who have obtained the appropriate authorization. While the amount of data made available has increased dramatically in recent years, relatively little has been done to facilitate phenotype harmonization across studies. Researchers currently have to analyze and compare increasingly larger numbers of variables with varying degrees of documentation associated with them to obtain the desired information. Information Explorer is a suite of tools we are developing that would allow researchers to (1) Quickly obtain the information needed to assess whether a specific study will be useful for the hypothesis of interest; (2) Exclude variables that do not meet research criteria; (3) Ascertain which studies have combinations of phenotype and genetic information of interest; and (4) More easily expand research questions beyond the most basic main-effects to more complex analyses such as gene-by-environment interactions and multivariate tests incorporating multiple phenotypes. The increased utility will also enable larger meta-analyses to be performed, as researchers will be able to more quickly hone in on outcomes, exclusionary variables and covariates of interest, leading to increased statistical power to detect genetic associations.

1440T

Data reduction techniques to construct new cellular and whole system biomarkers for ageing. *A. Brown[1], Z. Ding[1], L. Parts[2], D. Glass[3], D. Knowles[4], P. Deloukas[1], E. Dermitzakis[5], M. McCarthy[6,7,8], T. Spector[3], J. Winn[9], R. Durbin[1], MuTHER Consortium.* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Canadian Institute for Advanced Research, University of Toronto, Toronto, Canada; 3) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 4) University of Cambridge, Cambridge, United Kingdom; 5) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 6) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Churchill Hospital, Oxford, United Kingdom; 7) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 8) Oxford NIHR Biomedical Research Centre, Churchill Hospital, Oxford, United Kingdom; 9) Microsoft Research, Cambridge, United Kingdom.

Biological ageing is the progressive decline in the ability to withstand stress, damage and disease; resulting in degeneration. A consensus on how to measure the difference between biological age and elapsed age in years has yet to emerge. Here, we present a novel analysis to derive new biomarkers for ageing from gene expression in skin, and from a selection of ten phenotypes which all show strong correlations with chronological age. Applying guided factor analysis methods we constructed new phenotypes from linear combinations of skin gene expression data from the MuTHER project, so as to capture variation across groups of functionally related genes (pathway activations). We also apply a hierarchical model to ten ageing related phenotypes to create a new meta-phenotype representing biological age; this captures the common ageing structure across several biological systems, including the respiratory and musculo-skeletal systems. By associating the pathway activations with the ageing phenotypes and the derived biological age meta-phenotype, we see significant associations between three pathway activations and the biological age meta-phenotype. One of these concerns glutathione metabolism, and one is an immunity-related pathway. There is therefore the possibility of using gene expression in these pathways as biomarkers for ageing. This analysis also suggests that combining information across several systems can be informative of variation at the cellular level, and could shed light on the interdependencies in the processes which underlie ageing.

Prioritization of next-generation sequencing variants using data visualization. *A. Bigelow[1,2], M. Meyer[1], N.J. Camp[2].* 1) Scientific Computing and Imaging Institute, University of Utah School of Computing, Salt Lake City, UT; 2) Division of Genetic Epidemiology, University of Utah School of Medicine.

In complex traits, the underlying critical risk variants will likely include some that are involved in regulation and/or that influence risk via novel biological mechanisms. Such variants will not be conducive to discovery using more standard annotation techniques or formal algorithm-based probabilistic methods which focus on prioritization based on well-described biological mechanisms. Filtering based on multiple characteristics of potential importance, such as allele frequency differences from a background or sharing within a pedigree will likely be useful in identifying these more obscure risk variants; however, black-box hard-filters may inadvertently remove variants of potential importance. Data visualization can be extremely useful for informed heuristic prioritization. The observed structure of the data across multiple characteristics can be instructive and guide the sorting and prioritization of variants for follow-up functional studies.

We have developed an interactive visualization tool, *compreheNGSive*, to support investigation and prioritization of next generation sequence variants. The tool requires .VCF file(s) for variants and, optionally, additional variant-level and/or feature-level data. Variant level data can be categorical (e.g. annotations, sharing in a pedigree) or quantitative (e.g. correlations with known associated risk variants or a LOD score) and is read from columnar text format, such as .CSV. Feature-level data is read from .BED or .GFF format. The user defines sample groups for comparison (e.g. case group, control group, background population), which can be incorporated from one or multiple .VCF files. A target group is defined as the focus for comparisons (e.g. cases) and is used to identify the allele of interest at each locus. The viewer includes a scatterplot, parallel coordinates (to display all frequencies and other variant-level data) and a genome browser (for location, refseq gene context and other feature-level data). All displays are linked and update dynamically, and axes are interchangeable between views. Variant selection and provenance mechanisms, as well as the ability to cope with missing data attributes, are provided. Any selected subset can be exported in columnar text format. The software is written using Python and the Qt framework, which is compatible with Windows, Linux, Mac OS X, and potentially mobile operating systems, and is fully scalable to whole genome data.

Integrating genome-wide gene expression and genotype data to predict HDL cholesterol levels in the Cholesterol and Pharmacogenetic Study (CAP). *E. Holzinger[1,2], S. Dudek[1,2], A. Frase[2], M. Medina[3], R. Krauss[3], M. Ritchie[2].* 1) Ctr Human Gen Res, Vanderbilt Univ, Nashville, TN; 2) Pennsylvania State University, University Park, PA; 3) Children's Hospital Oakland Research Institute, Oakland, CA.

Technology is driving the field of human genetics research with advances in the ability to generate high-throughput data that interrogate various levels of biological regulation (genomic, transcriptomic, proteomic, etc). With this massive amount of data comes the important task of using powerful and creative bioinformatics techniques to sift through the noise to find true, meaningful signals that predict various human traits. A popular analytic method thus far has been the genome-wide association study (GWAS), which assesses the association of each DNA variation with the trait of interest. Unfortunately, GWAS has not been able to explain a substantial proportion of the estimated heritability for most common, complex traits. Due to the inherently complex nature of biology, this phenomenon could be a factor of the simplistic GWAS study design. A more powerful study design for this data may be a systems biology approach that integrates different types of data, or a meta-dimensional analysis. Low HDL cholesterol is a significant risk factor for cardiovascular disease. For this analysis, we integrated ~3 million SNPs and ~25,000 gene expression variables from 480 individuals that participated in the CAP simvastatin clinical trial to generate meta-dimensional models that predict HDL cholesterol levels. First, to reduce the noise in the data set, we used a statistical filtering method that allows for main and interaction effects. Next, we used the filtered variables (591 SNPs and 222 EVs)to find significantly enriched pathways that cluster into non-redundant biological functions. The most significant cluster involved cellular membrane pathways (p-value 1.8E-4). Cellular membrane processes play a major role in HDL-C synthesis and metabolism. Finally, to generate more parsimonious meta-dimensional models, we analyzed the filtered set of SNPs and expression variables using the Analysis Tool for Heritable and Environmental Network Associations (ATHENA). Our best model consisted of 3 expression variables and one SNP, which together explain 9.4% of the variation in HDL cholesterol in this cohort. This systems biology approach demonstrates that with the right methods, different types of high-throughput data can be integrated to generate meta-dimensional models that predict complex human traits.

1443T

ATOMIC - Assess genotype calling quality using R or Affymetrix' genotyping console software. *A. Ziegler, A. Schillert.* Inst Med Biometry & Statistics, Univ Luebeck, Luebeck, Germany.

Single nucleotide polymorphism (SNP) chips are used for the analysis of exomes, targeted SNP typing, and genome-wide association analysis. High data quality is required for especially for SNP chips focusing on rare variants because misclassified genotypes for only a few individuals can result in highly inflated type I errors. Several statistical approaches, such as collapsing methods for rare variants, gene-gene interaction studies, or data mining approaches also require extremely clean input data to avoid false positives. The best approach for quality control is the investigation of signal intensities, but this approach is computationally intensive and has therefore been limited to SNPs with positive association signals. We present the R package ATOMIC, an acronym for AuToMatic Inspection of Cluster plots. Its main features are 1) splitting of signal intensities into smaller, manageable datasets, 2) assessment of the clusterings utilizing the theory of cluster analysis, including tests for unimodality [1,2], an improved implementation of the ACPA [3] algorithm, and 3) modern graphical display of the resulting signal intensity plots [4]. The approaches implemented in the R package will also be available soon in Affymetrix' genotyping console software. [1] Larkin 1979, Behav Res Meth Instr 11:467–468 [2] Engelman and Hartigan 1969, J Am Stat Assoc 64:1647–1648 [3] Schillert et al. 2009, BMC Proc 3:S58 [4] Wickham, 2009, Springer New York.

Single Center Experience with Peripheral Blood Gene Expression Profiling in a Large Cardiovascular Cohort. *E.A. Burns[1], S. Feng[1], C. Haynes[1], K. Abramson[1], M. Chryst-Ladd[1], E.R. Hauser[1], L.K. Newby[2], S.G. Gregory[1], W.E. Kraus[1,2], S.H. Shah[1,2].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Medicine, Duke University Medical Center, Durham, NC.

BACKGROUND. Gene expression profiling can provide insight into disease processes. Whole genome expression microarrays provide high-throughput capabilities and comprehensive gene profiling. The overarching goal of our study was to assess the relation between gene expression profiles in blood and cardiovascular disease in a large cohort of 2022 individuals referred for evaluation of coronary artery disease at Duke University. Here we describe our experiences and obstacles in carrying out a large peripheral blood gene expression project with disease outcomes. METHODS/RESULTS. We selected a cohort of 2022 sequential individuals referred for diagnostic coronary artery catheterization at Duke University Hospital. RNA was extracted from frozen peripheral blood that had been stored in PAXgene tubes. RNA from 2022 samples was extracted at two different facilities, of those 298 (14.7%) failed extraction, 116 (5.7%) had RIN scores of less than 6, leaving 1608 (79.5%) to be run on the Illumina HT-12 Gene Expression chips. Basic quality control (QC) assessment followed the manufacturer protocol and included basic analysis such as, gene intensity and probes detected, using the Illumina GenomeStudio program. Data was then analyzed at the plate, chip, and individual sample level to identify outliers identified by principal components analysis of the Illumina QC measures. Outliers were excluded at the plate level (195 [12.1%] samples removed); chip level (103 [6.4%] samples removed) and then at the individual level (27 [1.7%] samples removed). In total 325 (20.2%) samples were excluded in this QC process, leaving 1283 samples for further analysis. These 1283 samples were analyzed in batches of 897 and 386 samples in which they were hybridized to the Illumina Gene Expression chips. Analysis showed that RIN score prior to total RNA processing (TotalPrep) and analysis batch did not contribute to quality of the RNA expression signals. CONCLUSIONS. We describe the QC procedures and factors we found to be important in developing high quality gene expression datasets from peripheral blood. Our experience highlights the potential obstacles in dealing with large datasets and demonstrates how incorporation of multiple QC measures is necessary to ensure data quality. These expression data are being used concurrently with GWAs, DNA methylation, metabolomics and clinical outcomes data to discover human systems biology related to cardiovascular disease and its risk factors.

Best practices and joint calling of the Illumina HumanExome BeadChip: the CHARGE consortium. *M.L. Grove[1], B.J. Cochran[1], T. Haritunians[2], J.C. Bis[3], K.D. Taylor[2], M. Hansen[4], C.J. O'Donnell[5,6], J.I. Rotter[2], E. Boerwinkle[1], CHARGE Exome Chip Genotyping Committee.* 1) Human Genetics Center, University of Texas HSC at Houston, Houston, TX; 2) Medical Genetics Institute, UCLA Cedars-Sinai Medical Center, Los Angeles, CA; 3) Cardiovascular Health Research Unit, University of Washington, Seattle, WA; 4) Illumina, Inc., San Diego, CA; 5) Cardiology Division, Massachusetts General Hospital, Boston, MA; 6) Framingham Heart Study of the National, Heart, Lung, and Blood Institute, Framingham, MA.

Objective: Exome and whole genome sequencing is becoming more affordable and allows for the detection of novel rare variation in the human genome. Yet, genotyping arrays are a more cost effective approach when typing previously-identified genetic polymorphisms in large populations. One limitation of SNP arrays with low population minor allele frequencies is the ability of clustering algorithms to accurately detect and assign genotype calls. Thus, participating studies in the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium consented to have their array data analyzed collectively in order to increase the ability to accurately genotype rare variants. **Methods:** Approximately 60,000 ethnically diverse samples from the following eleven CHARGE cohorts were genotyped with the Illumina HumanExome BeadChip across seven genotyping centers: Age, Gene/Environment, Susceptibility—Reykjavik (AGES) Study, Atherosclerosis Risk in Communities (ARIC) Study, Cardiac Arrest Blood Study (CABS), Cardiovascular Health Study (CHS), Coronary Artery Risk Development in Young Adults (CARDIA), Erasmus Rucphen Family (ERF) Study, Multi-Ethnic Study of Atherosclerosis (MESA), Family Heart Study (FamHS), Framingham Heart Study (FHS), Health, Aging, and Body Composition (HABC) Study, Jackson Heart Study (JHS) and Rotterdam Study (RS). Each cohort genotyped a common set of unrelated HapMap samples for quality control and determination of batch effects. The raw data files for the samples were transferred to a central location and assembled into a single project for joint calling. Performance of the experiment was tested by examining the concordance of genotypes in a subset of individuals with both exome array and exome sequence data. **Results:** Of the 247,870 markers on the array, 247,485 had call rates > 95%. After exclusion of low performing SNPs on the array and non-overlap of SNPs derived from sequence data, 191,557 genotypes were compared in 530 individuals (85,867 were monomorphic). A total of 101,525,210 pairs of genotypes were tested and 99.7% matched, 0.17% had missing data, and 0.13% was discordant. Mismatches were attributed equally to both sequencing and genotyping which suggests the small number of miscalls are due to the random result of genetic detection technology. **Conclusion:** These data document the ability to accurately genotype rare variation using array technology when a large sample size is available and best practices are followed.

A Supervised Approach for Filtering and Genotyping High Quality Short Indels from Next Generation Sequencing Data. *A. Tan, H.M. Kang.* University of Michigan, Ann Arbor, MI.

Identifying short indels from Next Generation Sequencing (NGS) technologies is much more challenging than single nucleotide variant detection due to complex patterns of systematic errors in sequencing and alignment procedures. Current available indel calling algorithms produce highly discordant call sets, often showing less than 50% concordance between different algorithms on the same set of mapped reads. Extracting high quality indels from one or more call sets with minimal loss of sensitivity is very important to reliably and powerfully identify potentially causal variants in sequenced-based association studies. We developed and implemented a novel method for extracting high-quality short indels from arbitrary sets of candidate indels by utilizing available resources from independent technologies such as Affymetrix Exome Genotyping Arrays or Complete Genomics' public genomes. By annotating each candidate indel variant with informative sequence-based features such as allele balance, excessive heterozygosity, complexity of sequence context and cycle bias, our method builds a support vector machine trained by the external data. Applying our method to 1000 Genomes Phase 1 indel calls with Affymetrix Exome Array training data, we reduced the estimated false positive rate from 13% to 5%. We found that features like posterior probability of likelihood of indels, allele balance, and excessive heterozygosity helped improve the quality of Indels. Our method is publicly available through a user-friendly software pipeline that provides genotyping and variant filtering simultaneously from candidate indels and aligned sequence reads. Along with the ongoing efforts to improve existing individual indel calling algorithms, we anticipate that our method will contribute to increasing our understanding and discovery of genetic risk factors beyond single nucleotide variants.

Merging Genomic Data for Research in the Electronic MEdical Records and GEnomics Network: Lessons learned in eMERGE. *M.D. Ritchie[1], S. Setia[1], G. Armstrong[1], L. Armstrong[2], Y. Bradford[3], D.C. Crawford[3], D.R. Crosslin[4], M. de Andrade[5], K. Doheny[6], M.G. Hayes[2], G. Jarvik[4], I.J. Kullo[5], R. Li[7], T. Manolio[7], M. Matsumoto[5], C.A. McCarty[8], D. Mirel[9], S. Nelson[4], L. Olson[3], E. Pugh[6], S. Purcell[10], G. Tromp[11], J.L. Haines[3].* 1) Biochemistry & Molecular Biology, Pennsylvania State University, University Park, PA; 2) Northwestern University, Chicago, IL; 3) Vanderbilt University, Nashville, TN; 4) University of Washington, Seattle WA; 5) Mayo Clinic, Rochester, MN; 6) CIDR, Johns Hopkins; 7) NHGRI, Bethesda, MD; 8) Essentia Rural Health, Duluth, MN; 9) Broad Genotyping Center, Boston, MA; 10) Mt Sinai, New York, NY; 11) Geisinger Medical Center, Danville, PA.

Biobanks linked to electronic health records (EHR) is an emerging area of research for dissecting the architecture of complex human traits. Electronic phenotyping algorithms are deployed in large EHR systems to “ascertain” samples for analysis. To achieve success, sample size is an important consideration to maximize statistical power. To this end, merging data generated from different genotyping platforms is often desired. The eMERGE network, an NHGRI funded initiative, has developed a pipeline for merging genomic data generated on a single platform as well as a new pipeline for merging data from different genotyping arrays based on imputation. eMERGE consists of seven sites, each with DNA databanks linked to EHRs. Over 42,000 samples have been genotyped using one of the available Affymetrix and Illumina genome-wide genotyping arrays. These data have been imputed using BEAGLE and the October, 2011 release of the 1000 Genomes cosmopolitan reference dataset. Because of the computational complexity of imputation and the large sample size of the merged eMERGE dataset (42,807 individuals), a distributed imputation pipeline was implemented. In this scheme, the genome was divided by SNPs into 30,000 marker “SNPlets” with 700 markers of overlap on each side, resulting in 510 SNPlets; the data were also divided into sample sets of n=2000 or less. This parallelized pipeline resulted in over 556 billion SNPs (more than 13 million per individual) based on hundreds of thousands of CPU hours. The dataset generated consists of genome-wide SNPs on thousands of individuals all linked to EHR systems where numerous phenotypes can be explored. The genotype data will be available for research in dbGAP. The lessons learned by this group of investigators will be valuable for the genomics community also dealing with the combining of large-scale genomic datasets. We will present the details of our imputation pipeline, including our quality control investigations in data of this scope and magnitude. This merged eMERGE dataset is an invaluable resource for the genomics community to discover genetic risk factors for common, complex diseases and pharmacogenomic traits.

Detecting Sample Contamination. *M. Flickinger[1], G. Jun[1], K.F. Doheny[2], J. Romm[2], K.N. Hetrick[2], G.R. Abecasis[1], M. Boehnke[1], H.M. Kang[1].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, Michigan 48109-2029; 2) Center for Inherited Disease Research (CIDR), Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

While advances in genotyping and next-generation sequencing have resulted in higher throughput, lower costs, and reduced error rates, DNA sample contamination remains a threat to data quality. Here we describe methods to detect whether a DNA sample contains DNA from more than one individual. Our goal is to detect and quantify low-levels of contamination early in the analysis pipeline for sequencing and genotyping studies. Our methods allow us to estimate contamination given (a) aligned sequence data and genome-wide, array-based genotypes ; (b) aligned sequence data alone; and even (c) prior to sequencing, when only genotype array data are available. Our sequenced based methods assume that two samples are mixed and that the probability of observing a read from one sample is proportional to the mixture proportion. To estimate a contamination proportion, we maximize the likelihood of observing a particular set of reads for a given mixing proportion while also accounting for read quality scores. Detection of contamination using only genotype-array data can either be accomplished by modeling the observed probe intensities as a Gaussian mixture, or by performing a linear regression of the Illumina reported B-allele frequency against a reference population minor allele frequency. To validate the sequence-based methods, we contaminated reads in silico from pairs of CEU individuals sequenced as part of the 1000 Genomes Project to have specific, known levels of contamination ranging from 0.1%–50%. We observed a Pearson correlation coefficient between our estimated contamination proportion and the truth of r=.9996 using both genotype-array and sequence data and r = .9840 using sequence data alone. To validate the genotype-array methods, we analyzed mixtures of DNA samples from HapMap individuals created to have specific, known levels of contamination ranging from 0.5%–10%. We genotyped these samples using the Metabochip genotyping array (a custom Illumina iSelect SNP array with ~200,000 markers in regions previously shown to be associated with metabolic traits). The mixture and regression models produced highly concordant results and correctly identified at least 34 of the 36 mixtures. These methods reliably detect contamination as low as 1%. Application of these DNA contamination detection methods provides a sensitive approach to identify contaminated samples and to maximize data quality.

Regression Models to "Explain" Departure from Hardy-Weinberg Equilibrium. *D.J. Schaid, JP. Sinnwell, GD. Jenkins.* Health Sciences Research, Mayo Clinic, Rochester, MN.

Testing whether genotype frequencies depart from Hardy Weinberg equilibrium (HWE) plays a major role in evaluating the quality of measured genotypes; gross departures often result from genotype misclassification errors. It is now standard practice to test HWE for SNPs used for genome wide association studies, and discard those with extreme p-values (e.g. p-value < 1e{hyphen}6). Yet, it is not unusual to find a relatively large number of SNPs whose chi-square statistics do not fit the null expected distribution based on quantile-quantile plots, a finding that could result from population stratification. In this situation, it would be helpful to determine whether measured covariates (such as principal components, geographic coordinates, or ethnic group indicators) could "explain" departures from HWE; departure from HWE implies correlation of alleles within subjects. Explained departures could occur when allele frequencies depend on measured covariates, yet there is minimal residual correlation of alleles within subjects. To address this need, we have developed a two-level strategy that first robustly evaluates which covariates should be included in regression models (allowing for the possibility of residual correlation between alleles), and then tests whether the residual correlation significantly differs from zero after adjusting for covariates. The statistical properties of our approach are illustrated by simulations, along with applications to real data. Because our methods are based on standard software for generalized linear models, they can be readily applied in standard practice, adding to the array of useful tools to analyze and understand large-scale genomic data.

SNP genotyping is a valuable tool for assessing the quality of next generation sequencing data. *J. Park[1], B. Vecchio-Pagán[2], H. Cuppens[3], G. Cutting[1].* 1) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Cellular and Molecular Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 3) Center for Human Genetics, KULeuven, Leuven, Belgium.

Linkage analysis of families can localize rare risk alleles. However, identification of the risk alleles is usually challenging due to the magnitude of the genomic region that has to be investigated. Targeted sequencing using next-generation sequencing (NGS) technology affords a cost-effective method to find rare variants that underlie linkage signals. Comparison with array based genotyping provides an opportunity to assess to the accuracy of NGS results. To assess the quality of targeted sequencing data, we analyzed a 1.6Mb linkage region on 20q13.2 (LOD=5.03) that harbors a modifier of lung function in cystic fibrosis. Four families of 4 individuals (2 parents and 2 affected children) underwent sequencing in 2 batches of 2 families each. Data were generated on Illumina HiSeq2000 after target enrichment with Nimblegen custom array. Approximately 90.4% (4779/5291) and 81.4% (3194/3929) of the variants mapped to the targeted regions at a minimum read depth of 8x (common default threshold) in batch 1 and 2, respectively. On average, 1.02 ± 0.45 and 0.63 ± 0.33 variants were found per kb in each batch. The mean depth of off-target variants found on chr20 was significantly lower (3.5x and 3.7x) compared to that of on-target variants (34.9x and 17.9x) in the 20q13.2 region. Also, the mean mapping quality of off-target variants was lower (36.6 and 37.1) than that of on-target variants (46.8 and 47.1). Overall, poor capturing in the second batch of 8 individuals resulted in lower depth and more off-target variants compared to the first batch of 8 individuals. To evaluate the accuracy of the sequence, NGS calls were compared to the genotypes generated by Illumina 610K array. Of 307 calls from the array in the 20q13.2 linkage region, 296~305 calls were present in batch 1 at a minimum read depth of 8x, representing 98.4% of coverage. Furthermore, 98.9% of the genotype calls were consistent between the array and sequencing. The majority of the discordant calls were due to incorrect variant calling by SAMtools. As expected, the lower sequence coverage obtained for batch 2 resulted in fewer matched SNPs (222~281), representing 82.9% of coverage, and lower accuracy (95.4%). A high-density SNP array data is useful in assessing NGS data quality and evaluating the variants found in targeted sequencing. Based on the SNP array comparison, the minimum depth can be lowered below 8x for high quality NGS data or raised for poor quality data in future analysis.

Imputation quality thresholds for rare and common variants. *G. Pistis[1,2,3], C. Sidore[1,2,3], A. Mulas[1], M. Zoledziewska[1], R. Berutti[3,4], F. Reinier[4], MF. Urru[4], A. Maschio[1,2], M. Marcelli[4], A. Angius[1,4], C. Jones[4], G. Abecasis[2], S. Sanna[1], F. Cucca[1,3].* 1) Istituto di Ricerca Genetica e Biomedica-CNR, Monserrato (CA), 09042, Italy; 2) University of Michigan, School of Public Health, Ann Arbor, MI, 48109; 3) Università degli Studi di Sassari, Dip Scienze Biomediche, Sassari, 07100, Italy; 4) Center for Advanced Studies, Research and Development in Sardinia - CRS4, Italy.

Genotype imputation allows the analysis of variants discovered by sequencing to extend across much larger numbers of individuals. A key issue in these analyses is deciding which variants can be well imputed. Here, we use a large panel of 1,146 sequenced individuals to drive genotype imputation and investigate the behaviour of commonly used imputation quality thresholds. For this analysis, we compared imputed and real genotypes at 47,010 high quality SNPs from the ExomeChip, typed in 6,020 individuals from the SardiNIA study. We observed that for MAF ≥1% (28,267 SNPs), the standard imputation quality cutoff of RSQR >0.3, suggested for the algorithms implemented in MACH and minimac, discards the highest proportion of bad quality SNPs (genotype-dosage correlation <0.5) while keeping the highest proportion of good quality ones (genotype-dosage correlation >0.9). Indeed, with this threshold, we would discard 96.7% of poor quality SNPs and keep 99.7% of those with good quality. On the other hand, if we consider less common variants (0.5%≤ MAF <1%) (4,071 SNPs), the same RSQR threshold will exclude only 89.7% of the low quality imputed markers. Using instead an RSQR >0.55, the percentage of low quality markers excluded increases to 97.2%, while losing only 2.9% of those imputed with high accuracy. Finally for rare variants (0.05%≤ MAF <0.5%) (9,266 SNPs), an RSQR >0.65 can guarantee 96.7% and 4.7%, respectively. Our results thus suggest that more restrictive quality cutoffs might reduce false positive signals in association analyses, particularly for imputed rare variants.

1452T

Error rates for very low MAF SNP's on the Illumina Exome Array. *E.W. Pugh[1], H. Ling[1], J.M. Romm[1], I.A. McMullen[1], J.R. Huyghe[2], M. Boehnke[2], K.F Doheny[1].* 1) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor MI.

Some GWAS analyses filter low MAF SNPs due to concern about higher error rates and increased type I errors. As genotyping and analyzing low MAF SNPs is the focus of Illumina's Exome array, we wanted to estimate the error rates for the SNPs at different allele frequencies looking at both minor allele frequency and the count of genotypes not in the major homozygote cluster (nmgc). For this analysis we took a subset of samples from a large exome project of over 11,000 samples of European ancestry plus Hapmap samples. We used GenomeStudio version 2011.1, Genotyping Module version 1.9.4, GenTrain Version 1.0 to cluster the 87 unrelated HapMap samples one pair of HapMap duplicates and project together with 4111 randomly selected investigator samples. This created a 4200 sample project, which is our median project size for exome content array projects. To assess error in multiple ways, we then applied the clustering from the 4200 samples to 142 additional HapMap samples, run with the project and computed reproducibility and Mendelian inheritance rates. We manually reviewed cluster plots for subsets of the SNPs to determine the proportion that appeared poorly clustered such that a genotype would be misspecified. We also compared the genotypes to 1KGP (Oct 2011 release) for 62 out of the 87 samples that are present in1KGP. In the 4,200 sample data set out of the 247,870 SNP on the exome array, 1,259 (0.5%) SNPs were not called, 131,239 (53%) were monomorphic, 26,271 (11% maf .0001-.0003) were singletons, and 11,051 (4% maf .0002–.0005) were doubletons. There were 13683, 11899, 9568 SNPs with nmac of three to five (maf .0003–.0012), 6–15 (maf .0007–.0035), and 16–50 (maf .0018–.0117) respectively. The median number of singletons heterozygote SNPs per HapMap population for the unique samples were: CEU:38, TSI: 57.5, GIH:42.5, MXL:96, CHB: 147 JPT:159, YRI: 313. The proportion of SNPs with one or more Mendelian inheritance, reproducibility error or genotype discordant with sequencing increased with the count of non major genotypes. This may reflect decreased power for these methods to detect errors rare SNPs. Preliminary results of manual review suggest that the proportion with errors is more consistent across the count of non major genotypes and that intensity based filters (for example low intensity values (R) for singleton heterozygote calls) may be useful to flag additional genotyping errors.

An Algorithm for Identifying High-Order Gene-Gene Interactions from Pairwise Statistical Epistasis Networks. *T. Hu, A.S. Andrews, M.R. Karagas, J.H. Moore.* Department of Genetics, Institute for Quantitative Biomedical Sciences, The Geisel School of Medicine, Dartmouth College, Lebanon, NH.

Bladder cancer is the fourth most common malignancy in western countries. Besides the major contributor of tobacco smoking, hereditary factors have also been suggested playing an important role causing bladder cancer. Many single-locus biomarkers have been reported but could only be used to explain very limited heritability of this complex disease. The interaction effects among multiple genes, i.e., epistasis, could lead provide insights into the complex genetic architecture of bladder cancer. Detecting and characterizing epistasis is computationally challenging due to the large number of combinations in genome-wide association study (GWAS) data. Previously we identified a statistical epistasis network (SEN) using pair-wise interactions among approximately 1500 single nucleotide polymorphisms (SNPs) spanning nearly 500 cancer susceptibility genes in a large population-based study of bladder cancer in the state of New Hampshire. Unlike many existing techniques, SEN provides a model-free and global pair-wise interaction landscape. Here, we used the structural information from this pairwise SEN and evaluated all the three-way interactions that are directly connected in the network using multifactor dimensionality reduction (MDR). Using the pairwise SEN as a guide, we were able to find significant evidence for three-ways gene-gene interactions. The pairwise SEN significantly reduced the computational complexity of exhaustive evaluation all possible three-way combinations. In addition, the model we found also outperformed the results of a number of other commonly used filters such as ReliefF or Chi-square. Our study suggests that using knowledge of pairwise epistasis may aid in the detection and characterization of high-order interactions in GWAS data.

Fine-Mapping in a Covariate-based Genomewide Linkage Scan of Lung Cancer Susceptibility. *C.L. Simpson[1], T. Green[1], B. Doan[1,2], C.I. Amos[3], S.M. Pinney[4], E.Y. Kupert[4], M. de Andrade[5], P. Yang[5], A.G. Schwartz[6], P.R. Fain[7], A. Gazdar[8], J. Minna[8], J.S. Wiest[9], H. Rothschild[10], D. Mandal[10], M. You[4], T.A. Coons[11], C. Gaba[12], M.W. Anderson[4], J.E. Bailey-Wilson[1].* 1) Inherited Disease Res Branch, NHGRI, NIH, Baltimore, MD; 2) Johns Hopkins School of Medicine, Baltimore, Maryland; 3) Department of Epidemiology, University of Texas, M.D. Anderson Cancer Center, Houston, Texas; 4) Medical College of Wisconsin, Milwaukee,Wisconsin; 5) Department of Health Sciences Research, Mayo Clinic Rochester, Minnesota; 6) Karmanos Cancer Institute, Wayne State University, Detroit, Michigan; 7) University of Colorado, Denver, Colorado; 8) University of Texas Southwestern Medical Center, Dallas, Texas; 9) National Cancer Institute, NIH, Bethesda, Maryland; 10) Louisiana State University Health Sciences Center, New Orleans, Louisiana; 11) Saccomanno Research Institute and John McConnell Math & Science Center of Western Colorado, Grand Junction, Colorado; 12) University of Toledo, Toledo, Ohio.

Lung cancer (LC) is a leading cause of death in the developed world, with over 160,000 deaths expected in the US in 2012. Environmental risk factors such as smoking and asbestos exposures are well known. However, only 15% of smokers develop LC, suggesting genetic effects or gene-environment (GxE) interactions. We previously mapped a major LC susceptibility locus to 6q23–q25, and discovered a rare risk haplotype in linked families that exhibits a GxE interaction between the 6q susceptibility locus and smoking. Genome-wide association studies have suggested other loci with common alleles of small effect on LC risk. However, these loci do not explain all familial risk of LC, suggesting that additional risk alleles exist. We have also found additional susceptibility loci using linkage analysis including environmental covariates on 6p (LOD=5.75, 74cM) and 6q (LOD=3.25, 173cM), with novel evidence of linkage on 12q24 (LOD=5.46, 150cM) and 22q11 (LOD=5.19,10cM). Linkage to lung and throat cancer was observed on 9p21 (LOD=4.97, 64cM). All analyses were on microsatellite data. Here we present the results of a fine-mapping linkage analysis, with data from the microsatellite study combined with a dense SNP map. The data were checked for Mendelian inconsistencies and low call rate and the marker allele frequencies were estimated from the data. Linkage analyses of LC (adjusting for personal smoking) to the combined microsatellite/SNP dataset using LODPAL will be presented.

Meta-analysis of 2,526 individuals demonstrates strong evidence for gene-environment interaction between *NAT1* and tobacco smoke exposure in multiple sclerosis. F.*B.S. Briggs[1], B. Acuna[2], L. Shen[2], P. Ramsay[1], H. Quach[1], A. Bernstein[2], I. Kockum[3], L. Alfredsson[4], T. Olsson[3], C. Schaefer[2], L.F. Barcellos[1].* 1) Genetic Epidemiology and Genomics Laboratory, Division of Epidemiology, School of Public Health, University of California, Berkeley, Berkeley, CA; 2) Division of Research, Kaiser Permanente, Oakland, CA; 3) Center for Molecular Medicine, Department of Medicine, Karolinska Institute, Sweden; 4) Institute of Environmental Medicine, Karolinska Institute, Sweden.

Multiple sclerosis (MS) is a neuro-inflammatory autoimmune disease with a multifactorial etiology, involving both genetic and environmental components. Exposure to tobacco smoke has consistently demonstrated association with increased MS risk. However, not all smokers develop MS, and only some individuals with MS were ever smokers. We hypothesized that host genetics contribute to metabolism of tobacco smoke constituents, and thus, the development of MS in smokers. A gene-environment (GxE) investigation was conducted to assess whether variation within *NAT1*, *NAT2*, *GSTM1*, *GSTP1* and *GSTT1*, modifies the MS risk conferred by tobacco smoke. These loci are known for their critical role in tobacco smoke constituents metabolism, and their variation has been well-established in several cancers. The discovery data set used comprehensive smoke exposure (including smoking at age 20 and childhood passive smoke exposure) and genetic data collected from ~1,600 White MS case and control members of the Kaiser Permanente (KP) Northern California Region HealthPlan. The replication data set used a study population of ~1,000 White MS cases and controls from Sweden (SW). A history of tobacco smoke was significantly associated with greater MS risk (KP: odds ratio [OR]=1.3, p=0.005; SW: OR=1.4, p=0.009). In the discovery analysis, logistic models adjusted for age, gender, education, and population ancestry, investigated GxE interactions using dense genetic data for the 5 loci (745 SNPs). Specific metabolism phenotypes were also explored (*GSTM1* and *GSTT1* null, *NAT1* and *NAT2* slow acetylator phenotypes). 101 NAT1 variants had significant interactions ($p<0.05$). 85 *NAT1* SNPs were in the replication data set. A variant (rs7388368) within a dense transcription factor (i.e. NF-YB, USF1, USF2) binding region had significant interactions in both data sets (KP: odds ratio of interaction (OR_I)=1.7, p=0.004; SW: OR_I=1.6, p=0.03). In the combined meta-analysis, rs7388368 had an OR_I=1.6, p=0.0005, conferring MS risk among smokers only. Similar results were observed for SNPs in linkage disequilibrium: rs4921877 (OR_I=1.4, p=0.01) and rs6586711 (OR_I=1.4, p=0.01); their minor alleles have been correlated with decreased *NAT1* expression in lymphoblastoid cells. We have identified and replicated the first non-MHC GxE interaction in MS, identifying *NAT1* as a MS susceptibility locus important in the context of the environment. These results provide novel insight to underlying disease mechanisms in MS.

Algebraic Statistics and Markov Bases in Gene-Environment Interactions. *M. Rao, S. Venkatesan.* Environmental Hlth, Univ Cincinnati, Cincinnati, OH.

The data of interest structurally has three components: Disease (Present or Absent); Genotype (AA, Aa, aa); Environment (categorized into a finite number of categories). For a random sample of subjects from a population of interest, data has been collected whose structure has been outlined as above. The goal is to test the null hypothesis of absence of gene-environment interaction. Classical tests such as Cochran-Mantel-Haenszel test are not applicable for a variety of reasons. We will introduce an analogue of Fisher's exact test, normally used in the context of contingency tables, in our data environment. We will outline how Algebraic Statistics, Markov bases, and Monte Carlo Markov chain simulations can be integrated in the development of our exact test. The test is applied to the data collected from an island population, where the disease is Metabolic syndrome and environment is age, fasting glucose level, or a composite index of their dietary habits. A choice number of SNPs are investigated.

AprioriGWAS, a frequent itemset mining approach, detects angiogenesis gene interacting with CFH in age-related macular degeneration. *Q. Zhang, Q. Long.* Gregor Mendel Institute, Vienna, Austria.

Identifying gene-gene interaction is a hot, albeit difficult, topic in genome-wide association studies. There are two fundamental challenges: (1) How to smartly identify combinations of variants that are associated with a trait from the astronomical number of possible combinations; and (2) how to test for the presence of interaction when large numbers of associated combinations have been identified. We developed an algorithm called AprioriGWAS, which brings two innovations: (1) It is based on Apriori, a successful method in the field of frequent itemset mining in which a specific pattern growth strategy is leveraged to reduce the search space. It can enormously reduce the number of possible genotype patterns to be checked. (2) We developed conditional permutation to test the interaction effect between variants to reduce the artifacts of association between genotype patterns and phenotype outcomes generated by one variant with high marginal effect. Using simulations following Marchini et al's procedure, it is demonstrated that AprioriGWAS can approximately achieve the coverage of all associated pattern as exhaustive search, but with much less CPU time. Also, as a benefit of conditional permutation, AprioriGWAS has much higher power than logistic regression based on exhaustive search when the type I error is adjusted to be the same. We applied AprioriGWAS to age-related macular degeneration (AMD), which has been deemed a good example of a small number of variants explaining a large proportion of heritability. We found that ANGPT1, BBS9, MPP7, MED27, CHRM2 are interacting with a well-known AMD gene, Complement Factor H (CFH). An exciting finding is ANGPT1, which is a protein with important roles in vascular development and angiogenesis. Drugs for anti-angiogenic activity have been approved by the FDA in the United States for the treatment of cancer and AMD. As far as we know, its interaction with CFH is reported for the first time here. Other genes, e.g. BBS9, MPP7, MED27 are also reported to be important for retinal disease. We also found LPHN2 and PLXNA4A, that both play roles in nervous system are interacting, despite an absence of a marginal effect. Genes with similar functions are interacting with each other. Overall, the potentially interacting genes are enriched in the glycosaminoglycan biosynthetic process (P=1.39E-06). In conclusion, interactions in AMD pathways are abundant and AprioriGWAS is a good tool to find epistasis from GWAS.

Genotype-by-environment interaction for multivariate environments using the Mahalanobis distance. *V.P. Diego, H.H.H. Göring, J. Blangero.* Genetics, Texas Biomedical Research Institute, San Antonio, TX.

Complex traits are determined largely by genetic and environmental effects and their genotype-by-environment interactions (GEI). Here we propose a novel approach for modeling the role of GEI in complex traits in relation to multivariate environments in human pedigrees. We employ multivariate dietary measures as our environment in an example. To quantify an individual's total dietary environment, we used food frequency questionnaires to obtain measures on total-carbohydrate, -protein, -saturated fat, -unsaturated fat intake, and other indices. These variables together make up a multivariate environment. We developed a method that uses the Mahalanobis distance (MD) between each pair of individuals based on their vectors of dietary variables. The resulting MD matrix contains all pair-wise dissimilarities amongst individuals in the sample. It is employed in the context of a stochastic Ornstein-Uhlenbeck process to model shared environmental covariation as a measured environmental kernel for structuring a dietary-derived variance component. We can then extend this model to allow for GEI by adding another variance component representing the interaction between additive genetic effects and multivariate dietary effects. Under this approach, we are also able to model an across-environment genetic correlation. The two GEI null hypotheses under this model are an interaction variance equal to 0 (IV0), and a genetic correlation equal to 1 (GC1). The first null implies that there is no interaction effect whereas the second null implies that the same genes are involved across environmental contrasts. Rejection of either or both is evidence of GEI. As an example, we tested for GEI in relation to the MD representation of 19 diet-related variables in large Mexican American pedigrees from the San Antonio Family Heart Study. Of the 12 metabolic syndrome traits examined, we found evidence of GEI for serum leptin (IV0 $p = 0.02$; GC1 $p = 0.01$), systolic blood pressure (IV0 $p = 0.03$; GC1 $p = 0.04$), and high-density lipoprotein cholesterol (IV0 $p = 0.02$). We also show how this approach can be extended to utilize high-dimensional gene expression data. A straightforward application is to treat a given gene expression network (GEN) as an environment, and to use this model to search for potential GEIs with a focal clinically-related phenotype. This general framework for the measurement of multivariate environments is being incorporated into our statistical genetics software, SOLAR.

Interactions between maternal genotypes and metabolites are associated with incidence of congenital heart defects. *S. Erickson[1, 2], S. Chowdhury[3], S.L. MacLeod[2], M.A. Cleves[2], S. Melnyk[2], S.J. James[2], P. Hu[4], C.A. Hobbs[2].* 1) Department of Biostatistics, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Department of Pediatrics, University of Arkansas for Medical Sciences, Little Rock, AR; 3) Clinical Molecular Genetics Department, Providence Sacred Heart Medical Center, Spokane, WA; 4) Buccaneer, a General Dynamics Company, Little Rock, AR.

The development of non-syndromic congenital heart defects (CHDs) involves a complex interplay of genetics, metabolism, and lifestyle. Previous studies have implicated maternal single nucleotide polymorphisms (SNPs) and altered metabolism in folate-related pathways as CHD risk factors. We sought to discover associations between maternal SNPs and metabolites involved in the homocysteine, folate, and transsulfuration pathways, and determine if these associations differ between CHD cases and controls. Genetic, metabolic, demographic, and lifestyle information was available for 335 mothers with CHD-affected pregnancies and 263 mothers with unaffected pregnancies. Analysis was conducted on 1160 SNPs, 13 plasma metabolites, and 2 metabolite ratios. A two-stage multiple linear regression was fitted to each combination of SNP and metabolite/ratio. We identified 4 SNPs in the methionine adenosyltransferase II alpha (MAT2A) gene that were associated with methionine levels. Three SNPs in tRNA aspartic acid methyltransferase 1 (TRDMT1) gene were associated with total plasma folate levels. Glutamylcysteine (GluCys) levels were associated with multiple SNPs within the glutathione peroxidase 6 (GPX6) and O-6-methylguanine-DNA methyltransferase (MGMT) genes. The regression model revealed interactions between genotype and case-control status in the association of folic acid, total glutathione (GSH), and free GSH, to SNPs within the MGMT, 5,10-methenyltetrahydrofolate synthetase (MTHFS), and catalase (CAT) genes, respectively. Our study provides further evidence that genetic variation within folate-related pathways accounts for inter-individual variability in key metabolites. We identified specific SNP-metabolite relationships that differed in mothers with CHD-affected pregnancies, compared to controls. Our results underscore the importance of multifactorial studies to define maternal CHD risk.

A unified generalized multifactor reduction method for detecting gene-gene interactions in family and unrelated samples with application to nicotine dependence. *X. Lou[1], G. Chen[1], N. Liu[1], Y. Klimentidis[1], X. Zhu[2], D. Zhi[1], X. Wang[3].* 1) Dept Biostatistics, Univ Alabama Birmingham, Birmingham, AL; 2) Dept Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Dept Physics and the Comprehensive Diabetes Center, Univ Alabama Birmingham, Birmingham, AL.

Gene-gene and gene-environment interactions govern a substantial portion of the variation in complex traits and diseases. In convention, a set of either unrelated or family samples are used in detection of such interactions; even when both kinds of data are available, the unrelated and the family samples are analyzed separately, potentially leading to loss in statistical power. In this report, based on the theory of principal components analysis, we propose a generalized multifactor dimensionality reduction method that unifies analyses of nuclear families and unrelated subjects within the same statistical framework to detect gene-gene interactions. Through comprehensive simulations, we demonstrate that the proposed method can remarkably increase power by pooling unrelated and offspring's samples together as compared to each of two individual analysis strategies while it retains a controlled type I error rate in the presence of population structure. In application to a real dataset, we detected two significant (after Bonferroni correction) tetragenic interactions among CHRNA4, CHRNB2, BDNF, and NTRK2 associated with Fagerstorm Test for Nicotine Dependence in the Study of Addiction: Genetics and Environment (SAGE) sample, suggesting the biological role of these genes in nicotine dependence development. (This study is being supported by NIH grants DA025095, GM081488, GM077490, HG003054, and DK080100.).

The 5p15 locus is associated with bronchial hyperresponsiveness in siblings unexposed to tobacco smoke in early life in French families ascertained through asthma. *R. NADIF[1,2], P. MARGARITTE-JEANNIN[3,4,5], E. BOUZIGON[3,4,5], F. KAUFFMANN[1,2], M. LATHROP[6], F. DEMENAIS[3,4,5], M-H. DIZIER[3,4,5].* 1) INSERM U1018, CESP Centre for research in Epidemiology and Population Health, Respiratory and Environmental Epidemiology Team, F-94807, Villejuif, France; 2) Univ Paris-Sud 11, UMRS 1018, F-94807, Villejuif, France; 3) INSERM, U946, F-75010, Paris, France; 4) Univ Paris Diderot, Sorbonne Paris Cité, Institut Universitaire d'Hématologie, F-75007, Paris, France; 5) Fondation Jean Dausset-Centre d'Etude du Polymorphisme Humain (CEPH), Paris, F-75010, France; 6) Commissariat à l'Energie Atomique, Centre National de Génotypage, F-91057 Evry, France.

A genome-wide linkage analysis conducted in the French Epidemiological study on the Genetics and Environment of Asthma (EGEA) detected four chromosomal regions linked to bronchial hyperresponsiveness (BHR) and interacting with exposure to tobacco smoke (ETS) in early life (Dizier et al, 2005, 2007). Among these four regions, 1q43–q44 and 4q34 showed linkage to BHR in presence of ETS while 5p15 and 17p11 showed linkage in absence of ETS. Our goal was to conduct fine-scale mapping of these 4 regions to identify the genetic variants interacting with ETS that have an effect on BHR. Association analyses using the family-based association test (FBAT) were conducted in the whole sample of 388 EGEA families (322 sibs with BHR), and in sub-sets stratified according to ETS exposure (138 unexposed sibs with BHR and 184 exposed sibs with BHR). We used a two-step strategy including: 1) selection of SNPs showing association signals with BHR ($p<5\times10\text{-}3$) in the subset where linkage was detected; 2) test of homogeneity of association of selected SNPs with BHR between exposed and unexposed siblings using FBAT to detect SNPxETS interaction. We then applied logistic regression analysis to those variants showing significant interaction with ETS by FBAT, as internal validation to confirm the interaction. In the 5p15 and 17p11 regions, 18 and 15 SNPs showed association signals with BHR ($p<5\times10\text{-}3$) in unexposed siblings, while in the 1q43–q44 and 4q34 regions, 27 and 8 SNPs showed association in exposed siblings. Among these SNPs, only one in 5p15 showed significant evidence for interaction with ETS in the stratified analysis ($p=8\times10\text{-}4$ before correction and $p=0.05$ after correction for multiple testing). Logistic regression provided some support for this interaction ($p=0.11$, in 490 siblings with 63% of them having BHR) Although replication of our results is needed, it is interesting to note that the 5p15 locus that is found associated with BHR in ETS-unexposed siblings has been previously reported to be associated with lung cancer in non-smoking women.

1462F

Systematic identification of interaction effects between genome- and environment-wide associations in Type 2 Diabetes Mellitus. *C.J. Patel[1], R. Chen[1], K. Kodama[1], J.P.A. Ioannidis[2], A.J. Butte[1].* 1) Division of Systems Medicine, Department of Pediatrics, Stanford University School of Medicine, Stanford, CA; 2) Stanford Prevention Research Center, Department of Medicine, and Department of Health Research and Policy, Stanford University School of Medicine, Stanford, CA.

Type 2 Diabetes (T2D) may result from the interplay of both environmental and genetic factors. Genetic loci discovered through genome-wide association studies (GWAS) explain only a small portion of the disease risk variance and some of the unexplained risk may be due to gene-environment interactions. However, documenting gene-environment interactions has been difficult due to lack of concurrent genetic and environmental measurements, factor selection bias, and lack of multiple hypothesis control. We address these challenges by focusing on risk factors that emerge from GWAS and environment-wide association studies (EWAS) for T2D. Using data from 2 surveys (N=1003–3201) from the National Health and Nutrition Examination Survey (NHANES), we systematically screened for statistical interaction in association to T2D 18 genetic loci that have reached genome-wide significance in GWAS along with 5 environmental factors, including 2 pollutants and 3 dietary factors that had false discovery rate (FDR) < 1% in EWAS.T2D was determined by fasting blood glucose (≥126 mg/dL) and environmental factors were measured in serum. We determined we had adequate power (median 70%) to proceed and we implemented 2 methods for multiple hypothesis control, including a false discovery rate (FDR) method via the parametric bootstrap. We adjusted all logistic regression models for age, sex, body mass index, and race. We conducted sensitivity analyses, verifying the strength of interactions by race group. In the end, we found 8 interactions with nominal $p<0.05$ of which 4 had FDR<20%. One interaction withstood Bonferroni correction: non-synonymous SNP rs13266634 (SLC30A8) and trans-β-carotene (Bonferroni-corrected interaction $p=0.006$, FDR<1.5%). The per-risk-allele effect sizes, after adjusting for age, sex, body mass index, and race for those with low trans-β-carotene levels (OR=1.8, 95% CI: 1.3, 2.6) were 40% greater than the marginal genetic effect size of the SNP. We also found an interaction between rs13266634 and γ-tocopherol, a nutrient factor found in corn oil (FDR<20%) imparting 20% higher risk than rs1326634 alone. We present an approach for systematically screening for interactions between genetic and environmental factors. Further prospective validation of the identified novel interactions and/or examination in model systems is warranted. Our results suggest re-framing GWAS with consideration of common environmental factors to identify larger effect sizes for T2D risk.

A New Bayesian Framework for Detecting Gene-Environment Interaction. *X. Wen[1], M. Stephens[2], P. Zheng[1].* 1) Dept of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Dept of Statistics and Human Genetics, University of Chicago, Chicago, IL.

Study of Gene-Environment interaction is critical for understanding the biological processes of complex diseases. In this research, we propose robust and easy-to-interpret Bayesian statistical approaches for detecting potential gene-environment interaction. The proposed framework has two unique features that are distinctly advantageous to existing methodologies: 1. We propose a new statistical formulation to model potential GxE interactions. In particular, we subgroup the samples according to different environment exposures and quantify the interaction as the degree of heterogeneity of genetic effects in subgroups. We show the traditional GxE interaction model is a special case of this general formulation however with a stronger, non-robust assumption. 2. We provide flexible and powerful Bayesian priors to model the relationship of genetic effects in various environmental conditions and expected heterogeneity. This allows us not only to “test” for potential GxE interaction, but also to infer the interaction pattern by Bayesian model comparisons. We demonstrate our approach in detecting eQTLs in different cell environments varied by different Hormone treatment. These interaction eQTLs unveil the interplays between the gene regulatory network and environment conditions.

Overlapping G × G interactions associated with caries in permanent and primary dentition. *K. Cuenco[1], M.K. Lee[1], Z. Zeng[1], J.R. Shaffer[1], X. Wang[1], E. Feingold[1], D.E. Weeks[1], S.M. Levy[2], R.J. Weyant[1], R.J. Crout[3], D.W. McNeil[3], M.L. Marazita[1].* 1) Univ Pittsburgh, Pittsburgh, PA; 2) Univ Iowa, Iowa City, IA; 3) West Virginia Univ, Morgantown, WV.

Oral health affects quality of life and systemic disease at all ages. Caries disease risk may vary by topologic characteristics of the tooth. Genome-wide association studies of primary and permanent dentition separately have identified a few suggestive candidate genes by single variant examination, but no single SNP has reached genome-wide significance. Clinical effects may be the result of gene-gene interactions (GxG) that have not been investigated. We screened for GxG associated with surface-specific caries measures obtained from children and adults. Tooth surface assessment measurements were obtained for child and adult participants from the Center for Oral Health in Rural Appalachia (COHRA, n = 1017 adult, n = 547 child), and Iowa (IOWA, n= 459 child) studies. Subjects included were Caucasian. Clinical assessment of pit/fissure (PF) and smooth (SM) tooth surfaces was recorded for primary and permanent dentition separately. Four dependent variables (PF & SM primary, PF & SM permanent) were dichotomized and used for GxG assessments. Input candidate gene sets were previously identified top 50 ranked genes from single SNP GWAS of caries and additional genes identified from pathway analyses. GWAS used SNP genotypes generated (Illuimina 610-Quad) or imputed (~1.4 million SNPs) by the NIH Gene, Environment Association Studies Consortium. We used multifactor dimensionality reduction (MDR) software to identify GxG of potential importance. MDR regroups SNPs based on similar direction of effects and evaluates predictive ability of the SNP set to generate evidence of GxG. Putative GxG are being generated for each caries measure and similarity comparison. The identified GxG interactions provide more information about the underlying biology of caries. Supported by U01-DE018903, R01-DE 014899, R01-DE09551, and R01-DE12101.

Associations and Interactions of genetic polymorphisms in innate immunity genes with early viral infections and susceptibility to asthma and asthma-related phenotypes. *D. Daley[1], J.E. Park[1], J. He[1], J. Yan[1], L. Akhabir[1], D. Stefanowicz[1], A.B. Becker[2], M. Chan-Yeung[3], Y. Bossé[4,5], A.L. Kozyrskyj[6,7], A.L. James[8], A.W. Musk[9], C. Laprise[10,11], R.G. Hegele[12], P.D. Paré[1], A.J. Sandford[1].* 1) Dept Med, i-CAPTURE Ctr, Univ British Columbia, Vancouver, BC, Canada; 2) 2Department of Pediatrics and Child Health and Manitoba Institute of Child Health, University of Manitoba, Winnipeg, MB, Canada; 3) Occupational and Environmental Lung Disease Unit, UBC, Vancouver, BC, Canada; 4) Institut Universitaire de Cardiologie et de Pneumologie de Québec, Québec, Canada; 5) Department of Molecular Medicine, Laval University, Québec, Canada; 6) Department of Pediatrics, Faculty of Medicine and Dentistry, University of Alberta, Edmonton, Alberta, Canada; 7) Department of Pediatrics and Child Health, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada; 8) Department of Pulmonary Physiology and Sleep Medicine, Sir Charles Gairdner Hospital, Perth, Western Australia; 9) Department of Respiratory Medicine, Sir Charles Gairdner Hospital, Western Australia; 10) Département des Sciences Fondamentales, Université du Québec à Chicoutimi, Saguenay, Québec, Canada; 11) Université de Montréal Community Genomic Medicine Center, Chicoutimi Hospital, Saguenay, Québec, Canada; 12) Department of Laboratory Medicine and Pathobiology, University of Toronto, Ontario Canada.

The innate immune system is essential for host survival because it recognizes invading pathogens and mounts defensive responses. We used four large samples (n=5565) to investigate associations of 321 single nucleotide polymorphisms (SNPs) in 26 innate immunity genes with four phenotypes: atopy, asthma, atopic asthma and airway hyper-responsiveness (AHR) in three Canadian family-based studies and one Australian population-based case control study. Interactions between innate immunity genes and early viral exposure to three common viruses (parainfluenza, respiratory syncytial virus and picornavirus) were examined using data collected from the Canadian Asthma Primary Prevention Study. Analyses were conducted using both an affected-only family-based transmission disequilibrium test and case-control methods. **Results:** Six SNPs (rs1519309 (TLR3), rs740044 (ILIR2), rs4543123 (TLR1), rs5741812 (LBP), rs917998 (IL18RAP), and rs3136641 (NFKBIB)) are significant (P<0.05, confirmed with 30,000 permutations) in both the combined analysis of main genetic effects and SNP*viral interaction analyses in both case-control and family based methods. The TLR1 variant (rs4543123) is associated with both multiple viruses (RSV and PIV) and multiple phenotypes. **Conclusion:** We identified susceptibility genes for asthma and related traits and interactions between these genes and early life viral infections that may prove to be of predictive value for the development of allergic diseases.

1466W

Evidence for Genetic Interactions Beyond Variability Explained by Single SNPs in Ulcerative Colitis. *M.H. Wang[1], X. Zhu[2], R.H. Duerr[3], C. Fiocchi[1], J.P. Achkar[1], The Wellcome Trust Case Control Consortium.* 1) Gastroenterology and Hepatology, Digestive Disease Institute, Cleveland Clinic, Cleveland, OH, United States; 2) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH, United States; 3) Gastroenterology, Hepatology, & Nutrition, University of Pittsburgh, Pittsburgh, PA, United States.

BACKGROUND: A limited fraction of ulcerative colitis (UC) heritability is explained by current genome wide association studies (GWAS). Logic regression (LR) is a method that identifies multi-dimensional logical single nucleotide polymorphism (SNP) combinations and thus could explain phenotypic variability better than single SNP additive models. **MATERIALS & METHODS**: All UC-associated SNPs from the Wellcome Trust Case-Control Consortium (WTCCC Affy6.0; 2361 UC, 5417 controls) with nominal P values <10E-04 (i.e., 314 SNPs) were selected and recoded as binary predictors (dominant and recessive). We applied LR to identify multi-dimensional logical SNP combinations (called `Tree'). The odds ratio (OR) of the identified Tree was estimated by logistic regression and then we examined the same Tree in an independent replication cohort, the Cleveland Clinic/University of Pittsburgh (CC/UP) GWAS (Illumina Omni-1 Quad; 566 UC, 1428 controls). Ungenotyped markers in the replication cohort were imputed in BEAGLE using the 1000 Genome haplotypes data. The R package Logic.Reg was used to conduct LR analysis. Model comparisons were conducted through the ROC functions in SAS 9.2. Gene by gene interactions were tested using logistic regression models. **RESULTS**: In the WTCCC GWAS dataset, a Tree model built on 3 SNPs (rs16870123, *BTNL2*; rs3129868, *HLA-DRA*; rs9267798, *TNKB*) was identified through LR: rs3129868 in recessive mode or (rs16870123 [dominant] and rs9267798 [dominant]). The UC risk of carrying this Tree is OR 2.23 (95%CI:1.93–2.56), P=4.32×10E-28. After controlling the 3 SNPs, the adjusted OR is 2.46 (95%CI:1.89–3.21), P=1.25×10E-11. Compared with the additive mode of 3 SNPs, model predictability was significantly improved when adding the logical interactions term (i.e., Tree) (P=0.002).We examined the same Tree model in an independent CC/UP GWAS and found a similar significant association: OR 2.63 (95%CI:1.95–3.56), P=4.70×10E-10; adjusted OR 1.94 (95%CI:1.14–3.32), P=0.01. These 3 SNPs in the chr6p21 region are not in linkage disequilibrium (pairwise R^2 <0.2) and not in the same haplotype block. There are significant interactions between rs16870123 (*BTNL2*) and rs9267798 (*TNKB*) in the WTCCC and the replication cohort CC/UP ($P_{interaction}$ 2.34×10E-12 and 0.01, respectively). **CONCLUSION**: Interactions among SNPs can be identified through LR. Similar genetic interactions patterns were observed in the WTCCC and the independent replication cohort CC/UP GWAS datasets.

Influence of SNPxSNP interaction on BMI in European American adolescents: Findings from the National Longitudinal Study of Adolescent Health. *K.L. Young[1,2], M. Graff[1,2], K.E. North[1,3], A.S. Richardson[2,6], L.A. Lange[3,4], E.M. Lange[3,4], K.M. Harris[2,3,5], P. Gordon-Larsen[2,6].* 1) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 2) Carolina Population Center, University of North Carolina, Chapel Hill, NC; 3) Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC; 4) Department of Genetics, University of North Carolina, Chapel Hill, NC; 5) Department of Sociology, University of North Carolina, Chapel Hill, NC; 6) Department of Nutrition, University of North Carolina, Chapel Hill, NC.

Adolescent obesity is predictive of future weight gain, obesity, and adult-onset severe obesity (BMI ≥ 40kg/m^2). A greater understanding of underlying factors, including possible gene-gene interactions, can help explain the "missing heritability" in these complex traits, as well as identify potential biological mechanisms affecting weight gain during this critical developmental period. In adolescent participants of European descent (EA) from the National Longitudinal Study of Adolescent Health (N = 5072, ages 12–21, 52.5% female), we tested established BMI-related SNPs (Speliotes et al. 2010) for gene-gene interaction effects on BMI (measured height and weight). We used mixed effects regression, assuming an additive genetic model and adjusting for age, sex, and geographic region, and allowing random effects for clusters by family and school.

The prevalence of obesity was 12.3%. The overall discordance rate across SNPs was 0.3%, and the average call-rate 97.9%. SNPs that diverged from HWE (p<0.001) (1 SNP), showed no association with BMI in the main effects analyses (p>0.2) (17 SNPs), or had main effects which were directionally inconsistent with results from EA adults (1 SNP) were excluded, leaving 23 potential SNPs for analysis. Of 253 SNP*SNP interactions, two had p values <0.01: in/near *POMC-NEGR1* (p=0.004)and in/near *LZTR2-MC4R* (p= 0.005), and an additional nine had interaction p values <0.05. Six SNPs also had nominal evidence for interaction with at least two other loci. For example, there was nominal evidence for rs987237 (*TFAP2B*) interacting with rs2241423 (*MAP2K5*) (p = 0.016), rs4712652 (*PRL*) (p=0.013), and rs3810291 (*TMEM160*) (p=0.045) in association with BMI. We prioritized SNPs with nominally significant interactions and performed bioinformatic analysis to identify possible biological connections among positional candidate genes. Of the 11 nominally significant interactions, six were positive, suggesting that in the context of epistasis, the effect of the BMI increasing alleles is exacerbated. In contrast, five epistatic interactions reduced the effect of the single variant. While our study is limited by small sample size, our results are currently being replicated in whites from the Atherosclerosis Risk in Communities (ARIC) study, and are suggestive of epistatic effects on BMI during adolescence and point to potential underlying biological pathways important in the development of obesity.

1468F

Analyzing Genome-wide SNP interactions using the Random Forest Fishing method. *W. Yang[1], J. Chu[1], C.C. Gu[1,2].* 1) Division of Biostatistics, Washington University in St Louis, St Louis, MO; 2) Department Genetics, Washington University in St Louis, St Louis, MO.

Despite the importance of pervasive interactions among genetic and environment disease risk factors, genome-wide interactions analysis is seldom carried out, mainly due to the lack of powerful and efficient tools to handle the extreme noise level and computational requirement. We have therefore proposed a fast search method called Random Forest Fishing (RFF), which applies a genetic algorithm based on Random Forest, by repeatedly updating a set of predictors to find a variable set predictive of the disease outcome. This set captures both marginal and interactive effects in their collective effect when making predictions. RFF was applied to analysis hypertension status in a large scale genome-wide association study (GWAS) sample, which consisted of 2,768 African Americans (AA; 832,077 SNPs after QC), and 4,986 Caucasians (CA; 828,744 SNPs after QC). Analyses were performed within races, starting with initial SNP sets of either random SNPs (RFFr) or top SNPs in single SNP tests (RFFt). Briefly, (1) Even though started with different set of SNPs, after long search iterations, RFFr and RFFt results began to converge and had a large number of SNPs in common. In the AA sample, RFFt output 597 SNPs, and RFFr output 914 SNPs, with 393 in common; In CA, RFFt ouput 1071 SNPs, and RFFr 787 SNPs, with 395 SNPs in common. (2) Among the 149 blood pressure related genes reported by past GWAS studies (GWAS catalog as of 05/03/2012), 15 genes were re-discovered by RFFt in CA, and 8 re-discovered in AA. (3) Most RFF identified SNPs were likely to be missed in single SNP or pairwise interaction tests. Only 5 SNPs had single SNP test p values less than 1e-6 in both CA and AA, and the minimum p values for pairwise interaction test were 2.2e-7 and 1.7e-6 in CA and AA, respectively. (4) There were only 7 SNPs common to both races by RFFt. However, identified SNPs were in 222 common genes and 264 common pathways, indicating the same genes and pathways likely underlying hypertension risk. (5) Some know biology pathways were found enriched in the RFF results, such as GO:0044267 pathway (cellular protein metabolic process; with 46 SNPs in RFFt AA results, 64 in CA), and has04510 pathway (Focal adhesion, with 10 SNPs in RFFt AA result, 12 in CA). In summary, our test shows that RFF is able to identify sets of biologically interesting SNPs considering both marginal and interaction effects. RFF could serve as a first step to explore complex interactions in the GWAS studies.

Hunting for rare genetic variants in a complex disease? Do not forget about gene-environment interactions! *R. Kazma, J. Witte.* Department of Epidemiology and Biostatistics and Institute for Human Genetics, University of California San Francisco, San Francisco, CA.

The interest in evaluating the potential association between disease and rare genetic variants, measured by next-generation sequencing or exome chip arrays, is growing rapidly. A critical issue here is the limited power to detect associations due to the low frequency of genetic variants. To improve power, several methods, aggregating the information of rare variants over a region like a gene, have been proposed. However, none of these methods have considered potential gene-environment interactions. To determine if accounting for gene-environment interactions improves the power to detect associations with rare variants, we have extended three methods (Min-P, CAST, and SKAT) and compared their statistical properties under various simulated disease models. To test for association of a group of rare variants with the disease, Min-P uses permutations to determine the null distribution of the lowest P-value within the group of variants, CAST (Cohort Allelic Sum Test) uses an indicator variable of the presence of at least one rare allele (or the sum of the rare alleles) within the group of variants, and SKAT (Sequence Kernel Association test) uses a kernel machine approach. We extended these three methods by incorporating a term for the gene-environment interaction and testing for the genetic association and the gene-environment interaction simultaneously. Accounting for gene-environment interaction improves the power to detect association of complex diseases with rare genetic variants interacting with the environment, in particular if the interaction is strong and the genetic marginal effect is weak. In the absence of gene-environment interaction, the decrease in power of the test accounting for gene-environment interaction is small (1 to 5%) compared to the standard test of genetic association. SKAT (using a weighted linear kernel) had the best overall power and is the fastest method of those three. However, the kernel choice introduces implicit assumptions and can impact power. CAST was sensitive to the arbitrary choice of the threshold, below which variants are aggregated. Finally, Min-P had a power close to the power of SKAT but its long computational time makes it inappropriate for large data.

Searching for an enrichment of genetic interaction signals in SNPs within known protein-protein interactions. *J.E. Mollon[1,2], B. Lehne[2], S. Sacks[1], T. Schlitt[2], M.E. Weale[1,2].* 1) MRC Centre for Transplantation, King's College London, London, United Kingdom; 2) Medical and Molecular Genetics, King's College London.

The existence of interactions between single-nucleotide polymorphisms (SNPs) has been hypothesized as a possible contributor to the risk of complex disorders. This seems plausible since many physical interactions between proteins have been demonstrated through functional studies such as yeast two-hybrid screening (Y2H). However, detecting such physical interactions statistically at the SNP level in genome-wide association studies (GWAS) in complex disorders has proven difficult. The search space is very large, for example there are approximately 1.25 billion possible interacting SNP pairs from a 500k SNP genotyping panel. The interaction signal required to overcome the burden of genome-wide multiple testing corrections in such data would have to be very strong, and such strong signals have not yet been found. We created software that takes GWAS data, a list of paired SNPs and a SNP-to-gene map, and searches for a general enrichment of low, but not genome-wide significant, interaction p-values between the SNP pairs. We permuted the gene labels many times and recalculated the test statistic, thereby generating an empirical null distribution while maintaining the gene structure with in the data. Application of this method to the Wellcome Trust Case Control Consortium GWAS in Crohn's disease suggested some enrichment, but this depended on the threshold used to define a low interaction p-value for inclusion in our test statistic.

RAPID Detection of Gene-Gene Interactions Underlying Quantitative Traits. *N. Udpa[1], V. Bafna[1,2].* 1) Bioinformatics and Systems Biology, University of California at San Diego, La Jolla, CA; 2) Computer Science and Engineering, University of California at San Diego, La Jolla, CA, 92093.

In complex phenotypes, the trait under question may not be explained adequately by single locus effects - multiple loci might interact to confer the phenotype. For instance, two proteins may interact in a lock-and-key mechanism, and a mutation in one protein can be offset by a complementary mutation in the other. In this situation, a specific genotype value for either individual SNP does not matter as much as the relationship between the two genotypes. The problem with detecting these interactions is primarily computational - a naive way takes $O(nm^2)$, where n is the number of individuals and m is the number of variants. This is infeasible for a typical human GWAS, where $n \sim 10^3$ and $m \sim 10^6$. Previously, we developed a tool, RAPID (Brinza et al., Bioinformatics, 2010), which improves upon this significantly. RAPID takes advantage of the fact that we can represent genotypes as a series of binary vectors (where each dimension represents an individual haplotype). Given this framework, correlated loci are proximal, and the problem reduces to finding such adjacent pairs efficiently. RAPID uses a geometric approach (locality-sensitive hashing) to solve this without explicitly checking every pair of loci. Here we extend this approach to handle quantitative phenotypes, as opposed to the standard “case” and “control” delineations. The correlation between quantitative phenotypes and multilocus genotypes is usually performed using ANOVA statistics that do not lend themselves to geometric/discrete approaches. To get around this, we follow a two stage strategy: first, we describe an algorithm to partition the continuous phenotypes into two sub-populations under the assumption that the phenotypes are a mixture of Gaussians. Second, we use the RAPID framework to identify epistatic loci within each sub-population. We use simulated datasets to determine the best way to partition these points given different levels of mixture and relative abundance between the two phenotypes. In addition, we use simulations to explore the impact of the underlying genotype-phenotype models on the ability of RAPID to identify correlations. An application of this algorithm to the WTCCC hypertension datasets show the speed and power of our approach.

Nonsyndromic cleft palate (CP) is one of the most common human birth defects and both genetic and environment risk factors contribute to its etiology. We conducted a genome-wide association study (GWAS) using 550 CP case-parent trios who were ascertained through subjects collected in an international consortium. Family-based association tests of single nucleotide polymorphisms (SNP) and four common maternal exposures (maternal smoking, alcohol consumption, multivitamin supplementation and environment tobacco smoke) were used in a combined 2 *df* test for gene (G) and gene-environment (GxE) interaction simultaneously, plus a separate 1 *df* test for GxE interaction alone. While no SNP achieved genome-wide significance when considered alone, markers in several genes attained or approached genome-wide significance among 253 Asian trios when GxE interaction was included. Among these, *SLC2A9* and *WDR1* on chromosome 4p16.1 showed multiple SNPs resulting in an increased risk if the mother exposed to environment tobacco smoke (ETS) during the peri-conceptual period (3 months prior to conception through the first trimester). When maternal ETS was considered, five of 137 SNPs mapping to *SLC2A9* gave strong evidence of GxETS interaction in the 1 *df* test using conditional logistic regression models ($P<10^{-6}$). SNP *rs3733585* and *rs12508991* yielded $P=9.63\times10^{-8}$ in the 1 *df* test for GxETS interaction. A cluster of 61 SNPs identified a region spanning 125 kb where evidence of GxETS interaction was apparent. In this region, nineteen of these SNPs yielded significance ($P<10^{-3}$) in both the 1 *df* test for GxE interaction alone and in the 2 *df* test for combined effects of G and GxE interaction. *WDR1* was located next to *SLC2A9* and it encompassed 65 SNPs. A block of 12 SNPs (spanning 63 kb) yielded seven SNPs with significant *P*-values in the 1 *df* test for GxE interaction when maternal ETS was considered. SNPs *rs717615* and *rs7699512* yielded $P= 8.30\times10^{-7}$ and $P=6.09\times10^{-7}$ in the 1 *df* test for GxE interaction in conditional logistic regression models and two adjacent SNPs *rs6834555* and *rs6820756* approached genome-wide significance (*rs6834555*, $P= 1.73 \times 10^{-6}$; *rs6820756*, $P= 1.37 \times 10^{-6}$). Another three SNPs located 147kb downstream from *rs7699512*, also yielded significant GxETS interaction at $P<10^{-4}$ level. These results emphasize the need to consider GxE interaction when searching for genes influencing risk to complex and heterogeneous disorders, such as nonsyndromic CP.

Pathway-based analysis of gene-gene interactions for complex diseases. *J.G. Zhang, J. Li, H.W. Deng.* Department of Biostatistics and Bioinformatics, Tulane University School of Public Health & Tropical Medicine, New Orleans, LA.

Background: Gene-gene interactions play an essential role in determining individual susceptibility to complex diseases, and many genes in the same pathway are involved in such interactions. Hence, identifying gene-gene interactions associated with complex diseases within gene pathways can help us better understand the disease genetics. However, current analytical methods for gene-gene interaction identification either limit their tests only on SNPs showing marginal effects, or may suffer from high computational complexity, especially for genome-wide association (GWA) data and next-generation sequencing (NGS) data. **Results:** In this study, we propose a novel method to identify disease-associated gene-gene interactions within biological pathways. The method first applies principal components analysis (PCA) to reduce the dimension of genetic variants within each gene of a pathway. Pairwise products of the first principal components (PCs) from all genes in a pathway were computed as interaction terms. Then the likelihood ratio test was applied to determine the statistical significance of interactions in the pathway. We have applied our method to GWA data set for studying osteoporosis and have detected 16 pathways enriched with gene interactions potentially contributing to the susceptibility of osteoporosis. **Conclusion:** Our new method proved fast and efficient for identifying pathways with gene-gene interaction effects associated with complex diseases. It will aid in the deciphering of the genetic mechanisms of complex diseases.

Identification of host gene-gene interaction in saliva flow and *Streptococcus mutans* using MDR. *M. Lee[1,2], K.T. Cuenco[1], Z. Zeng[3], X. Wang[1], J.R. Shaffer[3], E. Feingold[2,3], D.E. Weeks[2,3], R.J. Weyant[4], R.J. Crouot[5], D.W. McNeil[6], M.L. Marazita[1,3].* 1) Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 2) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 4) Department of Dental Public Health and Information Management, School of Dental Medicine, University of Pittsburgh, PA; 5) Department of Periodontics, School of Dentistry, West Virginia University, Morgantown, WV; 6) Dental Practice and Rural Health, West Virginia University, Morgantown, WV.

Appalachian populations have limited healthcare access and experience more frequent negative health outcomes like oral disease than the general population. As part of its mission to identify risk factors for poor oral health, families recruited through the Center for Oral Health Research in Appalachia (COHRA) participated in the NIH Gene, Environment Association Studies Consortium (GENEVA) genome-wide association study (GWAS) of dental caries. Low saliva flow and risk of Streptococcus mutans infection have been associated with increased caries, each of which is a complex trait likely controlled by host genetics. We investigated host gene-gene interactions responsible for saliva flow and presence of S. mutans in the COHRA study population. We applied a gene-gene search method to saliva flow and Streptococcus mutans data from the COHRA-GENEVA population. 1506 Caucasian subjects of age 5 to 75 years were available with saliva flow measures. 1554 subjects had S. mutans data available. Saliva flow was categorized as abnormal (≤0.6 ml/min) or normal (>0.6 ml/min). 20 genes obtained from previous GWAS findings were selected for evaluation of gene-gene interactions with saliva flow and present of S. mutans . Gene-gene interactions were detected with multifactor dimensionality reduction (MDR) software, which implements a model free approach and k-fold cross-validation after reducing SNP categories by identifying high or low risk SNPs for an outcome and combining these SNPs into a single category. MDR successfully identified host gene-gene interactions associated with saliva flow and S. mutans. Identified host gene-gene interactions provide insight into additional gene relationships and help prioritize genes for further inquiry. Supported by: DE018903, DE014899.

Meta-analysis of gene by gene interaction. *RG. Hoffmann[1], K. Yan[1], TJ. Hoffmann[2], P. Simpson[1].* 1) QHS, Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 2) Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA.

Purpose: Since gene by gene interaction always results in substantially smaller numbers in the cells corresponding to the interaction terms, correct estimation of the effect sizes and validation of the results will usually require combination of multiple studies. The purpose of this study was to compare methods for combining QTL studies with gene by gene interaction. Methods: The motivating data consists of age of onset of type I diabetes from two separate Scandinavian countries. Both cases and controls were available; controls were considered as censored at their current age. Thus both case-control and case-only studies could be performed. Methods that were compared were proportional hazards regression, binary logistic regression, and ordinal logistic regression for the case-control meta-analysis. For the case-only meta-analysis linear regression, proportional hazards regression, ordinal logistic regression and a generalized linear model (a lognormal model for when the data is skewed to the left). Simulations based on permuting the observed subjects were used to examine the effect of sample size on type I and type II errors without losing the inherent structure of the data. Results: Small studies tended to be very unstable and often missed the underlying gene by gene interactions. Studies in the 2000 subject range were still somewhat unstable; unless there were more studies to combine. Case-control studies were quite sensitive to the level of overlap of the QTL and to the age of “censoring” in the controls.

Identification of Gene-Gene Interactions For Alzheimer Disease Using Co-Operative Game Theory. *B. Vardarajan[1], G. Jun[1], R. Mayeux[2], J.L. Haines[3], M.A. Pericak-Vance[4], G. Schellenberg[5], K.L. Lunetta[2], L.A. Farrer[1], Alzheimer's Disease Genetics Consoritum.* 1) Boston University, Boston, MA; 2) Columbia University, New York, NY; 3) Vanderbilt University, Nashville, TN; 4) Hussman Institute of Human Genomics, Miami, FL; 5) University of Pennsylvania, Philadelphia, PA.

The multifactorial nature and large proportion of unexplained genetic variance of Alzheimer disease (AD) suggests that gene-gene interactions contribute to risk of the disorder. Contemporary approaches to detect interactions in genome-wide data are mathematically and computationally challenging. We investigated gene-gene interactions for AD using a novel algorithm based on co-operative game theory applied to 15 genome-wide association study (GWAS) datasets comprising of a total of 11,840 AD cases and 10,931 cognitively normal elderly controls from the Alzheimer Disease Genetics Consortium (ADGC). We adapted this approach, which was developed originally for solving multi-dimensional problems in economics and social sciences, to compute the rank-order values (called Shapely values) in order to identify genetic markers that contribute most to coalitions of SNPs in predicting AD risk. Treating each GWAS dataset as independent discovery, SNPs were ranked according to their contribution to coalitions formed with other SNPs. Using a backward elimination strategy, SNPs with low Shapley values were eliminated and the statistic was recalculated iteratively. We tested all two-way interactions between top Shapley SNPs in regression models which included the two SNPs (main effects) and a term for their interaction. Models yielding a p-value<0.05 for the interaction term were evaluated in each of the other datasets and the results from all datasets were combined by meta-analysis. Statistically significant interactions were observed with multiple marker combinations in the APOE region. Analyses also revealed statistically strong interactions between markers in 6 regions; CTNNA3-ATP11A (p=4.1E-07), CSMD1-PRKCQ (p=3.5E-08), DCC-UNC5CL (p=5.9e-8), CNTNAP2-RFC3 (p=1.16e-07), AACS-TSHZ3 (p= 2.64e-07) and CAMK4-MMD (p=3.3e-07). CTNNA3, CNTNAP2, CAMK4 and CSMD1 have been previously associated with neurological disorders in genetic or functional studies. The Game-Theory algorithm outperformed other methods in detecting a previously identified interaction between APOE and GAB2. Our approach also revealed strong interactions between SNPs in novel genes with weak main effects, which would have been overlooked if only SNPs with strong marginal association were tested. This method will be a valuable tool for identifying gene-gene interactions for other complex diseases and traits.

Overestimation of relatedness in admixed and ancestrally heterogeneous populations using method of moments estimation. *J. Morrison.* Biostatistics, Univ Washington, Seattle, WA.

Inference of identity by descent (IBD) in pairs of individuals is a common computational task undertaken in studies involving genome-wide SNP data. One of the most commonly used tools for inference of genome-wide allele sharing probabilities is the method of moments technique implemented in PLINK and other software which estimates the proportions of the genome at which two individuals share 0, 1, or 2 alleles IBD. These estimates can be used to check pedigrees, estimate heritability and adjust association analyses. In these last two applications, it is especially important that the estimates are accurate. The method of moments technique is computationally efficient and accurate when the sample size is large and ancestrally homogenous. However, in many cases, the assumption that samples are drawn from a single, homogeneous, randomly mating population does not hold. This assumption is violated if the study sample is small and there is no close population match in publically available datbases, if the study sample contains bi-ancestral pedigrees or if the study sample is drawn from an admixed population. I used publically available genome-wide SNP data to simulate pedigrees under these different conditions. I am able to demonstrate that in these cases method of moments estimation will lead to overestimation of relatedness between many pairs of individuals. Finally, I propose a simple method easily implemented without additional software for improving genome-wide IBD estimates when the assumption of a single, homogeneous population is violated.

1478W

Genome-wide patterns of identity-by-descent sharing in the French Canadian founder population. *H. Gauvin[1,2], C. Moreau[2], JF. Lefebvre[2], H. Vézina[3], D. Labuda[2,4], MH. Roy-Gagnon[1,2].* 1) Dept. of Social and Preventive Medicine, Université de Montréal, Montreal, Quebec, Canada; 2) Sainte-Justine Hospital Research Center, Université de Montréal, Montreal, Quebec, Canada; 3) Dept. of Human Sciences, Université du Québec à Chicoutimi, Chicoutimi, Quebec, Canada; 4) Dept. of Pediatrics, Université de Montréal, Montreal, Quebec, Canada.

In genetics the ability to accurately describe the familial relationships among a group of individuals can be advantageous and sometimes essential. Recent statistical tools succeed in assessing the degree of relatedness up to 6–7 generations with good power using dense genome-wide SNP data to estimate the extent of identity-by-descent (IBD) sharing. However, genome-wide patterns of IBD sharing have not been described for more remote and complex relatedness between individuals, such as that observed in a founder population like Quebec. In this study, we take advantage of the extended genealogical records of the French Canadian founder population to 1) compare different tools to identify regions of IBD, and 2) describe genome-wide IBD sharing and its correlation with genealogical characteristics. We first compared the performance of GERMLINE, Plink, and FastIBD among other tools in a sample of 140 individuals from seven regional populations of Quebec with both genotypic and genealogical data. We calculated genealogical measures such as the kinship and inbreeding coefficients, the number of lowest common ancestors and the minimum and average genetic distance to the lowest common ancestors. We used linear regression models to describe how well the genealogical characteristics are captured by genome-wide IBD sharing. Results showed that the extent of IBD sharing identified with FastIBD correlates best with relatedness measured using genealogical data. Total length of IBD sharing explained 85% of the genealogical kinship's variance. In addition, we observed significantly higher sharing in pairs of individuals with at least one inbred ancestor compared to those without any. Furthermore, patterns of IBD sharing and average sharing were different across regional populations, consistent with the settlement history of Quebec. Our results suggest that, as expected, the complex relatedness present in founder populations is reflected in patterns of IBD sharing. Using these patterns, it is thus possible to gain insight on the types of distant relationships in a sample from a founder population like Quebec.

1479T

Identity-by-descent-based heritability analysis in the Northern Finland Birth Cohort. *S.R. Browning[1], B.L. Browning[2].* 1) Dept Biostatistics, Univ Washington, Seattle, WA; 2) Div Medical Genetics, Univ Washington, Seattle, WA.

For most complex traits only a small proportion of heritability is explained by statistically significant associations from genome-wide association studies (GWAS). In order to determine how much heritability can potentially be explained through larger GWAS, several different approaches for estimating total narrow-sense heritability from GWAS data have recently been proposed. These methods include variance components with relatedness estimates from allele sharing [1], variance components with relatedness estimates from identity by descent (IBD) segments [2], and regression of phenotypic correlation on relatedness estimates from IBD segments [3]. These methods have not previously been compared on real or simulated data. We analyzed the narrow-sense heritability of nine metabolic traits in the Northern Finland Birth Cohort [4] using these methods. We found substantial estimated heritability for several traits, including LDL cholesterol (59% heritability), HDL cholestrol (46%) and fasting glucose levels (39%). When we used a variance components approach, IBD-based estimates of heritability were higher than allele-sharing based estimates for many of the traits, which is consistent with a significant role of rare variants in these traits because rare variants are generally not well tagged by SNPs but are captured by long IBD segments. Estimates of heritability from the regression-based approach are much lower than variance components estimates in these data, which may be explained by the presence of strong population structure in these data. Simulation results substantiate the downward bias of the regression-based approach in the presence of population structure.

Many methods have been proposed to detect rare variant associations, but they assume expensive sequence data. The identity-by-descent (IBD) mapping can be an inexpensive alternative for detecting regions including causal rare variants and can be an intermediate step suggesting target regions before sequencing. IBD mapping approaches detect associated regions by detecting an excessive haplotype sharing between cases. The widely known IBD mapping method is the pairwise method that compares the IBD rate of case/case pairs to control/control pairs or non-case/case pairs. However, the pairwise method has several limitations. First, the method is susceptible to population structure. Second, the method requires permutation and is inefficient taking years of CPU time for genome-wide data. Third, the analysis cannot include covariates. Fourth, associations to quantitative traits cannot be mapped. Here we propose a new IBD mapping method called GraphIBD that is efficient, general, and robust to population structure. The core idea of our approach is that the IBD information can be represented by a graph where the nodes are individuals and the edges between nodes are pairwise IBDs. Our idea is to split the edges and count the number of edges attached to each node, which we call virtual marker. Then we test association between virtual marker and phenotype. Testing based on virtual marker has a close relationship to the pairwise method that they are exactly equivalent in the balanced case/control study. Our simulations show that the new method has similar power to the traditional method but is thousands times faster taking only hours for genome-wide data. When applied to the isolated population data of Tourette syndrome, our method dramatically reduces the p-value inflation compared to the traditional method showing that our method is more robust to the population structure.

Optimization of sequencing studies in population isolates using shared ancestral haplotypes. *D. Glodzik[1], P. Navarro[1], V. Vitart[1], R. McQuillan[2], S. Wild[2], H. Campbell[2], A. Wright[1], J. Wilson[2], P. McKeigue[2].* 1) The Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, Midlothian, United Kingdom; 2) Center for Public Health Sciences, University of Edinburgh, Edinburgh, Midlothian, United Kingdom.

In an isolated population individuals are likely to share large genetic regions inherited from common ancestors. The phase and the underlying haplotype sharing can be inferred from SNP genotypes, which is useful in a number of applications, including identifying genetic variants influencing complex disease risk, and planning efficient cohort genotyping and sequencing strategies. We present a method for phasing in population isolates that is based on identity by descent. The purpose of our method is to detect haplotype sharing with maximum accuracy, at low computational effort. Implementation of the algorithm has been made available as the R library ANCHAP. We demonstrate the method using SNP genotypes from three isolated island populations, as well as in a cohort of unrelated individuals. In samples of around 1000 individuals from an isolated population, an average individual shares a haplotype at a genetic locus with 9–12 other individuals, compared to only 2 individuals within the non-isolated population. High genomic kinship in the isolates translates into high potential imputation gain. With sample sizes of ~1000 individuals from an isolated population genotyped using a dense SNP array, and with 20% of these individuals sequenced, 77% of sequences of the unsequenced subjects can be partially inferred. We describe an application of ANCHAP in optimization of resequencing studies.

1482T

Novel statistical model and computational methods for predicting HLA alleles from dense genotype data. *Y. Guan[1], Y. Shen[2].* 1) Pediatrics Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Biomedical Informatics, Columbia University, New York, NY.

Predicting human leukocyte antigen (HLA) alleles is an important problem in statistical genetics that remains an open challenge. The difficulty lies in the complicated linkage disequilibrium pattern in the major histocompatibility complex (MHC) region of the genome that contains HLA alleles. We present a novel statistical method for predicting HLA subtype and demonstrate its effectiveness via cross validation using real data from Wellcome trust case control consortium. The predicting method relies on a two layer clustering model that approximates the coalescent with recombination to quantify patterns of linkage disequilibrium. The model can jointly infer the haplotype sharing (identity by descent) between each pair of individuals, and the HLA allele type prediction is based on the degree of haplotype sharing between individuals. Since HLA alleles are plenty and many are rare, a large number of clusters is required to capture subtle differences between closely related HLA alleles. This makes the computation prohibitively difficult because the model fitting is quadratic in number of clusters for diploid individuals. We developed a novel computational method that is linear in number of clusters for diploid individuals, which is crucial for successfully predicting HLA alleles.

1483F

Haplotype clusters of rare variants in Korean genomes. *S. Hochreiter, G. Klambauer, G. Povysil, D.-A. Clevert.* Institute of Bioinformatics, Johannes Kepler University Linz, Linz, upper Austria, Austria.

A haplotype cluster corresponds to a DNA segment that is descended from a single founder and, therefore, some haplotypes are similar to each other in this segment. The advent of new sequencing technologies facilitates the identification of rare variants and therefore haplotype clusters containing rare variants ("rare haplotype clusters"). However, LD-related methods fail to extract rare haplotype clusters because of the high variance of LD measures for rare variants. IBD detection methods require sufficiently long IBD regions to avoid high false positive rates. We propose identifying rare haplotype clusters by HapFABIA which uses biclustering to combine LD information across individuals and IBD information along the chromosome. To identify rare haplotype clusters in the Korean population, we applied HapFABIA to data from the Korean Personal Genome Project (KPGP). Genotyping data from the KPGP was combined with those from the 1000-Genomes-Project leading to 1,131 individuals and 3.1 million single nucleotide variants (SNVs) on chromosome 1. HapFABIA identified 113,963 different rare haplotype clusters marked by tagSNVs that have a minor allele frequency of 5% or less. The rare haplotype clusters comprise 680,904 SNVs; that is 36.1% of the rare variants and 21.5% of all variants. The vast majority of 107,473 haplotype clusters contains Africans, while only 9,554 and 6,933 contain Europeans and Asians, respectively. We characterized haplotype clusters by matching with archaic genomes. Haplotype clusters that match the Denisova or the Neandertal genome are significantly enriched by Asians and Europeans. Interestingly, haplotype clusters matching the Denisova or the Neandertal genome contain, in some cases exclusively, Africans. Our findings indicate that the majority of rare haplotype clusters from chromosome 1 are based on ancient founder segments from times before humans migrated out of Africa. The enrichment of Koreans in Neandertal haplotype clusters (odds ratio 10.6 of Fisher's exact test) is not as high as for Han Chinese from Beijing, Han Chinese from South, and Japanese (odds ratios 23.9, 19.1, 22.7 of Fisher's exact test). In contrast to these results, the enrichment of Koreans in Denisova haplotype clusters (odds ratio 36.7 of Fisher's exact test) is is higher than for Han Chinese from Beijing, Han Chinese from South, and Japanese (odds ratios 7.6, 6.9, 7.0 of Fisher's exact test).

Evaluation of different phasing and imputation strategies in an isolated population with a mixture of unrelated individuals and extended pedigrees. *J. O'Connell[1], O. Delaneau[2], N. Pirastu[3], S. Ulivi[3], P. Gasparini[3], J. Marchini[1,2].* 1) The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Statistics, University of Oxford, Oxford, United Kingdom; 3) IRCCS Burlo Garofolo Hospital, University of Trieste, Italy.

Genotype imputation (and associated haplotype phasing) has become a standard tool in genome wide association study pipelines and there are a number of popular implementations available. Linkage-disequilibrium (LD) based models assume individuals are distantly related. When this assumption does not hold, "long range phasing" techniques can exploit long contiguous segments of identical-by-descent (IBD) loci between individuals to achieve more accurate haplotype estimates (and hence better imputed genotypes). Additionally, genetic isolates may contain a mixture of unrelated individuals and small pedigrees. Pedigrees are highly informative of haplotype phase and standard software does not take advantage of this.

The INGI Friuli-Venezia Giulia cohort contains genotype data from 1476 individuals from six different isolated villages in northern Italy. The cohort consists of a mixture of unrelated (or distantly related) individuals and small pedigrees. We use this data to evaluate two interesting scenarios for phasing and imputation;

-a large group of unrelated individuals from an isolate
-a mixture of unrelated individuals and pedigrees

Popular IBD and LD based phasing methods (and downstream imputation) are compared in both these scenarios. In addition, we investigate modifications to the LD-based phasing algorithms to exploit large contiguous regions of IBD between individuals and approximate methods for handling extended pedigrees.

Local ancestry inference using identity by descent. *Z. CAI[1], B.L. Browning[2], S.R. Browning[1].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA.

Disease risk differs among groups that have diverse ancestries. Accurate inference of information regarding genetic ancestry will become a useful tool for improving the diagnosis and treatment in clinical studies. The 1000 Genomes Project provides a great opportunity for us to study the genetics of worldwide populations, including populations of admixed ancestry that are from America. We will present a new method that uses identity-by-descent information to infer local ancestry (ancestry of haplotypes at each point along the genome), with the goal of improving genetic mapping in data from admixed populations.

1486F

Detection of identity by descent based on rare variants. *G. Povysil, G. Klambauer, S. Hochreiter.* Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Austria.

Identity by descent (IBD) between two individuals means that their alleles are identical because they were inherited from a shared common ancestor. Detection of IBD tracts is important for population genetics and association studies. IBD detection methods perform well for family studies where pedigrees are available and for common single nucleotide variants (SNVs). However, recent genotyping projects utilizing next generation sequencing comprise unrelated individuals and detect mostly rare variants. Currently, rare variants are of high interest in genetics because they are assumed to cause complex human diseases. However, their association with a disease is hard to detect as standard tests on rare variants yield low power. IBD mapping can be used to increase the power by two approaches. First, SNVs can be grouped based on IBD and subsequently their joint effect tested for disease association. Secondly, local genetic similarities between individuals can be measured by IBD and used for association tests like implemented in the sequence kernel association test (SKAT).

We compare two of the most commonly used IBD detection techniques, BEAGLE's fastIBD and PLINK, on simulated rare SNVs with implanted IBD tracts of different sizes and different proportions of minor alleles. Both methods miss a large proportion of short tracts and tracts that are tagged by few minor alleles. Overall fastIBD has higher power than PLINK, which is traded off against a higher false discovery rate. Besides correctly identifying IBD tracts, an exact estimation of IBD length and location is essential for identifying disease loci by IBD mapping. In this respect fastIBD systematically overestimates the length of IBD tracts while PLINK is very accurate. Our findings may help to choose an appropriate IBD detection method for studies involving rare variants. Summarizing, fastIBD finds almost all IBD tracts on the cost of many false positives whereas PLINK finds a smaller number of IBD tracts of which only a few are false positives.

Refined IBD: a new method for detecting identity by descent in population samples. *B.L. Browning[1], S.R. Browning[2].* 1) Medicine, Med Genetics, University of Washington, Seattle, WA; 2) Biostatistics, University of Washington, Seattle, WA.

Identity-by-descent (IBD) from a recent common ancestor is ubiquitous in large population samples. IBD manifests as a long haplotype shared by two or more individuals, and IBD can be detected with high power when the recent common ancestor is within the past 25 generations. The power to detect IBD can be increased by modeling haplotype phase uncertainty, but this modeling has been computationally expensive.

We have developed a new method for IBD detection called Refined IBD that solves the computational problem of incorporating haplotype phase uncertainty. First, candidate IBD tracts are identified by searching for shared haplotypes that exceed a length threshold. Candidate tracts are efficiently identified using IBD detection methods such as GERMLINE or fastIBD that do not model haplotype phase uncertainty. We then compare the likelihood of the genotypes in each candidate tract under IBD and non-IBD models using a likelihood ratio test. This test incorporates haplotype phase uncertainty and identifies the subset of candidate tracts with the greatest evidence for IBD.

We have applied Refined IBD to the WTCCC2 control data (n=5200). After tuning methods to achieve equal false positive rates, Refined IBD detected fourfold more IBD than the GERMLINE and fastIBD algorithms.

Refined IBD is implemented in BEAGLE version 4 (http://faculty.washington.edu/browning/beagle/beagle.html).

1488T

IBD Estimation With Whole-genome Sequence Data. *L. Han, M. Abney.* Human genetics Dept, University of Chicago, Chicago, IL.

Accurate knowledge of identity by descent probabilities (IBDp) between a pair of related individuals at a locus enables sequence imputation methods, improves phasing and detects deletion variants. Next-generation sequencing of personal genomes has revealed numerous rare variants, many of which may play an important role in the risk for common diseases. However, incorporating rare variants while ignoring linkage disequilibrium (LD) affects the accuracy of IBDp estimates. Here we present a method that can estimate IBDp at each locus using whole-genome sequence data. The method incorporates rare variants and extends the standard hidden Markov model to include LD by conditioning on multiple SNPs. At the same time, genotyping errors and missing data are considered in this method. We validate it through simulations and apply it to a real whole genome sequence data set.

1489F

Evaluating type 1 error and power for association and linkage in large complex pedigrees. *A.C. Cummings[1], E. Torstenson[1], M.F. Davis[1], L.N. D'Aoust[1], W.K. Scott[2], M.A. Pericak-Vance[2], W.S. Bush[1], J.L. Haines[1].* 1) Center for Human Genetic Research, Vanderbilt University, Nashville, TN; 2) Hussman Institute of Human Genomics, University of Miami, Miami, FL.

Studying population isolates, like the Amish, with large, complex pedigrees has many advantages for discovering genetic susceptibility loci; however, analyses can be quite complicated. Association tests need to be corrected for relatedness, and linkage analysis requires subdividing and simplifying the pedigree structure. Using simulated pedigrees with the same structure as an Amish pedigree (4998 total, 796 genotyped, 106 affected) we evaluated type 1 error and power for association using the Quasi-Likelihood Score (MQLS) test and for 2-point and multipoint linkage analyses using PedCut for pedigree splitting and Merlin for linkage analyses. To assess type 1 error we simulated null SNP data, and to assess power we simulated dominant, recessive, and additive inheritance models across three odds ratios (1.1, 1.5, and 2.0) for a total of 9 disease models. 1000 replicates were performed for each analysis. We see essentially no inflated type 1 error rate (5.06% for p-values ≤ 0.05; 0.13% for p-values ≤ 0.001) when using MQLS. We also see very low type 1 error rates of 0.01% and 0.02% under dominant and recessive models using a 2-pt heterogeneity lod score (HLOD) threshold of 3. Under both dominant and recessive models, we see type 1 error rates of 2.50% when using multipoint analysis and an HLOD ≥ 3. Power to detect $p \leq 0.05$ using MQLS was >50% for the simulated additive and dominant models with OR's 2.0 (96% add; 91% dom) and 1.5 (66.6% add; 50.2% dom). For the recessive model with OR=2.0, we calculated power to be 26% for $p \leq .05$. Power for all models was less than 50% for $p \leq 5 \times 10\text{-}5$. Power to detect linkage (HLOD>=3) using 2-point and multipoint parametric analysis is very low with these small effect sizes. The highest power to detect a 2-pt and MPT HLOD ≥ 1.0 was 12.3% and 30.7% respectively for the simulated additive model with OR=2.0 when linkage was calculated assuming a dominant model (10.4% assuming a recessive model). These results demonstrate that type 1 error is not inflated using this pedigree structure for either linkage or association analyses. For small effect sizes, characteristic of common complex diseases, there is little to no power to detect linkage using classical criteria, suggesting that association methods are more powerful for detecting variants of modest effect even in isolated populations such as the Amish. More disease models need to be evaluated to make a full assessment of power using these analysis protocols.

1490W

Loss-of-co-Homozygosity (LOcH) mapping: a novel non-parametric linkage analysis leveraging exome sequencing data. *Y. Okada[1,2], N. Gupta[2], D. Mirel[2], S. Gabriel[2], T. Arayssi[3], F. Mouassess[4], WAL. Achkar[4], LA. Kazkaz[5,6], RM. Plenge[1,2].* 1) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 3) Weill Cornell Medical College-Qatar, Education City, Doha, Qatar; 4) Molecular Biology and Biotechnology Dept, Human Genetics Division, Damascus, Syria; 5) Tishreen Hospital, Damascus, Syria; 6) Syrian Association for Rheumatology, Damascus, Syria.

Mapping the ancestry-shared genetic regions from pedigrees with genome-wide sequence data represents an effective method to identify causal rare mutations in Mendelian disorders. Although classical linkage analysis is widely used to detect regions harboring causal mutations, its usage is restricted to diseases with typical modes of genetic inheritance. Here, we develop a novel non-parametric linkage analysis we term “Loss-of-co-Homozygosity” (LOcH) mapping that extends homozygosity mapping to include any type of inheritance mode. The fundamental principal underlying LOcH is that a disease-causing mutation in a pedigree resides on a single ancestral haplotype, and that affected cases will carry at least one copy of the mutation - but are never homozygous for the non-mutated allele. That is, genetic markers adjacent to the causal mutation lose homozygous genotypes for at least one of the alleles. LOcH mapping uses genome-wide SNP data to search the regional stretches that lose one or both homozygous genotypes (i.e., lose “co-homozygosity”) in affected cases, which serve as candidate regions harboring causal rare mutations. Within the detected LOcH stretches, our method enables genotype imputation of the mutations identified by exome sequencing, by evaluating the presence of the LOcH stretches in other non-exome-sequenced subjects. To demonstrate our approach, we applied LOcH mapping to a 4-generation, 48-person consanguineous Syrian pedigree in which 8 individuals were affected with rheumatoid arthritis (RA). We used GWAS data and LOcH mapping on a subset of 4 affected and 12 unaffected family members to identify ~12% of the genome in which the same ancestral haplotype was shared among all RA cases. We sequenced the exomes of these 4 RA cases, and identified 13 nonsense or missense mutations shared among all cases but not observed in dbSNP, the 1000 Genomes Project, or the Exome Sequencing Project. All 13 mutations reside within the 12% of the genome defined as LOcH using GWAS data ($P < 10^{-11}$), suggesting that at least one might be the causal mutation. We imputed these 13 candidate mutations in all unaffected family members. We found that 1 mutation in the *phospholipase B1* (*PLB1*) gene at 2p23 preferentially segregated in cases compared to controls ($P < 0.05$). While additional investigation of this mutation is required to confirm the association with risk of RA, the approach highlights a novel method of statistical analysis of genome-wide sequence data.

Patterns of Indel Variation: Comparison of calling methods and LD with SNPs. *K. Huang[1], M. Ehm[2], N. Bing[2], Y. Liu[3], J. Xu[4], A. Slater[2], D. Fraser[2], J. Novembre[5], J. Li[4], M. Neison[2], Y. Li[1,3,6].* 1) Biostatistics, University of North Carolina - Chapel Hill, Chapel Hill, NC, USA; 2) Quantitative Sciences, GlaxoSmithKline, RTP, NC, USA; Upper Merion, PA, USA; and Stevenage, UK; 3) Computer Science, University of North Carolina - Chapel Hill, Chapel Hill, NC, USA; 4) Human Genetics, University of Michigan, Ann Arbor, MI, USA; 5) Ecology and Evolutionary Biology, University of California - Los Angeles, Los Angeles, CA, USA; 6) Genetics, University of North Carolina - Chapel Hill, Chapel Hill, NC, USA.

Insertion and deletion variants (indels) are an important but poorly studied type of genetic variation. The advancement of massively parallel sequencing technologies and improvement of indel calling methods enables us to systemically measure indels, evaluate their variation and linkage disequilibrium (LD) patterns within and across populations, and assess their impact on human traits. We have investigated the quality and patterns of indel variations within the exons of 202 drug target genes sequenced in over 14,000 individuals. Indels were called using a pipeline involving Dindel, pindel, samtools and GATK. In addition to standard filters from the indel calling algorithms used, we have implemented additional quality control (QC) criterion based on duplicate concordance analysis. Our QC, aimed to reach 96% heterozygous concordance, was confirmed to reach the goal by genotypes determined experimentally through actual genotyping and Sanger sequencing. As expected, a considerable proportion (45.6%) of common (minor allele frequency [MAF] > 0.5%) indels can be tagged by SNPs: 45.6% by GWAS (Affymetrix 6.0) SNPs alone and 58.3% by the combination of GWAS and sequencing identified SNPs. Coding indels are predominantly rare (95.5% with MAF <0.5%), and only a small proportion of coding indels can be tagged by SNPs. Missing genotype calls have relatively little impact on common indel LD inference but cause severe underestimation of LD with rare coding indels. Frequency estimation could be distorted by differential missingness. We have found in our study that excluding indels with call rate < 70% leads to accurate MAF estimation (Pearson correlation > 0.992 when compared with MAF estimated using experimentally determined genotypes with negligible missingness). Our study estimates the accuracy of indel calls with current algorithms across a large sample of sequenced exons, presents the previously undescribed LD pattern for rare indels, and provides insight into the impact of missing genotype calls on LD inference and frequency estimation.

Estimating disease associations with common, low-risk alleles using pedigree data: Applications to breast cancer. *D. R. Barnes[1], D. Barrowdale[1], J. Hopper[2], D. Goldgar[3], G. Chenevix-Trench[4], A. C. Antoniou[1], G. Mitchell[5], kConFab Investigators, AOCS Group.* 1) Centre for Cancer Genetic Epidemiology, Department of Public Health and Primary Care, University of Cambridge, United Kingdom; 2) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, Melbourne School of Population Health, University of Melbourne, Australia; 3) Department of Dermatology, University of Utah School of Medicine, Salt Lake City, Utah, USA; 4) Genetics and Population Health Division, Queensland Institute of Medical Research, Brisbane, Australia; 5) Peter MacCallum Cancer Centre, Melbourne, Australia.

Pedigrees in which several family members are genotyped may be a valuable resource for investigating genetic associations with disease risk. We developed an analytical framework to characterise SNP associations with breast cancer (BC) risk using family data and applied it to evaluate the utility of SNP profiles for risk prediction in the context of families with multiple affected members. We used data from 736 families ascertained due to having multiple cases of BC and in which several (on average 8) family members had been genotyped for 25 SNPs previously associated with BC and from 897 unrelated unaffected controls. Disease incidence was assumed to be a function of age (t) $\lambda(t)=\lambda_0(t)\exp(\beta g+P)$, where g represents the SNP genotype, β is the log-relative risk (RR) and $P\sim N(0,\sigma_R^2)$ is a polygenic component. The sum of the residual polygenic variance (PV), σ_R^2, and variance due to the locus of interest was constrained to agree with external estimates of the total PV for BC. Parameters were estimated by maximising the retrospective likelihood (RL) of observed family genotypes conditional on family disease phenotypes. Models were extended to assess parent-of-origin effects (POE), testing risk differences between maternally and paternally inherited alleles. For comparison purposes, data were analysed by case-control analysis. From the pedigree-RL analyses, 13 SNPs were nominally significant. These analyses generally gave SNP association estimates consistent with those from population-based studies. Logistic regression models comparing affected family members against unrelated unaffected controls and ignoring pedigree structure generally gave larger RRs and p-values. For example, for *FGFR2* SNP rs2981582 the estimated RR was 1.26, 95% CI:1.17–1.36, $p=9\times10^{-10}$ under RL compared with OR= 1.44, 95% CI:1.26–1.65, $p=2\times10^{-7}$ under logistic regression. *LSP1* SNP rs3817198, previously shown to exhibit POE with BC risk yielded maternal and paternal RR estimates similar to those previously reported ($RR_{paternal}$= 1.12 (0.99–1.27), p=0.08, p-one sided=0.04; $RR_{maternal}$=0.94 (0.84–1.06), p=0.3). POE were not observed for any other SNP. We estimated AUC= 0.63 (95% CI:0.60–0.66) for discriminating between affected women with BC family history and unaffected, based on combined SNP profiles alone. This was higher than previous estimates based on random case-control studies, suggesting SNPs are more informative for discrimination in the context of multiple-case families.

1493W

Improving association tests by learning mode of inheritance from parental data. *Z. Yu[1], D. Gillen[1], C. Li[2], M. Demetriou[2,3].* 1) Dept Statistics, Univ California, Irvine, CA; 2) Dept Neurology and Institute for Immunology, Univ California, Irvine, CA; 3) Dept Microbiology and Molecular Genetics, Univ of California, CA.

Information regarding the true underlying genetic model, i.e., the mode of inheritance, is crucial in detecting association. For family-based association studies, we show that the underlying genetic model can be learned from parental data. Specifically, for parental mating type data, we propose a novel statistic to test whether the underlying true genetic model is additive, dominant, or recessive; for parental genotype-phenotype data, we propose several strategies to learn the underlying true genetic model. We then illustrate how to incorporate the learned information into family-based association tests. Because family-based association tests are conducted conditional on parental genotypes, their type I error rates are not inflated by the information learned from parental data, even if such information is weak or learned when the assumption of Hardy-Weinberg equilibrium is violated. Our simulations demonstrate that incorporating parental data into family-based association tests improves the power of association tests. The application of our proposed methods to a candidate-gene study of type 1 diabetes successfully detects a recessive effect that would otherwise be missed using the conventional family-based association tests.

1494T

Enhanced maternal origin of the 22q11.2 deletion in velo-cardio-facial/DiGeorge syndrome. *M. Delio[1], T. Guo[1], D. Mcdonald-McGinn[2], E. Zackai[2,3], S. Herman[1], A. Higgins[4], K. Coleman[5], T. Wang[6], A. Auton[1], R. Shprintzen[4], B. Emanuael[2,3], B. Morrow[1].* 1) Albert Einstein College of Medicine, Bronx, NY; 2) Division of Human Genetics, Children's Hospital of Philadelphia and Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA, USA 19104; 3) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA 19104; 4) Syracuse, NY, USA 13210; 5) Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, USA 30322; 6) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY, USA 10461.

Velo-cardio-facial syndrome/DiGeorge/22q11.2 deletion syndrome (VCFS/DGS/22q11DS) is a congenital malformation disorder associated with a de novo 3 Mb hemizygous 22q11.2 deletion, occurring in 1/4,000 live births. The deletion is mediated by meiotic non-allelic homologous recombination (NAHR) events between flanking low copy repeats also referred to as segmental duplications. One important question has been whether there is a parent of origin biases for mediating the deletion. The mechanism and timing of maternal and paternal meiosis differ, suggesting that there may be gender-based genetic factors that alter risk for the deletion. Risk factors might not reveal themselves in studies of individual nuclear families or smaller cohorts but can be identified by studies of a large number of simplex families. Previous studies exist but they were small in size, with conflicting results. A total of 451 DNAs from probands with 22q11DS and their normal parents were genotyped to determine whether there is a parent of origin bias to the de novo 22q11.2 deletion. We found that 219 (56%) patients with 22q11DS had maternal origin and 177 (45%) had paternal origin of the deletion, a ratio of 1.24, resulting in a statistically significant increase of maternal origin (p = 0.0172). A meta-analysis including previous studies resulted in 355 deletions that were of (56%) of maternal origin and 275 (44%) of paternal origin, a ratio of 1.29, resulting in a statistically significant maternal bias in origin of the deletion, based on Fishers's combined probability test (n= 630; p = 0.0016). The ratio is similar to the female to male genetic distance ratio, suggesting that increased maternal origin may be due to increased meiotic recombination rate. We are currently analyzing the potential association of advanced parental age at the time of conception, which could provide insights into the mechanism of the deletion and offer enhanced genetic counseling for 22q11.2DS. We are in the process of analyzing the conception age for over 700 families.

1495F

Connection between heritability and polygenic risk score: Implications for the genetic architecture of complex traits. *V.V. TRUBETSKOY[1], E.R. GAMAZON[1], M.E. DOLAN[2], N.J. COX[1], H.K. IM[3].* 1) Section of Genetic Medicine, Department of Medicine, The University of Chicago; 2) Section of Hematology and Oncology, Department of Medicine, The University of Chicago; 3) Department of Health Studies, The University of Chicago.

Heritability is a fundamental parameter that may yield insights into the genetic architecture of complex traits. Genome-wide association studies (GWAS) have, to date, identified thousands of loci highly significantly and reproducibly associated with a broad spectrum of complex human traits, but these established loci account for only a small proportion of the heritability for any given disease. A recent analytic development, based on linear mixed models, has enabled quantification of the proportion of phenotypic variance attributable to SNPs contributing to susceptibility that are in linkage disequilibrium with SNPs interrogated in GWAS. Indeed, studies based on this approach have shown that a substantial portion of the missing heritability to at least some complex traits may be explained by a large number of common SNPs of small effect size. A second analytic development, namely polygenic modeling, has established a polygenic component in variation to certain traits, such as schizophrenia, height and body mass index. A polygenic score that is calculated from the risk alleles and the effect sizes of a select set of SNPs in a first GWAS is tested in a second GWAS for its association with the trait. In this study, we establish the connection between a polygenic score and heritability. From this connection, we propose a novel method, PolyScore, for calculating the proportion of phenotypic variation due to additive genetic risk factors. In addition to the insights PolyScore provides into recent analytic approaches on the polygenic component to complex traits, the method provides a computationally efficient approach to calculating heritability. As an example, we applied our method to the phenotype of intrinsic growth rate measured in HapMap cell lines. Despite the small sample size (n=108), we were able to get an estimate of heritability of 10%, which we verified is significantly different from 0 by using permutation. The linear mixed model approach yielded an estimate of heritability consistent between 0 and 1, suggesting that our method may be more robust for small sample sizes. Our method can be extended to handle rare variations, which would allow us to explore the contribution of rare and common variants to a cellular phenotype of fundamental significance to pathophysiology and complex traits.

Genetic variants in DNA repair pathway genes and upper aerodigestive tract cancers: Combined analysis of data from genome-wide association studies. *M.-C. Babron[1,2], R. Kazma[3], V. Gaborieau[4], J.D. McKay[4], P. Brennan[4], A. Sarasin[5,6,7], S. Benhamou[1,2], INHANCE consortium.* 1) Inserm, U946, Paris, France; 2) Univ Paris Diderot, Institut Universitaire d'Hématologie, UMRS946, Paris, France; 3) Department of Epidemiology and Biostatistics and Institute for Human Genetics, University of California San Francisco, San Francisco, CA, USA; 4) International Agency for Research on Cancer, Lyon, France; 5) University Paris-Sud, Villejuif, France; 6) CNRS UMR8200, Villejuif, France; 7) Institut de Cancérologie Gustave Roussy, Villejuif, France.

Upper Aerodigestive tract (UADT) cancers are a related group of cancers located in the oral cavity, pharynx, larynx and esophagus. While tobacco smoking and alcohol consumption are the prime environmental risk factors, genetic factors and several biological pathways are also thought to contribute to UADT cancer risk. Among these pathways, those involved in DNA repair are good candidates because of their critical role in maintaining genome integrity. Our aim is to assess the role of single nucleotide polymorphisms (SNPs) in genes involved in DNA repair pathways on UADT cancer risk, and their interactions with tobacco smoking and alcohol consumption. We pooled individual data from two genome-wide association studies (GWAS) covering Europe comprising 1,981 cancer cases and 3,151 controls. Demographic information (age, sex, and country of origin) as well as lifetime tobacco smoking and alcohol consumption were available for cases and controls. Cancer site of cases was also documented. We investigated 1,760 SNPs present of the Illumina HumanMap300 chip located in 222 genes involved in 13 DNA repair pathways. First, we tested for disease association with SNPs using unconditional logistic regression adjusting for age, sex, tobacco smoking, and alcohol consumption. To account for population stratification, we included in the regression the eigenvalues of the top 4 axes of the Principal Component Analysis performed on the GWAS data. To account for multiple testing, we used the Bonferroni correction for the effective number of tests, obtained from the Linkage Disequilibrium matrix of the 1,760 SNPs (Li et al, Heredity 2005;95:221–227). Second, we tested for disease association with SNPs grouped by DNA repair genes and pathways using the SNP-set Kernel Association Test (Wu et al, Am J Hum Genet 2010;86:929–942).This method is specifically designed to investigate the disease association of a given set of SNPs. Preliminary results suggest that five distinct DNA repair pathways are involved in UADT cancer risk: telomerases (TEL), DNA polymerases (POL), homologous recombination (HR), base excision repair (BER), and chromatin structure (CHS). Interestingly, three of these pathways (POL, CHS, and HR) are involved in the susceptibility to lung cancer, a cancer in which tobacco smoking also plays a central role (Kazma et al, Carcinogenesis 2012;33:1059–1064).

1497T

Venous Thromboembolism (VTE)-susceptibility Pathways by Gene Set Analyses. *J. Heit[1], S.M. Armasu[2], J.P. Sinnwell[2], D.J. Schaid[2], M. de Andrade[2].* 1) Internal Med/Hematology Res, Mayo Clinic, Rochester, MN; 2) Div Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN.

Background: Gene set analysis is a promising approach for complementing and interpreting genome-wide association studies. **Objective:** To identify groups of functionally related genes associated with VTE. **Methods:** Genome-wide scan (Illumina 660W Quad [561,408 SNPs]) genotypes from 1270 white adults with objectively-diagnosed VTE (cases; no cancer, venous catheter or antiphospholipid antibodies) and 1302 controls (frequency-matched on case age, gender, race, stroke/myocardial infarction status) were mapped to genes, and genes to the Gene Ontology (GO) and KEGG structures. Gene sets analyses were performed using two methods, a score-statistic method where positive effects of genes on the trait do not cancel, and a p-value combination approach. The analyses were adjusted for age, sex, USA state of residence and stroke/MI status. **Results:** After controlling for multiple comparisons, the following three gene sets were significantly associated with VTE: (1) Positive Regulation of Fibrinolysis (ID 0051919; *KLKB1*, *F11*, *F12*, *PLG*) within the GO Biological Process structures by both analysis methods, either adjusting for covariates only, or for covariates and *F5* rs6025 (Factor V Leiden); relatively strong single SNP association in *F11* may drive this result; (2) Glycoprotein-fucosylgalactoside Alpha-N-acetylgalactosaminyltransferase Activity [ID 0004380; *ABO*] within the GO Molecular Function structures; and (3) Granular Component (ID 0001652; *CDKN2AIP*, *SURF6*, *FBL*) within the GO Cellular Component (nucleolus) structures. None of the gene set structures within KEGG achieved statistical significance. **Conclusion:** Fibrinolysis, glycosyltransferase and nucleolus granular component gene sets are associated with VTE.

Genetic pathways for ADHD show association to hyperactive/impulsive symptoms. *A. Arias Vásquez[1], J. Bralten[3,7], B. Franke[2], I. Waldan[5], S. Faraone[6], J. Buitelaar[3,4].* 1) Departments of Psychiatry, Human Genetics & Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behavior, Radboud University Nijmegen, Nijmegen, Gelderland, Netherlands; 2) Departments of Psychiatry & Human Genetics, Donders Institute for Brain, Cognition and Behavior Radboud University Nijmegen, Nijmegen, Gelderland, Netherlands; 3) Department Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behavior, Radboud University Nijmegen, Nijmegen, Gelderland, Netherlands; 4) Karakter Child and Adolescent Psychiatry University Center, Nijmegen, The Netherlands; 5) Department of Psychology, Emory University, Atlanta, GA, USA; 6) Department of Psychiatry and Neuroscience and Physiology, SUNY Upstate Medical University, Syracuse, NY, USA; 7) Department of Human Genetics, Radboud University Nijmegen Medical Centre, The Netherlands.

Attention-Deficit Hyperactivity Disorder (ADHD) is a highly heritable disorder but finding genes involved in its etiology has been challenging. Compared to single-SNP or haplotype analysis, pathway based analysis might increase the explained phenotypic variance, thereby boosting the power of genetic studies. Alterations in dopamine, noradrenalin and serotonin neurotransmission have been hypothesized to play a role in ADHD, being associated to behavioral aspects of the disorder. Genes involved in neurite outgrowth that appeared when analyzing the top results of the performed GWAS of ADHD are also of interest. Therefore, we decided to investigate the association of these pathways with ADHD symptom count. Data from the International Multicentre ADHD Genetics (IMAGE) study was used. Phenotypic data were the DSM-IV symptom counts for inattention and hyperactivity/impulsivity. Selection of the genetic pathways was based on Ingenuity Pathway Analysis software in combination with literature. From the imputed (HM2) and pruned (r^2=0.8) genome-wide data 6501 SNPs were selected for the association analysis. The analysis consisted of SNP-by-SNP linear regression including age and gender as covariates and the summation of the individual SNP model effect of the complete set of SNPs. Permutations were ran investigating whether the observed pathway-based statistic fell into the extreme 5% of the distribution and empirical p-values were obtained. Post-hoc analyses were conducted for the Connors' Parent Rating (CPR) Scale, for the separate pathways, to investigate single pathway contribution and for neuropsychological data. Analysis of the three pathways showed significant association to ADHD hyperactive/impulsive symptoms (p=0.0081) but not to inattentive symptoms (p=0.73). Investigating (CPR) hyperactive/impulsive score also showed a significant association (p=0.0049). Post-hoc analyses showed contribution of all pathways (dopamine/noradrenalin p=0.0004, serotonin p= 0.0149, neurite outgrowth p=0.0452) to the hyperactive/impulsive score. The analysis of a neuropsychological measure of inhibition (n=187), also showed association to the three pathways (p=0.0045). These findings show that pathway-based association analyses may overcome power problems in association testing by taking into account allelic heterogeneity and our results suggest a specific genetic contribution to the hyperactive/impulsive component of ADHD.

Graphical Models and Intervention Calculus for Causal Inference of Genetic Epidemiology Studies. *P. Wang[1], L. Jin[1], M. Xiong[1,2].* 1) MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, Shanghai, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX, USA.

Complex diseases are caused by genetic variants and environments that are organized into complicated networks. To evaluate their causal relationships among multiple phenotypes and genetic and non-genetic factors plays an essential role in risk prediction and treatment of complex diseases. In the past several years, graphical models coupled with intervention calculus are developed for discovering causal relations among variables and estimate the causal effects. However, such methods can only been applied to thousands of variables. They are difficult to be applied to millions of variables which will be produced by next-generation sequencing. Identifying causal relationships among millions of genetic and non-genetic variables raises great challenges. In this report, we first use high dimensional data reduction techniques to compress genetic information in a gene or genomic region into a variable that follows a Gaussian distribution. We use directed acyclic graph (DAG) model to represent causal relations generating observational data. We then use L1 regularization to estimate the equivalence class of a DAG. Finally, intervention calculus is used to discover causal relations among variables and estimate their causal effects. In summary, we propose to combine high dimension data reduction techniques, graphical models and intervention calculus together to develop a causal inference tool for causal inference of genetic epidemiology studies of complex diseases with next-generation sequencing data. The developed causal inference is applied to the NHLBI's Exome Sequencing Project (ESP) dataset. The preliminary results are encouraging. They demonstrate that the developed causal inference tools will have important implication in risk prediction and treatment of complex diseases.

Multi-SNP analysis of GWAS reveals important gene-gene interactions and gene networks implicated in breast cancer. *L. Briollais[1], A. Dobra[2], H. Massam[3], H. Ozcelik[1].* 1) Samuel Lunenfeld research Institute, Mouint Sinai Hospital, Toronto, Ontario, Canada; 2) Dept. of Mathematics and Statistics, University of Washington, USA; 3) Dept. of Mathematics and Statistics, York University. ON, Canada.

The emergence of new high-throughput technologies for SNP genotyping has generated great promises that the genetic basis of many common human diseases could be elucidated. These expectations have been partially fulfilled and indeed, genome-wide association studies (GWAS) have identified hundreds of genetic variants associated with common human diseases and complex traits. GWAS have also given rise to many criticisms and increasing skepticism because of its relative difficulty to identify important functional variants and genetic variants that have good prediction ability. The actual paradigm to analyze GWAS is to perform an exhausting testing of all single SNP associations with the response variable. However, there is no theoretical justification of the implicit claim that the resulting set of genetic variants can be converted into a good predictive model and that those variants have any biological relevance. Indeed, many GWAS findings have no clear biological interpretation and fall into inter-genic regions. As a shift to the usual paradigm, we propose a novel statistical method for performing multi-SNP analysis in the context of GWAS. Our working hypothesis is that SNPs interacting together might be more functionally relevant and have a better predictive ability. Our statistical method is based on Bayesian graphical model, which offers a comprehensive framework for studying conditional dependence patterns between discrete random variables. The Bayesian framework allows its application to high-dimensional GWAS data by use of efficient stochastic search algorithms. The multi-SNP models with the highest posterior probability are then selected. Our application to the CGEM breast cancer GWAS data illustrates the advantages of our approach. We were able to detect important SNP-SNP interactions associated with breast cancer, involving important genes previously found implicated in breast cancer (FGFR2, APC, BUB3, NTSR1, etc.). Some of these interactions were validated experimentally and correspond to proteins that interact physically. They could involve both rare and common genetic variants. Importantly, our analysis also suggests important gene networks associated with breast cancer through our SNP discoveries. The predictive ability of our multi-SNP models was superior to previous models with an AUC of 63.5%. We will also discuss how our approach can be further developed for a more systemic investigation of gene networks generated from SNP data.

Connecting genome-wide association studies with a biological gene interaction network to uncover epistasis. *D.S. Himmelstein[1,2,3], J.S. Witte[1,3,4], O.G. Troyanskaya[2,5], C.S. Greene[2].* 1) Institute for Human Genetics, UCSF, San Francisco, CA; 2) Lewis-Sigler Institute, Princeton University, Princeton, NJ; 3) Biological and Medical Informatics, UCSF, San Francisco, CA; 4) Epidemiology and Biostatistics, UCSF, San Francisco, CA; 5) Computer Science, Princeton University, Princeton, NJ.

Genome-wide association studies (GWAS) have implicated over 1100 genetic loci in conferring susceptibility to 165 complex traits in humans. However, these loci explain only a small portion of the estimated heritability for most complex diseases. Missing heritability may result from the implicit assumption of standard statistical approaches that common allelic variants combine independently to influence phenotype. Such approaches fail to consider potential non-additive relationships between loci that contribute to disease (epistasis). Inappropriately ignoring epistasis may hinder the search for risk loci and lead to overestimation of total disease heritability. Here, we present a method to assess the role of epistasis in a disease's etiology. Our method measures the extent of genetic signal in a GWAS by comparing statistical relationships between gene-pairs and disease to a gold standard of known biological gene-gene relationships. We assess whether the concordance between biological and genetic relationships increases when disease models incorporate the possibility of non-linear interactions in addition to additive gene-disease associations. An increase in concordance indicates epistasis in a disease's etiology. Appropriate permutation of case-control status ensures the findings result from real genetic signals rather than spurious dataset biases. By assuming disease susceptibility genes function within genetic pathways captured by the biological relationship network, our approach uses our understanding of biological interactions to evaluate statistical epistasis. With our method we evaluate the role that epistasis plays in common human diseases. We apply our method to studies of psoriasis, breast cancer and prostate cancer. By using ROC curves to quantify the ability of genetic relationships to predict biological relationship status and by comparing the disease association distributions between biologically related and unrelated gene-pairs, we observe modest but discernible signatures of epistasis in all three GWAS. When contemplating whether complex human disease models should account for genetic interactions, researchers are faced with a paucity of replicated examples of statistical epistasis to guide their analyses. Our method provides a disease specific indication of whether epistasis plays an appreciable role in disease etiology.

Gene-based collapsing methods may not be powerful for pathway-based association analysis for exome sequencing data. *G. Wu, D. Zhi.* Biostatistics, University of Alabama at Birmingham, Birmingham, AL.

Exome sequencing emerges as a powerful approach for the detection of coding variants, enabling genetic association studies for both common and rare variants. Most current rare variant association methods are gene-based and have insufficient power even for moderately sized genome-wide sequencing data. Pathway association analysis tests the enrichment of phenotype-associating variants and genes in biological pathways, even when few of them reach genome-wide significance individually. Therefore, pathway association may offer insight for most exome sequencing data that were insufficiently powered for gene-base tests. Current pathway association analysis methods, designed for genome-wide association studies (GWAS) data, may not be appropriate for sequencing data. In particular, there may be multiple coding variants which have different directions and magnitude of effects in a gene. Existing pathway association methods typically collapse information at gene-level, and conduct a gene set enrichment test. This approach may lose power when multiple variants in a gene carry association signals. In this study, we evaluate the applicability of GWAS-based pathway association methods to exome sequencing data. In particular, we propose to directly include all variants' information onto the pathway level enrichment analysis for exome sequencing data. Based on extensive simulations using exome sequencing genotype information in 1000 Genome project, and some realistic assumptions on underlying genetic model, we show that, contrary to current beliefs, pathway-based analysis without gene-level collapsing may have higher power than pathway-based analysis with gene-level collapsing. We also provide a guideline in which situation pathway analysis with or without collapsing may be optimal.

High-throughput DNA microarray technology now provides us with a detailed view of the human mRNA transcriptome under different biological conditions. The increasing amount of publicly available microarray data helps in identifying and predicting genes that contribute to the same biological processes. To create a gene co-regulatory model of the human transcriptome, enabling the prediction of gene function, we analyzed 55,000 human, 17,000 mouse and 6,000 rat Affymetrix microarrays from the Gene Expression Omnibus. We created an integrated three-species gene network with 20,000 unique human gene orthologs and developed a principal component based algorithm to predict function for individual genes. We benchmarked the algorithm against several pathway databases (including Gene Ontology, KEGG and Reactome) and observed that empirically validated gene functions could be predicted with high accuracy. As the current method relies solely on expression data, it is not affected by reporting biases in (PPI) databases, abstracts or research questions. We applied our framework to various complex traits for which multiple genome-wide significant SNP associations have been reported. For most traits, our predictions were biologically relevant and often highlighted several pathways that had not been implicated before. For example, “regulation of ossification” was the most significantly enriched pathway among loci associated with human height. In order to pinpoint the most likely causative genes per locus and predict downstream effects of SNPs, we subsequently integrated eQTL data of 5,311 unrelated human peripheral blood samples. We investigated the aforementioned pathways that we had expanded with genes that are likely to be part of these pathways based on the co-expression of the 80,000 samples. When concentrating on SNPs that are known to be associated with complex traits we identified many SNPs for which downstream pathways showed strong enrichments of eQTL signals. These results further support our functional predictions, and indicate that through integration of many gene expression arrays biological knowledge can be obtained for SNPs that have been implicated in disease.

Constructing biological network using RNA-seq data. *Y. Choi[1], M. Coram[2], H. Tang[1].* 1) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 2) Department of Health Research and Policy, Stanford University School of Medicine, Stanford, CA.

Next-generation technologies that generate large-scale genomic data allow the construction of complex networks that provide a new insight for understanding the molecular process. A number of statistical methods have been developed for constructing networks based on Gaussian assumption that may not be appropriate for non-Gaussian data such as RNA-seq. In this study, we propose a novel statistical approach to model a complex covariance structure on multivariate counts data. This method uses penalized likelihood method to estimate sparse partial correlations. However, the implementation of the method is problematic due to complexity of likelihood. Laplace integration technique is used to approximate the likelihood and its derivatives and Newton-Raphson method is applied to find Maximum-likelihood estimator (MLE). In the simulation studies, we show the proposed method performs better than the Gaussian models, especially in the case that the RNA expression levels are low and the distribution is skewed. We also apply the proposed method to two published RNA-seq data and construct networks that may generate testable hypotheses of genetic regulatory interactions.

Network Inference, Integrative Dynamic Omics and Personalized Medicine. *G.I. Mias, H. Im, E. Mitsunaga, R. Chen., J. Li-Pook-Than, L. Jiang, M. Snyder.* Genetics Dept, Stanford University, Stanford, CA.

The longitudinal monitoring of global molecular components and physiological states can offer medical insights in the diagnosis and treatment of disease. Such information allows for network inference that can be leveraged to personalized medicine through dynamically following multiple omics technologies. Pathway changes over time and associated network interactions (inferred nodes & connections) were first observed using multi-omic information from a proof-of-principle investigation, which explored the implementation of personalized medicine in an initially healthy individual over a period of (now) 30 months. The included observations spanned multiple healthy and two virally infected states (as well as the clinically diagnosed onset of Type 2 Diabetes). A novel dynamic network framework will be presented, building on a dynamic integrated Personal Omics Profiling analysis, which allows for observing associated known pathway changes from omics information (transcriptome, proteome, metabolome) in any system. The network framework infers novel pathways components and topological changes and has been extended to other longitudinal studies to display changes as an individual or system transitions through dynamical biological states. This observation of dynamic network changes and related pathways will provide a medically relevant interpretation of associated molecular interaction changes that has potential applications to a more personalized, precise and preventative medicine.

1506T

Stress-induced changes in gene interactions in human cells. *R. Nayak[1], M. Kearns[2,4], V.G. Cheung[3,4,5].* 1) Medicine, University of California - San Francisco, San Francisco, CA; 2) Department of Computer and Information Science; 3) Departments of Pediatrics and Genetics; 4) University of Pennsylvania, Philadelphia, PA; 5) Howard Hughes Medical Institute, Philadelphia, PA.

Cells encounter numerous stressors, and failure to cope can lead to human disease. Cellular response to stress includes altering the expression levels of genes and how genes interact with each other. Here, we sought to understand the cellular response in human B cells following exposure to ionizing radiation (IR) or endoplasmic reticulum (ER) stress. We measured the expression levels of over 5,000 genes in over 95 individuals, constructed coexpression networks, and examined interactions among genes. The analyses revealed that many genes change expression levels, and fewer genes change interactions, but genes that change interactions tend to be specific and critical to the stress response. Expression levels of over 70% and 25% of genes changed following ER and IR stress, respectively, which is more than reported previously in the literature. Gene coexpression networks were constructed by measuring correlation in gene expression levels across >95 individuals. Coexpression networks representing stressed states had similar “hubs” but increased clustering coefficients compared to unstressed states; this was true for both ER and IR stress. Further analysis revealed that while thousands of genes changed expression levels, only hundreds of genes changed interactions with other genes. Genes that changed interactions were enriched for known key players that are critical for responding to stress; these genes were also specific to the stress response. For example, key genes that changed interactions only following ER stress included *BIP*, *ERp72*, and *VCP*. Key genes that changed interactions specifically following IR stress included *DDB2*, *Survivin*, and *BNIP3*. Using this knowledge about genes that change interactions, we were able to identify new roles for genes in ER or IR stress, including genes that do not change expression levels. Together, these results suggest that cells tend to use existing interactions in response to acute stress, but will alter the interactions of key genes critical to the stress response. Thus, examining human gene interactions provides information on key genes and their functions in the cellular stress response.

1507F

An exploration of the use of low coverage whole genome sequencing datasets as additional controls for exome sequenced case series. *D. Gurdasani[1, 2], MS. Sandhu[1, 2], P. Kellam[2, 3], PJ. Openshaw[4], JK. Baillie[5], The MOSAIC and GenISIS Investigators.* 1) Department of Public Health and Primary Care, University of Cambridge, Cambridgeshire, UK; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, UK; 3) Division of Infection and Immunity, University College London, London, UK; 4) Centre for Respiratory Infection, National Heart and Lung Institute, Imperial College, London, UK; 5) Division of Genetics and Genomics, The Roslin Institute, University of Edinburgh, UK.

Exome sequencing approaches are increasingly being applied to the study of complex and rare disease. Due to cost limitations, sequencing is often restricted to case series of interest. Exome sequence data from cases with other diseases are often used for comparison, which can bias results. In this context, approaches that utilise a broad range of control sets, including general population controls, may improve power, reduce bias, and lower type I error. Although large publicly available whole genome sequence data can provide additional controls and improve statistical resolution, comparison of data generated using different sequencing methods can also cause bias. We explored the utility of using low coverage 1000 Genomes Project (1000GP) data as controls for a case series of severe influenza. Methods: Cases of severe influenza were recruited from the UK MOSAIC and GenISIS consortia. We carried out deep (80x) exome sequencing on a Hiseq platform. Reads were realigned around indels and base qualities recalibrated. All polymorphic sites within defined exome target regions in 1000GP were called in cases using GATK and Samtools (standard filters). Only sites called in >80% samples with genotype concordance>80% between algorithms were included. Samples with <95% sites called were filtered. Single locus association testing was carried out using logistic regression with principal components as covariates. Wilcoxon Rank Sum test (WRST) was used to assess if p values were statistically lower for variants within genes implicated in influenza replication. Fisher exact test (FET) was used to assess GO term enrichment among the top 100 loci. Results: 1,092,514 sites from 60 influenza cases and 1092 1000GP controls were included in analyses. The genomic inflation factor was 1.04 for variants with MAF>0.05. Variants implicated in influenza replication in previous siRNA studies had lower p values (WRST p<2.2e-16). Variants predicted as deleterious using Polyphen, CONDEL or SIFT and those with predicted functional consequence had lower p values (WRST p<2.2e-16). The top 100 candidates were significantly enriched for GO terms related to inflammatory (FET p=0.001) and immune response (FET p=0.003). Conclusion: In this proof-of-concept study, we show that with stringent filtering thresholds, low coverage sequencing sets may serve as additional sources for controls for exome sequencing case series and identify plausible variants consistent with known pathogenic mechanisms.

1508W

Genome Profile-based Disease Risk Prediction. *P. Hu[1], E. Boerwinkle[2], L. Jin[1], M. Xiong[2,1].* 1) MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX, USA.

There is bit debate about whether DNA variation has value to predict disease. Recently, a study published in Science Translational Medicine claimed that whole genome sequencing is not informative to predict common disease for all. However, many geneticists questioned their methods, models, assumptions and conclusions (http://blogs.nature.com/news/2012/04/questioning-value-personal-genomics.html). The purpose of this paper is to investigate the predictive values of common and rare genetic variants for complex disease by one set of GWAS (psoriasis: 1,346 cases and1, 377 controls, 429,499 SNPs and a set of exome sequencing data (early of myocardial infarction: 611 cases and 940 controls, 278,191 SNPs). The current paradigm for genetic diagnosis is to predict disease risk of individuals by limited loci known to affect risk of complex diseases. Fast and economic next generation sequencing (NGS) technologies will generate millions or even ten millions of genetic variants. Reducing the dimensionality of data without losing intrinsic information is a key step for genome-wide prediction of common diseases. We use genomic information content in a region and LASSO regulation techniques to develop a novel global feature selection method that can reduce dimensions from millions to hundreds to optimally select important variables as prediction sets where the classification accuracy of these variables are assessed. Bayesian discriminant analysis and logistic regression methods are used to predict individual disease risk. We use 10 fold cross validation to quantify the value of prediction of genetic risk to diseases. We find that the media AUC values of classifying psoriasis and early of myocardial infarction in the test sets are 69% and 70.6% by logistic regression analysis, respectively. These empirical results suggest that genetic variants have valuable value to prediction of individual disease risk.

1509T

Whole Genome Sequencing based Imputation: A Comparison between the 1000 Genomes data and the UK10K Sequencing Data. *J. Huang.* Human Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

Whole-genome sequencing provides the most-comprehensive characterization of genetic variation, but it is still prohibitive for researchers to conduct whole-genome sequencing on all samples from large population-based cohorts. Statistical inference of missing genotypes (imputation) has been proved successful in Genome-wide association studies. The 1000 Genomes project provides phased haplotypes for more than 1,000 samples covering 11 populations, including 379 samples of European ancestry. As part of the UK10K cohorts project, 4,000 whole genomes are being sequenced at low coverage (average 6x) from two population based UK studies: TwinsUK and ALSPAC. We report a comprehensive evaluation on the imputation performance by using the publically available 1000 genomes reference panel versus the latest sequencing data from the on-going UK10K project. We adopt a 2-step approach by first pre-phasing target genotype data and then running imputation based on haplotype matching between target and reference panels. The pre-phasing step uses SHAPE-IT for each of the 22 autosomal chromosomes without splitting into chunk. The second step uses IMPUTE2, where 5MB segments were extracted for parallel processing. We evaluate imputation quality for 5,667 samples in the WTCCC2 common controls genotyped by the Illumina1M panel, which includes 1,158,122 SNPs for 5,667 unrelated individuals. The imputation quality metrics include imputation information score, correlation coefficient and concordance between true and imputed genotype. We assess the overall genome-wide imputation quality, as well as quality in different spectrum of allele frequency and functional annotations. Our analysis and results will provide empirical information that aids investigators to choose reference panels for imputing their own genotype data.

1510F

EPACTS : A flexible and efficient sequence-based genetic analysis software package. *H.M. Kang, X. Zhan, X. Sim, C. Ma.* Biostatistics Dept, Univ Michigan, Ann Arbor, Ann Arbor, MI.

The advent of next-generation sequencing technologies presents an unprecedented opportunity to identify genetic variants causal for complex traits. At the same time, existing and novel sequence-based statistical methods have major software challenges because innovative statistical methods often stay only as in-house software and fail to become widely available. This is primarily bottlenecked by the implementation cost of supporting a complex variety of genetic variants in a computationally efficient manner. We developed a flexible and efficient sequence-based genetic analysis software package EPACTS (Efficient and Parallelizable Association Container Toolbox for Sequence Data), which allows methods developers to dynamically plug-in user-defined single-variant tests or burden tests in both binary and quantitative traits with simple R script. Methods developers do not need to implement low-level data processing, but leverage efficient and parallelizable back-end libraries to directly access the Variant Call Format (VCF) files, up to orders of magnitude faster than most widely available software.

EPACTS provides users and developers with the following key features: (1) Integrated support of variant annotation and association summary and visualization, including QQ plot, Manhattan plot, locus zoom plots. (2) Built-in implementations of a wide variety of single variant tests and rare variant burden tests, including standard regression, score, and likelihood ratio tests, non-parametric rank test, collapsing methods, variable threshold test, Sequence Kernel Association Test (SKAT), and mixed model methods accounting for hidden relatedness. (3) Efficient and concurrent access to VCF files enabling a genome-wide association in half an hour across thousands of individuals and tens of millions of variants on a single machine. (4) Support both for discrete hard genotype calls and likelihood-based soft genotypes. (5) Support for SNPs, short indels, and structural variants (6) Support for efficient permutation and multiple imputation of missing genotypes, and (7) Convenient utilities for basic quality control and population genetic analysis with visualization support. EPACTS is publicly available with an open interface for users to submit new statistical tests. We provide tutorials demonstrating that EPACTS provides a seamless connection between scientific analysts and statistical methods developers in the era of next-generation association studies.

A Monte Carlo procedure for assessing co-occurring and anti-co-occurring gene mutations in cancer genome sequencing studies. *P. Liu, X. Hua, H. Xu, Y. Lu.* Dept Physiology and Cancer Center, Medical College of Winconsin, Milwaukee, WI.

Cancers are caused by the accumulation of genomic alterations. Next-generation sequencing technologies have revolutionized cancer genomics research by providing an unbiased and comprehensive method of detecting somatic cancer genome alterations, including nucleotide substitutions, insertions and deletions (indel), copy number alterations, and chromosomal rearrangements. Recent sequencing experiments have brought success in the identification of several cancer genes that were highly frequently mutated in tumors including IDH1, IDH2, DNMT3A, BAP1, ARID1A, ARID2, MLL2, GRIN2A, GRM3 and PBRM1. These experiments have provided a large catalogue of somatic mutations in individual tumors. Mutations in some cancer genes tend to co-occur (termed co-occurring mutations), suggesting that both of them provide additively proliferative advantages to tumors. However, mutations in other genes tend to occur mutually exclusively, suggesting that they may be involved in the same pathway with similar downstream effectors. To better understand these functional interactions among cancer genes, we introduced a Monte Carlo procedure for assessing co-occurring and anti-co-occurring mutations in cancer genes. Our method accounts for variations in gene length and differences in background mutations among individual tumors that were not addressed by previous methods. To demonstrate the utility of our method, we applied it to the analysis of the significantly mutated genes from lung cancer sequencing projects. The results from our analysis provide unprecedented insights into mutational processes and gene networks associated with lung cancer.

1512T

Using whole exome sequencing to identify rare causal variants for oral clefts in multiplex families. *T.H. Beaty[1], I. Ruczinski[1], M.M. Parker[1], J.B. Hetmanski[1], P. Duggal[1], M.A. Taub[1], S. Szymczak[2], Q. Li[2], C. Cropp[2], H. Ling[3], E.W. Pugh[3], Y.H. Wu-Chou[4], J.E. Bailey-Wilson[2], M.L. Marazita[5], J.C. Murray[6], E. Mangold[7], M.M. Noethen[7], K. Ludwig[7], A.F. Scott[8].* 1) School of Public Health, Johns Hopkins Univ., Baltimore, MD; 2) Inherited Disease Branch, NHGRI, NIH, Baltimore, MD; 3) Center for Inherited Disease Research, Baltimore, MD; 4) Chang Gung Memorial Hospital, Taipei, Taiwan; 5) School of Dental Medicine, Univ. of Pittsburgh, Pittsburgh, PA; 6) School of Medicine, Univ. of Iowa, Iowa City, IA; 7) Institute of Human Genetics, Univ. of Bonn, Bonn, Germany; 8) School of Medicine, Johns Hopkins Univ., Baltimore MD.

Non-syndromic oral clefts (cleft lip, cleft palate and cleft lip & palate) are common birth defects with a complex and heterogeneous etiology. Several genes and regions have been associated with risk in case-control and case-family studies, and genome-wide linkage studies of multiplex families have identified additional regions likely to harbor causal genes. This whole exome sequencing (WES) study used 108 affected 2º and 3º relatives drawn from 52 multiplex families originally recruited for linkage (4 families with 3 affecteds and 48 families with 2 affecteds each). While the WES approach has been successful in identifying novel causal genes for Mendelian diseases, it has not previously been applied to oral clefts.

WES was done by the Center for Inherited Disease Research using the Agilent SureSelect v.4 capture reagents & Illumina HiSeq 2000 sequencers. Initially, we focused on truly novel single nucleotide variants (SNVs), i.e. not previously reported, shared by affected relatives within a family (exact genotype matches only) and predicted damaging by SIFT score (≤0.05). A total of 516 novel SNVs were identified as shared between affected relatives in 52 families. Only one truly novel SNV (A→G at hg19 position 3056632) in ZNF764 was shared by affected relatives across 2 families, and these 2 families came from the same recruitment site. We focused on 334 candidate genes (plausible by molecular function, biological process or pathway) identified in Jugessur et al. (2009, PLoS ONE 4:e5385), and identified 5 genes: CDH1 (16q22), FGF8 (10q24), FGFR4 (5q35), GAD2 (10p11), and TRPS1 (8q24). Most of these genes are recognized candidates for oral clefts or cancers. Mutations in FGF8 underlie Kallman syndrome, which can include oral clefts; mutations in CDH1 have been reported in families with oral clefts and diffuse gastric cancer (MIM 192090); mutations in TRPS1 cause the abnormal craniofacial development of tricho-rhino-phalangeal syndrome. Observed SNVs included 1 Stop/Gain and 4 nonsynonymous SNVs. These affected individuals all have apparently inherited forms of oral clefts, and because they are heterozygous for damaging SNVs, they may result from haploinsufficiency of distinct gene products. Additional studies are needed to confirm causality.

Analyzing Deep Whole Genome Sequence and Genotype Data of >1,000 Individuals from Large Mexican-American Pedigrees in the T2D-GENES Study. *G. Jun[1], M. Almeida[2], P. Cingolani[3], A. Wood[4], C. Fuchsberger[1], T. Teslovich[1], T. Dyer[2], M. Rivas[8], K. Gaulton[8], J. Maller[8], J. Curran[2], J. Grunstad[5], T. Blackwell[1], D. Lehman[6], R. Grossman[5], S. Lincoln[7], J. Laramie[7], M. Boehnke[1], M. McCarthy[8], T. Frayling[4], R. Sladek[3], R. Duggirala[2], J. Blangero[2], G. Abecasis[1].* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, Ann Arbor, MI, United States; 2) Texas Biomedical Research Institute, San Antonio, TX, United States; 3) McGill University, Montreal, QC, Canada; 4) University of Exeter, United Kingdom; 5) University of Chicago, Chicago, IL, United States; 6) University of Texas Health Science Center at San Antonio, San Antonio, TX, United States; 7) Complete Genomics Inc, Mountain View, CA, United States; 8) Oxford University, Oxford, United Kingdom.

Deep whole genome sequencing from large pedigrees has the potential to provide unique insights into the role of rare and private variants in disease. Through the T2D-GENES Consortium, we selected for deep whole genome sequencing 600 of 1,040 individuals from 20 Mexican American pedigrees. Our design allows sequenced data to be combined with GWAS genotypes to impute whole genome data on all remaining family members. Our current data includes deep sequence data on 551 individuals, sequenced by Complete Genomics at an average depth of 60x. Rich longitudinal phenotypic data is available for most individuals, including 316 with type 2 diabetes. We took a series of quality control steps to identify samples with low data quality. Pedigree information was verified by estimating kinship coefficients. Variants are annotated for various sequence quality metrics and filtered by support vector machine to separate likely variants from likely false-positives. We then annotated the impact of each variant on protein structure. This study allows us to examine the segregation of rare and private variants through multiple generations, together with diabetes disease status and related quantitative traits. In the genome of an average individual, we observed 3.4M SNPs, 450K indels, and 2K larger structural variants. Overall, we discovered 24.9M SNPs, including 6.5M singletons, 6.2M indels, and 2.0M multi-nucleotide variants. >50% of SNPs had frequency <1%. After SNP filtering, the Mendelian inconsistency rate was 0.63% and the overall transition to transversion ratio was 2.20. Typically, sample specific rare variants are extremely rare - making it challenging to evaluate their phenotypic effects. Our design means that many sample specific rare variants are seen in many individuals, because they are shared in many individuals that share a particular haplotype as it segregates through a family. Our initial analysis will focus on assessing the impact of identified 170K missense, including 37 variants in genes previously implicated in mature onset diabetes of the young (MODY), and 4K nonsense variants on the risk of type 2 diabetes. Also planned are analyses that evaluate the association between the overall burden of rare variation in individual genes and disease status and analyses that include non-coding variants. Our large set of deeply sequenced large pedigrees provides a unique resource in which to evaluate the association of individually rare variants with type 2 diabetes.

A Flexible and Effective Poisson Mixed Model Framework for RNA Sequencing and other Count Data. *X. Zhou[1], J. Tung[2], Y. Gilad[1], S. Mukherjee[3, 4], M. Stephens[1, 4].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Evolutionary Anthropology, Duke University, Durham, NC; 3) Department of Statistics, Duke University, Durham, NC; 4) Department of Statistics, University of Chicago, Chicago, IL.

High throughput sequencing is extremely widely used in genetics and genomics, providing unprecedented insights into many basic biological questions by accurately quantifying RNA abundance, identifying protein-DNA binding sites and measuring open chromatin regions. However, analyzing read count data presents several important statistical and computational challenges. For example, many expression studies have noted and illustrated the importance of taking account of sample structure, batch effects, and unmeasured confounding factors, in the analysis. However, the analytic tools used to take account of these factors are currently only implemented for normally-distributed data, and not for the kinds of count-based data generated by sequencing. As a result, previous count-based models (e.g. based on Poisson, negative binomial, or beta-binomial distributions) fail to account for sample similarity caused by confounding factors and/or individual relatedness. Here, we rectify this problem, using a Poisson mixed effects model with two random effects terms to account for both independent variation and sample relatedness. We present a novel and efficient posterior sampling algorithm for the model, taking advantage of the recently published genome-wide mixed model association (GEMMA) algorithm. We illustrate our model using two applications: estimating gene expression heritability and detecting differentially expressed genes. Using a real data set, we show that the heritability estimates for gene expression obtained from our model closely resemble those obtained from several previous microarray experiments. Using both simulations and real data sets, we further show that our model is much more powerful than several widely used count based approaches in detecting differentially expressed genes.

Sequence-based analysis identifies variants associated with serum lipids in African Americans. *A. Bentley[1], D. Shriner[1], A. Doumatey[1], J. Zhou[1], H. Huang[1], J. Mullikin[2], R. Blakesley[2], N. Hansen[2], G. Bouffard[2], P. Cherukuri[3], B. Maskeri[2], A. Young[2], A. Adeyemo[1], C. Rotimi[1].* 1) Center for Research in Genomics and Global Health, Natl Human Genome Research Institute, Bethesda, MD; 2) NIH Intramural Sequencing Center, Natl Human Genome Research Institute, Rockville, MD; 3) Office of the Clinical Director, Natl Human Genome Research Institute, Bethesda, MD.

Interethnic differences in serum lipid distributions are consistently observed, with African Americans (AA) generally having healthier lipid profiles than other US ethnicities despite a higher prevalence of risk-associated lifestyle factors. Additionally, interethnic differences in the relationship between lipids and metabolic disorders have been identified. Given the disproportionate burden of these disorders among AA, understanding the genetic determinants of lipid concentrations are critical. To identify genetic factors that influence lipids in AA, we sequenced four lipids-influencing genes (*LPL*, *ABCA1*, *PON1*, and *SERPINE1*) in a subset of Howard University Family Study participants. Participants selected for the sequencing were at the extremes of lipid distribution, either at high risk (high TG and low HDL, n=24) or low risk (low TG and high HDL, n=24). From the variants identified, 103 SNPs were genotyped in the full sample (n=2181). A variety of techniques for analyzing common, rare, and joint common and rare variants were employed to evaluate and confirm associations between these SNPs and serum lipids. A common *LPL* variant rs328 was associated with dramatically increased HDL and homozygosity for the variant allele was associated with 12.7 mg/dl higher HDL (p=0.008). The minor allele of this variant was additively associated with 5% lower TG (p=0.0004). The association with TG was confirmed in a sample of West Africans (3% lower TG, p=0.049). When a method that simultaneously evaluated common and rare variants was used, another common *LPL* SNP, rs1059611, that was not in LD with rs328, was found to be associated with higher HDL (2.6 mg/dl, p=0.02). Rare variant collapsing methods identified positively-associated *ABCA1* variants (n=9, +4% TG, p=0.01) and negatively-associated *PON1* variants (n=2, -8.4 mg/dl HDL, p=0.008) as having roles in serum lipid distributions. In summary, we have identified rare and common variants associated with serum lipids in AA. Beginning the analysis with sequencing has clear advantages for the identification of rare variants; however, this strategy also supports inferences about common variants. For instance, rs328 has been identified previously, but debate exists regarding its role as a causal or proxy SNP; haplotype analysis from this work supports the direct association of rs328 with lipids. Results from this analysis provide new evidence into the genetic determinants of serum lipids in AA.

1516F

Genetic factors associated with levels of immune cell types. *M. Steri[1], V. Orrù[1], E. Fiorillo[1], G. Sole[1], C. Sidore[2,3], F. Virdis[1], M. Dei[1], S. Lai[1], A. Mulas[1], M.G. Piras[1], M. Naitza[1], M.B. Whalen[1], A. Angius[1,5], C.M. Jones[6], D. Schlessinger[8], G. Abecasis[2], S. Sanna[1], F. Cucca[1].* 1) Istituto di Ricerca Genetica e Biomedica (IRGB), CNR, Monserrato, Italy; 2) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 3) Dipartimento di Scienze Biomediche, Università di Sassari, SS, Italy; 4) Dipartimento di Scienze Biomediche e Biotecnologie, Università di Cagliari, CA, Italy; 5) CRS4, GSP group, Parco tecnologico della Sardegna, Pula, Cagliari, Italy; 6) CRS4, AGCT group, Parco tecnologico della Sardegna, Pula, Cagliari, Italy; 7) Dipartimento di Allergologia e Immunologia, Università di Cagliari, CA, Italy; 8) Laboratory of Genetics, NIA, Baltimore, MD, United States.

Genome-wide association scans (GWAS) have identified thousands of regions associated with quantitative traits of biomedical interest, but they mostly focused on broadly classified biomarkers and used incomplete genetic maps. We employed a GWAS approach with enhanced genetic and phenotypic resolution to better understand genetic factors regulating the immune system and its involvement in diseases. We evaluated quantitative variation of 272 immune traits, representing the majority of the leukocyte populations like monocytes, granulocytes, circulating dendritic cell subsets as well as lymphocytes subdivided into NK cells, B cells and T cell subsets (regulatory T cells and T cell maturation states), using flow cytometry, in 1,629 volunteers of the SardiNIA project. Subjects were genotyped with Affymetrix arrays, the MetaboChip and ImmunoChip, and ~8.2 Million variants were imputed from a reference panel of 1,656 haplotypes deriving from 828 Sardinian samples sequenced at 3x coverage, on average. Heritability estimates showed that levels of most cells showed considerable heritability, with the genetic component accounting for >40% of the phenotypic variation for most of the traits (ranging from 3% to 87%). We performed a GWAS for each trait and observed, overall, 93 independent variants at 56 loci ($1\times10^{-202}<P<5\times10^{-8}$), including 4 hitherto unreported variants. These 93 variants accounted for 2% of the phenotypic variation, with 14 explaining >5% and 3 >15%. In addition, 32 of them were associated with more than one trait, suggesting the presence of major genetic components that regulate different parts of the immune system. These large genetic effects are in contrast with findings in other GWAS for quantitative traits, for which effect sizes are typically small, leaving a large proportion of heritability unexplained. Indeed, when considering all the independently associated variants, the heritability that remains to be explained was <20% for 8 traits and <50% for 45 traits. Variants at five loci are also associated with autoimmune diseases, such as multiple sclerosis and type 1 diabetes, crucially several associations were found with diseases for which an immunological component is yet unclear. Our results thus demonstrate that sequencing based GWAS, coupled with highly specific phenotype measurements, can improve our understanding of genetic factors and related biological mechanisms underlying physiological and pathological variations in the population.

Characterization of rare variants in melanoma-associated genes in melanoma-prone families without CDKN2A/CDK4 mutations using exome sequencing data. *R. Yang, K. Jacobs, M. Cullen, J. Boland, L. Burdett, M. Malasky, M. Rotunno, M. Yeager, S. Chanock, M. Tucker, A. Goldstein.* Dept DCEG, NCI, Bethesda, MD.

Approximately 10% of cutaneous malignant melanoma (CMM) cases occur in a familial setting. CDKN2A and CDK4 are the two major susceptibility genes for CMM identified to date. However, these two genes only account for melanoma susceptibility in a small proportion of melanoma-prone families, suggesting the existence of other high-penetrance genes. Exome sequencing has been successful in identifying rare genetic variants underlying rare Mendelian diseases. The goal of this study was to identify additional high-penetrance genes in melanoma-prone families without known mutations. We conducted exome sequencing in blood-derived DNA in 46 CMM cases from 14 melanoma-prone families with three or more affected members. We sequenced five CMM cases in one family, four cases in two families, and three cases in the remaining families. We first filtered out synonymous and common variants that had minor allele frequency >0.05 among our internal controls or in public databases (dbSNP, 1000 Genomes, or NHLBI's Exome Variant Server [ESP]). After this initial filtering step, we observed 1,275 to 3,301 variants in each family. We then applied a dominant segregation model that required variants to be present in all patients (for 3 cases sequenced in a family) or in all but one patient (for >3 cases sequenced in a family) within a family. The number of variants was thus narrowed to 46 to 254 (median 150) in each family. Since disease causing variants are likely to be very rare in the general population, we further filtered variants that were seen more than once among our internal controls (>1/200) or more than five times in ESP. Even with all of these filtering steps, each family still showed many potentially disease-related rare variants (8–84, median 35) and most variants occurred in genes with potential relevance to cancer-related processes. Variants in the same genes were rarely observed in multiple families, suggesting that yet-to-be identified high-penetrance genes may be much rarer than CDKN2A. Our findings suggest that identifying causative variants using exome sequencing for complex diseases like melanoma may be challenging and will require careful prioritization of variants, sequencing of large numbers of families, additional information from other types of evaluations such as gene expression, and potentially functional studies.

1518T

Comparison of variant calling strategies for large-scale exome sequencing projects. *J. Floyd, A. Hendricks, L. Crooks, K. Walter, S. McCarthy, C. Anderson, The UK10K Consortium.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Large-scale sequencing projects in which many hundreds of both affected and unaffected samples are sequenced, as opposed to only one or a handful of disease-affected individuals, are becoming more numerous. When undertaking large-scale whole-genome sequencing projects, it is the norm to analyse the sequence data of all individuals simultaneously in order to accurately call variants. This is because for large-scale whole-genome sequence-based association studies, sequencing depth is typically too low to call variants on a per sample basis. With exome sequence data however, the depth is typically much higher, and calling variants on an individual sample basis becomes possible. However, whether this is always the optimal strategy is not certain, and will depend on the specific aims of the project. For projects with the aim of identifying common (>5% MAF) or low-frequency (1% - 5% MAF) variants affecting common complex disease, multi-sample calling across all sequenced individuals is likely to be the best strategy. However, if the objective is to identify extremely rare high-penetrance variants that may be causing rare Mendelian disease, or even private de novo mutations, then single-sample calling may instead be most powerful. Using data from the UK10K project - a large-scale Wellcome Trust funded sequencing project with the aim of identifying novels genes and pathways for a variety of human diseases - direct comparisons will be made across more than 3,000 exomes called by both single-sample (using a combination of SAMtools and GATK) and multi-sample calling (using SAMtools). Comparisons will be made with respect to how well each method performs in identifying variants at differing minor allele frequency. Comparisons of the filtering stringencies to which the variant calls were subjected will also be performed, since this can have a large effect upon the final number of variants brought forward for analysis. Finally, the call-sets will be assessed with regard to their ability to call a set of known disease causing variants that were validated experimentally.

1519F

A catalogue of structural variants identified in disease-based whole genome sequencing. *A. Kumar[1,2,3], R.D. Pearson[1], R.E. Handsaker[4], K.J. Gaulton[1], S.A. McCarroll[4], M.I. McCarthy[1,2], GoT2D consortium.* 1) WTCHG, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) OCDEM, University of Oxford, Oxford, United Kingdom; 3) Swiss Tropical and Public Health Institute, University of Basel, Switzerland; 4) Department of Genetics, Harvard Medical School, Boston, Massachusetts, USA.

Structural variants (SVs) are a class of human variation representing deletions, duplications and inversions of genomic regions varying from several hundred bases to megabases in size. They have been implicated in the pathogenesis of numerous disorders. Whole genome sequence (WGS) data affords the opportunity to interrogate SVs for contribution to disease across a wider range of allele frequencies and genomic size than previously possible. We have generated a map of SV deletions using WGS data from the Genetics of Type 2 Diabetes (GoT2D) study, which is characterising the contribution of low frequency and rare variants to T2D using a combination of low-coverage WGS data, deep exome sequencing and Illumina Omni 2.5M array genotyping. Discovery and genotyping of SVs was performed using GenomeSTRiP, which integrates sequence read pair and read depth features to identify deletions, applying quality control criterion similar to those of the 1000 Genomes (1000G) project. In an interim freeze of 918 samples of Northern European origin, we discover a total of 16,136 SVs genome-wide. Comparison of chromosome 20 SVs from these samples reveal high concordance with SVs from 1092 samples (AFR=246, AMR=181, ASN=286, EUR=379) in 1000G phase 1. Of 169 variants with HWE > 1e-10 (143 in 1000G), 16/169 were singletons (13/143 in 1000G) and 43/169 had MAF>0.05 (28/143 in 1000G). On chromosome 20, 1000G reports 22 SVs in Europeans, while GoT2D finds 43 SVs, 21 of them overlapping with 1000G (reciprocal overlap > 0.97). The remaining 22 common SVs have a much smaller length distribution (17 SVs <1000bp) owing to tight insert size distribution. In a preliminary analysis, we identified several rare SVs that overlap genes with known involvement in monogenic and polygenic forms of T2D including HNF1A, PPARG, HMGA2, IGF2BP2 and SLC30A8. We are extending discovery and genotyping to a final set of 2,772 whole-genome low coverage (~4x) samples. This will give an unprecedented opportunity to investigate the role of SVs in type 2 diabetes and related traits as well as providing an improved catalogue of SVs in European populations.

1520W

On the analysis of rare, exonic variation amongst subjects with autism spectrum disorders and population controls. *L. Liu[1], E. Boerwinkle[2], J. Buxbaum[3], E. Cook Jr.[4], B. Devlin[5], G. Schellenberg[6], J. Sutcliffe[7], M. Daly[8], R. Gibbs[2], K. Roeder[1], ARRA Autism Sequencing Consortium.* 1) Department of Statistics, Carnegie Mellon University, Pittsburgh, Pennsylvania, 15213; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas, 77030; 3) Seaver Autism Center for Research and Treatment, Mount Sinai School of Medicine, New York, New York, 10029; 4) Department of Psychiatry, University of Illinois at Chicago, Chicago, Illinois, 60608; 5) Department of Psychiatry, University of Pittsburgh Medical School, Pittsburgh, Pennsylvania, 15213; 6) Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania, 19104; 7) Vanderbilt Brain Institute, Department of Molecular Physiology & Biophysics and Psychiatry, Vanderbilt University, Nashville, Tennessee 37232; 8) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, 02114.

Whole exome sequencing (WES), performed at the Baylor and Broad sequencing centers, produced data from 1039 subjects diagnosed with autism spectrum disorders (ASD) and 863 controls selected from the NIMH repository to be of similar ancestry to cases. We report on a case-control analysis with several goals: (1) contrast the distribution of rare variation between cases and controls to determine if ASD risk genes can be identified in a sample of this size; (2) investigate the impact of population structure on association test statistics and efficacy of traditional remedies for confounding arising from this structure; and (3), due to the structure of the data, assess the efficiency of meta- versus mega-analysis for common gene-based analyses of association. Data produced by two different centers and using two different sequencing platforms make (3) a particularly rich problem to be solved. Using a variety of gene-based tests and both meta- and mega-analysis, we find no new risk genes for ASD in this sample of cases and controls. Even for known risk genes the evidence from gene-based tests is not sufficiently compelling to “replicate” any gene. Our results suggest that standard gene-based tests will require much larger samples of cases and controls before being effective for gene discovery, even for a disorder like ASD, for which rare variants are known to play an important role in risk. Like other recent studies, we find evidence that population structure can confound case-control studies by the clustering of rare variants in ancestry space. Yet unlike recent studies we find that principal component based analyses are sufficient to control for ancestry and produce test statistics with appropriate distributions. A surprising result from our study involves the performance of meta- versus mega-analysis. It is widely understood that mega- and meta-analysis are typically equivalent for tests of common variant association. But the tests involved are of linear form, whereas many gene-based tests are quadratic. In the quadratic setting we show by theory and simulations that mega-analysis has better power than meta-analysis. The drawback, of course, is that combining datasets presents other challenges, which will be discussed.

1521T

Resolving dependence between overlapping reads in next-generation sequencing data. *Y. Lo[1], G. Abecasis[1], S. Zöllner[1,2].* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Psychiatry, University of Michigan, Ann Arbor, MI.

Generating genotype calls from paired-end next generation sequencing data assumes that each paired-end mate gives independent genotype. In practice read ends often overlap, especially in exome sequencing data, when PCR fragments are short. This overlap violates the independence assumption because overlapping reads replicate the same PCR error. Assuming independence at overlapping bases leads to overestimation of genotype call accuracy. Hence, one of the overlapping reads is typically removed from the data. However, each base in an overlapping region is sequenced twice; each sequencing reaction provides additional evidence about the true underlying genotype. Hence, ignoring one read may lead to substantial data loss. For example, in a low-pass sequencing study, about 13% of the read pairs overlap, and the average length of overlapping region is 44bp out of the 100bp reads. We propose a method (RESCORE) to remove the dependence in overlapping reads, while retaining genotype information from sequencing. To resolve dependence, we calculate a preliminary base quality statistic per overlap position based on the concordance of the bases and on the original quality scores. We turn these preliminary statistics into calibrated quality scores by binning genotypes by their statistic and comparing the reads in each preliminary quality statistic category with the reference genome, excluding known sites of variation. Assuming that all mismatches are genotyping error, we can thus estimate calibrated quality for each category. We apply RESCORE on 1,200 individuals with aligned sequence reads from the 1000 Genomes Project Exome data. We compare genotype calls from original reads, reads modified by RESCORE, as well as reads modified by retaining one read at the overlapping regions. Using RESCORE, quality score at each overlapping base is higher than each original read base, suggesting more accurate estimates of genotype uncertainty. Comparing resulting SNP calls on chromosome 20, RESCORE gives slightly fewer number of singletons, but at higher overall quality. Improved transition-transversion ratio suggests that the call set from RESCORE contains fewer false positives. At the shared singletons, we see higher SNP and genotype qualities using RESCORE. We recommend incorporating RESCORE into standard variant calling pipeline, especially for low-pass sequencing studies.

1522F

Single point and rare variant analysis by whole genome sequencing in 4,000 samples in the UK10K cohorts project. *J.L. Min, The UK10K Consortium (Cohorts Group).* School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom.

The UK10K project is a collaboration between multiple research centres mainly in the UK aiming to uncover rare genetic variants contributing to disease and health status by sequencing 10,000 people. As part of UK10K, 4,000 individuals from two deeply phenotyped cohorts - TwinsUK and the Avon Longitudinal Study of Parents and Children (ALSPAC) - have been sequenced to average 6.5x coverage using next-generation sequencing technology. In the current release of 2,357 whole genome sequences (1,617 from TwinsUK and 740 from ALSPAC), we tested single variants and collapsed sets of variants for association with 46 quantitative traits using several statistical methods. Genotype accuracy is high and there is no evidence for inflation of association summary statistics. Several variants were found confirming previously known genome-wide association results, including CETP for HDL, UGT1A1 for Bilirubin, SLC2A9 for Uric acid, ABO for alkaline phosphatase, APOE for Total cholesterol and LDL and HBS1L-MYB for several blood count measurements. Using six different collapsing methods to test the combined effect of multiple rare coding variants on 10 known loci with common and/or rare variants for various traits also revealed consistent results indicating positive signals for CETP and HDL and SLC2A9 and uric acid (empirical $p<0.01$, $p\sim1e\text{-}5$). As an example of the possibility of extra information at known or new signals found by these methods, preliminary results show that after conditioning on rs1800775 for HDL and rs11727666 for uric acid, additional variants in the allele frequency range of 1–5% and 2–46% appear to contribute to the signal around CETP and SLC2A9 in the collapsing test ($p\sim0.001$). Initial novel signals are being followed up. Currently analysis of a final set of 3910 samples is under way, and variants discovered through genome-wide sequencing of the TwinsUK and ALSPAC cohorts are being imputed into the full genotyped cohorts to increase the power of the UK10K study. Our results provide insights into how large-scale whole-genome sequencing efforts are likely to reveal for the genetic architecture of complex traits and might significantly increase the initial estimates of explained heritability.

1523W

A Statistical Framework for the Evaluation of *De Novo* Variation in Psychiatric Disease. *K.E. Samocha[1, 2, 3, 4], B.M. Neale[1, 2, 3], M.J. Daly[1, 2, 3], ARRA Autism Sequencing Consortium.* 1) Departments of Genetics and Medicine, Harvard Medical School, Boston, MA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 4) Program in Genetics and Genomics, Biological and Biomedical Sciences, Harvard Medical School, Boston, MA.

With the increasing number of exome sequencing studies focused on *de novo* mutation discovery, it has become critical to have a rigorous method to evaluate the *de novo* findings. Particularly, it is important to determine the potential significance of genes that harbor multiple *de novo* events, especially as the number of sequenced individuals rises. The need for this statistical framework was recently highlighted by four exome sequencing studies of autism spectrum disorders that found an apparent excess of genes that had two loss-of-function (LoF) mutations (Neale et *al*. 2012; Sanders et *al*. 2012; O'Roak et *al*. 2012; Iossifov et *al*. 2012). While rough estimations were used to determine significance, we propose here a systematic approach to estimating individual gene significances as well as the significance of experiment-wide excesses. To properly evaluate the probability of mutation, it is key to precisely estimate the expected mutation rate. To do so, we plan to apply a mutational model based on intergenic SNPs identified by the 1000 Genomes Project to each gene region in the genome. This mutational model incorporates local sequence information to determine the probability of each possible base change for every genomic base. We define the target bases of mutation as those in coding sequence or in the conserved splice sites. We then combine the individual probabilities of each possible substitution to determine the overall probabilities of a synonymous, missense, nonsense, splice site, frameshift, and inframe mutation per gene per trio sequenced. These probabilities can be used directly to evaluate individual gene observations, as well as to simulate efficiently large sequencing studies similar to the ones recently conducted for autism spectrum disorders. While this method is applied to exome sequencing for autism spectrum disorders, it can also be applied more generally. It not only takes into account the targeted sequence context, but also the coverage found in our studies and the number of trios sequenced. These probabilities, therefore, can be scaled and applied to other exome sequencing studies to assess the significance of potentially promising candidate genes for further evaluation.

1524T

Efficient Two-Stage Analysis Approach for Complex Trait Association with Arbitrary Depth Sequencing Data. *S. Yan, Y. Li.* University of North Carolina-Chapel Hill, Chapel Hill, NC.

Sequencing-based genetic association analysis is typically performed by first generating genotype calls from sequence data and then performing association testing on called genotypes. Accurate genotype calling requires either high sequencing depth if a small number of individuals are sequenced or if single individual calling is performed; or computationally intensive multi-sample linkage disequilibrium (LD) aware genotype calling. Here, we propose an economically and computationally efficient two-stage approach in which candidate genetic regions are screened out in the first stage via a rapid likelihood based method on sequencing data directly (without first calling genotypes) and then candidate regions are scrutinized in the second stage by performing association tests on genotypes from LD-aware multi-sample calling. Our simulations show that depth ranging from 4 to 16 benefits most from the 2-stage approach. Among those depth ranges, the overall powers are around 0.5 or more when the 0.05 bonferroni-corrected type I error is achieved with the screening ratio being 0.5 or less. For example, when sequencing depth equals to 16 and screening ratio is only 0.3, the estimated overall power is around 0.73 and the bonferroni-corrected type I error is controlled at 0.05. Genotyping calling only 30% of the markers at the second stage spares a great deal of time compared with the one step testing. We will also show the effectiveness of our two-stage approach using real sequencing data.

1525F

Improving the Accuracy and Efficiency of Sequencing Experiments, by Using Previously Sequenced Genomes. *X. Zhan, H.M. Kang, G. Abecasis.* Center for Statistical Genetics, Department of Biostatisitcs, Univeristy Michigan, 1415 Washington Heights, Ann Arbor, MI 48109.

DNA sequencing is now an indispensable technology in medical genetic research studies. Genome scale sequencing experiments are constrained by the expense required to sequence each sample to high depth, which is required to ensure accurate genotype calls when samples are examined individually. When samples are analyzed jointly, or together with many previously sequenced samples, accurate genotype can be produced by haplotype aware analyses of the short read data.

Here, we report on improvements to our software for the analysis of low pass sequencing experiments. We then use our software to call genotypes at sites with low coverage data (using the 1000 Genomes reference panel to guide haplotype aware analyses) and explore the trade-offs between sequencing depth and genotype accuracy.

We show that moderately deep 12x data allows for >99.5% accuracy at hard to call heterozygous and non-reference homozygote sites. Lower 0.5x coverage, provides 94% genotype accuracy at these hard to call sites using our methods (versus 24% accuracy when using single sample analysis methods).

We also explore the relationship between analysis method, sequencing depth and power. We expect the results are helpful in designing the sequencing experiments of the future.

1526W

Estimating and Testing Genetic Effects for Complex Traits in Sequence-Based Association Studies and Power Comparisons. *J. Zhou, N. Laird.* Harvard Sch Public Health, Boston, MA.

Genetic studies have been haunted by the mystery of “missing heritability”. Although genome-wide association studies (GWAS) have identified many variants associated with some common diseases and traits, these variants typically explain only a small fraction of the heritability. With emergence of the next generation sequencing (NGS) technology, many novel statistical methodologies have been proposed to assess the contribution of rare variations to complex disease etiology. In this paper we explore the application of linear mixed model (LMM), which has been recently used to estimate genetic variance using variants in current GWAS platform, to the estimation and testing of genetic variance based on SNP panels of NGS data. In general, through the estimation of genetic component, LMM provides an association testing strategy that can detect both rare and common variants, deal with both additive and interaction effects, handle both quantitative and dichotomous traits, and incorporate non-genetic covariates. We explore the theoretical connection between LMM and kernel-based association testing such as SKAT and carry out extensive simulation studies to evaluate the power of LMM under various distribution assumptions of traits, proportions of the causal variants and the quality control (QC) stringent thresholds. Our studies show superior performance of LMM under various conditions compared to other existing methods.

1527T

A unified statistical framework to correct for unknown population stratification, family structure and cryptic relatedness in the sequence-based association studies. *Y. Zhu[1], J. Zhao[1], Y. Shugart[2], M. Xiong[3].* 1) Biostatistics and Epidemiology, The University of Oklahoma Health Science Center, Oklahoma City, OK; 2) Unit of Statistical Genomics, Division of Intramural Division Program, National Institute of Mental Health, National Institute of Health, USA; 3) Division of Biostatistics, School of Public Health, the University of Texas Health Science Center at Houston.

In this study, we will address two issues in sequence-based association studies. The first issue is how to correct for population stratification in testing the association of rare variants. Although structured association, principal component analysis (PCA) and manifold learning can be used to correct for population stratification in the test of the association of common variants, how to correct for population structure in the test of the association of rare variants remains a challenge . The commonly used methods such as PCA to correct for population stratification in the GWAS of common variants use summary measures of ancestry as covariates to correct for population stratification. However, many existing statistical methods for testing the association of rare variants are typically incapable of incorporating covariates in the test. To overcome issues, we propose to develop unified, and computationally feasible statistical methods for sequence-based association analysis in samples with arbitrary combinations of related and unrelated individuals using the quasi-likelihood score approach. The second issue is how to use the within family information to correct for family structure and between family information to correct for cryptic relatedness and population stratification. Our approach estimates the information for both within and between family from sequence data and thus can simultaneously correct for family structure, cryptic relatedness and population stratification while maintaining high power. Consequently the proposed novel statistical methods can be applied to several study designs including (1) an isolated population in which individuals may be related, (2) admixed populations, (3) pedigrees, and (4) combination of pedigrees with unrelated individuals. To evaluate theperformance our methods under different study designs, we useintensive simulations to calculate the type 1 error rates of the proposed tests and conduct power comparisons with other existing population stratification correction methods. The proposed statistics have also been applied to the early-onset myocardial infarction (EOMI) exome sequence data from the NHLBI's Exome Sequencing Project. Our results demonstrate that the proposed methods substantially outperform other population structure correction methods.

1528F

Genome-wide association study of primary tooth eruption identifies pleiotropic loci association with craniofacial distances. *G. Fatemifar[1,2], C. Hoggart[3], L. Paternoster[2], J. P. Kemp[1,2], I. Prokopenko[4,5], M. Horikoshi[4,5], J. H. Tobias[6], S. Richmond[7], F. Geller[8], B. Feenstra[8], M. Melbye[8], T. Sørensen[9], A. Zhurov[7], A. M. Toma[7], S. Ring[1], B. S. Pourcain[2], N. J. Timpson[2], G. D. Smith[2], M. Jarvelin[3], D. M. Evans[2].* 1) Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 2) MRC Centre for Causal Analysis in Translational Epidemiology (CAiTE), University of Bristol, United Kingdom; 3) Department of Epidemiology and Biostatistics, Imperial College London, St Mary's Campus, Paddington, London, United Kingdom; 4) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 6) Academic Rheumatology, Musculoskeletal Research Unit, Avon Orthopaedic Centre, Southmead Hospital, Bristol, United Kingdom; 7) Department of Applied Clinical Research and Public Health, Cardiff University, Cardiff, United Kingdom; 8) Department of Epidemiology Research, Statens Serum Institute, Copenhagen, Denmark; 9) Institute of Preventative Medicine, Copenhagen University Hospital, Copenhagen, Denmark.

Twin and family studies indicate that the timing of primary tooth eruption is highly heritable, with estimates typically exceeding 80%. To identify variants involved in primary tooth eruption we performed a population based genome-wide association study of `age at first tooth' and `number of teeth at one year' using 5998 and 6609 individuals respectively from the Avon Longitudinal Study of Parents and Children (ALSPAC) and 5403 individuals from the 1966 Northern Finland Birth Cohort (NFBC1966). We tested 2,363,918 SNPs common to both studies. Analyses were controlled for the effect of gestational age, sex and age of measurement. Results from the two studies were combined using fixed effects inverse variance meta-analysis. We identified nine loci reaching genome-wide significance ($p<5\times10-8$) for `age at first tooth' and a further ten loci for `number of teeth at one year'. This included six previously unidentified loci (rs17563 (BMP4), rs1888693 (CACNB2), rs4937076 (CDON), rs1799922 (CALU/OPN1SW), rs997154 (JUB) and rs9316505 (DLEU7)), some of which are known to play a role in tooth and other developmental pathways. Two of these loci (rs17101923 and rs997154) showed evidence of association with craniofacial distances particularly those indexing facial width. Our results suggest that the genome-wide association approach is a powerful strategy for detecting variants involved in dentition, craniofacial growth and development.

1529W

General framework for meta-analysis for sequencing association studies. *S. Lee, X. Lin.* Biostatistics, Harvard school of public health, Boston, MA.

We propose a general statistical framework of meta-analysis for rare variants association test. To identify disease susceptibility genetic variants, meta-analysis has become an effective approach since it effectively combines data from different cohorts to increases the statistical power. In spite of the fact that it has been widely used in genome-wide association studies to identify the disease susceptible common variants, only limited effort has been made for rare variants analysis. To fill the gap, we develop a novel meta-analysis method that extends popular burden tests, sequence kernel association test (SKAT), and more recent optimal unified test (SKAT-O). The proposed method uses gene-level summary statistics to conduct association test and is flexible enough to apply for homogeneous or heterogeneous genetic effects across different cohorts. Furthermore, the proposed method is as powerful as conducting a mega-analysis with all individual level genotype data. Simulation studies and a real data analysis with Dallas Heart Study data will confirm the superior performance of the proposed method.

1530T

General class of family-based association tests for sequence data, and comparisons with population-based association tests. *I. Ionita-Laza[1], S. Lee[2], V. Makarov[3], J.D. Buxbaum[3,4,5], X. Lin[2].* 1) Department of Biostatistics, Columbia University, New York, NY; 2) Department of Biostatistics, Harvard University, Boston, MA 02115; 3) Seaver Autism Center for Research and Treatment, Mount Sinai School of Medicine, New York, NY 10029; 4) Department of Psychiatry, Mount Sinai School of Medicine, New York, NY 10029; 5) Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY 10029.

Recent advances in high-throughput sequencing technologies make it increasingly more efficient to sequence large cohorts in many complex traits. Making sense of these massive data depends critically on the use of efficient study designs and appropriate statistical methods. We discuss a general class of sequence-based association tests for family-based designs, that corresponds naturally to previously proposed population-based tests, including the classical burden and variance-component tests. This framework allows for a direct comparison between the power of sequence-based association tests for family-based, and population-based designs. We show that for dichotomous traits, family-based designs result in similar power levels as the population-based designs (although at increased sequencing costs for the family-based design), while for continuous traits (in random samples, no ascertainment) the population-based designs can be substantially more powerful. A possible disadvantage of population-based designs is that they can lead to increased false-positive rates in the presence of population stratification, and although adjustment for population substructure using principal component analysis can properly adjust for stratification at a small loss in statistical power, in more subtle scenarios, it can fail to completely adjust for such confounding. This is unlike the family-based designs, which are, by definition, robust to population stratification. We also present results from an application to an exome-sequencing family-based study on autism spectrum disorders.

1531F

A novel statistical approach to prioritize variants from deeply sequenced NGS samples using publicly available sequence controls. *L. J. Strug[1,2], A. Derkach[2], T. Chiang[1], L. Addis[3], S. Dobbins[4], I. Tomlinson[5], R. Houlston[4], D. K. Pal[3].* 1) Program in Child Health Evaluative Sciences, the Hospital Sick Children, Toronto, ON, Canada; 2) University of Toronto, Toronto, ON, Canada; 3) Department of Clinical Neuroscience, Institute of Psychiatry, Kings College London, UK; 4) Institute of Cancer Research, London, UK; 5) Wellcome Trust Centre for Human Genetics, Oxford, UK.

Next generation sequencing (NGS) is a powerful tool to identify variants responsible for rare Mendelian disorders. Putative causal variants can be prioritized for follow-up by their novelty and known/predicted functional consequence. However, variant prioritization of NGS data for complex disorders is more challenging: in this situation contributory variants are expected to have an appreciable frequency in healthy subjects. A sufficiently powered case-control design is prohibitively expensive. Population whole genome data is publically available, but its generally low read-depth introduces a bias that complicates comparison with higher read-depth NGS data from cases. We therefore developed novel statistical methodology that adjusts for bias and provide a general framework to use publically available sequence data to prioritize variants in studies of complex disorders. We apply this method to NGS data from a 600kb linkage region for an epilepsy endophenotype present in ~2% of the general population. With DeCode genetics we used long-range PCR and NGS on 27 epilepsy cases, with average read-depth of 197x. We compare the 27 cases with 178 1000 genomes controls (release May 21st 2011), and validate the results by comparison with 200 NGS controls sequenced by Complete Genomics (CG) with ~35x depth. Genotype quality filters were common across the epilepsy and CG datasets; in the 1000 genomes data we used the low coverage calls as released. Using variants seen in both case and control datasets (novel functional variants are prioritized for follow-up by default), we developed a conditional exact score statistic that calculates the probability of observing 2×3 contingency tables with statistics as extreme or more so under the selection scheme. Using this statistic we compared our cases to 1000 genomes, our cases to CG controls, and the control groups to each other. Results using 1000 genomes highlight the need to adjust the statistic for NGS differences, while comparing CG controls to cases shows an absence of bias requiring adjustment. We show that an average genomic control λ=1.65, calculated from re-sampling 1000 sets of variants with pairwise LD<20%, can remove bias and identify the same associated variants as with the CG high-depth control group. These variants can then be prioritized by association and annotation and added to a prioritization list for follow-up, consequently increasing the utility of public NGS controls.

1532W

Variable Selection Based Weighting Schemes for Implicating Rare Variants in Sequence Data. *A.E. Byrnes[1], M. Li[2], M.C. Wu[1], F.A. Wright[1], Y. Li[1,3].* 1) Biostatistics, University of North Carolina, Chapel Hill, NC; 2) Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Genetics, University of North Carolina School of Medicine, Chapel Hill, NC.

The improvements in and dropping costs of next generation sequencing technologies allow us to access rare genetic variants (RVs) in increasingly large samples of individuals. This in turn augments our ability to find associations between RVs and human complex traits. Even so, power to detect associations between individual RVs and complex traits is limited and this has motivated the development of burden tests wherein a trait is regressed on the weighted average of multiple RVs across a region. Several such schemes have been proposed, but there is little consensus on which is the best. Here, we compare several weighting schemes using extensive simulations that mimic large-scale sequencing studies of a quantitative trait under a variety of situations. We simulate data in which there are single and multiple truly causal RVs as well as cases where the causal RVs contribute to the quantitative trait in the same and opposite directions. We investigate several existing phenotype-independent and -dependent weighting schemes and introduce variable selection to some of the phenotype-dependent schemes in order to increase the number of zero weights. We assume that most RVs are not associated with the trait under study and, in the hopes of clarifying the association signal, use variable selection to eliminate the weights of the less informative markers by setting their estimates to exactly zero. Our simulations show that phenotype-dependent weighting schemes have increased power over phenotype-independent schemes in most cases. This stands to reason since the phenotype-dependent schemes take the outcome information into account whereas phenotype-independent schemes do not. Further, we show that variable selection can significantly increase the power to detect the effect of multiple RVs in phenotype-dependent schemes since it allows us to select only the most informative variants and to assign non-zero weights preferentially to these. In the majority of the situations we considered with multiple truly causal rare variants, we observed power near or above 80%. Results on a real data set of ~2000 sequenced individuals are also shown.

1533T

Accurate local ancestry inference in exome sequence samples. *Y. Hu, G. Abecasis, H. Kang.* Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Deciphering the ancestry of specific chromosomal regions in admixed individuals is significant for studies of human evolutionary history and disease gene mapping. Typically, this ancestry deconvolution relies on genotypes generated using high-density GWAS arrays; data that is not always available in exome sequenced samples. We show that even a relatively small number of off-target reads from exome sequencing experiments can be used to accurately estimate the ancestry of admixed individuals.

To reconstruct local ancestry, we use a Hidden Markov Model that models sequence data directly, without requiring intermediate genotype calls. We evaluate the accuracy of our method through simulation and the analysis of admixed individuals sequenced by the 1,000 Genomes Project and ongoing disease studies. In African-Americans, we show local ancestry estimates derived using our method are extremely similar to those derived using Illumina's Omni 2.5M genotyping array (average r2 between the two estimates is 0.99); and much improved in relation to estimates that rely use only exome genotypes and ignore off-target sequencing reads.

In 2000 African American individuals, we use our method to evaluate patterns of coding variation in portions of the genome with recent European and African ancestry. We estimate that ~20% of the genome of each individual (range 2–53%) is of European ancestry and that the heterozygosity rate is lower in portions of the exome with recent European ancestry (0.72 per kilboase of coding sequence, compare to 0.87 for African ancestry). Among the heterozygous sites, the ratio of the number of nonsynonymous to synonymous sites is higher in European portions (0.95 versus 0.85). In addition, the number of nonsynonymous and loss of function heterozygous sites per kilobase are higher in portions with European ancestry (195 non-synonymous variants and 10 loss-of-function variants per megabase of coding sequence, compared to 191 non-synonymous and 9 loss-of-function variants per megabase in portions of the genome with recent African ancestry).

Our method should be useful to anyone undertaking exome or targeted sequencing of admixed populations, both for analysis of human population history and for disease gene mapping studies.

1534F

Internal reference panel selection methods for genotype imputation: a novel sequencing study design strategy for genotyped samples. *P. Zhang[1], N. A Rosenberg[2], S. Zöllner[3].* 1) Dept Computational Medicine and Bioinformatics, Univ Michigan, Ann Arbor, MI; 2) Department of Biology, Stanford University, Stanford, CA; 3) Dept Biostatistics, Dept Psychiatry, Univ Michigan, Ann Arbor, MI.

The recent dramatic cost reduction of next-generation sequencing technology enables investigators to identify risk variants for complex diseases with sequencing studies. However, sequencing all individuals in a study is still prohibitively expensive for large sample sizes. For study samples with existing genotype data, such as data from genome-wide association studies (GWAS), a cost-effective approach is to sequence a subset, and use the sequenced subset as an internal reference panel to impute the rest of the study sample. As of today, there are thousands of existing GWAS with a total of millions of individuals involved. Effective use of these genotype data when planning sequencing studies on these individuals make it possible to carry out large-scale sequencing studies with limited cost. We have focused on how to select an internal reference panel in such studies on the basis of the existing genotype data. Using an internal reference panel precludes the possibility of a substantial mismatch of ancestry background between the study population and the reference population. It also allows the variants that are unique to the study sample to be imputed. The goal of this study is to find the optimal internal reference panel for imputing the sequences of the study sample so that we can (1) maximize the number of polymorphic sites in the study template and (2) achieve the optimal imputation accuracy. We propose two strategies for choosing optimal internal reference panels: first, the “most diverse subset,” defined as the subset with maximal phylogenetic diversity, thereby incorporating individuals that span a diverse range of genotypes within the sample. Second, the “most representative subset,” defined as the subset that has the minimum genetic distances to unselected individuals, such that each unselected individual is represented well by at least one individual in the selected subset. Using data both from simulations and from sequences from the 1000 Genomes Project, we show that carefully calibrating the internal reference panel can significantly improve the imputation accuracy, especially for the imputation of rare variants. We further compare the performances of the two panels in genotype imputation for data generated under different scenarios. We seek to provide guidelines for selecting optimal subsets, thereby recommending a novel strategy to obtain sequence information comparable to that available by sequencing the entire study sample.

1535W

Statistical methods for inference in population genetic studies with uncertain genotype data. *E. Han.* Biostatistics, UCLA, Los Angeles, CA.

Next-generation sequencing (NGS) techniques are opening a new era in population genetic studies. However NGS data suffers from errors in read-level base calling, errors in read-mapping, and variable coverage, and these create non-negligible uncertainty in genotype calls in many datasets. Ignoring genotype uncertainty in population genetic inference can lead to serious biases in estimation and mistaken conclusions in subsequent analysis, such as in genome-wide selection scans or studies of population structure. Here we present a statistical approach to infer population genetic properties of the sample such as the number of segregating sites (S), the nucleotide diversity (π) and the population structure fixation index (F_{ST}). Our method computes the posterior probability of the allele frequency at each site, and summary statistics are then calculated by summing over these posterior probabilities. We present software to compute these metrics, compare the behavior of the method to naïve approaches that ignore genotype uncertainty, and explore the properties of these estimators as a function of coverage and base qualities. We have applied the method to next-generation sequencing data from six canid genomes (two dogs, three wolves, and one golden jackal) to detect signatures of adaptation during dog domestication.

1536T

On association analysis of rare variants under population-substructure: An approach for the detection of subjects that can cause bias in the analysis. *D. Qiao[1], M. Mattheisen[2], C. Lange[1,3,4].* 1) Biostatistics, Harvard School of Public Health, Boston, MA; 2) Department of Medicine, Brigham and Women's Hospital, Boston, MA; 3) Institute for Genomic Mathematics, University of Bonn, Bonn, Germany; 4) German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany.

For the analysis of rare variant data in population-based designs, we propose a method to detect study subjects that may create population substructure in the study sample, potentially introducing bias into the association analysis. Our approach is computationally fast and simple, permitting applications to whole-genome sequencing studies. The approach does not require variant data to be in linkage equilibrium and can be applied to all the genetic loci that are available in the study. For both rare and common variants, we assess the performance of our approach by application to HapMap 3 data, 1000 Genome Project phase I data and simulated datasets. The results are compared to those from Principle Component Analysis (PCA). The statistical power of both approaches to detect outliers based on common variant data and based on rare variant data are comparable in most of the scenarios, but the power of PCA in detecting outliers is relatively small in the presence of LD as shown in the simulations. Also, the observed number of false-positive errors appears to be different for the two approaches as the outlier detection algorithm using PCA cannot adjust for the number of subjects included in the dataset. The results of the HapMap analysis and the simulation studies suggest that our approach maintains the type I error. Taking additionally into account the minimal computational requirements of our approach and the ability to incorporate all marker information, the proposed method will have practical utilization for sequencing studies and genome-wide association studies.

1537F

Identity-by-descent analysis of sequence data. *S.M. Smith[1], S.R. Browning[1], B.L. Browning[2].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Medicine, Div of Medical Genetics, University of Washington, Seattle, WA.

Individuals are identical by descent if they share a haplotype by inheritance from a recent common ancestor. A shared haplotype with length greater than 2 centimorgans corresponds to a common ancestor within approximately the past 25 generations, and these long shared haplotypes can be detected with high power using existing methods for SNP array data.

Identity by descent (IBD) detection methods can also be applied to sequence data, and the detected IBD can be used to phase rare variants and to detect genotype errors. In theory, the complete marker coverage in sequence data will maximize power to detect IBD. However in practice, alignment and sequencing artifacts, reduced phase accuracy at low frequency markers, and recent mutations pose challenges to IBD detection in sequence data. We will present and evaluate several methods for improving IBD detection in sequence data using 1000 Genomes Project and simulated data.

1538W

Robust similarity regression for population substructure in rare variant aggregation analyses. *J. Tzeng[1,2], C. Smith[2].* 1) Department of Statistics, North Carolina State University, Raleigh, NC., Select a Country; 2) Bioinformatics Research Center, North Carolina State University, Raleigh NC.

Population substructure, which included population stratification and cryptic relatedness as two extreme manifestations, is a major confounder in genetic association studies. Recent studies found that rare variants are more geographically localized or private to specific populations. It is indicated that the impact of population substructure is more complex and stronger on rare variants than common variants. Furthermore, the number of variants collapsed also impact the inflation level of the test statistics. When substructure is caused by discrete clusters (e.g., continental-wise stratifications), stratified permutation or incorporating principal component covariates can be effective at controlling the confounding effect. However, for regional and complex substructure, existing correction methods for single marker analysis may fail to control for confounding effects. Using the framework of similarity regression, we propose to model the whole genome sharing at the rare variants loci, a measure that is suggested to reflect the local substructure. By modeling average allele sharing level across genome, it corrects the non-zero baseline sharing induced by population substructure and explicitly controls the substructure effect on the phenotype. The proposed method is robust to a wide range of substructure induced by genealogy, from continual to regional, and from population stratification to cryptic relatedness. We evaluate the performance of the proposed framework based on grid genotype simulation, and demonstrate the robustness, validity and utility of the proposed approaches.

1539T

Detecting differential expression in splice variants in the absence of annotated isoforms using RNAseq. *N.J.I. Lewin-Koh, T. Bhangale, M. Huntley, J. Kaminker, F. Cai, M. van der Brug.* Genentech Inc, South San Francisco, CA.

Differences in isoform expression, inherited or spontaneous, lead to differences in phenotype or disease susceptibility. Identifying these differences enables us to find genes associated with disease and shed light on the underlying biological mechanisms. Current technologies allow sequencing of transcriptomes (RNAseq) and expression quantification of known isoforms. To our knowledge, methods for RNAseq do not explicitly try to quantify differential isoform expression, except in cases where a known alternate splicing event is being tested. However, evidence suggest that the differences can be subtle involving multiple events in a gene, each with a small effect on phenotype. Moreover, available methods are not applicable to novel/unknown splicing events. We present a method based on kernel regression that addresses these problems.

Our method detects overall splice-variant-level differences using RNAseq data. The method uses Kernel regression. A kernel is a matrix of pairwise functions that produces a positive semidefinite matrix of pairwise dissimilarities between the samples. Under squared error loss, kernel regression reduces to a mixed effects model, and can be fit with standard software. We use the counts of reads that map to exon junctions as random effects, modified by a kernel e. g. for a case control study, we fit a logistic mixed effects model and using a score test, assess the over/under dispersion of the coefficients from the random effects. We explore two kernels: 1. a linear kernel where all junction combinations are weighted equally, and 2. a crude distance kernel, where exon skipping is penalized by the distance in exons skipped. We compare our models among each other and against a DEXSeq model using simulation and two RNAseq data sets: 1. cancer data set with tumor and matched normal tissue within patient and 2. brain tissue datasets from Parkinson's disease patients and matched controls.

In preliminary tests with cancer data our method detected differential isoform expression in known cancer genes. Simulation and theoretical results in other contexts have shown kernel regression to be quite powerful in situations where data is sparse. The advantage is isoforms do not need to be pre-specified as in existing methods such as the TopHat/Cufflinks workflow or MISO (Mixture of Isoforms), where isoform discovery is a separate step in the pipeline.

Identification of new genetics variants for T2D in WTCCC data using genome-wide interaction analysis followed by core SNP and gene determination. *Z.-X. Zhu[1,2], Z.-H. Zhu[1], X. Tong[1], M. Liang[1], W.-C. Cui[2], M. Yang[3], L. Zhou[3], M.D. Li[2,4], J. Zhu[1].* 1) Institute of Bioinformstics, Zhejiang University, Hangzhou, Zhejiang, China; 2) State Key Laboratory for Diagnosis and Treatment of Infection Diseases, First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China; 3) Microsoft Research Asia, Beijing, China; 4) Department of Psychiatry and Neurobehavioral Sciences, University of Virginia, Charlottesville, VA, USA.

Although a significant number of genome-wide association studies have been reported for different diseases, only a relatively small number of vulnerability loci have been replicated for each disorder, and a large proportion of the loci for most complex diseases has yet to be uncovered. It has been suggested that ignorance of gene-gene interactions might have contributed greatly to such a low replication rate. Current interest and effort are focused on detecting gene-gene interactions that might fail to be identified using traditional single-locus tests. Previously, we reported a model-free Generalized Multifactor Dimensionality Reduction (GMDR) approach for detecting SNP-SNP interactions in both dichotomous and quantitative phenotypes while allowing covariate justification and handling of unbalanced data. However, the computational burden and less efficient implementation of the original programs make them impossible to use for genome-wide association studies (GWAS). In this study, we developed a graphics processing unit (GPU)-based GWAS-GMDR program, which is able not only to analyze GWAS data but also to run much faster than the earlier version of the GMDR program. We then used the GWAS-GMDR software to analyze a publicly available genome-wide dataset on type 2 diabetes (T2D) from the Wellcome Trust Case Control Consortium. Through an exhaustive search of pairwise interactions and a selected search of three- to five-way interactions conditioned on significant pair-wise results, we identified 24 core single nucleotide polymorphisms (SNPs) in 6 genes that appear to be important for T2D. Of these core SNPs, 11 have been reported to be associated with T2D, obesity, or both, providing an independent replication of previously reported SNPs. More importantly, we identified three new susceptibility genes for T2D. To make this program more useful, versions for Windows, Mac OS X, and Linux systems have been developed for free distribution to the scientific community.

Imputing Genotypes in Large Pedigrees: A Comparison between GIGI and BEAGLE. *C.Y.K. Cheung, E. Wijsman.* Dept Biostatistics, Univ Washington, Seattle, WA.

Imputation of dense genotypes facilitates identification of rare risk variants. GIGI (Genotype Imputation Given Inheritance) is a new genotype imputation approach that can handle large pedigrees. While GIGI uses correlation from identity-by-descent in pedigrees, BEAGLE uses correlation from linkage disequilibrium in the population. Here we used a 95-member pedigree to compare the imputation quality from GIGI and BEAGLE when BEAGLE was used while ignoring the pedigree structure. In a 50 cM region, 60 subjects were observed for 323 SNPs. In an initial analysis, we kept complete data on only 13 subjects and masked all but 35 evenly spaced SNPs on 47 other subjects. Then, we imputed missing genotypes on 288 other SNPs using GIGI and BEAGLE. In BEAGLE, we also evaluated the effects of adding 202 outside reference subjects from 3 other pedigrees of similar ethnic background, as well as providing denser SNPs in the reference panel in a “Leave-One-Out” analysis. In the “Leave-One-Out” analysis, we sequentially omitted one SNP from the 47 subjects who received incomplete data, imputed missing genotypes of this omitted SNP, and repeated for each SNP. We called genotypes using the most probable configuration and compared the accuracy of imputation in all genotypes and in a subgroup considering only genotypes having at least 1 rare allele from SNPs with Minor Allele Frequency of less than 0.05. In calling the overall genotypes, GIGI was more accurate than BEAGLE under the initial setup (79.7% vs. 70.2%) but was less accurate when the outside reference subjects and denser SNPs were included (79.7% vs. 95.4%). However, in calling rare genotypes, GIGI was more accurate under all settings (62.9% vs. 4.5–28.1%) and also detected an extra 46.2% of the rare alleles in the 35 completely un-typed relatives, which BEAGLE could not do because it could not impute genotypes on completely unobserved subjects. These results demonstrate advantages in use of large pedigrees for identifying rare risk variants through explicitly modeling the co-transmission of alleles to multiple affected individuals. Supported by NIH GM046255.

A Hidden Markov Model for Coalescent-Based Mapping of Complex Trait Loci from Sequencing Data in Large-Scale Case-Control Studies. *Z. Geng[1], P. Scheet[3], S. Zoellner[1, 2].* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Psychiatry, Univ Michigan, Ann Arbor, MI; 3) Dept Epidemology, UT MD Anderson Cancer Center, Houston, TX.

Association mapping based on linkage disequilibrium (LD) is widely used to localize positions of disease variants. However, due to the complicated genetic dependence structure, apply LD mapping to complex diseases is challenging. Potentially, with the hope of modeling the evolutionary process that produces our sequencing data, coalescent-based approaches may extract more information to improve our mapping. Such methods, by tracing all sampled alleles to a single ancestral copy known as the most recent common ancestor (MRCA), provide the genealogy at all sites in the region we have sequenced. Hence, we can model the probability of carrying risk variants at all loci jointly, and obtain confidence intervals where true risk variants are most likely to occur. Such methods may provide extra benefits when we have low coverage sequences — its Bayesian framework is more tolerant to each single site's being at low quality. However, existing coalescent-based methods typically suffer from two major challenges: correctly modeling LD, and efficiently scaling to large sample sizes. Indeed, we propose a novel approach which may overcome the two difficulties simultaneously. First, we use hidden Markov models (HMM) to improve LD modeling. Such careful modeling of LD allows us to integrate over phase uncertainty such that our results do not depend on pre-phase accuracy. In simulation studies, our HMM-enhanced method shows better specificity to avoid false positives caused by incorrectly modeling the dependence structure of markers. Second, we improve our model efficiency to handle large-scale sequencing data. Since the space of all coalescent histories is of high dimension, sampling from this space is computationally extremely intensive. Instead, we first identify several clusters of closely related haplotypes from the present sequence data and estimate the ancestral sequence of each cluster. As a result, we can ignore the genealogy within each cluster, and the sampling space reduces to the pre-determined number of ancestral sequences. In the end, we are able to model phenotypes and localize risk variants, based on both the cluster pattern of our sample and the coalescent history between ancient clusters. In summary, we have developed a novel approach to estimate the coalescent genealogy throughout sequenced regions. In fine mapping of complex trait loci, our method provides higher specificity, and is applicable for large-scale case-control studies using sequencing data.

Genetic Simulation Resources (GSR): A website for the registration and discovery of genetic data simulators. *B. Peng[1], B. Racine[2], H. Chen[3], L. Mechanic[3], L. Clarke[2], E. Gillanders[3], E. Feuer[3].* 1) Dept of Genetics, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Cornerstone Systems NorthWest Inc; 3) Division of Cancer Control and Population Sciences, National Cancer Institute.

Many genetic simulation programs have been developed to simulate evolutionary processes under realistic ecological and genetic scenarios and generate genetic data resulting from such processes. Such simulations have been used, for example, to predict properties of populations retrospectively or prospectively according to mathematically intractable genetic models, and to assist the validation, statistical inference and power analysis of a variety of statistical models. In a 2010 NIH meeting (Mechanics, et al. 2012), a catalogue of simulation programs was identified as a tool which could help advance the development of genetic epidemiology analytic tools. However, due to the differences in type of genetic data of interest, simulation methods, evolutionary features, input and output formats, terminologies and assumptions for different applications, choosing the right tool for a particular study can be a troublesome process that usually involves searching, downloading and testing many different tools. Here we present Genetic Simulation Resources (GSR) (http://popmodel.nci.nih.gov/geneticsimulation), a web service provided by the National Cancer Institute (NCI) that aims to help researchers compare and choose the right simulation tools for their studies. This service allows authors of simulation software to register their applications and describe them with well-defined attributes, and users to search and compare simulators according to specified features. Activities such as citations, updates from authors, number of visitors, and user feedbacks from a planned extension to GSR will be tracked and provide updated information about the status of the applications to help users weed through a large number applications to select the most appropriate program to support the research questions.

Rare-variant tests in stratified populations. *M. Schmidt, D. Kinnamon, E. Martin.* Hussman Inst Human Genomic, Univ Miami, Miami, FL.

Population stratification is well-known to cause spurious associations with individual common variants in case-control studies. In sequence data with rare variants, this effect may be particularly magnified by gene-based tests that combine information across multiple variants due to the accumulation of population-specific variants. We recently suggested that gene-based tests that combine non-negative single-variant test statistics using permutation inference provide robust and efficient alternatives to approaches that combine minor allele counts or that require complete genotype data (Kinnamon et al. PLoS One, 2012). Though originally proposed for homogeneous populations, our approach can be modified to incorporate information about population structure with an appropriate choice of test statistic and permutation procedure. Specifically, we have implemented a modified approach for gene-based association testing in unrelated cases and controls that first assigns individuals to a specific subpopulation based on genotypes from a set of genome-wide markers using a clustering algorithm such as Ward's method. These clusters are then used as strata in calculating a generalized Cochran-Mantel-Haenszel chi-square statistic using all available genotype data for each variant within the gene. Like the original approach, the statistics can be combined across the gene by taking either the maximum statistic or sum of statistics. A p-value for the combined statistic is obtained by permuting affection status within each cluster, which maintains between-marker correlations and does not rely on asymptotic approximations. Using computer simulations, we demonstrate that the approach maintains the correct type I error in stratified populations. We compare the approach to the alternative Sequence Kernel Association Test (Wu et al. AJHG, 2010) in the presence of varying levels of stratification and missing data. Our results suggest that the modified approach provides a valid and robust method for analysis of rare variants in sequence data in the presence of population stratification. The method is implemented in a C++ computer program RVStrat that takes advantage of multi-processor machines.

Software pipeline to detect SNPs and call their genotypes. *M. Trost, H.M. Kang, G. Jun, G.R. Abecasis.* Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI.

As the volume of next-generation sequencing data increases, the need for high quality, high performance data processing pipelines that can convert short read sequence data into genotypes becomes more pressing. Converting short read sequence data into high-quality genotypes is a multi-step process that requires alignment, alignment refinement, identification and filtering of variant calls across many samples, and haplotype aware genotype calling. Each of these steps can require multiple compute and disk intensive tasks, so that analysis of even a few hundred samples can require many terabytes of intermediate storage, months of compute time and coordination of thousands of computing jobs.

Our UMAKE pipeline automates variant calling for whole genome or targeted exome sequencing projects including many samples. The process of converting aligned sequence data (typically stored in a BAM file) into a list of variant sites and genotypes (typically stored in a VCF file) is decomposed into many small tasks which are then executed in a coordinated fashion. UMAKE is configurable, so that alternate analysis tools that use standard formats can be used as replacements for our default set of components. In addition, UMAKE is designed to allow incremental analysis where a project is gradually updated to incorporate new samples.

UMAKE is currently used for variant calling in a variety of projects, ranging from the 1000 Genomes Project to the NHLBI Exome Sequencing Project, and totaling >15,000 whole genome or whole exome sequenced samples and we provide examples of the computing requirements and call quality for several of these projects. UMAKE and related documentation are freely available at: http://genome.sph.umich.edu/wiki/UMAKE.

Bidimensional scale analysis: A novel approach to genographic analysis. *Q. Huang, Y. Wu, Z. Li, X. Liu, W. Xie.* Instutite of Life Sciences, Nanjing, Jiangsu, China.

Human leukocyte antigen (HLA) is the most complex and highest polymorphic genetic system and is one of the first genetic markers used in the study of population relationship. Many studies had shown diversity and similarity of global populations using phylogenetic tree and multidimensional scale (MDS) analysis, but traditional MDS analysis only presents clustered information, without showing more genographic information. Here we report a novel bidimensional scale (BDS) analysis for genographic analysis to study difference of population's geographical distribution. Method: Datasets were compiled from published studies from 1990 to 2012 and the International Histocompatibility Workshops, containing locus A, B and DRB1 high-resolution allele frequency. These data represent approximately 339,900 chromatids and 95 populations from five continents (Africa, Europe, Asia, Australia and America) and Pacific islands. The reconstructed datasets of allele frequency were comparable after correcting variety of errors in original data, normalizing different statistical methods, and redesigning ambiguous alleles. Phylogenetic trees of HLA-A, -B, -DRB1 and -ABD (combined by locus A, B, and DRB1) were constructed by four commonly used genetic distance algorithms. The distances computed by these algorithms were analyzed by the BDS algorithms, and the results were dot-plotted in two-dimensional figure. Results: Most of studied populations in each continent were clustered together according to their geographical distribution in each phylogenetic tree, but some neighbor populations were separated by other populations. The location of populations in dot-plotted figure of BDS was basically consistent with that of populations sampled from. African, European, Amerindian and native Australian were located at four quadrants. East Asian was located in middle of the dot-plotted figure. Moreover, North African was plotted between European and South African, West Asian was among European, North African and East Asian. Overall, the figure of BDS plotted by worldwide population resembled the sampling map. The figure plotted by novel BDS method contained directed information of geographical distribution of the population. Conclusion: Our results suggest that the BDS analysis method proved to generate more genographic significance than the traditional MDS analysis, and it can be broadly used in the field of genographic analysis.

Genotype probability distributions on complex pedigrees, with applications to relationship testing. *M. Vigeland[1], T. Egeland[2].* 1) Dept of Medical genetics, Oslo University Hospital, P.O. Box 4956 Nydalen, 0424 Oslo, Norway; 2) Dept of Chemistry, Biotechnology and Food Science, Norwegian University of Life Sciences, P.O. Box 5003, NO-1432 Aas, Norway.

This work is motivated by power considerations in connection with relationship estimation applications. For example, paternity cases are well studied in forensics but are not straightforward if the alleged father is related to the mother. Other areas, including linkage and association studies, also provide examples where relationship testing is important. We focus on cases where all or most individuals have not yet been typed and aim at calculating the prior probability that a specific relationship will be rejected or excluded. We present software (implemented as an R package) for computing joint genotype distributions for any set of pedigree members. The program handles a wide range of pedigrees, including complex pedigrees with inbreeding. Furthermore, it is possible to condition on known genotypes, including partial genotypes with one missing allele. In addition to exact probabilities, the program also provides fast simulation of marker genotypes, again with the possibility of conditioning on known alleles/genotypes. These simulations are useful in cases with many alleles and many unknown individuals (making exact distributions unfeasible). Furthermore, simulations are used to compute confidence or prediction intervals in our applications. As an application we show how to measure the ability of a battery of tests to detect inconsistencies in claimed family relationships. We present examples for autosomal as well as X-linked markers and some formulae to validate the results. Calculations for a previously reported immigration case are extended to account for possible inbreeding and cases where some genotypes are known.

Trait specific genetic relatedness matrices for heritability estimates using linear mixed models. *J. Mefford, J. Witte.* Department of Epidemiology and Biostatistics, UCSF, San Francisco, CA.

Trait heritability estimated from genome-wide SNP datasets using the linear mixed model (LMM) framework estimates the variance in the phenotype of interest that is explained by causal variants or quantitative trait loci (QTLs). Genetic data is introduced into the LMM estimators through a genetic relatedness matrix (GRM) that represents how the individuals in the dataset are related (correlated) at the causal genetic variants for the phenotype. Since the causal variants are not known, a GRM can be estimated using genome-wide SNP observations, relying on the correlation of the genotyped SNPs with the QTLs due to linkage disequilibrium (LD). In the development of the GCTA software for heritability estimation using the LMM framework [Yang et al (2010) Nature Genetics], the developers run simulations to explore the estimation of a GRM using tagging SNPs having incomplete LD with causal variants. Their simulations explore different numbers of causal and tagging SNPs for the calculation of ideal GRMs (estimated from causal SNPs) and approximating GRMs (estimated from tagging SNPs). Those simulations had thousands of QTLs randomly distributed on the genome. Our study further explores the estimation of GRMs. In particular, we try to address the following questions: (1) How is the estimation of a GRM affected by the inclusion of SNPs that are not in LD with QTLs? (2) Can we improve the approximation to an ideal GRM by developing trait-specific approximations to the GRM? In our simulations, causal variants are concentrated in particular chromosomal regions rather than randomly spread across the genome. The greater the fraction of the genome that is unlinked to the causal SNPs, the poorer the estimates of the GRM using whole genome data. Trait-specific GRM estimates are constructed by several methods. SNPs are selected for inclusion in the estimate of the GRM or their contributions are weighted by using the results of single-SNP tests for association with the phenotype. Alternatively, multi-SNP tests (minP, SKAT) are used to identify genes and regions that are associated with the phenotype, and all SNPs within those regions are uses for estimation of the GRM. There is a tradeoff between improvements to the GRM by excluding parts of the genome that are unrelated to the QTL, and damage to the GRM by rejection of relevant SNPs and genes in the GRM construction. Resampling methods are used to assess this tradeoff.

The confounding effect of cryptic relatedness on cohort studies for environmental risks. *K. SHIBATA, G. Tamiya, M. Ueki, T. Nakamura, H. Narimatsu, I. Kubota, Y. Ueno, T. Kato, H. Yamashita, A. Fukao, T. Kayama, Yamagata University Genomic Cohort Consortium.* Yamagata University, Yamagata, Japan.

In general, cryptic relatedness in epidemiological association studies, have been disregarded. However, cryptic relatedness might be cofounding environmental factors. Especially, in a regional cohort studies, the effect of cryptic relatedness could be large. Here, we investigated the confounding effect of cryptic relatedness on the association between phenotype and environmental risk factors. We selected blood pressure as the quantitative phenotypes and body mass index (BMI), smoking, and alcohol consumption as environmental risk factors. In practice, using the genome-wide 657,366 SNP data in 1,622 subjects in Yamagata, we detected 20–30% cryptic relatedness of epidemiological sampling by software program PLINK. We compared the results of association tests between hypertensive disease groups with and without cryptic relatedness and detected significantly differences. In addition, we show that genetic adjustments can be useful to complement confounding environmental risk factors. Further, we examine mixture model to detect association in the case of a population with confounding effect of cryptic relatedness. We suggest that haplotypic variance contrast measure is informative to detect association in the case of cohort studies with confounding effect of cryptic relatedness.

Genome wide mutation-rate map for the analysis of recurrent de-novo mutations. *P. Polak[1,2], S.R. Sunyaev[1,2].* 1) Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Broad Institute, Cambridge, MA.

The fast advances in sequencing technology enable identification of de novo mutations in human pedigrees. This opens the perspective to analyze the contribution of de novo mutations to sporadic cases of oligogenic and polygenic diseases. The main challenge in the analysis is to pinpoint individual genes harboring de novo mutations causally involved in the phenotype. This is achieved by finding genes with recurrent de novo mutations. The analysis is greatly complicated by the heterogeneity of mutation rate along the human genome. Genes exhibiting higher rates of spontaneous mutations would be falsely associated with phenotypes. Currently, mutation rate heterogeneity is being ignored. Comparative genomics has identified mutation rate heterogeneity at different scales. It was shown that this heterogeneity is partially explained by regional differences in DNA methylation and replication timing. We propose a new statistical approach to gene mapping based on recurrent de novo mutations. Our method appropriately takes into account mutation rate variation along the human genome. Mutation rate variation model incorporates sequence context and uses comparative genomics and functional genomics data to estimate gene-specific mutation rate. This model allowed us to estimate expected rates of de novo mutations per gene in all functional categories (e.g. missense and nonsense mutations). Our method ranks genes harboring de novo mutations with the help of Z-scores relative to expectation.

JBASE: A Bayesian Mixture Model for Joint Analysis of Sub-phenotypes and Epistasis. *R. Colak[1,2,3], T. Kim[1,2], H. Kazan[1,2], P.M. Kim[1,2], A. Goldenberg[1,2,3].* 1) Department of Computer Science, University of Toronto, Toronto, Ontario, Canada; 2) Donnelly Center for Cellular and Bimolecular Research, University of Toronto, Toronto, Ontario, Canada; 3) Genetics & Genome Biology Program, The Hospital for Sick Children (SickKids), Toronto, Ontario, Canada.

Genome Wide Association Studies (GWAS) have emerged as the preeminent tool for mapping variants that give rise to a specific disease/trait. So far, more than >1200 loci harboring variants associated with >160 diseases/traits have been discovered, yet the explained phenotypic variability is still far from the theoretical inheritability estimates [1]. This so called missing heritability problem presents a big challenge for personalized medicine and is at the center of extensive discussion in the statistical genetics community. Among the many potential reasons for missing heritability are two major ones: First, there are interactions between markers, a phenomenon known as epistasis, which has been addressed in a number of newer approaches [2]. Second, a factor that is not commonly addressed but potentially even more critical is the heterogeneity in the phenotypic landscape of a disease, addressed via sub-phenotyping [3]. To date, there are no methods that take into account both of these important issues. Here, we propose a Bayesian mixture model that simultaneously accounts for epistasis and sub-phenotyping. We explicitly model the hidden phenotypic and genotypic differences within the given population. Using MCMC, we simultaneously identify subpopulations with homogenous phenotypes along with their associated epistatic and marginally acting markers. We performed extensive simulations using several well-known disease models and their combinations, while taking into account the observed odd ratios and MAF distribution of the published GWAS results [2]. We compare six different methods - from classical GWAS approaches to those specifically developed to detect sub-phenotypes. Power and Type-1 Error analysis showed that our proposed method (JBASE) outperformed all competitors across the full spectrum of MAF, odd ratio and disease heterogeneity combinations. Most notably, when associations are weak, i.e. small odd ratios, and sub-phenotypic differences exist, our method is the only method that can recover true associations. References: [1] Zuk et al. (2012). The mystery of missing heritability: Genetic interactions create phantom heritability, Proc Natl Acad Sci., 109(4):1193-8. [2] Zhang et al. IMProve: An R package for parallelizing 1000 Genomes based genotype imputation, statistical analyses, and extraction of independent hit loci. *T.A. Johnson[1], Y. Nakamura[2], M. Kubo[3], T. Tsunoda[1].* 1) Lab Med Informatics, RIKEN Yokohama Inst/CGM, Yokohama, Kanagawa, Japan; 2) Human Genome Center, Inst of Medical Science, University of Tokyo, Shirokanedai, Tokyo, Japan; 3) Research Group for Genotyping, RIKEN Yokohama Inst/CGM, Yokohama, Kanagawa, Japan.

Imputation is an important part of the modern analytical pipeline for Genome-wide Association Studies (GWAS). The 1000 Genomes Project (1000G) reference haplotypes, which possess close to complete ascertainment of common variant sites, have dramatically improved coverage and quality compared to previous HapMap datasets. This has increased power for fine-mapping disease and quantitative trait loci but also increased the number of loci requiring analysis; the current 1000G dataset has ≈11 million loci after filtering for MAF≥0.01 in East Asians. Especially with modern GWAS datasets' increasing sample sizes, this places a burden on computational infrastructure and necessitates methods to parallelize the process of imputation and data analysis. Also, with numerous loci potentially in linkage disequilibrium (LD) with the most significant SNPs, the extraction of independent hits and determination of boundaries of linked variants is a main consideration for post-imputation analysis and locus prioritization for validation studies. To facilitate these processes, we have developed an R package named IMProve, which includes methods to: 1) divide GWAS datasets into manageable chunks for phasing/imputation, 2) import and split 1000G vcf reference haplotype files, 3) export into SHAPEIT, Impute2, or MACH/minimac formats for phasing/imputation, 4) submit chunks to a compute cluster for phasing, imputation, or statistical analyses, 5) import imputation output into Bioconductor's snpStats package's compressed format, 6) summary and statistical analysis using snpStats' built-in functions, and 7) step-wise top SNP adjustment procedure (TOPSNP) for extraction and definition of independent hits. We have applied these methods to several quantitative trait and case-control analyses in Japanese samples and illustrate our methods using a height QTL analysis in ≈27k BioBank Japan samples genotyped on the Illumina 610k array and imputed with Impute 2.2.4 and 1000G Phase 1 Ver. 3. ≈8.1 million loci remained after quality control filters (MAF≥0.01, info≥0.4) and 1,776 loci had $p \geq 5 \times 10^{-8}$. The TOPSNP procedure reduced those loci to 26 independent hits, with each hit having 25±31 linked SNPs with $p \leq 5 \times 10^{-8}$ and 193±141 (median±MAD) nominally significant loci ($p \leq 10^{-4}$). Along with a normal and a single page “expanded” version of Manhattan plots, IMProve produces a novel “fireworks” plot that highlights independent hits along with the unadjusted and adjusted -log10(p-values) of linked loci.

1553W

An automatic toolbox for genome-wide association analyses. *J. Luan, S.J. Sharp, N.J. Wareham, J.H. Zhao.* MRC Epidemiology Unit, Institute of Metabolic Science, Cambridge, CB2 0QQ, United Kingdom.

Background: Numerous research consortia have been established in recent years to share data from GWASs, primarily to provide sample sizes much higher than can be achieved in any one study. Members of each consortium are expected to provide results using their own GWAS data based on a standard analysis plan developed to address a particular research question. Different analysis plans vary in terms of their requirements with respect to outcomes, covariates, interactions, subgroup analyses and methods of analysis. To meet all these different needs in a timely manner while minimising the potential for error, we have developed a toolbox of programs which automate as much of the work as possible for GWAS data from the Fenland and EPIC-Norfolk studies (www.mrc-epid.cam.ac.uk/Research/Studies), taking advantage of all available computer resources. Methods: We have developed generic programs which take advantage of the functionality of different software packages, including Stata, SNPTEST, QuickTest and ProbABEL. We also make use of Linux clusters whenever available. The application of these programs to data from a new study is straightforward, and typically uses imputed data from either HapMap or the 1000 Genomes Project. Results: A typical genome-wide association analysis using SNPTEST or QuickTest or ProbABEL is implemented with a single Stata command allowing multiple analyses to be performed in one Stata session, with types of outcomes and their transformations, the inclusion of covariates, etc, specified as options. The results can be provided as ASCII or Stata files which can be formatted to meet the specific requirements of the consortium. This work has not only improved efficiency and reproducibility for specific consortia-based analyses, but also been used in other large projects including InterAct (www.inter-act.eu) and an eQTL study of brain gene expression. One analysis of the eQTL data involved over 1000 gene expression levels each as a whole-chromosome analysis, to be used for result look-up for a genome-wide association study, and the analyses were implemented through a macro (each corresponding to an expression level and chromosome) in a batch file. Conclusion: These programs have been instrumental for analyses of our own data and can easily be adapted to analyse data from other studies. They have the potential to be used as benchmark for programs developed in other software packages such as R (http://www.r-project.org).

Variant association tool: A pipeline to perform quality control and association analysis of sequence and exome chip data. *G. Wang[1], B. Peng[2], SM. Leal[1].* 1) Baylor College of Medicine, Houston, TX; 2) The University of Texas MD Anderson Cancer Center, Houston, TX.

Currently there is great interest in detecting associations of complex human traits with rare SNVs. Association analysis of rare variants differs from those applied to common variants, because methods used to analyze common variants are underpowered to detect rare variant associations. To increase power, many rare variant association methods have been developed which aggregate variants across a genetic region (usually a gene). Before testing for rare variant associations, quality control which is specific to sequence data must be performed; where variant sites and calls are removed that do not meet specific criteria. e.g. read depth, etc. It is also necessary to annotate variants before performing association analysis to determine which variants meet inclusion criteria. To facilitate the analysis of rare variants we developed variant association tools (VAT), a tool-set that implements best practice for rare variant association studies. Highlights of the pipeline include variant site/call level quality control, phenotype/genotype based sample selections, variant annotation and selection of gene regions for analysis. Summary statistics can be generated, e.g. MAF, HWE, Ti/Tv ratios, etc. Within this pipeline a large number of rare variant association tests have been implemented to analyze both qualitative and quantitative traits including CMC (Li & Leal 2008), WSS (Madsen & Browning 2009), GRANVIL (Morris & Zeggini 2010), VT (Price et al. 2010), SKAT (Wu et al. 2011), etc. Our association testing framework is regression based which readily allows for flexible construction of association models with multiple covariates, weighting (i.e. based on frequency or predicted functionality), interactions terms (i.e. gene x gene & gene x environmental) and models for pathway analysis. VAT is capable of rapidly scanning through the entire exome using multi-processes computation, adaptive permutation approaches and conducting multiple association tests simultaneously. In addition to outputting results in tabular format they can be graphical viewed as QQ or Manhattan plots. Additionally it provides a programming interface to allow for user implementation of novel association methods. The VAT pipeline can be applied to sequence data, imputed sequence data and exome chip array data. This pipeline should be extremely beneficial in performing association analysis on the large amounts of sequence and exome chip data which is currently being generated for complex traits.

MaCH-Admix: Genotype Imputation for Admixed Populations. *E.Y. Liu[1], M. Li[2], W. Wang[1], Y. Li[1,3].* 1) Dept of Computer Science, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Dept of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Dept of Genetics and Dept of Biostatistics, University of North Carolina, Chapel Hill, NC Hill.

Imputation in admixed populations is an important problem but challenging due to the complex linkage disequilibrium (LD) pattern as a result of recent admixture. The emergence of very large reference panels such as that from the 1000 Genomes Project enables more accurate imputation in general, and in particular for admixed populations and for uncommon (minor allele frequency, MAF, < 5%) genetic variants. To efficiently benefit from these large reference panels, one key issue to consider is on how to traverse the reference space harboring the most probability mass with minimum computational efforts. In modern genotype imputation framework, this corresponds to the selection of effective reference panels. In this work, we evaluate a number of methods for effective reference panel construction inside a hidden Markov model (HMM) and specific to each target individual. These methods fall into two categories: identity-by-state (IBS) based and ancestry-weighted approach. We have implemented all the methods in our software package MaCH-Admix. We evaluated the performance on individuals from recently admixed populations, including African Americans and Hispanic Americans. Our target samples include 8421 African Americans and 3587 Hispanic Americans from the Women's Health Initiative (WHI), which allow assessment of imputation quality for uncommon variants. Our experiments include both large and small reference panels; large, medium, and small target samples; and in genome regions of varying levels of LD. We also include BEAGLE and IMPUTE2 for comparison. Experiment results suggest that our novel piecewise IBS method yields consistently higher imputation quality than other methods/software. The advantage is particularly noteworthy among uncommon variants where we observe up to 5.1% information gain with the difference being highly significant (Wilcoxon signed rank test P-value < 0.0001). Our work is the first that considers various sensible approaches for imputation in admixed populations and presents a comprehensive comparison.

Two roads both taken: walking the phenotypic and genotypic paths to disease gene implication. *A. Javed, P. Ng.* Genome Institute of Singapore, A*STAR, Singapore.

Next Generation Sequencing has proven to be an invaluable search tool for pinpointing causal variants for Mendelian inherited rare disorders. Despite the constant flux in sequencing technology, the broad steps in downstream analysis of such studies show remarkable consistency. Our contribution to this analysis is twofold. Firstly, we quantify the performance of deleteriousness predictors commonly used to sift out the culprit variant. This is done both individually and in conjunction using a naïve Bayesian approach. Secondly, we use available knowledge of the phenotype to set the prior expectation of involvement of each gene. These two paths, followed independently, are combined within a Bayesian framework where the phenotype dictates the priors and the genetic data defines the observation. We estimate deleterious impact of coding and regulatory variants and benchmark these predictions using Human Gene Mutation Database as a positive set; and for each class of variants an appropriate neutral set. The continuum of predicted probabilities, after applying appropriate thresholds, yields an accuracy of 80% (or better) at the expense of 3% (or less) false positives across the board. In particular for non-synonymous mutations we combine SIFT and PolyPhen-2 predictions to achieve 91% accuracy with less than 2.1% false positives; which compares favorably to MutationTaster at 87% accuracy and 4% false positives using the same data. The predictions are pooled within each gene, extending the boundaries to incorporate cis regulatory interactions. Prior knowledge of phenotype-gene involvement comes in two flavors. Direct knowledge of it being implicated for the same or similar phenotype; or guilt by association due to known interaction with the fore mentioned. We use significance of mapped phenotype ontology to establish informativeness of direct knowledge; and a random walk of protein interaction networks to quantify association. Each step of our loosely coupled pipeline is evaluated first individually; and then in totality. It is currently being used to study a shared rare disease inflicting three unrelated families. The designed software will be made available for public use. To our knowledge, this is the first comprehensive analysis to systematically quantify, and recommend, deleteriousness predictors for both coding and regulatory mutations. Our objective of travelling the phenotypic path less travelled by makes all the difference in causal variant prediction.

1557T

Inferring Highly Polymorphic Gene Alleles Using Sequence Data and SNP Genotypes in the Han Chinese Population. *S. Chang[1], C. Fann[2], A. Hsieh[2], C. Shiu[2].* 1) Clinical Informatics and Medical Statistics Research Center, Chang Gung University, Taoyuan County, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

To dissect fully the complication of human leukocyte antigen (HLA) genetic variations, direct typing and deep re-sequencing will be of great help to reveal the disease-specific and shared risk factors involved in multifactorial, complex diseases or traits. However, high resolution HLA typing remains a laborious and expensive task due to the complexity and ambiguity of the sequence variations and thus prohibits clinicians and scientists from widespread application of HLA alleles in practice and research. Recent studies have demonstrated the usefulness of SNPs on or near the HLA loci for predicting or inferring classical HLA alleles. To date, different types of such methodologies are a few but not many. We seek to develop an ethnic-specific predictive model of highly polymorphic gene alleles, e.g., the class I and II HLA genes. Building upon available phased and unphased SNP genotype data obtained from family trios and unrelated individuals in a Han Chinese population whose HLA allele information are known, our methodology will be able to identify a small set of most informative SNPs and to accurately predict HLA alleles in a general population. By cataloging the prediction condition and dissecting the performance for a Han Chinese population, we will gain more insights into the HLA genetic variations across different ethnic populations. Besides, with the construction of a reference panel with dense SNP marker data and known HLA allele genotypes for inferring HLA alleles in Han Chinese populations, many HLA associated studies in the same population can be realized and thus may lead to the construction of allele prediction models of various associated diseases. The inferred HLA alleles can aid in mapping causal or functional variants across the MHC region, increase the power for disease or phenotype association studies, and may facilitate meta-analysis of whole-genome association data and help dissect the genetic basis of complex diseases and traits.

The Design of Custom-made Genotyping Arrays to Study Asthma in Populations of African Descent. *J. Gao[1], Y. Hu[2], J.S. Lee[3], N. Pearson[3], G. Abecasis[4], I. Ruczinski[5], T.H. Beaty[6], Z. Qin[1,2], R.A. Mathias[7], K.C. Barnes[7].* 1) Center for Comprehensive Informatics, Emory University, Atlanta, GA; 2) Department of Biostatistics and Bioinformatics, Rollins School of Public Health, Emory University, Atlanta, GA; 3) Knome Inc., Cambridge, MA; 4) Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI; 5) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 6) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 7) Division of Allergy and Clinical Immunology, School of Medicine, Johns Hopkins University, Baltimore, MD.

Asthma is a complex disease, and its increased prevalence and severity in populations of African ancestry are partially attributed to genetic ancestry. While genome-wide association studies (GWAS) on populations of European ancestry have discovered strong associations between genetic factors and asthma susceptibility and mortality, few studies have focused on populations of African descent, and even fewer have found genome-wide-significant associations. It is unclear to what extent the coverage of current state-of-the-art and commercially available genotyping chips explain the paucity of GWAS findings in populations of African ancestry for asthma. To address the challenge, we established the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA) to perform whole genome sequencing in 1,000 individuals of African ancestry (50% asthmatic), and leverage discoveries in public catalogs including the 1,000 Genomes Project, to find novel single nucleotide polymorphisms (SNPs) in African and African admixed populations, in order to develop a custom, African-ancestry gene-centric 200K SNP genotyping array ("African Power Chip"). In a preliminary analysis, we examined whole genome sequencing (WGS) data from a small group of individuals of African descent and compared this to the latest genotyping chip (HumanOmni5-Quad chip), which contains the largest list of SNPs commercially available to date. We found that among all bi-allelic SNPs that we identified, only a small proportion (~20%) is included in the HumanOmni5-Quad chip. We next attempted genotype imputation for other SNPs using Hapmap phase III data as the reference panel. We implemented the minor allele frequency- (MAF-) adjusted R^2 criteria to identify SNPs that can be well imputed. Under this criterion, we found only an additional 3% of the SNPs could be accurately imputed. Our results indicate that the current genotyping chip, aided with imputation, is highly inadequate to cover the majority of SNPs found in samples of African descent. This suggests that a specially designed genotyping panel is needed, in order to efficiently screen genetic variation, and discover genes conferring risk to asthma and other diseases, in these populations. We believe that the new chip will complement current commercially available GWAS chips, for which common and rare variants are not adequately tagged by the existing SNPs, and thereby facilitate GWAS studies on populations of African descent.

1559W

Detecting rare variants for both quantitative and qualitative traits using pedigree data. *W. Guo, Y. Y. Shugart.* Division of Intramural Division Program, National Institute of Mental Health, National Institute of Health, USA.

With the advent of sequencing technology opening up a new era of personal genome sequencing, huge amounts of rare variants data have suddenly become available to researchers seeking genetic variants related to human complex disorders. There is an urgent need of developing novel statistical methods to analyze rare variants in a statistically powerful manner. While a number of statistical tests have already been developed to analyze collapsed rare variants identified by association tests in case-control studies, to date, only two FBAT tests-for-rare (described in the updated FBAT version v2.0.4) have applied collapsing methods analogously in family-based designs. To further research in this area, we introduced three new beta-determined weights-based tests for detecting rare variants for quantitative traits in nuclear families [Guo & Shugart, 2012]. In addition to evaluating the performance of these new methods, we also evaluate the power and validity of the two FBAT tests-for-rare, using extensive simulations of situations with and without linkage disequilibrium. Results from these simulations suggested that the four tests using beta-determined weights out-perform the two collapsing methods used in FBAT (-v0 and -v1). Four new beta-determined weight methods of statistical analysis in a computer program have been submitted to the Comprehensive R Archive Network (CRAN) for general use. We now propose to extend our methods to analyzing the qualitative traits by using logistic regression model and modify the script to handle data structure of general pedigrees for both quantitative and qualitative traits.

1560T

IsoDOT detects differential RNA-isoform usage between two or more samples with high sensitivity and specificity. *W. Sun.* Biostatistics, University of North Carolina, Chapel Hill, NC.

The study of RNA isoform expression is of great importance for understanding gene expression regulation and the molecular basis of complex phenotypes, such as human diseases. Using RNA-seq data, we have developed a statistical framework and software for transcriptome reconstruction, isoform abundance estimation, and Differential isOform usage Testing (DOT). Here differential isoform usage refers to the changes of RNA-isoform expression relative to the total expression of the corresponding gene. We model the numbers of RNA-seq fragments covering any exon set by a negative binomial distribution, and achieve accurate isoform abundance estimation by a penalized regression approach. Differential isoform usage of a gene is assessed by a likelihood ratio statistic. Both simulation and real data studies demonstrate that IsoDOT achieves accurate isoform abundance estimation and delivers greatly improved sensitivity and specificity to detect differential isoform usage.

1561F

Identification of Loss of Heterozygosity from Unpaired Tumor Samples Using Next-Generation Sequencing. *J. Lee, N. Pearson.* Knome Inc., Cambridge, MA.

Loss of Heterozygosity (LOH) is one key event observed during cancer development. Inference of LOH regions is typically drawn by sequencing or genotyping tumor and matching normal DNA samples and locating chromosomal regions where heterozygous markers in a normal sample are shown to be homozygous in the matching tumor sample. Since a pair of normal and tumor sample often may not be available, several methods have been developed for SNP genotyping data for an unpaired tumor sample. However, normal sample contamination can complicate the detection of LOH region based on those methods. In addition to that, the next-generation sequencing technologies are being actively utilized in cancer research. So we developed a model for the detection of LOH regions based on a hidden Markov model (HMM) that takes into account the estimated tumor purity in a given tumor sample. We investigated 10 impure tumor samples for patients with chronic lymphocytic leukemia (CLL) of which the range of the estimated percentages of tumor cells is 50–94%. We identified long LOH segments in chromosome 6q and 21. We also spotted shorter segments shared by many of those samples in 21q11 and 13q14. We implemented the algorithm in an R package, knomeLOH.

1562W

A robust and well-defined method for Single Nucleotide Variant and Indel detection. *N. Tuzov.* Partek Incorporated, Saint Louis, MO.

A number of present methods for SNV and Indel detection try to incorporate the information from annotations such as base quality scores supplied by the sequencer and alignment quality scores supplied by the aligner of choice. In the currently available algorithms, the outcome is sensitive to a large number of optional parameters that must be set either by the user or by the software developer. Such latitude provides a rather questionable way out for the cases when the algorithm is not stable enough to deliver any sort of answer. While the pool of annotations to choose from may be large, the user is given insufficient means to determine which particular annotations, if any, contribute to better SNV and Indel detection. In addition, the introduction of integer-valued and categorical annotations is problematic or impossible. To address these shortcomings, we develop a supervised learning method for SNV and Indel detection that (i) trains the model based on available SNP databases, such as dbSNP, (ii) is fast and robust, (iii) accepts both quantitative and categorical annotations, such as transition / transversion factor, (iv) allows the researcher to build the model consisting of annotations that contribute the most to better SNV and Indel detection and (v) has few optional algorithm parameters, reducing the impact of subjective interference on the outcome and resulting in a simple user interface. We demonstrate the performance of our method on experimental data using both quantitative and categorical annotations. The results show a practically significant improvement in SNV and Indel calling compared to the baseline case with no annotations, and an important contribution of categorical annotations that are not accepted by the currently available SNV and Indel detection software.

1563T

DETECTANCE: Graphical software for study design and planning, based on evaluation of the detectance distributions for probands conditional on the phenotypes of relatives. *T. Hiekkalinna[1, 2], P. Norrgrann[2], J.H. Lee[8, 9, 10], K.M. Weiss[7], M. Perola[1, 2], J.D. Terwilliger[1, 2, 3, 4, 5, 6].* 1) Chronic Disease Prevention, Public Health Genomics Unit, National Institute for Health and Welfare, Helsinki, Finland; 2) Institute for Molecular Medicine Finland, Helsinki, Finland; 3) Genetics and Development, Columbia University, New York, NY; 4) Psychiatry, Columbia University, New York, NY; 5) Columbia Genome Center, Columbia University, New York, NY; 6) Division of Medical Genetics, New York State Psychiatric Institute, New York, NY; 7) Anthropology, Pennsylvania State University, State College, PA; 8) Epidemiology, Columbia University, New York, NY; 9) Sergievsky Center, Columbia University, New York, NY; 10) Taub Institute, Columbia University, New York, NY.

Medical genetics researchers most often think about effect size measured as the probability of a given phenotypic outcome conditional on genotype. However, most genetic epidemiology studies start from a collection of individuals or families ascertained conditional on phenotype, with the hope that the phenotypes of individuals in these families predict the underlying risk genotypes, which is the fundamental basis of mapping. To this end, it is important to consider the ramifications of an etiological model in terms of penetrances [P(Ph |G, E)] and ascertainment scheme on the detectance P(G, E | Ph; Ascertainment). As a trivial example, if we wanted to determine the probability that a randomly ascertained individual had genotype X at locus 1 conditional on observed phenotype Ph, the detectance would be simply

$P(G_1=X|Ph) = \sum_{G2}...\sum_{GN}\sum_{E1}...\sum_{EM} P(Ph|G_1=X,G_2,...,G_N,E_1,...,E_M)P(G_1 = X, G_2,...,G_N,E_1,...,E_M)/\phi$,

where ϕ is the probability of the phenotype in the population (i.e. the same sum over all possible genotypes for G_1). The detectance represents what you would therefore expect to see in a dataset conditional on phenotype.

DETECTANCE currently works on models with a small number of multiallelic genes influencing a qualitative or quantitative trait, and computes the detectance for a proband conditional on his phenotype and the phenotypes of others in his nuclear family. In real time it graphically displays the change in detectance as parameters of the etiological model, phenotypes, or linkage/LD among the genes change through the use of sliding bars. This visually makes the conditions in which family-based sampling or sampling on extreme phenotypes is much more powerful than cross-sectional association studies obvious. DETECTANCE software is freely available from the authors.

Genetic Instrumental Variable Studies of the Effects of Maternal Risk Factors on Oral Clefts. *G.L. Wehby[1], L.M. Moreno[2], P. Romitti[2], K. Christensen[4], L. DeRoo[6], A. Wilcox[6], R. Munger[3], R. Lie[5], J.C. Murray[2].* 1) Health Management and Policy, University of Iowa, Iowa City, IA; 2) University of Iowa; 3) Utah State University; 4) University of Southern Denmark; 5) University of Bergen; 6) National Institute of Environmental Health Sciences.

Several studies have suggested that maternal prenatal smoking, alcohol use, and obesity may each play a role in the etiology of cleft lip and/or cleft palate (CL-P). However, these studies do not account for unobserved or unmeasured confounders that influence maternal selection into these risk factors but are also related to CL-P risk. It is very difficult to observe and directly control for all relevant confounders in available data samples. Ignoring unobservable confounders may significantly bias the estimated risk factor effects and their interactions with genetic risk factors. The objective of this study is to identify the causal effects of maternal prenatal smoking, alcohol use, and obesity on CL-P risks using a genetic instrumental variable (IV) model (or Mendelian Randomization) to account for unobserved confounders. The IV model uses genetic variants (called instruments) that are: 1) strongly correlated with the risk factors of interest; 2) otherwise unrelated to CL-P through unobservable confounders. Under these two conditions, the model exploits variation in the risk factors that is predicted by instruments but is unrelated to unobservable confounders. Using appropriate instruments, the IV model provides unbiased estimates of the causal effects of these risk factors on CL-P. In addition, the IV model can be applied to obtain unbiased estimates of the interaction effects between these risk factors and genetic factors that modify their effects. The study includes a unique and large international consortium of population-based samples of 3800 mothers of children with CL-P and 5000 mothers of unaffected children. We are currently genotyping the top 50 candidate SNPs identified from the literature to be evaluated as instruments for prenatal smoking, alcohol, and obesity. We will use the SNPs that fit the above two IV conditions as instruments to estimate the average effects of these risk factors on CL-P as well as the interactive effects between these risk factors and 40 SNPs that include the top variants identified so far to affect CL-P risk and influence detoxification and metabolism. The presentation will report on the methodology and analysis results. This is the first large-scale study to estimate the causal effects of major maternal risk factors on CL-P. These estimates are essential for unraveling the etiology of CL-P and developing cost-effective programs for CL-P prevention and counseling at-risk women.

1565W

The Prevalence of X-linked Hypohidrotic Ectodermal Dysplasia (XLHED) in Denmark. *M. Nguyen-Nielsen[1], S. Skovbo[1], D. Svaneby[2], L. Pedersen[1], J. Fryzek[1,3].* 1) Department of Clinical Epidemiology, Aarhus University Hospital, Aarhus, Denmark; 2) Department of Clinical Genetics, Aarhus University Hospital (Skejby), Aarhus, Denmark; 3) Epidstat Institute, Ann Arbor, MI, USA.

X-linked hypohidrotic ectodermal dysplasia (XLHED, MIM 305100) is a genetic disease caused by a defect in the ectodysplasin-A gene (EDA, MIM 300451). The cardinal clinical features associated with XLHED are hypohidrosis (absence of sweat glands), thin/sparse hair, and abnormal teeth. Children with XLHED have been shown to have an increased risk of death from hyperpyrexia due to the inability to sweat and thereby regulate core body temperatures. XLHED is the most common form of hypohidrotic ectodermal dysplasia (HED); however, no population-based prevalence estimates are available. We aimed to: 1) estimate the prevalence of XLHED in the general Danish population per January 1, 2011; 2) determine the age group in which diagnosis most frequently occurs; and 3) quantify the most frequent clinical feature of XLHED. Subjects and Methods: Denmark (population 5.5 million) has an extensive collection of medical registries and each resident has a unique personal identification number which allows for unambiguous data-linkage across multiple registries. We conducted a nationwide cross-sectional study using registry data (the Danish National Patient Register and the Civilian Registration System) and data from clinical departments (Clinical Genetics, Dermatology, Pediatrics and Specialized Dentistry) in order to identify all XLHED cases in Denmark diagnosed between 1995–2010. We categorized XLHED patients into three groups: 1) molecularly-confirmed XLHED; 2) clinically-diagnosed HED and 3) probable HED (registered with a constellation of clinical features on the basis on a clinical algorithm that we designed). We calculated prevalence estimates on the basis of these groups and stratified by age and gender. We also investigated patients' medical history and quantified the occurrence of cardinal features. Results: We identified 90 molecularly-confirmed XLHED, 146 clinically-diagnosed and 988 possible HED cases (total n= 1224). The prevalence ranged from 1.6–22 per 100,000 across the three groups. Diagnosis occurred most frequently between the ages 11–18. Teeth abnormalities occurred in 79 percent of all cases and 52 percent of the molecularly-confirmed. Conclusion: We present the first ever population-based prevalence estimates of XLHED and show that the prevalence may be higher than previously estimated. Diagnosis of XLHED is most often delayed until late childhood. Teeth abnormalities were the most frequent clinical marker of XLHED.

1566T

The PhenX Toolkit: standard measures facilitate cross-study analyses. *C.M. Hamilton[1], W. Huggins[1], H. Pan[1], D.B. Hancock[1], J.G. Pratt[1], J.A. Hammond[1], T. Hendershot[1], D.R. Maiese[1], K.A. Tryka[2], K. Sher[3], K. Conway[4], M. Scott[5], W.R. Harlan[6], J. Haines[7], L.C. Strader[1], H.A. Junkins[8], E.M. Ramos[8].* 1) RTI International, Research Triangle Park, NC; 2) National Center for Biotechnology Information, National Library of Medicine, Bethesda, MD; 3) University of Missouri, Columbia, MO; 4) National Institute on Drug Abuse, Rockville, MD; 5) National Institute on Alcohol Abuse and Alcoholism, Bethesda, MD; 6) Retired, Associate Director for Disease Prevention, Office of the Director, National Institutes of Health, Bethesda, MD; 7) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 8) National Human Genome Research Institute, Bethesda, MD.

The PhenX (consensus measures for Phenotypes and eXposures) Toolkit (https://www.phenxtoolkit.org/) is an online resource that catalogs broadly validated and well-established measures of phenotypes and exposures for use in genomic and other types of studies involving human subjects. The PhenX Toolkit currently includes 339 measures covering a broad scope of 21 research domains including Demographics, Anthropometrics, Cancer, Nutrition, Environmental Exposures, Neurology and Social Environments, and six specialty areas related to Substance Abuse and Addiction (SAA). Since its initial release in 2009, the Toolkit has logged 300,000 visits, and currently has 800 Registered Users. Toolkit visitors come from every state in the USA and 148 countries. Investigators can find measures of interest by browsing domains, collections or measures, or by searching using the Smart Query Tool. For each measure, the Toolkit provides a description of the measure, the rationale for its inclusion, detailed protocol(s) for collecting the data, and supporting documentation. The goal of the SAA project was to create six “Specialty” collections and one “Core” collection of SAA related measures. The SAA project used a streamlined version of the established PhenX consensus process to select 44 new measures which were added to the Toolkit in February, 2012. Another project, PhenX RISING (Real world, Implementation, SharING), brings together seven investigators who were awarded funds to incorporate PhenX measures into existing, population-based genomic studies. Over the course of the project, these early adopters are evaluating PhenX measures and recommending improvements to the Toolkit. The Toolkit also provides tools to help investigators integrate PhenX measures into their study design. That is, the Toolkit provides custom data collection worksheets to support data collection and custom data dictionaries to facilitate data submission to the database of Genotypes and Phenotypes (dbGaP). In an effort to link PhenX measures with data that is already in dbGaP, PhenX measures were mapped to 16 dbGaP studies. Of the 822 non-administrative variables included in these dbGaP studies, 79% could be mapped to PhenX measures. This mapping will help investigators identify studies in dbGaP that may be well-suited for various cross-study analyses. Implications for integration of PhenX measures in dbGaP will be presented. Funding was provided by NHGRI 5U01HG004597 and 3U01HG004597-03S3.

1567F

Comparison of Genome-Wide association studies for smoking behaviour between self-reported and biomarker measures. *A.I. Stiby[1], N. Timpson[2], M. Hickman[1], D. Evans[2], J. Kemp[2], G. Davey Smith[2], S. Ring[2], B. St Pourcain[2], J. Henderson[1], J. Macleod[1].* 1) School of Social and Community Medicine, The University of Bristol, Bristol, United Kingdom; 2) MRC CAiTE Centre, School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom.

The validity of self-reported smoking is questionable as smokers tend to underestimate the amount they smoke and adolescents overestimate their cigarette consumption due to patterns in their social group. Cotinine is the principle metabolite of nicotine and is used as an objective assessment of cigarette smoking. Work here compares the results of genomewide association (GWA) analysis performed on self-reported (SR) smoking versus cotinine measures in individuals from the Avon-Longitudinal Study of Parents and Children (ALSPAC). It has been established that there are considerable power gains to be afforded using cotinine as a biomarker for smoking behaviour, though this has yet to be examined in the GWA setting. Genetic data from 9,912 participants were genotyped using the Illumina HumanHap550 quad genome-wide SNP genotyping platform by 23andMe. We used 4122 individuals with self-reported smoking data, of which 723 (17.5%) were smokers. 2843 of these also had data on cotinine levels, of which 260 (9.1%) were above the cut off for smokers (7 ng/ml of blood). Of note and highlighting the value of these data, 268 (9.7%) individuals who describe themselves as smokers were found to be non-smokers by cotinine assay and 20 (0.7%) cotinine-assessed smokers described themselves as non-smokers. Cotinine was associated with SR smoking status, although SR smokers had higher circulatory levels of cotinine than the normal cut-off between the biologically assessed non-smokers and smokers (39.35 ng/ml of blood, $p < 0.001$). GWA results showed a clear contrast between SR frequency of smoking within smokers and results of objectively assessed levels of cotinine which were above the active smoking cut-off. Whilst the former was underpowered to deliver even established signals for smoking behaviours, the analysis of cotinine gave multiple suggestive hits, the highest of which was rs12607939 ($p=9.53 \times 10^{-8}$), this was not maintained in SR smoking ($p = 6.12 \times 10^{-1}$). Two genes were found to exhibit suggestive evidence of association in both the cotinine and self reported GWA analysis (*DAB1* and *BTBD3*), although most hits were from the analysis of cotinine levels in smokers. Our results suggest problems with bias in the self-reported smoking data due to adolescent over-estimation of the amount they smoke; furthermore it suggests that cotinine is giving a more precise measure than SR smoking status in GWA studies.

Design of Sequencing Studies in Family Samples, With Application To The Study of Substance Use Disorders. *S. Feng[1], S. Vrieze[2], B. Tarrier[1], J. Bragg-Gresham[1], X. Zhan[1], C. Sidore[1,3], M. McGue[2], W. Iacono[2], G. Abecasis[1].* 1) Biostatistics Dept, Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) Psychology Dept, University of Minnesota, Minneapolis, MN; 3) Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy.

Next-generation sequencing is enabling complex trait studies to move beyond common variants and also examine the contribution of rare variants. Given the large per sample costs associated with sequencing experiments, an important step in these experiments is the selection of individuals likely to carry trait associated variants.

Here, we propose a likelihood based method for selecting individuals for sequencing which takes into account phenotypic information, individual specific covariates, and any available genotypes. Our method is applicable when information on related individuals is available and can prioritize families and individuals likely to carry trait associated rare variants. Using simulations, we show that our method is effective at identifying sets of individuals enriched for rare trait-associated alleles. Furthermore, we show that the resulting samples provide greater power for association analysis than samples selected using extreme phenotype-based strategies.

We apply our method to select 1,000 individuals likely to carry rare variants associated with a substance use phenotype measured in 4,934 individuals from the Minnesota twin and family study registry. We simulated rare variants explaining 0.1–1.0% of the trait variance. At 0.1% frequency, we expect about 10 copies of the variant to be present in the sample of 4,934 individuals. If these variants account for 1% of trait heritability (an effect size of 2.2 standard deviations per allele), simulations predict that using our method to prioritize 1,000 individuals for sequencing, would result in nearly all of these 10 copies (9.4 on average) being carried by one of the sequenced individuals. Simulations of downstream association analyses predict ~86% power (from permutation tests at $\alpha = 10^{-3}$) to detect trait associations for the above rare variants in samples selected using our method, and ~81% power from samples selected using extreme phenotype-based strategy (again, at $\alpha = 10^{-3}$). The power to detect association afforded by sequencing the original sample of 4,934 individuals would be ~93%. Our results show that with limited resources, using family information, phenotypes and covariates to prioritize individuals for sequencing can facilitate discovery of rare trait associated alleles.

1569T

Family-based designs for sequencing studies. *D. Thomas.* Preventive Med, Univ Southern California, Los Angeles, CA.

The cost of next-generation sequencing is approaching that of early genome-wide SNP genotyping panels, but still out of reach for the large-scale epidemiologic studies with the tens of thousands of subjects that will be required for testing association with disease. The many millions of rare variants that will be discovered in a genomewide scan also pose a major challenge for distinguishing causal from non-causal variants. Family-based designs for sequencing substudies provide a means to identify novel variants and prioritize them for their likelihood of causality by exploiting their co-segregation with disease (Petersen et al, AJHG 1998;62:1516-24 PMID 9585599). Other advantages include the possibility of enriching for family history, improved imputation (Li et al, Annu Rev Genomics Hum Genet 2009;10:387-406 PMIC 19715440), and efficient two-step analyses that exploit between- and within-family comparisons (Wason & Dudbridge, AJHG 2012;90:760-733 PMID 22560088). Using simulation, we compare simple rule-based, likelihood ratio, Bayes factor, and score statistics in terms of their ability to distinguish causal from non-causal variants. We find that the Bayes factor criterion of Petersen et al provides the best discrimination, but a novel generalization of the score test of Ionita-Laza & Ottman (AJHG 2011;189:1061-8 PMID 21840850) that combines the phenotype information from all pedigree members together with the available sequence data on the sequenced subset is a close contender, is model free, and computationally simpler. Two-phase designs using a family study for discovery and prioritization followed by a large case-control or family-based association test consistently provide better power for discovery, prioritization, and subsequent association testing than single-phase case-control association tests because of the considerable reduction in the multiple comparisons penalty. The approach is illustrated using two substudies within the Colorectal Cancer Family Registries, one large pedigree with 50 members genotyped at GWAS SNPs, one with whole exome data on a subset of families from a previous linkage scan.

1570F

From a large-scale discovery study to a replication study. *C. Kuo, D. Zaykin.* Biostatistics Branch, National Institute of Environmental Health Sciences, Durham, NC.

Thousands of susceptibility loci have been identified to date through large-sacle association studies. However, only a fraction of top hits are being successfully validated in replication studies. Replication is indispensable in that it allows researchers to eliminate study-specific biases, refine association signals, and generalize findings to other samples and populations. Usually, the most significant results are followed up, and a result is declared a replication if the statistical significance is reached and if the effect direction in the discovery and replication studies match. We propose a strategy for planning a replication study based on integrating the ranking false discovery rate, which is the proportion of false effects among the top follow-up loci (Kuo and Zaykin 2011, Genetics, 189:329–340) and our new developments for estimation of the number of true effects and their effect size distribution. We give guidelines for the number of follow-up loci and the optimal sample size for the replication stage.

Optimal Sample Selection for Large-Scale Next Generation Sequencing Experiments. *G.W. Beecham[1], R. Rajbhandary[1], E.R. Martin[1], L.S. Wang[2], K. Lunetta[6], R. Mayeux[4], J.L. Haines[5], L. Farrer[3], M. Pericak-Vance[1], G. Schellenberg[2], The Alzheimer Disease Genetics Consortium.* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) School of Medicine, University of Pennsylvania, Philadelphia, PA, USA; 3) School of Medicine, Boston University, Boston, MA, USA; 4) Taub Institute of Research on Alzheimer's disease, Columbia University, New York, NY, USA; 5) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA; 6) Boston University School of Public Health, Boston University, Boston, MA, USA.

Though next generation sequencing (NGS) costs continue to drop, they remain too high for comprehensive sequencing of all available samples in all but the smallest projects. As such, it is often necessary to select a subset of samples for large-scale NGS experiments. As part of a large NGS experiment for Late-Onset Alzheimer disease (LOAD) we have evaluated a variety of sample selection schemes and their impact on statistical power to find rare risk variants and rare protective variants.

We have evaluated designs based on random selection, extreme-phenotype, “super-controls” (low probability of conversion to AD), and protective effects. In these designs we have investigated the impact of misclassification rates (rate at which controls progress to case status), genetic heterogeneity (a case's disease status is essentially caused by other risk factors), and risk exposure (the amount of risk to which a control has been exposed; important in detecting protective variants). A large sample of 10,000 cases and 10,000 controls from the Alzheimer Disease Genetics Consortium were used to evaluate the different designs using real data. Baseline risk was taken from known sex, age, and apolipoprotein e genotype specific incidence measures and was modified using known common risk loci discovered in genome-wide association studies. Designs were evaluated by comparing the effective risk ratios after accounting for misclassification, heterogeneity, and exposure to that of an ideal study population.

While it is commonly held that extreme phenotype designs are more powerful when sample sizes are limited, we found that it greatly depends on the rates of misclassification. In LOAD the extreme phenotypes are also correlated with higher rates of misclassification, thereby limiting the power of the extreme phenotype designs. Additionally, some protective designs are poorly powered to detect association at risk loci, but do not offer significant gains in power at protective loci either.

As with any power calculation, the optimal study design will ultimately depend on the number of samples and specific rates of incidence, misclassification, heterogeneity, and exposure for the particular disease. For LOAD, a combination of the extreme-phenotype design and “super-control” design appear to be optimal in most projects.

Meta-analysis of ITGAM coding variant, rs1143679 (R77H) in systemic lupus erythematosus (SLE) cases and controls. *X. Kim-Howard[1], V. Pradhan[2], K.H. Chua[3], A. Maiti[1], K. Ghosh[2], S. Nath[1].* 1) Oklahoma Med Res Foundation, Oklahoma City, OK; 2) National Institute of Immunohaematology, Indian Council of Medical Research, Mumbai, India; 3) Department of Medical Microbiology, Faculty of Medicine, University of Malaya, Kuala Lumpur, Malaysia.

Background: We identified ITGAM (CD11b) as a novel SLE susceptibility gene. To date, ITGAM variant rs1143679 (R77H) is one of the few SLE susceptibility loci which consistently replicated in multiple populations with European, African, Hispanic, and Asian ancestries. Methods: Meta-analyses were performed using independent published data for ITGAM SNP rs1143679. This analysis included 26,603 individuals (10,992 cases and 15,611 controls) from 17 countries across North American, Europe, Asia and the Indian subcontinent. Breslow-Day tests were performed to assess the homogeneity of odd rations (OR) across populations and to estimate the overall strength of association between rs1143679 with SLE. Since ORs were homogeneous then a fixed model was appropriate in the meta-analysis, performed with R-Meta, CatMap software, and PLINK. Results: Meta-analysis of published data from multiple populations suggest that rs1143679 is strongly associated with SLE across diverse ancestries. A meta-analysis using published data from multiple European-derived, African-derived, Asian, and Hispanic populations greatly reinforces the ITGAM-SLE association. As expected, minor allele frequencies for rs1143679 varied across ethnic populations, from 0.51% in Chinese controls to 24% in Portuguese controls. Test for homogeneity was not significant (Q-statistic, PHET = 0.30) demonstrating that odds ratios were homogenous across populations. Results from the meta-analysis showed strong association between this SNP and SLE (Pmeta = 1.52×10-94, OR (95% CI) = 1.81 (1.71–1.92)). For all population specific analyses rs1143679 was strongly associated with SLE (European: P = 2.0×10-30, OR = 1.80; European-American: P = 1.8×10-35, OR = 1.79; African-American: P = 3.8×10-12, OR = 1.64; Latin-American: P = 1.8×10-13, OR = 1.97; Asian: P = 3.4×10-11, OR = 2.56). Conclusion: Our meta-analysis further confirmed the exon-3 coding SNP, rs1143679 (R77H) is highly associated with SLE across multiple populations across from North American, Europe, Asia and the Indian subcontinent.

1573F

Understanding missing data in a large STR dataset of over 100,000 Brazilian individuals genotyped with PowerPlex 16 kit. *V.R.C. AGUIAR[1], R.V. ROHLFS[2], K.E. LOHMUELLER[2], A.M. CASTRO[3], F.S.V. MALTA[3], A.C.S. FERREIRA[3], I.D. LOURO[1], R. NIELSEN[2].* 1) UNIVERSIDADE FEDERAL DO ESPIRITO SANTO, VITORIA, ES, BRAZIL; 2) UNIVERSITY OF CALIFORNIA BERKELEY, BERKELEY, CA, US; 3) LABORATORIO HERMES PARDINI, BELO HORIZONTE, MG, BRAZIL.

Short tandem repeat (STR) or microsatellite genotyping can be an error-prone process. This is especially challenging because these errors can have diverse, complex and cryptic origins, such as mutations in primer-biding sites, low quality or quantity of DNA template, or human errors in allele scoring.

All these errors can create bias in the estimates of heterozygosity, population size and structure, migration rates, kinship and parentage. It is therefore important in forensic and population genetic analyses to consider the possibility of genotyping errors, so that the reliability of the collected data is not compromised.

In this study, we investigate a large dataset of over 100,000 individuals whose DNA samples were submitted for paternity testing. These individuals were genotyped at 15 STR loci using the standard PowerPlex16 kit, manufactured by Promega Corporation. Preliminary results show that the amount of missing data per locus is very heterogeneous across loci, and there is some evidence of a correlation between missing data and Hardy-Weinberg departures at particular loci.We shall further investigate if the distribution of missing data across loci is correlated with marker length or fluorescent dye type. Finally, we will test whether the amount of missing data varies across individuals and whether it is correlated with an excess of homozygous genotypes per individual.

Our study will help illuminate the most common sources of errors in STR datasets of this kind.

1574W

Population based study of permanent teeth agenesis in Japanese schoolchildren. *J. Machida[1, 4], T. Nishiyama[2], M. Kamamoto[3, 4], S. Yamaguchi[4], M. Kimura[4], A. Shibata[4], K. Yamamoto[1, 4], S. Makino[1, 4], H. Miyachi[4], K. Shimozato[4], Y. Tokita[5].* 1) Oral and maxillofacial surgery, Toyota memorial hospital, Toyota city, Aichi, Japan; 2) Clinical Trial Management Center, Nagoya City University Hospital, Nagoya, Japan; 3) Oral and Maxillofacial Surgery, Himeji Red Cross Hospital, Himeji, Hyogo, Japan; 4) Maxillofacial Surgery, Aichi-Gakuin University, Nagoya, Aichi, Japan; 5) Perinatology, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Aichi, Japan.

Tooth agenesis is one of the most common congenital anomaly in human and it is characterized by developmental absence of teeth. Clinical and epidemiologic studies of defined geographic populations can serve as a means of establishing data for genetic counseling and as a first step in identification of causes. In this study, we carried out clinical and epidemiologic study at Aichi Prefecture, Japan. 4088 Medical records of 15 years old schoolchild from Toyota city were reviewed and prevalence rates calculated. In addition, medical and dental records of 68 unrelated patients with tooth agenesis of Aichi-Gakuin University were reviewed to obtain sibling recurrence risk. The prevalence rate of congenital missing teeth was 7.64 %(95% CI: 6.82%; 8.52%). The sibling recurrence risk was 0.29 (95% CI: 0.20; 0.40) overall. One, two, three to four, and more than 4 missing teeth count 0.26 (95% CI: 0.09; 0.51), 0.25 (95% CI: 0.07; 0.52), 0.21 (95% CI: 0.05; 0.51), 0.31 (95% CI: 0.17; 0.49) respectively. The study is population based and assure high data quality. Our findings on the intra oral distribution of agenesis of permanent teeth in children may help us better understand the etiology of agenesis.

1575T

Are heritability estimates of binary traits meaningful? *P.H. Benchek, N.J. Morris.* Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

It is commonly acknowledged that estimates of heritability from classical twin studies have many potential shortcomings. Despite this, in the post-GWAS era, heritability estimates have come to be a continual source of interest and controversy due to the so-called “missing heritability.” While the heritability estimates of quantitative traits are certainly subject to a number of biases, in this paper we will argue that the standard statistical approach to estimating the heritability of a binary trait relies on some additional untestable assumptions which, if violated, can lead to badly biased estimates. The ACE liability threshold model, assumes at its heart that each individual has an underlying liability or propensity to get the binary trait (e.g., disease), and that this unobservable liability is multivariate normally distributed (i.e., for a given twin pair). We investigate a number of different scenarios which violate this assumption, such as the existence of a major gene and the existence of a dichotomous exposure. We found in each case that substantial asymptotic biases can occur, which no increase in the sample size can remove. Thus, the meaningfulness of heritability estimates under the ACE liability model is questionable.

Genetic ancestry and mammographic density among US Caucasians. *J.L. Caswell[1], K. Kerlikowske[1,2], J. Shepherd[3], S.R. Cummings[2,4], D. Hu[1], S. Huntsman[1], E. Ziv[1].* 1) Department of Medicine, UCSF, San Francisco, CA; 2) Department of Epidemiology and Biostatistics, UCSF, San Francisco, CA; 3) Department of Radiology, UCSF, San Francisco, CA; 4) California Pacific Medical Center Research Institute, San Francisco, CA.

Background: Mammographic density (MD) is one of the strongest risk factors for breast cancer and is known to be approximately 60 percent heritable. Genome wide association studies (GWAS) have identified several variants associated with MD, but only a small fraction of the heritability has been explained. We performed a GWAS of women at the extremes of MD. Here we report an unexpected association between genetic ancestry and MD that has important implications for gene discovery for this trait. *Methods:* We used samples from women who participated in the California Pacific Medical Center Research Institute Cohort. MD was measured as percent fibroglandular volume using the single-energy X-ray absorptiometry technique and linked to blood samples via the San Francisco Mammographic Registry, which also collected data on ethnicity and breast cancer risk factors. We selected 1000 self-identified Caucasian women from the top and bottom quintiles of age and BMI-adjusted MD. After removing samples with low quality DNA, we were left with 478 women in the highest MD quintile and 472 in the lowest. We genotyped samples using the Illumina 1M platform at CIDR. We incorporated publicly available genotype information from European and Middle Eastern populations into principal component analysis (PCA) to infer the ancestry of the women in our study. *Results:* PCA identified a subpopulation of women defined the by 1st principal component representing approximately 15 percent of the sample. Women in this group were more likely to have high MD ($p = 0.0025$). Incorporating European and Middle Eastern populations into PCA identified these women as having Ashkenazi Jewish ancestry. Using multivariate regression to correct for epidemiologic factors associated with MD, including age at parity and use of postmenopausal hormone therapy, did not attenuate the association. *Conclusion:* Women of Ashkenazi Jewish descent are more likely to have high MD. Previous studies have demonstrated that BRCA1 and BRCA2 mutations do not affect MD and are therefore unlikely to explain our results. Since Ashkenazi Jews are a founder population, they may have a unique set of variants that increase MD. A better understanding of the genetic determinants of MD may open new avenues for breast cancer prevention and treatment.

Robust partitioning of local heritability at associated GWAS loci. *A. Gusev[1], G. Bhatia[2], B. Pasaniuc[1], N. Zaitlen[1], A.L. Price[1].* 1) Epidemiology, Harvard School of Public Health, Boston, MA; 2) Harvard-MIT Division of Health, Science and Technology, Boston, MA.

Recent work quantifying the heritability of complex traits accounted for by dense marker data has spurred interest in obtaining robust and biologically meaningful results from partitioned heritability. In particular, estimates of observed heritability (h^2) from one or more specific loci can yield additional insights that are fundamental to understanding the potential impact of discovered loci as well as designing follow-up and fine-mapping studies. Here, we explore the efficacy of estimating local h^2 from loci suspected to be harboring causal variants, as are typically identified in large-scale association studies. A major hurdle for this type of analysis is the presence of LD between markers, which has been known to deflate h^2 when causal variants are poorly tagged. Moreover, even when all causal variants are observed in the data, we find that the h^2 can still be biased due to differentially structured LD between allele frequencies. For example, in a simulation on 5000 individuals from the WTCCC the estimate of genome-wide h^2 is deflated by 40% if a majority of the observed causal variants are uncommon (where no such deflation is present when markers are uncorrelated). In a scenario where putative causal regions are known but the causal SNPs unobserved, local h^2 over the regions can recover 95% of the true heritability from common variants and 50% from low-frequency variants. After applying a regression-based technique to account for structured LD, the latter estimate increases to 70%. When the putative loci are previously unknown but genome-wide significant associations account for at least 5% of the phenotype variance, we can query the regions around these hits for additional missing heritability. Where the underlying causal SNP is uncommon (common), local h^2 can detect statistically significantly more heritability than traditional stepwise-conditional association 50% (28%) of the time. This value increases to 95% (67%) for uncommon (common) SNPs when multiple unobserved variants are causal at the locus. Measuring h^2 at GWAS loci in three real diseases where modest heritability is explained (Crohn's Disease, Rheumatoid Arthritis, and Type 1 Diabetes), all yield significant increases in observed-scale h^2 by a factor of 1.3, 1.5, and 2.2 respectively over the h^2 estimated from GWAS hits alone. These findings support the use of local h^2 to interrogate discovered loci for additional heritability and motivate subsequent fine-mapping studies.

1578T

Multiple mediation analysis in case-control studies: application to detecting joint mediating effects of smoking and chronic obstructive pulmonary disease on the association between CHRNA5-A3 genetic locus and lung cancer risk. *J. Wang, S. Shete.* Dept Biostatistics, UT MD Anderson Cancer Ctr, Houston, TX.

Mediation model is a statistical approach to explore the direct and indirect effects between an independent variable and a dependent variable by including another mediator (or mediators). Recently, there has been of interest using mediation analysis to dissect the direct and indirect effects of genetic variants on complex diseases using case-control studies. However, the case-control study design could cause bias in the estimates of the genetic variant-mediator associations, and in turn, lead to biased estimates for the specific indirect effects and percent mediated. We investigated a multiple mediation model involving a three-path mediating effect through two mediators using case-control study data. We proposed an approach to correct the biased coefficients and provided the accurate estimates for the specific indirect effects and percent mediated. Our approach can also be used when the original case-control study is frequency-matched on one of the mediators. We employed the bootstrapping approach to assess the significance of indirect effects. We conducted simulation studies to investigate the performance of the proposed approach and showed that it provides more accurate estimates for the indirect effects as well as the percent mediated compared with the standard regression approach. We applied the proposed approach to the multiple mediation study of simultaneous mediating effects of smoking and chronic obstructive pulmonary disease (COPD) on the association between CHRNA5-A3 genetic locus and lung cancer risk using lung cancer case-control study. The results of this analysis showed that the genetic variant influences the lung cancer risk indirectly through all three different pathways. The percent mediated was 18.3% through smoking alone, 30.2% through COPD alone and 20.6% through the three-way path including both smoking and COPD, and the total genetic variant-lung cancer association explained by the two mediators, smoking and COPD, was 69.1%.

Bayesian-Optimized Linkage Disequilibrium improves gene-based association tests. *H. Huang[1, 2, 4], S. Zahid[1], P. Chanda[1, 2], D.E. Arking[3], J.S. Bader[1,2].* 1) Department of Biomedical Engineering, Johns Hopkins University, Baltimore MD; 2) High Throughput Biology Center, Johns Hopkins University School of Medicine, Baltimore MD; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore MD; 4) Current address: Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital, Boston MA and Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge MA.

Genome-wide association studies have revealed that multiple associations can occur independently within a gene or locus. When individual genes or loci are enriched for independent association signals, multivariate gene-based tests that gather information across loci defined by gene annotations can have improved signal-to-noise and better power than univariate tests. Multivariate tests require knowledge of linkage disequilibrium (LD) within a locus. This information is typically unavailable for large-scale meta-analyses, and thus many gene-based tests employ LD from a reference population. It is plausible to assume that choosing a reference population whose LD resembles the study population will improve the performance of multivariate tests. Here we present Bayesian-Optimized Linkage Disequilibrium (BOLD), a method that infers LD for a study population given its marginal allele frequencies and a set of reference chromosomes. We first assign non-negative weights to chromosomes from a reference population so that the weighted sum reproduces the marginal allele frequencies for the study population. The weighted chromosomes are then used to impute the LD for the study population. The objective function for the non-negative regression is motivated by a Bayesian formulation for the probability of the observed marginal allele frequencies given the reference chromosomes and the weights. Non-negative regression is a computationally efficient convex optimization that can be performed rapidly. This approach is motivated in part by previous studies demonstrating the possibility of ascertaining whether an individual genotype has contributed to a study where marginal allele frequencies have been reported. Results demonstrate that BOLD significantly improves the imputed LD values. Furthermore, if the study population is a single ethnicity and the reference population contains a mix of ethnicities, the method is effective in giving higher weights to the reference chromosomes with matched ethnicities, and smaller or zero weight to other ethnicities. This addresses the current need for methods to select appropriate reference panels. The LD matrices imputed by BOLD are then compared with standard methods of uniform weighting, and with the ideal case of access to the true LD. In summary, we have shown that BOLD is able to infer LD successfully for a study population, and thus can increase power for gene-based tests conducted in large-scale meta-analyses.

Statistical models and inference methods for the in vivo DNA methylation process. *A.Q. Fu[1], D.P. Genereux[2], R. Stoeger[3], A.F. Burden[2], C.D. Laird[2], M. Stephens[1,4].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Biology, University of Washington, Seattle, WA; 3) School of Biosciences, University of Nottingham, Sutton Bonington Campus, Leicestershire, United Kingdom; 4) Department of Statistics, University of Chicago, Chicago, IL.

Single-molecule double-strand DNA methylation patterns collected in vivo using hairpin-bisulfite PCR provide an excellent opportunity to study the DNA methylation process and the properties of DNA methyltransferases in vivo. Each double-stranded methylation pattern contains the binary methylation states of multiple CpG sites on the parent and daughter strands of the DNA molecule from a single cell, although the data do not contain direct information on which strand is the parent strand and which is the daughter. We developed statistical models and Bayesian inference methods to analyze these data, quantifying the transmission fidelity of the DNA methylation process over cell division, as well as the processivity and substrate preference of DNA methyltransferases that are involved in the methylation process. Specifically, our Independent Events Model (IEM) estimates CpG site-specific rates of maintenance and de novo methylation events, as well as the site-site variation in the rates, while allowing for departure from the steady-state. Our Hidden Markov model (HMM) describes the behavior of the three primary DNA methyltransferases identified in mammals: DNMT1, DNMT3A and DNMT3B. The HMM captures the clustering of methylation states across CpG sites in our data, and yields statistical estimates of parameters that quantify enzyme processivity and substrate preference. Both models use multi-site information, infer parent/daughter strand identity, account for experimental errors, and estimate what activities likely gave rise to the observed methylation state at each CpG site. We applied these methods to our data collected from the promoter regions of two densely methylated inactive X-linked loci (FMR1 and G6PD), and that of a moderately methylated autosomal locus (LEP), in humans. Among the key results, applying the IEM to the FMR1 locus reveals a maintenance rate close to, but lower than, 1 per site per cell division, with little site-site variation. It also suggests very low rates of de novo methylation on both strands and more variable de novo rates on the parent strand. Results on DNMT1 from our HMM at all three loci are consistent with existing in vitro results, but suggest longer association tracts (i.e., stronger processivity), and much shorter non-association tracts for humans in vivo than for mice in vitro. The R code for these methods is publicly available.

1581T

A comparison of statistical methods for the analysis of methylome data. *M. LeBlanc[1,2], B. Kulle[1,2].* 1) Epi-Gen, Institute of Clinical Medicine, Akershus University Hospital, University of Oslo and Akershus University Hospital, Oslo, Norway; 2) Department of Biostatistics, University of Oslo, Oslo, Norway.

A major epigenetic modification is the methylation of cytosines (C), most commonly in cytosine-guanine dinucleotides (CpGs) (Rakyan et al. 2011). The methylation profile has been shown to be associated to different complex diseases such as cancer (Portela and Esteller 2010). Due to technical advances, methylation data is increasingly available, but presently there is no consensus on how to analyse this type of data. One interesting problem is the identification and analysis of DNA methylation features based on dependencies in the data. Using a case-control dataset typed using the Roche NimbleGen Human DNA Methylation 2.1M Deluxe Promoter Array, we compare statistical methods for the identification and analysis of DNA methylation features. A key issue is the calculation of p-values for regions in dense methylation data. We compare different techniques based on functional data analysis and permutation methods. Further, we consider how the definition of regions of interest itself influences the results.

Designing GWAS arrays for efficient imputation-based coverage. *Y. Zhan, Y. Lu, T. Webster, J. Schmidt.* Affymetrix, Inc. Santa Clara, CA.

Imputation has become increasingly popular as a standard step of GWAS data analysis. As a result, imputation-based coverage, instead of coverage based on pairwise tagging only, is becoming a more relevant metric for the value of a GWAS array with respect to the statistical power it offers for genome-wide association tests. However, traditionally whole-genome genotyping arrays have been designed via a tagging marker selection strategy, aiming for good pairwise tagging results, which do not align very well with the goal of having efficient imputation-based coverage. Taking advantage of the genotype data generated by the 1000 Genomes Project, the latest development of imputation tools, and our flexible in-house greedy algorithm for selecting markers based on LD, we came up with a GWAS array design strategy that iterates between an LD-based marker selection step and an imputation-based coverage evaluation step. The coverage evaluation step identifies and removes variants from the target set of markers when their genotypes are imputed well enough based on already selected markers, enabling the selection of markers more valuable for imputation-based coverage in the next iteration. This strategy generates markers for designing genotyping arrays that are better optimized for imputation-based coverage when compared with a set of markers selected with the pairwise-tagging-based selection strategy. Our results show that the new marker selection method makes it possible to design powerful yet efficient GWAS arrays with better imputation-based coverage compared to existing arrays that contain much larger sets of markers.

1583W

Does a higher BMI directly influence levels of physical activity in children? Mendelian Randomization using genotypic scores. *R.C. Richmond[1,2], G. Davey Smith[1,2], D.M. Evans[1,2], B. St Pourcain[1], J.P. Kemp[1,2], A.R. Ness[3], S.M. Ring[1], K. Tilling[1], N.J. Timpson[1,2].* 1) School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 2) MRC Centre for Causal Analysis in Translational Epidemiology, University of Bristol, Bristol, UK; 3) School of Oral and Dental Sciences, University of Bristol, Bristol, UK.

Declining levels of physical activity may be partly responsible for rising rates of childhood obesity and many studies have investigated this relationship. However, far fewer studies have considered reverse causation in this association, where a higher body mass index (BMI) leads to a direct reduction in physical activity levels. This was explored in the Avon Study of Parents and Children (ALSPAC), for which there is data on BMI and objectively assessed activity levels (uni-axial actigraph) for children at age 11, as well as genome-wide genotypic data. Using instrumental variable (IV) methods, we aimed to estimate the strength of the unconfounded and unbiased effect of BMI on physical activity. In this context, genetic instruments were used to proxy BMI in a Mendelian Randomization (MR) framework. These analyses were undertaken using established 32 genetic correlates of BMI singularly and combined in a weighted allele score, constructed from directly genotyped SNPs in the ALSPAC sample. The weighted allele score for each individual was derived as a sum of the putative risk alleles at each locus multiplied by their regression coefficients from genome-wide meta-analysis. Using MR, a 3.3 kg/m2 (one standard deviation) increase in BMI was seen to reduce total physical activity by 30.0 counts per minute (95% CI= -60.7,-0.7; P= 0.045), where the mean total physical activity was 607.2 counts per minute. The level of moderate or vigorous activity per day decreased by approximately 2.6 minutes (95% CI= -5.2,-0.1; P= 0.044), where the mean daily level was 20.0 minutes. In addition, sedentary activity was increased by 13.0 minutes (95% CI= 1.1,24.6; P= 0.031), where the mean daily level was 427.3 minutes. Results should be treated with caution until it is has been possible to statistically exclude activity as a mechanistic route to BMI allele score effect, however both crude adjustment for activity and use of randomly drawn combinations of BMI genotypes to form sub scores for sensitivity analyses showed consistent results. Identified associations suggest a causal, independent effect of BMI on activity levels and results have obvious public health implications in terms of tailoring physical activity interventions to children who are already overweight, and ensuring young children establish an active lifestyle before signs of adiposity appear.

Role of *GATA5*, *FBN1* and *TGFBR2* mutation in patients with bicuspid aortic valve. *N. Abdulkareem, J.A. Aragon-Martin, G. Arno, V. Ramachandran, A. Child, M. Jahangiri.* Cardiac and Vascular Sciences, St. George's University of London, London, United Kingdom.

Background: Bicuspid aortic valve (BAV) is the commonest cardiac defect found in 1–2% of the general population. However, the developmental basis of BAV and its associated complications is poorly understood. We aimed to examine the role of *GATA5, FBN1* and *TGFBR2* in patients with BAV. **Methods:** A consecutive series of 35 UK Caucasian patients were included in our study. BAV was confirmed at surgery. Patients with Marfan syndrome or other diagnosed connective tissue disorders were excluded. Genomic DNA was extracted from venous blood, and PCR was performed to amplify all the coding exons including the intron/exon boundaries of *FBN1, TGFBR2* and *GATA5*. Bi-directional gene sequencing was carried out and the sequences were compared with reference sequence (NM_000138, NM_001024847 and NM_080473) to check for sequence alterations. **Results:** Out of 35 BAV patients, twenty one patients (60%) had concomitant aortic root aneurysm. One patient (2.85%) carried a heterozygous missense mutation in *GATA5* exon-2 (c.698T>C), resulting in amino acid substitution of leucine with proline at 233 position (p.L233P). This change was not present in 100 controls. One heterozygous polymorphism was found in *GATA5* exon-3 (c.8A>G) resulting in amino acid substitution of glutamine with arginine at 3rd position (p.Q3R). This change was found in 2/100 controls of heterozygous state. According to UCSC Genome browser this polymorphism has a frequency >1%. No pathological mutations were found in *FBN1* and *TGFBR2* in BAV cohort. **Conclusion:** For the first time we demonstrate the association of *GATA5* mutation to human phenotype and BAV. The missense mutation p.L233P is located at the DNA binding site and probably affects the function of GATA5 protein. *GATA5* plays an important role in valvulogenesis already demonstrated in *GATA5* mouse model studies.

1585T

Re-sequencing of 3699 individuals reveals novel low-frequency missense polymorphism in *SCN10A* associated with PR interval that alters channel activation. *J.A. Brody[1], V.S. Macri[2], D.E. Background: PR interval from an electrocardiogram reflects cardiac atrioventricular conduction. *SCN10A*, encoding the Nav1.8 sodium channel, was the top locus in several large GWAS of the PR interval, but genetic variation at this locus has not been evaluated systematically. **Methods**: As part of CHARGE-S, a multi-cohort targeted sequencing effort, the 120 kb region containing the *SCN10A* gene was sequenced in 3699 participants of European descent. Adjusting for age, sex, height, BMI, and cohort specific variables, variants with at least 1% minor allele frequency (MAF) were evaluated individually using standard regression methods, while rare variants (MAF ≤ 1%) were tested using Sequence Kernel Association Test. Results were then meta-analyzed across cohorts. We sought to replicate our findings in an independent sample of 526 European descent samples from the Exome Sequencing Project (ESP). The functional impact of missense variants in *SCN10A* was examined by cellular electrophysiology. **Results**: A total of 3209 SNPs were identified, including 6 rare nonsense variants and 128 missense variants. Among the missense SNPs, the MAF was inversely correlated with the functional prediction scores PhyloP (p=1E-5) and Polyphen2 (p=0.015), but no significant association of PR with rare variation (≤1% MAF) was detected. As reported previously, rs6795970 (V1073A; 58% allele frequency) was associated with shorter PR interval (-3.9 ms, p=9E-12). By contrast, rs73062575 (P1045T; 2.5% allele frequency), a previously unrecognized missense variant that is uncorrelated with rs6795970 (r2 < 0.05), was associated with longer PR interval (5.6 ms, p=5E-4). The associations between PR interval and both rs73062575 and rs6795970 were independently replicated in ESP (p=8E-4 and 5E-4, respectively). Both SNPs were introduced into *SCN10A*, expressed in a neuroblastoma 2A cell line and examined by patch-clamp electrophysiology. Compared with wild-type *SCN10A* (4.1 ± 1.7 mV, n=4), both SNPs resulted in a marked change in the midpoint of channel activation. Rs73062575, associated with PR interval prolongation, resulted in decreased channel activation (13.5 ± 2.9 mV, n=5). Conversely, rs6795970, which is associated with shorter PR interval, resulted in increased channel activation (-3.0 ± 1.5 mV, n=4). **Conclusions**: Sequencing of the *SCN10A* locus for the PR interval has led to the identification and replication of a novel missense SNP missed by GWAS that alters *SCN10A* channel activation.

A functional SNP at APLN gene confers a risk to arterial stiffness in Chinese women. *Y.C Liao[1,2,3], S.W Huang[3], Y.S Wang[3], K.C Chen[3], S.H.H Juo[3,4].* 1) Section of Neurology, Taichung Veterans General Hospital, Taichung, Taiwan; 2) Department of Neurology, National Yang-Ming University, School of Medicine, Taipei, Taiwan; 3) Department of Medical Genetics, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan;; 4) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan;.

Background: Apelin (APLN) has been showed to be a potent vasodilator and cardiac inotropic agent. We hypothesized that single nucleotide polymorphisms (SNPs) at APLN gene are associated with susceptibility of arterial stiffness. **Methods and Results**: Stiffness parameters including beta (β), elasticity modulus (Ep) and pulse wave velocity (PWV) were obtained by carotid ultrasonography from the general population. Four tagging SNPs of APLN were initially genotyped in 799 subjects. Student's t test and regression analysis were used to evaluate the genetic effect. Men and women were analyzed separately since APLN was located at the X chromosome. The SNP rs3115757 showed significant associations with the stiffness parameters in women (p = 0.008, 0.032, and 0.036 for β, Ep, and PWV respectively), but not in men (p = 0.13–014). Another group of 937 subjects was genotyped for rs3115757 to validate the results. Combing the screening and validating data, rs3115757 was significantly associated with β, Ep, and PWV in women (p = 0.0003–0.0013). After adjustment of age, hypertension and body mass index (BMI), the SNP remained to be significantly related with stiffness parameters (p = 0.025–0.046). For both screening and validation data, rs3115757 was not related to arterial stiffness in men. In our previous study, the expression levels of APLN varied among human adipocytes carrying different rs3115757 genotypes. The influence of rs3115757 on vasculature needs further investigation. **Conclusions**: APLN polymorphism rs3115757 was significantly associated with carotid artery stiffness in Chinese women.

Impact of inflammatory gene polymorphisms on left ventricular dysfunction in coronary artery disease patients. *A. Mishra, A. Srivastava, T. Mittal, N. Garg, B. Mittal.* Sanjay Gandhi Post Graduate Institute of Medical Sciences (SGPGIMS), Lucknow, India.

Rationale: Inflammation affects almost all heart failure (HF) patients, provoke a number of deleterious effects on the heart, most notable being left ventricular dysfunction (LVD). However, cause and effect has so far not been proven, but the inhibition of inflammation in HF is expected to be beneficial. A promoter polymorphism of NFKB1 gene (encodes p50 subunit) results in lower protein levels of NFkB p50 subunit and recent evidences suggest that the NFkB p50 dimer has anti-inflammatory effects. The active NFkB transcription factor promotes the expression of over 150 target genes including IL6 and TNF-α. Therefore, the aim of the present study was to assess the association of NFKB1, IL6 and TNF-α gene polymorphisms with LVD in CAD patients in North Indian population. Methods and Results: The present study included a total of 830 subjects (600 CAD patients and 230 healthy controls) and was carried out in two independent cohorts. The primary cohort included 310 consecutive patients with angiographically confirmed CAD. Out of them, 95 with reduced left ventricle ejection fraction (LVEF≤45%) were categorized having LVD. LVEF was calculated quantitatively by echocardiography, just before angiography procedure, using Simpson's method. The NFKB1 -94 ATTG ins/del (rs28362491), IL6 -174 G/C (rs1800795) and TNF-α -308 G/A (rs1800629) polymorphisms were genotyped by PCR/ARMS-PCR methods. Our results showed that NFKB1 ATTG1/ATTG1 i.e. deletion genotype was significantly associated with LVD (primary cohort: p value=0.035; OR=2.44, replication cohort: p=0.040; OR= 2.38). Also, ATTG1/ATTG1 genotype was found to be associated with LV End diastole (p value=0.013), End systole (p value=0.011) dimensions, LV mass (p value=0.024), mean LVEF (p value=0.001) and Myocardial infarction (p value=0.038) but not with risk factors like diabetes mellitus, hypertension and smoking. In contrast, IL6 -174 G/C and TNF-α -308 G/A polymorphisms were not found to be associated with either CAD or LVD both at genotypic and allelic levels. The above findings were validated in an additional 290 cases with similar clinical characteristics. Conclusion: Our data suggest that NFKB1 -94 ATTG ins/del polymorphism plays significant role in conferring susceptibility of LVD and ATTG1/ATTG1 genotype may modulate disease severity by increasing ventricular remodeling and worsening LV function. Financial support from DBT (India) and ICMR.

Identification Of A New Chromosomal Locus for A Mutation Causing Left Ventricular Non-Compaction With Ventricular Tachycardia Cardio-Pathology. *E. Muhammad[1], A. Levitas[2], V. Sheffield[3], R. Parvari[1,4].* 1) Developmental Genetics, Ben-Gurion University, Beer-Sheva, Israel; 2) Soroka Medcal Center, Ben Gurion University of the Negev, Beer Sheva; 3) University of Iowa, Iowa City, IA, United States; 4) National Institute of Biotechnology in the Negev, Beer Sheva, Israel.

Structural and functional disorders of the heart are important causes of morbidity and mortality. Three Bedouin patients at ages 14–18 years of a single large consanguineous Bedouin family presented with Left ventricular non-compaction and sustained Ventricular Tachycardia. They were evaluated by Echocardiography which showed severe left side enlargement, severely depressed left ventricular (LV) function with focal lacunas in the LV free wall, but normal origin of the coronary artery. The 2 older patients were treated with recurrent electrical cardio version and intravenous administration of amiodarone and on discharge have undergone implantable cardioverter-defibrillator (ICD) implantation. The recessive pattern of inheritance in the consanguineous family suggested homozygosity of the mutation inherited from a common founder. We have performed homozygosity mapping using the affymetrix SNP 5 array on the patients and found a single large chromosomal block of homozygosity on chromosome 11q24 shared by all of them. Verification of this block with VNTR markers in all available family members proved linkage. The Lod score analysis, under the model of a recessive trait with full penetrance, using the PedTool server, was 2.46 for 2 point with marker D11S4958 and 4.59 for the multipoint analysis. This chromosomal locus does not contain any of the known genes causing this disease; efforts are now being done to identify the mutated gene.

Sequencing candidate genes associated with conotruncal heart defects. *K. Osoegawa[1], M. Ladner[1], K. Schultz[1], C. Parodi[1], N. Mohammed[1], D. Noonan[1], G. Shaw[2], E. Trachtenberg[1], E. Lammer[1].* 1) CHORI, Oakland, CA; 2) Pediatrics, Stanford University, Palo Alto, CA.

Congenital heart defects are one of the most common anatomical groupings of human birth defects, yet little is known about their etiologies. Conotruncal defects are an important pathogenetic subset of congenital heart defects, comprising nearly 20 percent of the total. DNA from a population-based sample of 389 California infants born during 1999–2004 with conotruncal defects were used for sequencing candidate genes for conotruncal defects. We developed an efficient and cost effective strategy for sequencing candidate genes associated with conotruncal defects. We selected FGF8, FOXH1, NKX2-5, GATA4, GATA5, GATA6, ISL1, ZFPM2, MEF2C and CRKL that are either expressed in secondary heart field, for which mutations have been reported in a few infants with conotruncal defects, or identified via array comparative genomic hybridization (array-CGH). Ninety-six DNA fragments or “amplicons” containing exons from these genes were amplified using Fluidigm's Access Array System. The system enabled us to amplify up to 48 samples, each with a unique multiplex identifier, x 48 amplicons (2304 independent PCRs) in a single chip. The amplicons were pooled, and sequenced using the Roche 454 GS FLX system. Resulting DNA sequences were aligned against reference human DNA sequences, and potential novel variations or single nucleotide polymorphisms (SNPs) identified within protein coding sequences using SeqNext software (JSI Medical Systems). SNPs were then confirmed by the Sanger DNA sequencing method. We eliminated rare SNPs that could be found in the 1000 Genome project and NHLBI Exome Sequencing Project (ESP) databases. We identified four subjects with novel mutations in GATA4 (H167Y), ZFPM2 (G164R and S210R) and GATA5 (L394P). In addition to the initial 10 candidate genes, we initiated sequencing of FAK, MAPK1, SOX7, SNAI2 and BMPR1A using the same study population and strategy. These genes were selected based on the identification of chromosomal microdeletions/duplications using array-CGH and gene prioritization.

Significant Association of Two Genetic Variants in the ENPEP Gene with Lone Atrial Fibrillation in Koreans. *D. Shin[1,3], H. Hwang[2], A. Park[3], N. Son[3,4], E. Shin[5], J. Lee[5], H. Pak[2], M. Lee[2], Y. Jang[2,3].* 1) Cardiovascular Research Institute, Yonsei Univrsity College of Medicine, Seoul, South Korea; 2) Division of Cardiology, Yonsei University Health System; 3) Cardiovascular Genome Center; 4) Department of Biostatistics, Yonsei University College of Medicine; 5) DNA Link Inc, Seoul, South Korea.

Atrial fibrillation (AF) is one of the most common cardiac arrhythmias by chaotic electrical activity of the atrial and is associated with increasing disability and mortality. Up to date, several evidences indicate the phenotypes of lone AF are more likely to occur in patient with a genetic susceptibility. The ENPEP gene has a crucial function in cardiac development and may be one underlying mechanism for AF development. The ENPEP gene encodes an aminopeptidase A (APA) ectopeptidase, which is responsible for the breakdown of angiotensin II in the vascular endothelium and a 20 exon gene located at human chromosome 4q25. We examined a case-control study for a total of 754 Korean subjects, comprising of 354 cases with AF and 400 controls. Genotyping for variants was carried out by direct DNA sequencing and TaqMan® assay. We examined 13 tagging single nucleotide polymorphisms (tSNPs) in the ENPEP gene. We observed the significant difference in the allele and genotype distributions of rs669262 between patients with lone AF and controls (P=0.011). Logistic regression analysis represented that tSNPs, rs669262 and rs2029073, confer the risk of lone AF. The significant associations were observed under a dominant model for rs669262 with an increasing risk of AF (OR, 1.769; 95% CI, 1.174-2.666; P=0.006). In addition, ENPEP rs2029073 showed significant association in Korean AF condition under a recessive model with an increasing risk (OR, 1.583; 95% CI, 1.077-2.327; P=0.019). We provide evidence that ENPEP novel variants may contribute to predispose Korean individuals to the risk of lone AF.

Molecular Investigation in Sudden Unexplained Death Syndromes in New York City. *Y. Tang[1], D. Wang[1], L. Eng[1], K. Shah[1], S. Um[1], B. Zhou[1], M. Prinz[1], B. Sampson[2].* 1) Forensic Biol, Office Chief Med Examiner NYC, New York, NY; 2) Forensic Pathology, Office Chief Med Examiner NYC, New York, NY.

Objective: Sudden unexplained death syndrome **(SUDS)** is sudden death in apparently healthy individuals which remains unexplained after a thorough investigation including a complete autopsy, examination of the death scene and review of clinical history. It is estimated that more than 8,500 such deaths occur in the United States every year. Currently, molecular genetic testing is the only means to diagnose certain cardiac arrhythmias that can result in SUDS, such as long QT syndrome. We performed molecular studies on 323 SUDS cases. **Methods and Results:** 323 SUDS cases, which were investigated from June 2001 to December 2011 at the City of New York Office of Chief Medical Examiner (NYC OCME), were included. Forensic examinations were conducted, including a full autopsy, toxicological testing, histological examination of major organs, review of available clinical history, and a thorough scene investigation. Molecular studies were performed by the genetics laboratory within OCME, accredited by College of American Pathologists (CAP). Six major cardiac channel genes (KCNQ1, KCNH2, SCN5A, KCNE1, KCNE2 and RyR2) previously reported to have disease-causing sequence variants in SUDS were analyzed. Entire coding regions were tested for KCNQ1, KCNH2, KCNE1, KCNE2, and selected exons were tested for SCN5A (exons 12 to 28) and RyR2 (exon 8, 14, 15, 44–47, 49, 88–93, 95–97, 100–105). Baseline characteristics of SUDS were compared amongst ethnic groups (Blacks, Hispanics, Whites, and Asian), by gender, and between various age groups (<1 year old, 1–5 years old, 6–18 years old, and >18 years old). Sequence variants were classified by relevance to clinical significance in the functional domain of each gene by age group. Approximately 15% of SUDS cases may be explained by the presence of possible disease-causing sequence variants in the decedents. **Conclusion:** Molecular testing has proven to be a valuable tool in the forensic investigation of SUDS. Expanded genome-wide testing is expected to increase our ability to elucidate the cause of death in the future.

Associations of NINJ2 sequence variation with incident ischemic stroke: analysis of common and rare variants in the Cohorts for Heart and Aging in Genomic Epidemiology (CHARGE) Consortium. *J.C. Bis[1], M. Fornage[2,3], A.L. DeStefano[4], J. Brody[1], M.A. Ikram[5,6], C. van Duijn[5], R. Gibbs[7], J.G. Reid[7], E. Boerwinkle[2,3,7], W.T. Longstreth[1,8], T.H. Mosley[9], S. Seshadri[10] on behalf of the CHARGE Neurology Working Group.* 1) Cardiovascular Health Research Unit and Department of Medicine, University of Washington, Seattle, WA, USA; 2) 2. Brown Foundation Institute of Molecular Medicine, Division of Epidemiology, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX, USA; 3) Human Genetics Center, Division of Epidemiology, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX, USA; 4) Department of Biostatistics, Boston University School of Public Health, Boston, MA, USA; 5) Department of Epidemiology; Erasmus MC Rotterdam, The Netherlands; 6) Departments of Radiology, Neurology; Erasmus MC Rotterdam, The Netherlands; 7) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 8) Department of Neurology, University of Washington, Seattle, WA, USA; 9) Department of Medicine (Geriatrics), University of Mississippi Medical Center, Jackson, MS, USA; 10) Department of Neurology, Boston University School of Medicine, Boston, MA, USA.

Stroke is the leading neurologic cause of death and disability. Despite studies suggesting a substantial genetic component, few genes underlying this risk in the general population have been identified. In a previous genome-wide association meta-analysis in the setting of the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium, we identified and replicated associations of single-nucleotide polymorphisms adjacent to the *NINJ2* gene with incident stroke ($P<5\times10^{-8}$). We therefore sequenced a 200kb window spanning *NINJ2* (12p13) among 3,979 European ancestry participants from the Atherosclerosis Risk in Communities Study, the Cardiovascular Health Study, and the Framingham Heart Study that included a random sample as well as a subset of 200 individuals who had had an ischemic stroke of atherothrombotic origin. We applied two methods of analysis for this region. Common variants, those with minor allele frequency (MAF) ≥ 1%, were analyzed independently with a fixed effect meta-analysis on each variant. Rare variants (MAF < 1%) were meta-analyzed in aggregate using the T1 count statistic, defined as the number of loci in the target window with MAF less than 1% at which a person has at least one rare allele. All associations of genetic variation with ischemic stroke were estimated using Cox proportional hazards models with adjustment for age and sex. While this targeted sample provided evidence of association for the original GWAS signals (rs11833579, p=0.0005; rs12425791, p=0.006), the most significant association in the meta-analysis of 290 common variants was a novel intronic SNP (MAF=0.012, p=0.0003) in the *NINJ2* gene, providing fine-mapping evidence that the responsible gene within the broad GWAS peak may be *NINJ2*. Further analysis of the 2,117 rare variants showed modest evidence that, in aggregate, rare variation in this gene also contributed to stroke risk (p=0.03). Sequencing of the *NINJ2* regions within the CHARGE cohorts demonstrated evidence of association between common and rare sequence variants and ischemic stroke. While additional investigation is needed to understand the role of these newly discovered variants, these findings may help clarify the genetic architecture of a region previously implicated in the incidence of stroke.

CCR5, TNF/LTA, CCL2, IL12B, IL10, MAL/TIRAP, ACTC1 genes are associated to the development of chronic Chagas' disease cardiomyopathy. *C. CHEVILLARD[1], A.F. FRADE[2], P. TEIXEIRA[2], B. IANNI[3], C. WIDE PISSETTI[4], A. FRAGATA[5], M. HIRATA[5], M. SAMPAIO[5], B. SABA[5], F. DIAS[6], E. DONADI[6], V. RODRIGUES JR[4], A. PEREIRA[3], J. KALIL[2], E. CUNHA-NETO[2].* 1) INSERM, U906, Faculté de médecine, Marseille, France; 2) Heart institute (Incor), University de Sao Paulo, Av. Dr. Enéas de Carvalho Aguiar, 05403-000 Sao Paulo, Brazil; 3) Hospital das Clinicas, Av. Dr. Enéas de Carvalho Aguiar, 255 Cerqueira César, 05403-000 Sao Paulo, Brazil; 4) Laboratory of Immunology, Universidade Federal do Triângulo Mineiro, 30 Frei Paulino, 38025-180 Uberaba, Brazil; 5) The Instituto Dante Pazzanese, Avenida Dr. Dante Pazzanese, 500 Vila Mariana, 04012-909 Sao Paulo, Brazil; 6) Faculdade de Ribeirao Preto, Av. Bandeirantes, 3900 - Monte Alegre, 14049-900 Ribeirao Preto, Brazil.

Chagas disease, due to Trypanosoma cruzi, occurs exclusively in the Americas, particularly in poor, rural areas of Mexico, Central America, and South America. An estimated 300,000 new cases and 50,000 fatilities occur per year. Chronic Chagas disease cardiomyopathy (CCC) is an inflammatory cardiomyopathy that affects approximately 30% of infected individuals. Approximately 1/3 of patients developing CCC present a particularly lethal form of dilated cardiomyopathy, with short survival. Familial aggregation of CCC suggests that there might be a genetic component to disease susceptibility. Here, we conduct a study on several main candidate genes on a large Brazilian population. This study was done on 315 CCC cases and 118 asymptomatic subjects considered as “controls”. Significant associations were detected for CCR5 (rs3176763: p=0.006 OR=1.79; rs11575815: p=0.030 OR=1.41), TNF/LTA (rs2844484: p=0.007 OR=1.51; rs909253: p=0.035; OR=1.50), CCL2 (rs909253: p=0.037 OR=1.56; rs2530797: p=0.028 OR=1.28), IL12B (rs1003199: p=0.008 OR=1.49; rs919766: p=0.007 OR=1.45), IL10 (rs3024496: p=0.020 OR=1.47), MAL/TIRAP (rs8177376: p=0.004 OR=1.42) genes. These associations are consistent with the fact patients who develop Chagas cardiomyopathy display an exacerbated Th1 immune response and a reduced numbers of IL-10-producing and CD4+CD25+FOXP3+ regulatory T cells. Cardiac muscle alpha Actin 1 is a protein that in humans is encoded by the ACTC1 gene. On heart biopsies from cases and controls, proteomic analysis, performed by 2-D DIGE experiments, has shown that the ACTC1 proteins are under represented into patient heart biopsies compared to control heart biopsies. This result was confirmed by western blot analysis. Some significant associations were detected with one polymorphism located into the promoter (rs640249: p=0.006 OR=1.59). Based on linkage disequilibrium map, a promoter haplotype of susceptibility was identified (rs640249-rs641563). Some functional studies done on primary human cardiomyocytes and an imputation analysis are ongoing in order to identify the functional variants. Authors hypothesized that ACTC1 mutations affecting sarcomere contraction leading to cardiomyopathy and that mutations affecting force transmission from the sarcomere to the surrounding syncytium lead to dilated cardiomyopathy.

1594T

Analysis of Candidate Genes Associated with Intermediate Traits Identifies Novel Variants Associated with Coronary Artery Disease Presence and Severity. *D.M. Craig[1], E.R. Hauser[1], E. Burns[1], M. Chryst-Ladd[1], C. Haynes[1], W.E. Kraus[1], I.C. Siegler[2], B.H. Brummett[2], R.C. Becker[2], R.B. Williams[2], S.H. Shah[1].* 1) Medicine, Duke Medical Center, Durham, NC; 2) Psychiatry, Duke Medical Center, Durham NC.

Background. Cardiovascular disease (CVD) is heritable but the genetic architecture remains incompletely understood. Genetic variants have been associated with endophenotypes (i.e. diabetes, hypertension) that are themselves CVD risk factors. We hypothesized that these genetic variants are also associated with CVD. Methods. A sequential cohort of CATHGEN Biorepository patients referred for cardiac catheterization to assess ischemic heart disease was identified. Eleven single nucleotide polymorphisms (SNPs) were genotyped using the Taqman platform. CVD was defined by three phenotypes: coronary artery disease (CAD, defined as 1+ epicardial coronary vessel ≥75% stenosis), degree of CAD (number of diseased epicardial vessels), and time to incident CVD events. Association between SNP and CVD was tested using logistic regression with a basic (age, sex) and multivariable model (age, sex, body mass, hypertension, diabetes, hyperlipidemia, ejection fraction, smoking) stratified by race (N=5092 Caucasian, N=1254 African-Americans) using dominant and additive genetic models. Time to incident CVD was modeled using Cox proportional hazards. Results. All SNPs were in Hardy-Weinberg equilibrium. In Caucasians, the T allele of rs2943641 (near insulin receptor substrate 1 [IRS1] gene) was associated with degree of CAD (basic model odds ratio [OR] 0.91, 95% CI 0.83, 0.99; p=0.04), with attenuation after adjustment in the multivariable model (OR 0.91, 95% CI 0.83, 1.01; p=0.06). Rs2943641 was not associated with CAD as a binary trait, and no other SNPs were associated with any CVD phenotype in Caucasians. In African Americans, there was association between the C allele of rs2131127 (in angiotensin II receptor, type 1 [AGTR1]) and CAD (basic OR 1.25, 95% CI 0.99, 1.58; p=0.07; multivariable OR 1.33, 95% CI 1.02, 1.72; p=0.03) and trend for association with degree of CAD (basic OR 1.11, 95% CI 0.91, 1.34; p=0.3; multivariable OR 1.19, 95% CI 0.97, 1.47; p=0.09). No SNPs were associated with CVD event times. Conclusions. We found evidence for modest association of a SNP near IRS1, previously associated with type II diabetes, and for a SNP in AGTR1 with CVD phenotypes. This latter finding is consistent with a previous study linking the rs2131127 TT genotype to lower blood pressure reactivity to stress and platelet aggregation. Genetic variants associated with CVD-related endophenotypes may serve as CVD risk markers, but with only modest effects.

A large body of epidemiologic, clinical and experimental data strongly suggests an association between excess adiposity and CAD. Low levels of adiponectin, a hormone secreted only from adipocytes, has been associated with an increased risk of CAD in observational studies. However, these associations cannot clarify whether this relationship is causal or due to a shared set of causal factors or even a consequence of reverse causality meaning that CAD secondarily results in low adiponectin levels. Genetic influences account for a large proportion of the variation in adiponectin levels and several genome-wide association studies have identified numerous common variants across the genome that influence adiponectin levels. These variants provide a valuable tool to examine the genetic relationship between adiponectin and CAD, enabling insights into the causality of this relationship. Using 145 genome-wide significant SNPs for adiponectin levels from the ADIPOGen consortium (n=49,891) we aimed to test whether adiponectin-decreasing alleles influenced risk of CAD in the CADRIoGRAM consortium (n=82,000). In single-SNP analysis, 5 variants among 145 SNPs were associated with increased risk of CAD after correcting for multiple testing (P < 4.4×10-4). Using independent SNPs from145 SNPs, we applied a multi-SNP genotypic risk score to test whether adiponectin levels and CAD have a shared genetic etiology, we found that adiponectin-decreasing alleles increased risk of CAD (P = 5.4×10-7). These findings demonstrate that adiponectin levels and CAD have a common allelic architecture and provide rationale to undertake a Mendelian randomization to understand if low adiponectin levels cause CAD.

Investigation of mutations in exons 19 and 22 MYH7 gene in HCM patients in Chaharmahal Va Bakhtiyari province, Iran. *S. Heydari Sodejani[1], R. Pourahmad[1], A. Khaledifar[2], M. Hashemzadeh[3], F. Azadegan[4], N. Bagheri[5], S. Badfar[6].* 1) Department of Genetics, shahrekord university, Shahrekord, chaharmahal va bakhtiyari, Iran; 2) Department of Cardiology, School of Medicine, Sharekord University of Medical Sciences, chaharmahal va bakhtiyari, Iran; 3) Department of Genetics, Molecular and Cellular Research Center, Sharekord University of Medical Sciences, chaharmahal va bakhtiyari, Iran; 4) Department of Genetics,School of Basic Sciences, Zabol University, Sistan Va Balochestan, Iran; 5) Department of Immunology, Sharekord University of Medical Sciences, chaharmahal va bakhtiyari, Iran; 6) Echocardiography Unit, Hajar Hospital of Shahrekord, chaharmahal va bakhtiyari, Iran.

Abstract: Background and Aim: Hypertrophic cardiomyopathy (HCM) is the most common kind of Mendelian inherited heart disease, affects 0.2% of the global population. HCM is also the most common cause of sudden cardiac death in individuals younger than 35 years old. To date more than 900 individual mutations has been identified in over 20 genes, such as MYH7, MYBPC3, and TNNT2. Interestingly, most of these genes encode sarcomeric proteins. In the present study, we investigated the possible presence of mutations in the 19 and 22th exons of the MYH7 gen, reported to accommodate the maximum mutations, in a cohort of 30 patients with HCM in Chaharmahal Va Bakhtiyari province. Materials and Methods: DNA was extracted using standard phenol- chloroform method and then was investigated by PCR- SSCP procedure. Finally, the suspected cases were selected for the direct sequencing and the results were analysed using chromas, BLAST and Clustal W online servers. Results: There is no mutation in the 19th exon but were found tow mutation in the 22th exon that including: a substitution G>A 10824 and an insertion Ins 10864G. Discussion and Conclusion: Two of probands had nucleotide changes. One of them was a 60 years old woman with family history of HCM and has Ins 10864G mutation. Another is a 73 years old women without family history and showed the G>A 10824 mutation. Our data indicated that mutation in the MYH7 gene can be found in patients without a family history of HCM. This is necessary the study of other exons to better assessment.

Polymorphisms in *CHRNA3-CHRNA5-CHRNB4* are associated with body mass index and systolic blood pressure in smokers in the Northern Finland Birth Cohort 1966. *M. Kaakinen[1,2], F. Ducci[3,4], M.J. Sillanpää[1,2], E. Läärä[1], M-R. Järvelin[1,2,5,6].* 1) University of Oulu, Oulu, Finland; 2) Biocenter Oulu, Oulu, Finland; 3) King's College, London, United Kingdom; 4) St George's University of London, London, United Kingdom; 5) National Institute for Health and Welfare, Oulu, Finland; 6) Imperial College London, London, United Kingdom.

The *CHRNA5-CHRNA3-CHRNB4* gene cluster on 15q25 has consistently been associated with smoking quantity, nicotine dependence, lung cancer and chronic obstructive pulmonary disease. Evidence for the involvement of this gene cluster on regulation of cardiovascular homeostasis has also been reported. One twin study reported an association between genetic variation within *CHRNA5-CHRNA3-CHRNB4* and systolic blood pressure, whereas results from two meta-analyses indicated that polymorphisms in *CHRNA3* influence body mass index and susceptibility to develop peripheral arterial disease, but only among smokers. More research is needed to examine the potential pleiotropic effects of *CHRNA3-CHRNA5-CHRNB4* gene cluster on blood pressure and BMI, and how smoking behavior may modify these effects. We studied the associations between 18 variants in the gene cluster and systolic blood pressure (SBP), diastolic blood pressure (DBP), and body mass index (BMI) in 5402 young adults from the Northern Finland Birth Cohort 1966. The analyses were performed separately in non-smokers and smokers, and finally in the entire sample including an interaction term for smoking. Several single nucleotide polymorphisms from the gene cluster were associated with SBP and BMI, while evidence for associations with DBP was weaker. The associations were manifest only in smokers, and in such a way that the smoking-associated alleles predicted lower SBP and BMI. Each additional copy of the rs1948 G-allele and rs950776 A-allele in *CHRNB4* were associated with about 1.20 mmHg lower SBP in smokers. The variants associated with BMI included rs2036534 in *LOC123688* and rs6495309, rs1996371, rs6495314, rs4887077, rs11638372 in *CHRNB4* and had an average effect size of -0.35 kg/m^2 per an additional copy of the risk allele in smokers. The results from interaction models provided further evidence of the interactive effects observed in stratified analyses. The associations with the phenotypes in smokers were driven by different loci with low linkage disequilibrium with each other suggesting that the gene cluster regulates SBP through biological mechanisms that partially differ from those regulating BMI. Large collaborative efforts are needed to find further evidence for the associations, to test for their existence in other populations and to understand the mechanisms by which the gene cluster influences BMI and SBP.

Genetic association studies of left ventricle dysfunction in coronary artery disease patients. *B. Mittal, A. Mishra, A. Srivastava, T. Mittal, N. Garg.* Sanjay Gandhi Med Inst, Lucknow, UP, India.

Rationale: Left ventricular dysfunction (LVD) often develops in response to an ischemic insult, ventricular remodeling and sarcomeric disorganization. The structural and extracellular matrix proteins can contribute to unfavourable ventricular remodelling followed by fall in cardiac output, which further leads to activation of Renin Aldosterone Angiotensin System (RAAS). Therefore, the present study was undertaken to evaluate association of genetic variations in cardiac myosin binding protein-C (MYBPC3), RAAS, and Matrix metalloproteinases (MMPs) with LVD in coronary artery disease (CAD) patients in North Indian population. Methods and Results: The present study was carried out in two cohorts. The primary cohort included 310 consecutive patients with angiographically confirmed CAD and 230 controls. Among CAD patients, 95 with reduced left ventricle ejection fraction (LVEF≤45) were categorized as LVD. LVEF was calculated quantitatively by echocardiography, just before angiography procedure, using Simpson's method. The 25 bp deletion in MYBPC3 gene and genetic variants in RAAS [angiotensin I converting enzyme; ACE I/D (rs4340), angiotensin II type1 receptor; AT1A1166C (rs5186), aldosterone synthase; CYP11B2 T-344C (rs1799998)] and MMPs [MMP2 C-735T (rs2285053), MMP7 A-181G (rs11568818) and MMP9 R279Q (rs17576), P574R (rs2250889) and R668Q (rs17577)] were determined by PCR/ARMS-PCR/PCR-RFLP methods. Our results showed that 25bp deletion in MYBPC3 (p value <0.001; OR = 4.49), AT1 A1166C (p value=0.013; OR=3.69) and MMP9 R668Q (p value=0.009; OR=3.82) were significantly associated with LVD. Also the frequency of haplotype MMP9 279R, 574P, 668Q was significantly higher in reduced LVEF subjects (p value = 0.008; OR = 1.83). We further performed a replication study in additional 200 cases with similar clinical characteristics and results again confirmed consistent findings: 25bp deletion in MYBPC3 (p= 0.029; OR=3.30), AT1 A1166C (p value=0.020; OR=5.20) and MMP9 R668Q (p value=0.033; OR=3.59) were significantly associated with LVD. Conclusion: The 25bp deletion in MYBPC3, AT1 A1166C and MMP9 R668Q were significantly associated with LVD in CAD patients. These findings may be important for the understanding of genetics of left ventricular dysfunction which is leading cause of heart failure. Financial support from DBT (India) and ICMR.

Associations of sequenced regions SLC17A4 and PIK3CG with common carotid intima-media thickness and plaque: a common and rare variant meta-analysis in the Cohorts for Heart and Aging in Genomic Epidemiology (CHARGE) Consortium. *C.J. O'Donnell[1,2], C.C. White[1,3], N. Franceschini[4], J. Brody[5], D. Muzny[6], R. Gibbs[6], E. Boerwinkle[7], B. Psaty[5,8,9,10], K.E. North[11], L.A. Cupples[1,3], J.C. Bis[5] on behalf of the CHARGE Subclinical Atherosclerosis Working Group.* 1) National Heart, Lung and Blood Institute's Framingham Heart Study, Framingham, MA, USA; 2) Cardiology Division, Department of Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA; 3) Department of Biostatistics, Boston University School of Public Health, Boston, MA, USA; 4) Department of Epidemiology, University of North Carolina Chapel Hill, Chapel Hill, NC, USA; 5) Cardiovascular Health Research Unit and Department of Medicine, University of Washington, Seattle, WA, USA; 6) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 7) Human Genetics Center, University of Texas Health Science Center at Houston, TX, USA; 8) Department of Epidemiology, University of Washington, Seattle, WA, USA; 9) Department of Health Services, University of Washington, Seattle, WA, USA; 10) Group Health Research Institute, Group Health, Seattle, WA, USA; 11) Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC, USA.

Atherosclerosis, the precursor to clinical coronary heart disease and stroke, is caused by an accumulation of fatty materials in the intimal-medial layers of the arteries. Common carotid intima media thickness (cca-IMT) and plaque, observed with ultrasonography, are subclinical atherosclerosis measures that predict cardiovascular disease events. Identifying genomic locations associated with cca-IMT and plaque might shed light on the mechanism of atherosclerosis and identify people at risk of cardiovascular disease. For this project, we sought additional information about two regions that previously demonstrated evidence for association with cca-IMT (*SLC17A4*) and plaque (*PIK3CG*) in a large-scale genome-wide meta analysis. We sequenced windows of 120kb around *SLC17A4* (6p22.2) and 251kb around PIK3CG (7q22.3) among 3,688 European ancestry participants from the Atherosclerosis Risk in Communities Study, the Cardiovascular Health Study, and the Framingham Heart Study that included a random sample as well as a subset of individuals with selected for high values of cca-IMT. We applied two methods of analysis for these regions. Common variants, those with minor allele frequency (MAF) ≥ 1%, were analyzed independently with a fixed effect meta-analysis on each variant. Rare variants (MAF<1%) were meta-analyzed in aggregate using the T1 count statistic, defined as the number of loci in the target with MAF<1% at which a person has at least one rare allele. In the meta-analysis of common variants, rs2286149 showed the smallest p-value in both analyses of cca-IMT (p-value= 0.0003) and plaque (p-value=0.0003). This variant falls in the 3' UTR of *CCDC71L*, itself upstream from the targeted *PIK3CG* gene. For the region spanning SLC17A4, the strongest finding was for a newly-discovered intronic variant with cca-IMT (p=0.008), which may provide modest evidence toward fine-mapping the broad GWAS peak. Further analysis of rare variants showed no evidence of association between the either region with cca-IMT, but found suggestive association of the *PIK3CG* region with plaque (p=0.054). Sequencing of the *PIK3CG* and *SLC17A4* regions within the CHARGE cohorts shows further evidence of association between plaque and the *PIK3CG* region for both common and rare variants. While not conclusive, these findings may help to better understand the genetic architecture of two regions previously implicated in subclinical atherosclerosis.

CNVs contributing to the cause of congenital heart defects may include not only those containing candidate genes but regions more commonly associated with autism and other disorders. *D. Warburton[1,6], M. Ronemus[2], J. Kline[3,4], M. Wigler[2], V. Jobanputra[5], D. Levy[2], K. Anyane-Yeboa[6], W. Chung[6], D. Awad[7].* 1) Dept. Gen & Development, Columbia Univ, New York, NY; 2) Cold Spring Harbor Laboratory, Cold Spring, NY; 3) NY Psychiatric Institute, New York, NY; 4) Mailman School of Public Health, Sergievsky Center, Columbia University, New York, NY; 5) Dept. Pathology, Columbia University, New York, NY; 6) Dept. of Pediatrics, Columbia University, New York, NY; 7) Dept. of Medicine, Columbia University, New York, NY.

Our study aimed to determine the contribution of CNVs to congenital heart disease (CHD) of two distinct types. We recruited 73 probands and their parents (trios) with hypoplastic left heart syndrome (HLHS) and 146 trios with conotruncal anomalies (CNT). All cases of DiGeorge syndrome were omitted. Using the Nimblegen 2.1 chip for aCGH and analytical software designed at Cold Spring Harbor Laboratory (CSHL), our primary focus was to determine the frequency and gene content of de novo (DN) CNVs in both types of anomalies. All DN lesions, ranging from 7 kb to 8.6Mb, were verified in probands and parents, by FISH or qPCR. The frequency of trios with DN lesions was higher for HLHS (12.3%) than for CNT (7.4%), and higher for male probands (11.3%) than for female probands, but neither difference is statistically significant. The frequency of de novo lesions in CHD is significantly higher than that in the 700 control families using the same platform and software (2%), indicating that a high proportion of the observed DN changes are contributing to the cause of the CHD. Five DN lesions involved genes or regions known to be associated with CHD or other pathology. These include a deletion in 8p23.1 containing GATA4, the common duplications in 16p13.11 and 1q21.1, a deletion in 2q23.1 including MBD5, and a 6Mb duplication in the Prader-Willi region. The last two have not been associated so far with CHD. We also examined inherited but ultra-rare CNVs (not seen in more than one of the control trios) and examined those that (1) were also found de novo (2) contained candidate genes for CHD (3) occurred more than once (4) and had an affected sib eith the lesion. Within this group we detected a deletion of NODAL and a duplication of CFC1 (genes known to be involved in heterotaxic heart defects) and also three cases of the 1q21.1 duplication and two cases of the 15q11.2 duplications found de novo. In all 213 trios, there were only 5% where the abnormality revealed by CNV analysis is most certainly related to the cause of the CHD. However more studies of clearly defined populations may reveal new repetitive CNVs and lead to identification of new genes involved in CHD. In particular the presence in multiple cases of CHD of lesions well recognized to lead to autism and other developmental disorders (16p13.11, 15q11–12, 2q23.1, 1q21.1) suggests that these areas may affect the activity of a wide variety of developmental processes by interracting with other genetic variation.

Whole exome sequencing and hypertrophic cardiomyopathy. *F. Dewey, S. Cordero, M. Wheeler, A. Pavlovic, K. Bommakanti, S. Pan, C. Caleshu, R. Chen, M. Snyder, E. Ashley.* Stanford Univ, Stanford, CA.

Background: Hypertrophic cardiomyopathy (HCM) is a common cause of sudden death in young people. Whole exome sequencing may provide novel insight into the pathogenesis of the disorder. **Methods:** We performed whole-exome sequencing on six related subjects in whom target sequencing had not identified a pathogenic mutation: four with manifest HCM, one obligate carrier, and one unaffected adult. First, we excluded common, benign polymorphisms using a combination of publicly available controls from the 1000 genomes variation database, dbSNP, and sequence data from our laboratory. Second, we used a novel phasing algorithm to identify candidate recent ancestral haplotypes across the three generation pedigree to narrow the search space for pathogenic variants. Non-synonymous or splice disrupting single nucleotide variants (SNVs), and frameshift coding indels (NS/SS/FI) were scored for evolutionary conservation using multiple sequence alignment of 46 mammalian species. Candidate variants were further prioritized by gene expression in myocardial tissue from 436 human subjects with heart failure, 49 human subjects with cardiac hypertrophy, 75 unused, structurally normal explanted donor hearts, and in non-cardiac tissues from 1,058 human subjects. **Results:** Sequence data was successfully generated for 97.9% of targeted exonic regions at an average read depth of 134x. We identified 12,649 NS/SS/FI variants in the pedigree, and 892 of these variants were not seen in population controls. Six of these private variants arose on a recent ancestral haplotype that co-segregated with disease. Additional phenotyping of thirteen related individuals revealed two additional affected subjects; targeted sequencing demonstrated co-segregation of three of these six candidate variants with disease. One SNV occurred in a gene that was highly and uniquely expressed in human myocardial tissue compared to non-myocardial tissue, wilms tumor interacting protein (WTIP). **Conclusions:** Whole exome sequencing in families can be combined with population variation, evolutionary conservation, linkage data, and gene coexpression for pathogenic gene identification in HCM. Experimental confirmation of the functional role of this variant allele of WTIP may illuminate a novel role for non-cannonical wnt signaling in the pathogenesis of HCM.

Fine Mapping the *SCN10A* Gene Region Identifies Novel Associations with PR Interval in African Americans from an Electronic Medical Record Population. *J. Jeff[1], M. Ritchie[2], J. Denny[3,4], H. Dilks[5], C. Sutcliffe[5], M. Basford[6], D. Roden[3,6,7], D. Crawford[1].* 1) Human Gen, Vanderbilt Univ, Nashville, TN; 2) Center for Systems Genomics, Penn State University; 3) Department of Medicine, Vanderbilt Univ, Nashville, TN; 4) Department of Biomedical Informatics, Vanderbilt Univ, Nashville, TN; 5) DNA Resources Core, Vanderbilt Univ, Nashville, TN; 6) Office of Personalized Medicine, Vanderbilt Univ, Nashville, TN; 7) Department of Pharmacology, Vanderbilt Univ, Nashville, TN.

Variations in the sodium channel gene, *SCN5A*, have been extensively studied by candidate gene studies in African Americans and are associated prolonged QT syndrome and sudden cardiac death. Recently, genome wide association studies (GWAS) have identified novel loci that contribute to electrocardiographic parameters such as atrioventricular conduction (PR interval). Most GWAS have been performed in European American populations collected from population-based cohorts or surveys. *SCN10A* variants, located in a sodium channel gene cluster (5A-10A-11A) on chromosome 3, have been consistently associated with PR interval by GWAS in Europeans; however, to date these associations fail to generalize in African Americans. In a previous study, GWAS-identified *SCN10A* SNPs in European Americans were rare and not associated with PR interval in African Americans (p>0.10); however, the effect sizes trended in the same direction. To identify alleles associated with PR interval in African Americans, we performed a fine-mapping experiment with variants in the *SCN10A* region with PR interval in 1,016 African Americans, without heart disease identified using electronic medical records. We genotyped 140 SNPs within 165kb of the *SCN10A* gene encompassing *SCN5A*, *SCN10A*, and *SCN11A*. We detected a total of 22 associations with PR interval at a liberal significance threshold of p<0.05. Our most significant association, rs3922844 (*SCN5A*, β=4.33, p= 1.6 × 10-6) has been previously associated with ECG traits in African Americans. In addition to rs3922844, we replicated four other SNPs and identified six novel associations in the *SCN5A* gene. As previously mentioned, there have been no significant associations reported in African Americans with *SCN10A* and none with *SCN11A* for any population. We detected two associations with intronic SNPs in the *SCN10A* (rs6599251, β=1.86, p=0.03; rs9848976, β=-2.18, p = 0.05) and four associations in *SCN11A* with PR interval in our African American sample (rs4284929, β=-2.61, p=7.5 × 10-3; rs4514993, β=-2.60, p=0.03; rs11924818, β=-2.50, p=0.04; rs9818979, β= 1.60, p=0.04). The exact role *SCN10A* and *SCN11A* have on atrioventricular conduction is poorly understood. Given the novelty of these associations, these results set a framework for future association and molecular studies to elucidate the function of these genes and their impact on atrioventricular conduction.

Association between 4q25 variants and cardioembolic stroke in the Vienna Stroke Registry. *M.M. Luke[1], C.H. Tong[1], J.J. Catanese[1], J.J. Devlin[1], S. Greisenegger[2], C. Mannhalter[3].* 1) Cardiovascular Disease, Celera, Alameda, CA; 2) University Clinic of Neurology, Medical University of Vienna, Vienna, Austria; 3) Clinical Institute of Laboratory Medicine, Medical University of Vienna, Vienna, Austria.

Background—Two single nucleotide polymorphisms (SNPs) on chromosome 4q25 (rs2200733 and rs10033464) have previously been reported to be associated with ischemic stroke—in particular with the cardioembolic stroke (CES) subtype. Aims—We evaluated the association of rs2200733 and rs10033464, both separately and in combination, with CES. Methods—The genotypes of rs2200733 and rs10033464 were determined for 202 CES cases and 815 controls in the Vienna Stroke Registry (VSR) case-control study. We then tested the two SNPs both separately and in combination for association with CES in regression models. We also estimated the effect sizes for the two SNPs in a random effect meta-analysis that combined results of VSR and previous studies. Results—While the association between rs2200733 and CES in VSR was statistically significant (p = 0.0004, odds ratio (OR) = 2.16, 95%CI 1.41-3.32 for each risk allele), the association between rs10033464 and CES in VSR was not significant (p = 0.26, OR = 1.23, 95% CI 0.86–1.76 for each risk allele). In combined results of VSR and previous studies, the combined odds ratio per risk allele for each SNP individually was 1.53 (95%CI 1.38–1.70) for rs2200733 and 1.18 (95%CI 1.07–1.31) for rs10033464. In VSR, we considered the effect of both SNPs together and found that, compared with noncarriers (those who did not carry a risk allele of either SNP, 60% of the control group), carriers of one risk allele (of either SNP, 35% of the control group) and carriers of more than one risk allele (of either SNP, 5% of the control group) had odds ratios for CES of 1.46 (95% CI 1.05–2.03) and 2.74 (95%CI 1.57–4.76) respectively, with p = 0.0002 in a trend test. Conclusion—In the VSR, carriers of one and carriers of more than one risk alleles of the 4q25 SNP rs2200733 or rs10033464, compared with noncarriers, had increasing risk of CES.

Common genetic variants do not predict CAD in Familial Hypercholesterolemia. *E.P.A. van Iperen[1,2], S. Sivapalaratnam[3], S.M. Boekholdt[3,4], G.K. Hovingh[3], S. Maiwald[3], M.W. Tanck[2], N. Soranzo[5], J.C. Stephens[6,7], J.G. Sambrook[6,7], M. Levi[3], W.H. Ouwehand[5,6,7], J.J.P Kastelein[3], M.D. Trip[3,4], A.H. Zwinderman[2].* 1) Durrer Center for Cardiogenetic research, Amsterdam, Netherlands; 2) Department of Clinical Epidemiology, Biostatistics and Bioinformatics Academic Medical Centre, Amsterdam, the Netherlands; 3) Department of Vascular Medicine, Academic Medical Centre, Amsterdam, the Netherlands; 4) Department of Cardiology, Academic Medical Centre, Amsterdam, the Netherlands; 5) Human Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 6) Department of Haematology, University of Cambridge, Cambridge, United Kingdom; 7) National Health Service Blood and Transplant, Cambridge, United Kingdom.

Objective: In recent years, multiple loci dispersed on the genome have been shown to be associated with coronary artery disease (CAD). We investigated whether these common genetic variants also hold value for CAD prediction in a large cohort of patients with Familial Hypercholesterolemia (FH).

Methods and Results: We genotyped a total of 146 SNPs in 1701 FH patients, of whom 482 patients (28.3%) had at least one cardiovascular event during 112.943 person-years follow-up. The association of each SNP with event-free survival time was calculated with a Cox proportional hazard model. In CVD risk adjusted analysis, the lead SNP at the well-known 9p21 locus rs1333049 near CDKN2B-AS1 had a HR for CAD risk of 0.82 (95%CI 0.77–0.87; p-value 0.000945). None of the other tested CAD-associated SNPs were significantly associated with CAD risk (p > 8.9*10-5 for each).

Conclusions: Of all the loci analyzed, the 9p21 locus had the strongest negative association with CAD in this high-risk FH cohort. None of the SNPs at neither this 9p21 locus, however, nor any of the other tested CAD-associated SNPs were significantly associated with risk of CAD according to a priori defined significance threshold that took into account multiple testing.

Genetic sources of variation in proprotein convertase subtilisin/kexin type 9 (PCSK9), a protein that mediates degradation of LDL receptors and increases LDL levels. *E.A. Rosenthal[1], R. Rajagopalan[1], J. Ranchalis[1], D. Szeto[2], K. Akinsanya[2], T.P. Roddy[2], J.M. Castro-Perez[2], G. Forrest[2], G. Wolfbauer[3], J.J. Albers[3,6], J.D. Brunzell[4], A.G. Motulsky[1,5], M.J. Rieder[5], D.A. Nickerson[5], E.M. Wijsman[1,5,7], G.P. Jarvik[1,5].* 1) Dept Medical Genetics, Univ Washington School of Medicine, Seattle, WA; 2) Molecular Biomarkers Team, Merck & Co., Inc., Rahway, NJ; 3) Northwest Lipid Metabolism and Diabetes Research Laboratories, UW, Seattle, WA; 4) Div of Metabolism, Endocrinology, and Nutrition, Univ Washington School of Medicine, Seattle, WA; 5) Dept of Genome Sciences, Univ Washington School of Medicine, Seattle, WA; 6) Dept of Pathology, Univ Washington School of Medicine, Seattle, WA; 7) Dept of Biostatistics, Univ Washington School of Public Health, Seattle, WA.

High levels of LDL are associated with cardiovascular disease. Statin drugs are effective at reducing LDL by up-regulating LDL receptors (LDLR). However, this up-regulation is compromised by statin associated increases in proprotein convertase subtilisin/kexin type 9, PCSK9, a serine protease which mediates degradation of mature LDLR. Thus, statin use effects associated with increased PCSK9 protein level counters its effects on LDLR. To identify genetic regulation of PCSK9 protein levels, we searched for novel genetic variation associated with PCSK9 level, using four large families (n= 462), previously ascertained for familial combined hyperlipidemia. PCSK9 level was measured on 215 individuals using a sandwich-based antibody immunoassay. Genotypes on 330 individuals were measured on an average 5.4cM microsatellite marker map, as well as the Illumina 50K HumanCVD Beadchip. We detected linkage to chrs 1 and 20 in a single family (n=94; 42 phenotyped, 79 genotyped) using Bayesian oligogenic Markov chain Monte Carlo linkage analysis (maximum Bayes factor =47 and 88, respectively). The linkage signal at chr 1 is 3' to the structural locus, *PCSK9*, and is explained by *PCSK9* SNPs in a measured genotype analysis (including rs2495478, p<0.0001). Model based linkage analysis confirmed the linkage to chr 20 with lod=2.3, suggesting a potential genetic regulator of PCSK9 protein level in this region. To further clarify possible genes of interest under this signal, exome sequencing of 4 informative family members, based on their influence to the linkage signal at chr 20, is underway. Additionally, we found significant association of PCSK9 level with log transformed VLDL (p= 0.004) in all families, adjusting for family structure. This association with VLDL is a novel finding in humans that supports results from previous studies in mice.

Twenty-three unreported genetic associations with lipid phenotypes: a dense gene-centric meta-analysis in 66,240 individuals across 32 studies. *Y. Guo[1,2,11], F.W. Asselbergs[3,4,5,11], E.P.A. van Iperen[6,7,11], S. Sivapalaratnam[8,11], V. Tragante[3,5,11], C. Elbers[4,9], H. Hakonarson[1], B.J. Keating[1,12], F. Drenos[10,12], IBC-Lipids consortium.* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) BGI-Shenzhen, Shenzhen, China; 3) Department of Cardiology, Division Heart and Lungs, University Medical Center Utrecht, Utrecht, The Netherlands; 4) Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, The Netherlands; 5) Department of Medical Genetics, Biomedical Genetics, University Medical Center, Utrecht, The Netherlands; 6) Durrer Center for Cardiogenetic Research, Amsterdam, The Netherlands; 7) Department of Clinical Epidemiology, Biostatistics and Bioinformatics, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands; 8) Department of Vascular Medicine, Academic Medical Center, 1105 AZ Amsterdam, The Netherlands; 9) Complex Genetics Section, Department of Medical Genetics (DBG), University Medical Center Utrecht, Utrecht, the Netherlands; 10) Centre for Cardiovascular Genetics, Institute of Cardiovascular Science, Faculty of Population Health Sciences, University College London, 5 University Street, London WC1E 6JF, UK; 11) Equal contribution; 12) Joint corresponding authors.

Genome wide association studies (GWAS) have identified many single-nucleotide polymorphisms (SNPs) underlying variations in plasma lipid levels. We set out to explore whether additional loci associated with plasma lipid phenotypes, such as high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), total cholesterol (TC) and triglycerides (TG) can be identified by a dense gene-centric approach. Our meta-analysis of32 studies in 66,240 individuals of European ancestry was based on the custom ~50,000 SNP genotyping array covering ~2,000 candidate genes (the ITMAT-Broad-CARe (IBC) array). SNP-lipid associations were replicated in a cohort comprising an additional 24,736 samples or within the Global Lipid Genetic Consortium. We identified 4, 6, 10 and 4 new SNPs in established lipid genes for HDL-C, LDL-C, TC and TG respectively. We also identified several lipid-related SNPs in previously unreported genes: *DGAT2*, *GPR109A*, *L0C338328*, *PPARG*, and *FTO* for HDL-C; *SOCS3*, *APOH*, *SPTY2D1*, *BRCA2* and *VLDLR* for LDL-C; *SOCS3*, *UGT1A1*, *BRCA2*,*UBE3B*, *FCGR2A*, *CHUK*, and *INSIG2* for TC; and *SERP1NF2*, *C4B*, *GCK*, *GATA4*, *INSR* and *LPAL2* for TG. The proportion of phenotypic variance explained in the subset of studies providing individual-level data was 9.9% for HDL-C, 9.5% for LDL-C, 10.3% for TC and 8.0% for TG. This large meta-analysis of lipid phenotypes using a dense gene-centric approach identified multiple SNPs not previously described in established lipid genes and several previously unknown loci. The explained phenotypic variance using this approach was comparable to meta-analysis of GWAS data suggesting that a focused genotyping approach can further increase the understanding of heritability of plasma lipids.

Paré, Laboratoire de Biochimie et Génétique Moléculaire, Boulogne-Billancourt, France; 10) Université Versailles Saint-Quentin-en-Yvelines, UFR de Médecine Paris Ile-de-France Ouest, Guyancourt, France.

Autosomal Dominant Hypercholesterolemia (ADH) is characterized by high LDL levels, high risk of premature cardiovascular disease and is due to mutations in *LDLR*, *APOB* or *PCSK9* genes and the HCHOLA4 locus at 16q22.1. We found further genetic heterogeneity of ADH through a genomewide scan in a large multiplex French family with a new disease locus at 19q13.31–13.32. Whole exome sequencing for three affected family members combined with Sanger sequencing of regional and functional candidate gene were performed to identify this new ADH gene. An unique mutation in the *APOE* gene, p.Leu167del, that was not detected in over 440 control chromosomes, segregated with ADH within the French family.This finding was unexpected since apo E mutants are essentially associated with familial combined hyperlipidemia (FCHL). *APOE* p.Leu167del was not detected in over 440 French control chromosomes and two other *APOE* mutations (p.Arg235Trp, p.Arg269Gly) were found in three other unrelated ADH probands. In silico structural prediction of the mutant protein p.Leu167-del showed an alpha-helix disruption within the receptor-binding region that could affect apo E activity and its affinity to lipoproteins and/or its receptors. Two carriers of the *APOE* p.Leu167del presented with apo E levels that were normal in total serum but decreased in LDL, which could affect LDL affinity to their receptor. In vivo apo B-100 kinetics from one *APOE* p.Leu167-del carrier, showed: an increased LDL pool, which was the consequence of both an increase in LDL production rate and a decrease in LDL catabolism. These findings are in keeping with those from patients with a mutation in the *LDLR* gene. Together, these observations indicate a decreased catabolism of LDL-bearing an apo E p.Leu167del thus explaining the ADH observed for carriers of this deletion, and underscoring the hypothesis that some mutations in the *APOE* gene may be responsible of ADH and should be looked for. The *APOE* p.Leu167del mutation was associated with FCHL and, here, *bona fide* ADH. The overlapping between FCHL and ADH phenotypes was also reported for *LDLR* gene mutations. Hypertriglyceridemia can sometimes be observed in ADH subjects, mainly because of the many common genetic and environmental factors contributing to triglyceride elevation. Mutations in the *LDLR* or *APOE* gene may amplify the effect of these factors, and thus, according to the number and/or the nature of these factors, could be associated with either FCHL or ADH.

Genome-wide association studies (GWAS) have revealed ~100 loci associated with lipids, but much of the trait heritability remains unexplained. We conducted a trans-ethnic study in individuals of African American (n=6,832), East Asian (n=9,452), and European (n=10,829) ancestry to analyze high-density genotyped Metabochip SNPs at 18, 22 and 18 GWAS loci for their association with triglycerides, high-density lipoprotein cholesterol (HDL-C), and low-density lipoprotein cholesterol (LDL-C). We aimed to identify the variants with strongest association at each locus, identify allelic heterogeneity and population-specific signals, determine whether trans-ethnic high-density genotyping would refine association signals, and assess whether previously described functional variants exhibit the strongest association at those signals. Among the 58 loci, 33 exhibited evidence of association ($P<10^{-4}$) in at least one population. Stepwise conditional analyses revealed a total of 34, 9 and 21 signals at 10, 4 and 9 loci in African Americans, East Asians and Europeans, respectively. All these signals led to a 1.3- to 1.8-fold increase in the explained phenotypic variance compared to the strongest signals alone. The seven signals at *PCSK9* in African Americans include six nonsense or missense variants shown previously to have functional effects, and five of them are African American-specific. Among the seven signals at the *TOMM40-APOE-APOC4* cluster in African Americans, the trait-lowering allele (freq=0.18) of the fourth signal (rs157588) was present on haplotypes containing the trait-raising allele (freq=0.35) of the third signal (rs1038026); after accounting for linkage disequilibrium ($r^2=0.35$) with the third signal, the fourth signal increased in significance ($P_{initial}=0.72$; $P_{condition}=2.0\times10^{-7}$). Trans-ethnic analyses localized one signal at *GCKR* to a reported functional variant P446L, and narrowed other signals at *PPP1R3B* from >10 SNPs spanning 50 kb to two SNPs (rs6601299 and rs4841132; LD $r^2>0.94$) located 1 kb apart and at *LCAT* from >100 SNPs spanning 800 kb to four SNPs within a 50 kb region. Of the 27 SNPs reported previously to affect gene expression or protein function, 74–84% exhibited the strongest association at the respective signal. In summary, trans-ethnic high-density genotyping allows the identification of allelic heterogeneity and population-specific variants, and reveals candidate SNPs for functional studies.

Identification of a Major Genetic Modifier in Mouse Models of TGFβ Vasculopathies. *J. Calderon[1], H. Dietz[1,2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Howard Hughes Medical Institute.

Multiple presentations of aortic aneurysm associate with a tissue signature for high TGFβ signaling and/or phenotypic rescue in response to TGFβ antagonists. These include Marfan syndrome (MFS, mutations in FBN1), Loeys-Dietz syndrome (LDS, mutations in TGFBR1/2), and LDS-like disorders (mutations in SMAD3 or TGFB2). The fact that some mutations would intuitively lead to low TGFβ signaling has engendered controversy in the field. Many prior studies document that the C57Bl/6J (BL6) background exacerbates TGFβ deficiency phenotypes when compared to 129SvE (SV129), but the source of modification is unknown. SV129 mice heterozygous for a LDS-associated mutation in Tgfbr2 (G357W/+) show late postnatal death due to aortic dissection. When G357W was crossed onto the BL6 background, there is near-complete penetrance of perinatal death due to persistent truncus arteriosus (PTA), a form of congenital heart disease that has been extensively associated with loss of TGFβ signaling in the cardiac neural crest. A single cross of isogenic SV129 LDS mice with pure BL6 mice results in 70% incidence of PTA among G357W/+ offspring, suggesting a dominant BL6 deleterious modifier with dosage-dependent PTA. Pure SV129 G357W/+ mice were bred to F2 mice with extensive recombination between BL6 and SV129 chromosomes and late gestation fetuses were phenotyped for PTA by intravascular latex injection. A GWA analysis was performed using the Illumina Mouse Medium Density Linkage Panel to identify haplotype enrichment in PTA+ mutation carriers. Remarkably, this analysis yielded a single BL6 locus on distal chromosome 9 (LOD=9) that was responsible for deleterious modification. Notably, the rare BL6 LDS mice that escape perinatal mortality due to PTA show protection from postnatal aneurysm progression and dissection, when compared to their SV129 counterparts. These data suggest that LDS mutations have the potential to impose TGFβ deficiency phenotypes during development, but that postnatal aneurysm progression manifests a switch to a high signaling state. Parallel work in the lab has shown that BL6 mice harboring a Fbn1 mutation causing MFS are remarkably protected against postnatal aneurysm progression and dissection ($p<0.0001$), when compared to SV129; the role of the chromosome 9 locus is under investigation. Taken together, these data suggest that genetic variation that attenuates TGFβ signaling is sufficient to blunt aneurysm severity in multiple disorders.

Upregulation of Twist1 expression during acute myocardial infarction. *J.B. Nevado.* Institute of Human Genetics, University of the Philippines Manila, Manila, Metro Manila, Philippines.

Myocardial infarction (MI) is a major cause of mortality and morbidity worldwide. During acute myocardial infarction, a series of events leads to fibrosis, which, if excessive, may hinder effective remodeling. Twist1 is a transcriptional repressor that has been well implicated in tissue fibrosis, including cardiac fibrosis. Speculatively, the fibrosis occurs through collagen-producing epithelial-derived fibroblasts via epithelial to mesenchymal transition (EMT). Due to fibrotic sequelae after an acute myocardial infarction, I hypothesize that Twist1 is likely to be expressed in the injured tissues a few days after an event, possibly triggering EMT. We used a mouse model for myocardial infarction in which the left anterior descending artery was ligated. Mice were sacrificed at selected timepoints (0-, 3-, 7- and 10-day). Immunohistochemistry of myocardial samples showed increased expression of Twist1 in the periinfarct region at day 3 with tapering at day 7, and eventual loss of expression at day 10. Comparatively, uninjured heart samples, Day 0 samples and remotely located non-injured tissues did not show significantly expression of Twist1. These results suggest that Twist1 is acutely expressed after myocardial infarction, and can be considered as a candidate molecular trigger of post-MI cardiac fibrosis.

Venous malformation-causing TIE2-mutations lead to AKT-mediated downregulation of PDGFB. *M. Uebelhoer[1], M. Nätynki[2], J. Kangas[2], J. Soblet[1], A. Mendola[1], C. Godfraind[3], L.M. Boon[1, 4], L. Eklund[2], N. Limaye[1], M. Vikkula[1, 5].* 1) Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 2) Oulu Center for Cell-Matrix Research, Biocenter Oulu and Department of Medical Biochemistry and Molecular Biology, University of Oulu, Oulu, Finland; 3) Neuroscience Center, Laboratory of Neuropathology, Université catholique de Louvain, Brussels, Belgium; 4) Center for Vascular Anomalies, Division of Plastic Surgery, Cliniques universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 5) Center of Human Genetics, Cliniques universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium.

Mutations in the endothelial-cell tyrosine kinase receptor TIE2 cause inherited and sporadic forms of venous malformation. The most recurrent somatic mutation, L914F, and the common germline mutation, R849W, have been shown to differ in terms of phosphorylation-level, as well as sub-cellular localization and trafficking of the receptor. We now show that PI3K/AKT and STAT1 are chronically activated by both mutant forms, with L914F exerting a stronger effect. Gene expression profiling of HUVECs overexpressing the mutant or wild-type forms of TIE2 indicates that L914F strongly dysregulates genes involved in vascular development and cell migration, while R849W has weak effects, making it indistinguishable from wild-type cells in global analyses. Interestingly, we show for the first time that VM-causative mutations inhibit the transcription factor FOXO1 in an AKT-dependent manner, resulting in deficient PDGFB-production. Lack of this mural cell attractant might explain the paucity of smooth muscle cells surrounding distended vascular channels in venous malformations.

1612T

Islet1 is a direct transcriptional target of the homeodomain transcription factor Shox2 in the sinoatrial node of the developing heart. *G.A. Rappold[1], I.M. Berger[2], A. Glaser[1], C. Bacon[1], L. Li[3], K.U. Schneider[1], N. Gretz[3], H. Steinbeisser[1], W. Rottbauer[2], S. Just[2], S. Hoffmann[1].* 1) Institute of Human Genetics, IUniversity of Heidelberg, NF 366, 69120 Heidelberg, Germany; 2) Department of Intermal Medicine II, University of Ulm, Albert-Einstein-Allee 23, 89081 Ulm, Germany; 3) Medical Research Center, University of Heidelberg, Theodor-Kutzer-Ufer 1-3, 68167 Mannheim, Germany.

The heart's rhythm is initiated and regulated by a group of specialized cells in the sinoatrial node (SAN), the primary pacemaker of the heart. Abnormalities in the development of the SAN can result in irregular heart rates (arrhythmias). Although several of the critical genes important for SAN formation have been identified, our understanding of the transcriptional network controlling SAN development remains at a relatively early stage. The LIM homeodomain transcription factor Islet1 (Isl1) represents a prominent marker for cardiac progenitor cells of the second heart field and has been proposed, very similar to Shox2, to play an essential early role in the specification and patterning of the SAN. Here, we compared gene expression levels in the right atria of wildtype and *Shox2*$^{-/-}$ hearts using microarray experiments and identified *Isl1* as one of its putative target genes. The downregulation of *Isl1* expression in *Shox2*$^{-/-}$ hearts was confirmed and the affected region narrowed down to the SAN by whole mount *in situ* hybridization. Using luciferase reporter assays and EMSA studies, we identified two specific SHOX2 binding sites within intron 2 of the *ISL1* locus. We also provide functional evidence for *Isl1* as a transcriptional target of *Shox2* by rescuing the Shox2-mediated bradycardia phenotype with *Isl1* using zebrafish as a model system. Our findings demonstrate a novel epistatic relationship between *Shox2* and *Isl1* in the heart with important developmental consequences for SAN formation and heart beat.

1613T

Analysis of sub-category for 141 cases of congenital heat disease (CHD) that have been surgically corrected during neonatal period. *Q-Y. Cao[1], J-Z. Zhu[2], N. Zhong[1,3,4].* 1) Shijiazhuan Maternal Hospital, Shijiazhuan, Hebei, China; 2) Hebei Provincial Hospital, Shijiazhuan, Hebei, China; 3) Peking University Center of Medial Genetics, Beijing, China; 4) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Congenital heart disease (CHD) is a leading condition in China as the most common visible birth defect national wide. It is also the one that could be surgically corrected right after the baby is born. Currently most of CHD is recognizable by the prenatal ultrasound and the family is prepared to have the baby gone through the surgical correction. Here we have analyzed the sub-category on 141 cases of CHD that have been surgically corrected in our local hospitals. Surgical correction was performed through a National Intervention Program for Saving the Babies with CHD. Surgical records were accessed through our provincial birth defect surveillance system or through hospital documents. The most common CHD among our patients is ventricular septal defect (VSD), which accounts for 55%. The order of sub-category of VSD is VSD without other anomaly (19.9%), VSD with patent foramen ovale (7.8%) and VSD with pulmonary hypertension (7.8%), VSD with atrial septal defect (ASD, 5.2%), and other VSD with variant complicated anomalies. Tetralogy of fallot listed as the second most common CHD (17.7%). The tetralogy of fallot usually is more complicated than expected. The atrial septal defect (ASD, 11.4%) accounts for the third common CHD among the 141 cases, within which the ASD with pulmonary hypertension (4.8%) is more than ASD with pulmonary valve stenosis (1.4%) and ASD alone (0.7%). The less common CHD are patent ductus arteriosus (PDA, 9.2%), pulmonary valve stenosis (PVS, 1.4%) and complete endocardial cushion defect partial endocardial cushion defect (0.7%), aortic regurgitation with stenosis (0.7%), main artery of ectopic (0.7%) and complicated heart anomilies (0.7%). Our data has provided information about the frequency of sub-category of CHD among Chinese patients that may help clinical genetic cousuling.

1614T

Analysis of cardiomyopathy using whole genome sequencing. *E.M. McNally[1], J.R. Golbus[1], L.L. Pesce[2], D. Wolfgeher[1], L. Dellefave-Castillo[1], M.J. Puckelwartz[1].* 1) Med, Sect Cardiology, Rm G611, Univ Chicago, Chicago, IL; 2) Computation Institute, Univ Chicago, Chicago.

Background: Congestive heart failure (CHF) is a disabling and costly medical problem that currently affects more than 5 million Americans. One of the leading causes of CHF is cardiomyopathy, a disorder with a high heritable component. There are few clinical clues to guide genetic diagnosis, and therefore genetic testing for familial cardiomyopathy may survey as many as 46 responsible genes. Recently the large TTN gene, which comprises 350 exons, was identified as being the cause of nearly 25% of dilated cardiomyopathy. Even with the inclusion of the TTN gene in gene panels for cardiomyopathy, the sensitivity of testing for dilated cardiomyopathy (DCM) is less than 50%. Because of the large number of genes required to diagnosis genetic cardiomyopathy and the improvement in high throughput sequencing approaches, we piloted whole genome sequencing for 11 subjects with dilated cardiomyopathy. Methods: WGS was performed to achieve an average of 35 fold coverage using paired end 100 bp reads. We focused our analysis on 212 genes linked to both syndromic and nonsyndromic cardiomyopathy as well as genes identified from animal modeling. Variants within these genes were analyzed using a pipeline that combined multiple prediction algorithms along with frequency data from the 1000Genomes project and the NHLBI Exome Sequencing Project. This pipeline yielded 3–15 potentially pathogenic variants per individual. Variants were confirmed in the proband using traditional Sanger sequencing and then sequenced in family members, where available, for confirmation by segregation. Results: Three subjects of 11 in dilated cardiomyopathy cohort had known primary mutations, and these three mutations were detected by the analysis pipeline. In five of eight subjects for whom the primary mutation was unknown, we identified mutations that either segregated with disease, had clinical correlates and/or additional pathological correlation to provide evidence as to causality. For at least two subjects, we identified additional variants that may be acting as modifiers to influence the severity of disease. In total, we identified the likely pathological mutation in 8 of 11 (73%). Conclusion: Cardiomyopathy is a genetically heterogeneous disease that lends itself to analysis by WGS. WGS can be used to identify clinically relevant variants of both therapeutic and prognostic importance.

THE ASSOCIATION BETWEEN NOS3 GENE VARIATIONS AND BRUGADA SYNDROME. *S. Mehrtashfar[1], A. Ebrahimi[2], M. Moghadam[2], A.S. Khatir[3].* 1) Biology Dept, Guilan University, Guilan, Iran; 2) Faculty of Medicine, Shiraz University of Medical Sciences, Shiraz, Iran; 3) Sasan Hospital, Tehran, Iran.

The brugada syndrome is the main cause of sudden unexplained death syndrome (SUDS) and suffering people have an abnormal electrocardiogram (ECG) with increased risk of sudden cardiac death without cardiac background. One of the most important genes involved in cardiac disease is nitric oxide synthase 3 (NOS3) gene which its product synthesize nitric oxide from L-Arginine. Nitric oxide plays a role as a mediator in several processes such as neurotransmission that failure in this process can be a reason of heart arrhythmia. We studied two variations with more clinical significance in cardiac disease (T786C and G894T) in 25 patients with brugada syndrome and 60 people with normal ECG as control group. These variations were studied by RFLP (T786C) and ARMS PCR (G894T) methods on extracted DNA from peripheral blood cells. Results showed T allele in G894T variation in patient group was significantly higher than control group ($p<0.5$), but there was no difference in T786C variation between patients and normal people. This study introduced G894T variations as a potential marker of brugada syndrome.

1616T

Targeted sequence capture and 454 sequencing of 23 cardiomyopathy genes; implementation into diagnostics. *O. Mook[1], M. Haagmans[1], R. Lekanne Deprez[1], F. Baas[2], M. Jakobs[2], N. Hofman[1], I. Christiaans[1], M. Mannens[1].* 1) Clinical Genetics, Academic Medical Center, Amsterdam, Amsterdam, Netherlands; 2) Dept of Genome Analysis, AMC, Amsterdam, the Netherlands.

Background—Genetic evaluation of cardiomyopathies poses a challenge. Multiple genes are involved but no clear genotype-phenotype correlation has been found so far. In the past, genetic evaluation for hypertrophic (HCM) and dilated (DCM) cardiomyopathies was performed by sequential dHPLC screening followed by Sanger sequencing of a very limited number of genes. Recent developments in sequencing has increased the throughput enabling simultaneous screening of multiple genes for multiple patients in a single sequencing run. Methods and Results—In order to increase the number of genes that can be screened in a shorter time period, we enriched all exons of 23 cardiomyopathy related genes using on-array multiplexed sequence capture followed by massively parallel pyrosequencing. We show that after optimization of array based sequence capture it is feasible to reliably detect a large panel of known and unknown variants in HCM and DCM patients, whereby the unknown variants could be confirmed by Sanger sequencing. Conclusions—The rate of variant detection in both HCM and DCM patients was increased due to a larger number of genes studied. Array based target enrichment followed by Next Generation Sequencing (NGS) is ready for implementation in diagnostics.

1617T

Targeted next generation sequencing of thoracic aortic aneurysmal genes. *L. Van Laer[1], D. Proost[1], G. Vandeweyer[1], J. Saenen[2], B. Paelinck[2], C. Vrints[2], B. Loeys[1].* 1) Center of Medical Genetics, Faculty of Medicine and Health Sciences, University of Antwerp and Antwerp University Hospital, Antwerp, Belgium; 2) Department of Cardiology, Faculty of Medicine and Health Sciences, University of Antwerp and Antwerp University Hospital, Antwerp, Belgium.

Aortic aneurysm/dissection represents an important cause of death in the industrialized world. The genetic contribution to thoracic aortic aneurysm (TAA) is significant; 20% of all affected individuals have a positive family history. The latter figure is likely to be underestimated, because many family members may not be aware of the presence of an aneurysm. TAA is genetically heterogeneous; more than ten causative genes have been identified so far. As a considerable clinical overlap exists between different types of TAA caused by mutations in different genes on the one hand, and as mutations in the same gene cause a wide phenotypic variability on the other hand, a clinical diagnosis is not always straightforward and the molecular confirmation of the clinical diagnosis is important for further patient management and therapy. However, the consecutive molecular screening of all TAA genes using conventional methods is expensive and labor-intensive. To shorten the turn-around-time, to increase the informativeness (i.e. identification of modifying variants) and to reduce the overall cost of molecular testing, we are developing a TAA gene panel for next generation sequencing of twelve TAA genes (*ACTA2*, *COL3A1*, *FBLN4*, *FBN1*, *FLNA*, *MYH11*, *MYLK*, *NOTCH1*, *SMAD3*, *TGFBR1*, *TGFBR2* and *SLC2A10*). We have opted for an innovative and simple enrichment method that does not require expensive, dedicated machinery: the Haloplex technology, which makes use of dual hybridization recognition. The complexity and the required hands-on time of sample preparation are significantly reduced through the addition of the sample identification barcodes and sequencing primers during the enrichment procedure. We have designed probes for a total of 320 exons (including intron/exon boundaries) or a total target size of approximately 62 kb using the Halo Design Wizard complemented with manual adjustments. We have obtained an overall coverage by design of 99.7%. We have performed three separate 2x 150 bp paired-end runs on a Miseq sequencer, analyzing both samples with known and with unknown genetic defects. We have achieved an overall sequencing coverage of 0.2x the average read depth for 95% of the regions. We are currently optimizing the filter settings for the analysis of the variant lists in order to reach a maximum sensitivity and specificity.

1618T

The use of next generation sequencing in clinical diagnostics of familial hypercholesterolaemia. *J. Vandrovcova[1], E. Thomas[1], S. Atanur[1], P. Norsworthy[1], C. Neuwirth[2], Y. Tan[2], L. Game[2], A. Soutar[2], T. Aitman[1], Generation Scotland.* 1) Physiological Genomics and Medicine Group, MRC Clinical Sciences Centre, Imperial College London, UK; 2) MRC Clinical Sciences Centre, Imperial College London, UK.

Familial hypercholesterolaemia (FH) is a common autosomal dominant condition that is associated with increased risk of early coronary heart disease. Treatment with statins is highly effective and the identification of affected individuals is therefore crucial. Currently only about 20% of FH patients are identified in the general population in England partly because of insufficient availability of molecular testing. The purpose of this study is to determine the sensitivity and specificity of amplicon library generation and massively parallel sequencing for the identification of causal mutations, and to investigate the potential for wider population molecular testing. In pilot studies, 23 DNA samples from patients with known mutations and 24 negative samples were screened using the Fluidigm Access Array. Amplicons were designed to cover the whole LDLR gene and mutation hot spots in PCSK9 and APOB genes. After amplification and barcoding reactions, samples were pooled and sequenced using the MiSeq platform. Data were processed using common bioinformatics tools including GATK and compared to variant calls produced by MiSeq Reporter. In addition, 100 patients referred to a local lipid clinic and 400 individuals from a population cohort were included in the study. Large insertions and deletions were screened using MLPA. All amplicons were successfully amplified and > 99% of reads mapped to target regions. In the confirmatory part of the study all 20 known point mutations (17 in LDLR, 1 pY374 in PCSK9 and 2 pQ3527 in APOB) as well as 3 short indels in LDLR were correctly identified with both GATK and MiSeq Reporter. No false positives were reported when using GATK. Several new diagnoses were made in patients included in the prospective part of the study with causative variants being detected in 20–40% of patients depending on clinical phenotype. Population cohort results from 400 patients are in progress and will be presented. The established protocol is fast, with a current turnaround including data analysis of less than a week for 48 patients, and highly accurate. We believe that in combination with MLPA it represents an alternative cost-effective high-throughput method for sequencing known FH genes that could open up molecular testing and subsequent treatment to broader populations. Moreover our results suggest that similar assays targeting other common diseases with Mendelian subtypes may be warranted with this approach.

Targeted next generation sequencing as a diagnostic test in patients with cardiomyopathies. *Y.J. Vos[1], B. Sikkema-Raddatz[1], L.F. Johansson[1], E.N. de Boer[1], L.G. Boven[1], K.Y. van Spaendonck-Zwarts[1], M.P. van den Berg[2], J.P. van Tintelen[1], J.D.H. Jongbloed[1], R.J. Sinke[1].* 1) Department of Genetics, University Medical Centre Groningen, Groningen, the Netherlands; 2) Department of Cardiology, University Medical Centre Groningen, Groningen, the Netherlands.

Introduction Next generation sequencing techniques offer novel possibilities to analyse large numbers of genes in parallel. Exome sequencing (ES) can be used to sequence the coding regions of the genome. To date, ES is not developed to a level at which it provides a reliable substitute for Sanger sequencing. Both incomplete representation and coverage of some exons would certainly result in missing clinically relevant mutations. Targeted enrichment circumvents this shortcoming by selecting only those genes involved in a particular disease. We developed a kit based on Agilent Sure Select Target Enrichment for mutation detection in 48 genes that were previously proven to be involved in hereditary cardiomyopathies.

Methods For validation purposes, two series of twelve patients were analysed applying this kit and Sanger sequencing for up to six genes. Moreover, several additional series of twelve patients were analysed. Sample preparations were performed according to the manufacturer's protocol. All samples were sequenced using 151 bp paired-end reads on an Illumina MiSeq sequencer and analysed using the MiSeq Reporter pipeline and/or Next gene software.

Results The average coverage in subsequent runs varied between 170 to 250 reads and only 1.5% of the targets showed a coverage <30 reads in more than one of twelve patients within a single run. All pathogenic mutations, Unclassified Variants (UV's) and single nucleotide polymorphisms previously detected by Sanger sequencing were identified. Furthermore all novel variants (not listed in db-SNP or 1000 genome databases) that were analysed so far could be confirmed by Sanger sequencing. Our analyses resulted on average in the identification of three mutations/UV's per patient. In a significant number of patients that previously were analysed without a disease causing mutation, a (potential) pathogenic mutation was identified. *In silico* analyses, confirmation experiments by Sanger sequencing and co-segregation analyses are performed to identify the causal mutation in each patient/family.

Conclusion Our data convincingly demonstrates that targeted resequencing of a disease specific subset of genes can reliably substitute Sanger sequencing as a diagnostic test.

1620T

Population Sampling and *in vitro* Modeling of a 25bp Deletion in MYBPC3 Associated With Hypertrophic Cardiomyopathy. *A.B. Chowdry[1], M.A. Mandegar[2], G.M. Benton[1], B.T. Naughton[1], B.R. Conklin[2].* 1) 23andMe Inc., Mountain View, CA; 2) The Gladstone Institute of Cardiovascular Disease, San Francisco, CA.

Hypertrophic cardiomyopathy (HCM) is the leading cause of sudden cardiac death (SCD) in young athletes. The prevalence of HCM has been estimated to be as high as 1 in 500 within the general population. However, due to cost and sensitivity problems, it is not screened for in the United States.

The majority of mutations leading to HCM have been identified in sarcomeric proteins, mainly the cardiac isoform of myosin-binding protein C (MYBPC3). Advances in DNA analysis could allow low-cost screening for high penetrance mutations in MYBPC3 and could inform selective echocardiograms. Of particular interest is a recently discovered 25bp deletion (rs36212066), known to have a high carrier frequency in South Asians, but previously unobserved in European populations.

23andMe has a database of over 150,000 genotyped individuals. This database contains over 160 carriers of the rs36212066 deletion, some of European ancestry, suggesting that this mutation has a broader distribution than initially reported. We are also able to observe homozygotes in the database, though at a reduced frequency consistent with previous studies. The large size of the 23andMe database uniquely positioned it to detect these individuals. We have performed an initial survey of these individuals to determine self-reported HCM status, but further follow up may be necessary.

While in vitro models of HCM have been created in human induced pluripotent stem (iPS) cells, none have been made so far for MYBPC3. We are using Transcription Activator-Like Effector Nuclease (TALEN)-directed homologous recombination to make an allelic series of MYBPC3 mutations in a common genetic background, including a heterozygous knockout. We are also engineering a FLAG epitope tag to reveal key binding partners of the of the ancestral and mutant forms of MYBPC3 via immunoprecipitation from iPS-derived cardiac myocytes.

Our work on the in vitro cellular phenotypes of iPS cells carrying this mutation can eventually be extended to population phenotyping using the 23andMe database. These studies will help explain the pathology and incomplete penetrance of rs36212066 and may provide targets for pharmaceutical therapy.

1621T

Co-localization of lipid biomarker associations with gene expression across human tissues. *C. Giambartolomei[1], H-J. Westra[2], M. Kivimaki[3], M. Kumari[3], E. Schadt[4], L. Franke[2], A. Hingorani[3], V. Plagnol[1].* 1) University College London (UCL) Genetics Institute, London, United Kingdom; 2) University Medical Centre, Groningen, Netherlands; 3) University College London (UCL) Department of Epidemiology and Public Health, London, United Kingdom; 4) Mount Sinai School of Medicine, New York, USA.

The genome-wide association study design has provided many new insights into the genetic basis of cardiovascular disease and associated biomarkers, in particular lipid traits. As the majority of these genetic findings map to regulatory rather than coding regions, the next step to understand the molecular basis of these associations is to assess the genes that are regulated by associated genetic variants. To achieve this goal, we combined two expression datasets (in liver, n = 966 samples and blood, n = 1,550 samples) with the Whitehall II cohort, a large scale prospective study with deep phenotyping for multiple lipid and disease traits. We also developed a novel statistical methodology to assess the concordance between disease and expression traits. We find that a large fraction of disease/biomarker associations are consistent with causal variant shared with an expression quantitative trait locus. Our findings provide information about the causal gene in associated intervals and have direct implications for the understanding of cardiovascular traits as well as the design of drugs to target disease pathways.

Silencing of Atp2b1 increases blood pressure through vasoconstriction. *B. Oh[1], Y-B. Shin[1], S-M. Ji[1], S-Y. Park[1], H-J. Lee[1], K-W. Hong[1], J-E. lim[1], M. Lim[2], Y-H. Lee[2].* 1) Biomedical Engineering, Sch Med, Kyung Hee Univ, Seoul, South Korea; 2) Department of Physiology, College of Medicine, Yonsei University, Seoul, South Korea.

Recent GWASs have identified 20 genetic loci that regulate blood pressure, increasing our understanding of the etiology of hypertension. However, it has been difficult to define the causative genes at these loci due to a lack of functional analyses. In this study, we aimed to validate the candidate gene ATP2B1 in 12q21, variants near which have the strongest association with blood pressure in Asians and Europeans. ATP2B1 functions as a calcium pump to fine-tune calcium concentrations—necessary for repolarization following muscular contractions. We silenced Atp2b1 using an siRNA complex, injected into mouse tail veins. In treated mice, blood pressure rose and the mesenteric arteries increased in wall:lumen ratio. Moreover, the arteries showed enhanced myogenic responses to pressure, and contractile responses to phenylephrine increased compared with the control, suggesting that blood pressure is regulated by ATP2B1 through the contraction and dilation of the vessel, likely by controlling calcium concentrations in the resting state. These results support that ATP2B1 is the causative gene in the blood pressure-associated 12q21 locus and demonstrate that ATP2B1 expression in the vessel influences blood pressure.

Metabolic imprints of genetically elevated body mass index in young adults. *P. Würtz[1,2], A.J. Kangas[2], P. Soininen[2], O. Raitakari[3], T. Lehtimäki[4], MR. Järvelin[5], M. Ala-Korpela[2,5], S. Ripatti[1].* 1) Institute for Molecular Medicine, University of Helsinki, Helsinki, UH, Finland; 2) Computational Medicine, University of Oulu, Finland; 3) Cardiovascular Research Center, University of Turku, Finland; 4) Clinical Chemistry, University of Tampere, Finland; 5) Epidemiology and Biostatistics, Imperial College London, United Kingdom.

Genetically elevated body mass index has been linked with the risk for future cardiovascular disease, yet it remains incompletely understood how this association is mediated. To address the impact of obesity-related loci on the systemic metabolic profile we tested associations of a genetic risk score composed of 32 previously identified variants with established cardiovascular risk factors and the serum metabolome profile in 6,774 young adults (mean age 31 ± 3 years) from two population-based cohorts in Finland. The genetic risk score was associated with increased body mass index ($P = 1\times10^{-30}$) in these young adults and had residual effects on blood pressure, insulin resistance index and low-grade inflammation as well as increased levels of liver enzymes in the circulation ($P < 0.0005$). Genetically elevated BMI was also associated with an adverse lipoprotein subclass profile characterized by elevated VLDL and decreased large HDL lipid levels while effects on LDL levels were only significant in women. The strongest metabolite abnormalities caused by the obesity-related genetic variants were found for circulating concentrations of branched-chain and aromatic amino acids. These amino acids have recently been associated with the risk for development of type 2 diabetes and our findings suggest that obesity is directly contributing to mediate this associations already in early adulthood. In conclusion, our results in apparently healthy young adults suggest that increased body mass index due to common genetic variants has a diverse impact on the global metabolite profile and that the association of body mass index with the risk for future heart disease is at least partly transmitted through established cardiovascular risk factors. These findings assist to elucidate the role of novel genetic loci for body mass index as well as emphasize risk factor monitoring in individuals genetically susceptible to obesity.

1624T

Mendelian randomisation studies do not support a causal effect of plasma lipids on insulin sensitivity. *T. Fall[1], W. Xie[2], K. Hao[3], J. Ärnlöv[4,5], F. Abbasi[6], E.E. Schadt[3], G. Background: Elevated plasma concentrations of triglycerides (TG) coupled with decreased concentrations of high-density lipoprotein cholesterol (HDL-C), are associated with decreased insulin sensitivity and type 2 diabetes. However, previous studies have provided conflicting evidence of whether these associations are causal or not. ***Objective***: We aimed to test the hypothesis that genetically-determined changes of TG, HDL-C, and low-density lipoprotein cholesterol (LDL-C) concentrations influence insulin sensitivity using a Mendelian randomisation approach. ***Research Design and Methods***: We meta-analysed four studies comprising 2,590 European non-diabetic individuals with available TG, HDL-C, LDL-C and gold-standard based measures of insulin sensitivity (through either euglycaemic-hyperinsulinaemic clamp or insulin-suppression measurements). For each lipid trait, we created individual genetic risk allele scores weighted on known effect sizes. We used these genetic risk scores to test the causal associations between lipid traits and insulin sensitivity using instrumental variable statistics. ***Results***: We observed strong associations of the genetic risk scores for TG, HDL-C, and LDL-C with the respective circulating lipid concentrations (all *P-values*$<10^{-29}$). Lipids were strongly associated with insulin sensitivity in standard linear regression (all *P-values*$<10^{-6}$). However, there was no evidence of a genetically-determined effect of the different lipids on insulin sensitivity. The estimated causal (genetically-determined) effect sizes of lipids on insulin sensitivity were close to null and, for TG and HDL-C, different to the effects observed in standard linear regression models (TG, $P_{difference} = 3.6\times10^{-5}$; HDL-C, $P_{difference} = 1.4\times10^{-4}$). ***Conclusion***: Our results provide evidence that dyslipidemia in non-diabetic subjects is not a cause of decreased insulin sensitivity.

Dissecting the genetic architecture of coronary artery disease by genome engineering. *D.J. Segal[1], M.S. Bhakta[1], K. ThevaDas[1], C. Sun[2], N.M. Grace[3], J.A. Nolta[3], A.A. Knowlton[4], D.M. Rocke[5].* 1) Genome Ctr & Biochem & Molec Med, Univ California, Davis, Davis, CA; 2) Biomedical Engineering, Univ California, Davis, Davis, CA; 3) Institute for Regenerative Cures, Univ California, Davis, Davis, CA; 4) Internal Medicine, Univ California, Davis, Davis, CA; 5) Public Health, Univ California, Davis, Davis, CA.

One of the greatest challenges facing biomedical research since the sequencing of the human genome has been to understand the role of genetic variation in human disease. Many genetic variants have been associated with common diseases. However, determining the functional consequences of these variants has been hard. Several variants are often inherited together in tightly linked blocks, making it difficult to determine which is the causative variant. People have millions of other genetic differences, making it difficult to correlate cellular phenotypes with a particular variant. Different gene sets are expressed in different cells, but it is difficult to extract disease-relevant cells from large numbers of patients. We describe a method with the potential to revolutionize the functional analysis of genetic variation, using custom nucleases to genetically modify individual variants in induced pluripotent stem cells. This process would provide unprecedented analytical power, present the first general method to determine if a variant is causative, and analyze function disease-relevant cell types. We will focus on variants at the 9p21 region of the genome that have been associated with coronary artery disease (CAD). The methods should provide a new way to unlock the wealth of data from genome wide association studies, and to probe the genetic architecture of common diseases. We will describe our improved methods for inexpensive and rapid construction of highly-active zinc finger and TALE nucleases to examine the functional role of polymorphisms at the 9p21 CAD risk locus.

Davey-Smith[1,2].* 1) MRC Centre for Causal Analyses and Translational Epidemiology, University of Bristol, Bristol, UK; 2) Department of Social and Community Medicine, University of Bristol, Bristol, UK; 3) MRC Epidemiology Unit, Institute of Metabolic Science, Addenbrooke's Hospital, Cambridge, UK; 4) Division of Community and Health Sciences, St George's University of London, London, UK; 5) Robertson Centre for Biostatistics, University of Glasgow, Glasgow, UK; 6) British Heart Foundation Glasgow Cardiovascular Research Centre, Faculty of Medicine, University of Glasgow, Glasgow, UK; 7) Department of Primary Care & Population Health, University College London, London, UK; 8) London School of Hygiene and Tropical Medicine, London, UK; 9) General Practice and Primary Care, Division of Community Based Sciences, University of Glasgow, Glasgow, UK; 10) University College London, London, UK; 11) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD, USA.

Observational studies show that ascorbic acid is negatively associated with blood pressure (BP). However, these studies are susceptible to confounding, bias and reverse causation. The application of Mendelian randomization (MR) using genetic variants has proved helpful in determining causal pathways of modifiable risk factors and disease related outcomes. Genetic variants in the SLC23A1 locus, encoding the sodium-dependent ascorbic acid transporter-1, have been identified and are associated with ascorbic acid. Work here aimed to assess the association between ascorbic acid and BP using SLC23A1 SNP (rs6596473) and SLC23A1 SNP (rs33972313) as instruments for ascorbic acid in 4 independent cohorts. Initial analyses were completed in the British Women's Heart and Health Study (BWHHS, n=4286) with replication in the British Regional Heart Study (n=3945), MIDSPAN (n=1477) and Ten Towns (n=1531) studies. In BWHHS, per-allele variation in rs6596473 and rs33972313 was associated with 2.69μmol/L increase (95%CI:1.22,4.16;P=0.0003) and 3.83μmol/L reduction (95%CI:-7.50,-0.17;P=0.04) in ascorbic acid respectively. Per-allele effect of rs6596473 and rs33972313 on ascorbic acid was 1.26μmol/L (95%CI:-0.23,2.74;P=0.1) and -3.99μmol/L (95%CI:-5.95,-2.03;P<0.0001) respectively, across all studies. In BWHHS, observational analysis showed that systolic BP (SBP) decreased by 0.76mmHg (95%CI:-1.47,-0.06;P=0.03) and diastolic BP (DBP) decreased by 0.08mmHg (95%CI:-0.42,0.26;P=0.64) per quartile increase in ascorbic acid. Meta analysis showed that per quartile increase in ascorbic acid was associated with -0.63mmHg (95%CI:-0.94,-0.32;P<0.0001) SBP and -0.37mmHg (95%CI:-0.84,0.09;P=0.11) DBP. Adjusting for confounders had little effect (pooled associations: -0.66mmHg SBP (95%CI:-1.05,-0.26;P=0.001) and -0.35mmHg DBP (95%CI:-0.80,0.09;P=0.12)). Instrumental variable analysis in BWHHS using a score of ascorbic acid increasing variants from both SNPs showed no evidence of increasing ascorbic acid causing a decrease in BP (2.36mmHg SBP (95%CI:-11.13,15.84;P=0.73) and 3.85mmHg DBP (95%CI:-2.96,10.67;P=0.27)). Here, MR gave evidence against the negative causal association between ascorbic acid and BP, suggesting that supplementation use may not improve BP. Due to weak instrument bias (F-statistic=10.21), further work with larger sample sizes using variants with greater per-allele effect is needed to understand the causal pathways underlying associations between ascorbic acid and BP.

1627T

Identification of a regulatory variant that binds C/EBPβ at the *GALNT2* human high-density lipoprotein cholesterol locus. *T.S. Roman[1], M.P. Fogarty[1], S. Vadlamudi[1], A.F. Marvelle[1], K.J. Gaulton[1], A.J. Gonzalez[1], Y. Li[1,2], K.L. Mohlke[1].* 1) Genetics, Univ North Carolina, Chapel Hill, Chapel Hill, NC; 2) Biostatistics, Univ North Carolina, Chapel Hill, Chapel Hill, NC.

Genome-wide association studies have identified numerous loci associated with blood lipid and cholesterol levels; however, many of the molecular and biological mechanisms underlying these association signals remain unknown. Common variants (MAF >5%) within intron 1 of *GALNT2* (encoding an N-acetylgalactosaminyltransferase) were found to be associated with HDL-C level. We sought to identify the molecular mechanism and functional variants underlying the association signal. 23 variants exhibit strong linkage disequilibrium (r^2>.8) with an HDL-C-associated SNP, and 16 of them overlap open chromatin, active histone modifications, and/or transcription factor ChIP-seq peaks. To examine the correlation of *GALNT2* HDL-C-associated variants with *GALNT2* expression, we measured allelic expression in hepatocyte RNA from 36 individuals heterozygous for an HDL-C-associated SNP. The HDL-C-increasing alleles were associated with a 7% increase in *GALNT2* intron RNA expression (P= 5.4×10^{-7}). The direction of expression effect is consistent with other *GALNT2* expression QTLs in human liver and carotid plaque. To determine which of the 23 variants play a regulatory role in *GALNT2* expression, we tested all of them in transcriptional reporter assays in HepG2 cells. A 3-variant haplotype of rs4846913, rs2144300, and rs6143660 and one additional SNP, rs2281721, showed allele-specific enhancer activity. Through site-directed mutagenesis, we found that at least two of the SNPs in the haplotype, rs4846913 and rs2144300, contribute to increased transcription. We assessed whether differential transcription factor binding influenced the allele-specific transcriptional activity. In EMSAs, the HDL-C-increasing allele of rs4846913 showed increased C/EBPβ binding. We confirmed differential binding of C/EBPβ to rs4846913 *in vivo* using allele-specific ChIP in HepG2 and Huh-7 cells. These data are consistent in terms of direction of effect; the HDL-C-increasing alleles, one of which binds C/EBPβ, are associated with increased *GALNT2* intron RNA expression and transcriptional activity. These data identify rs4846913 as a likely functional variant and provide evidence of a molecular mechanism at *GALNT2*. The data are inconsistent with the direction of effect on HDL-C level exhibited by a rare loss-of-function human variant and altered *Galnt2* liver expression in mice. Further work is needed to elucidate the mechanisms by which the *GALNT2* GWAS variants influence HDL-C level.

1628T

Maternally transmitted coronary heart disease is associated with the mitochondrial tRNAThr 15927G>A mutation. *M.X. Guan.* Genetics, Zhejiang University, Hangzhou, Zhejiang, China.

Mitochondrial DNA (mtDNA) mutations are associated with a wide spectrum of human diseases. However, the role of mitochondrial dysfunction in coronary heart disease (CHD) remains poorly understood. In this report, thirty six subjects from a Chinese family with maternally inherited (CHD) underwent clinical, genetic, molecular and biochemical evaluations. Nine of 13 members with CHD, three matrilineal relatives had CHD, hypertension and hyperlipidemia, 6 matrilineal relatives suffered from only CHD, two non-matrilineal relatives had hypertension and two non-matrilineal relatives had hypercholesterolemia. Mutational analysis of their mtDNA identified the homoplasmic 15927G>A mutation located at a highly conserved base-pairing (28C-42G) on the anticodon stem of tRNAThr. This mutation may cause structural and functional alteration of this tRNA. Approximately 80% and 39% reductions in the steady-state level and aminoacylated efficiency of tRNAThr were observed in the cells derived from 5 matrilineal relatives carrying the 15927G>A mutation, respectively. However, this mutation itself causes 44% reduced level but did not affect aminoacylated efficiency of tRNAThr, implicating defects in nuclear genes involved in tRNA metabolism. ~53% reduction in the rate of mitochondrial translation was observed in cells carrying the 15927G>A mutation. Impaired mitochondrial translation is apparently a primary contributor to the reductions in the rate of overall respiratory capacity, malate/glutamate-promoted, succinate/glycerol-3-phosphate-promoted, or N,N,N',N'-tetramethyl-p-phenylenediamine/ascorbate-promoted respirations and the increasing level of reactive oxygen species in cells carrying the 15927G>A mutation. These data provide the direct evidence that mitochondrial dysfunction caused by 15927G>A mutation is involved in CHD. Our findings may provide new insights into pathophysiology of maternally transmitted CHD.

1629T

Mitochondrial haplogroups and genomic ancestry showed association with heart failure in Brazilians. *C. Fridman[1], M.M.S.G. Cardena[1], A.K. Ribeiro-dos-Santos[2], S.E. Santos[2], J.E. Krieger[3], A.C. Pereira[3].* 1) Department of Legal Medicine, Ethics and Occupational Health, University of São Paulo, São Paulo, Brazil; 2) Laboratory of Human and Medical Genetics, Federal University of Pará, Belém, Pará, Brazil; 3) Department of Cardiology, Laboratory of Genetics and Molecular Cardiology, Heart Institute, Medical School, University of São Paulo, São Paulo, Brazil.

Brazilian population is one of the most heterogeneous and it is interesting to analyze genetic variations which influence diseases development. In 2007, cardiovascular diseases (CD) accounted for the third leading cause of hospitalization in the public health system; among all possible causes heart failure (HF) was the most frequent. Studies have been suggested that mitochondrial haplogroups (mtDNA Hg) or genomic ancestry may contribute to development of some types of CD. Herein, we evaluated a possible association of mtDNA Hg and genomic ancestry in 511 patients with HF compared with 188 healthy individuals. mtDNA was sequenced for control region using BygDye Terminator v3.1 and polymorphisms were determined comparing the sequences with the Cambridge Reference Sequence (rCRS). A set of 48 Ancestry Informative Markers (AIMs) INDELs type from autosomal chromosomes was used to measure proportions of three different ancestries (African, European and Amerindian) and was analyzed via multiplex PCR. Population structure and estimation of global ancestry proportions analyzes were done using Structure v.2.2; statistical analysis was done with SPSS 14.0. Within patients group, 46% showed African Hg, 28% showed Ameridian/Asian Hg and 26% showed European Hg. In relation to AIMS, the means of European ancestry was 57%±22%, Amerindian ancesty was 14%±10%, and African ancestry was 28%±21%. For control group, 36% showed African Hg, 36% presented Ameridian/Asian Hg and 28% showed European Hg. The AIMS showed the mean of European ancestry was 61%±19%, Amerindian ancestry was 14%±9% and African ancestry was 24%±18%. These results showed association for African haplogroup (OR1,55 [95%I.C(1,09-2,18) p=0,013]) and African ancestry (OR 2,78 [95%I.C(1,18-6,54) p=0,019) with risk to development HF. Interestingly, the Amerindian haplogroup (OR 0,69 [95%I.C(0,48-0,98) p=0,042]) and European ancestry (OR0,43 [95%I.C(0,19-0,97) p=0,043]) conferred protection to HF. The risk factor showed for African haplogroup and ancestry is consistent with clinical practice where there is a higher prevalence and worse prognosis of CD in black patients. The protection observed for Amerindian haplogroup and European ancestry is a new data and could be attributed to environmental factors and/or lifestyle. In the next stage of this study we will analyze separately four different etiologies of HF find within our sample to check the results in patient's substructure. Supported: FAPESP, LIM40-HC.

RNAi-based functional profiling of loci from blood lipid genome-wide association studies. *H. Runz[1,3], P. Blattmann[2,3], Ch. Schuberth[1,3], R. Pepperkok[2,3].* 1) Institute of Human Genetics, University of Heidelberg, Heidelberg, Germany; 2) European Molecular Biological Laboratories (EMBL), Heidelberg, Germany; 3) Molecular Medicine Partnership Unit (MMPU), Heidelberg, Germany.

Genome-wide association studies (GWAS) have proven powerful to unravel genomic loci associated with common traits and complex human disease. However, GWAS only rarely reveal information on the exact genetic elements and pathogenic events underlying an association. In order to extract functional information from genomic data, strategies for an objective follow-up of GWAS-findings on a phenotypic level are required. Here we address these limitations by applying RNAi to systematically analyze >100 candidate genes within 55 loci identified by GWAS as associated with blood lipid levels, coronary artery disease and/or myocardial infarction for a function in regulating cholesterol levels in cells. The genes were knocked-down with siRNAs and the consequences on cellular free cholesterol (FC) and the efficiency of LDL-internalization into cells were quantified using automated microscopy and multiparametric image analysis. We will show evidence that loss-of-function of a surprisingly high number of the trait-associated genes affected LDL-uptake, FC, or both. For several genes without previously known lipid-regulatory roles the functional effects upon gene knockdown and overexpression were analyzed and in several instances closely correlated with altered LDL-receptor levels. By providing strong evidence for disease-relevant functions of lipid trait-associated genes our study demonstrates that quantitative, cell-based RNAi is a scalable strategy for a systematic, unbiased detection of functional effectors within GWAS loci.

Kawasaki disease (KD) is an acute systemic vasculitis syndrome of infants and young children. Recently we carried out a genome-wide association study (GWAS) and one of the association peaks was seen on rs4813003, a SNP located 4.9kb downstream of *CD40* gene. It is known that there is a functional SNP of CD40 gene. The SNP (rs1883832) is located within the Kozac sequence and alters translation efficiency of CD40 protein. As GWASs for other adult autoimmune diseases revealed associations peaked at SNPs linked with rs1883832, it has been considered that modulated activity of CD40 protein underlies the pathogenesis of these diseases. To see whether rs1883832, which was not studied in our GWAS, is the responsible variant of *CD40* gene region also for KD, we assessed the association of the SNP in our Japanese KD cases (n = 1182) and controls (n = 4326). Pairwise LD analysis revealed that there is a moderate LD between rs1883832 and rs4813003 (D' = 0.86, r^2 = 0.55). Associations in logistic regression analyses were more significant for rs4813003 (OR = 1.33, 95%CI = 1.20–1.47, $P = 4.1 \times 10^{-8}$) than that for rs1883832 (OR = 1.27, 95%CI = 1.15–1.40, $P = 1.5 \times 10^{-6}$). When these 2 SNPs were studied by a conditional analysis, *P* value for rs4813003 remained significant (P = 0.003) but that for rs1883832 diminished (P = 0.25). These data indicated that the association in this region was driven by rs4813003 (or its proxy SNPs) and the responsible variant must be involved in the pathogenesis of KD by a mechanism other than alteration of protein translation efficiency. Then next, we conducted quantitative PCR to compare *CD40* transcript level as well as ratio of two major isoforms generated by alternative splicing using B-lymphoblastoid cell lines of different genotypes (n = 139). The number of risk alleles at rs4813003 was not correlated with gross *CD40* mRNA expression (P = 0.81) but significantly correlated with reduced ratio of the shorter isoform ($P = 4.9\times10^{-9}$) which is translated into a truncated protein. Re-sequencing study performed in search for the variation responsible to the regulation of the exon6 inclusion/exclusion identified two plausible candidate SNPs which are in high LD (r^2 = 0.96 ~ 0.98) with rs4813003 and located within intron 5. Further investigation is warranted to specify the responsible variant and to elucidate the mechanism by which the responsible variant is involved in the pathogenesis of KD.

1632T

The AA genotype of Tumor Necrosis Factor Induced Protein 2 (TNFAIP2) rs8126 polymorphism is associated with increased mortality in septic shock. *SA. Thair[1], JH. Boyd[1], TA. Nakada[2], JA. Russell[1], KR. Walley[1].* 1) Medicine, University of British Columbia, Critical Care Research Laboratories, Vancouver, British Columbia, Canada; 2) Chiba University Graduate School of Medicine, Department of Emergency and Critical Care Medicine, Chiba, Japan.

One of the central mediators of the pathophysiology of septic shock is the transcription factor nuclear factor κB (NF-κB). TNFα induced NF-κB signaling is one of the earliest signaling pathways up regulated in septic shock and yet the genetics of this pathway are not fully understood. We tested the hypothesis that genetic variation in inflammatory mediators of the TNFα induced NF-κB pathway are associated with increased 28-day mortality in patients who have septic shock. HeLa cells were treated with or without TNFα for 4 hours. Gene expression was interrogated using the Illumina Human HT-12 array. Data was normalized and analyzed with FlexArray (v.1.4.1). tagSNPs were selected using a linkage disequilibrium based method (r^2 threshold =0.65, MAF >5%) and were genotyped in all patients of the Vassopressin and Septic Shock Trial (VASST) cohort. We interrogated 68 SNPs in the region +/− 50,000bp of TNFAIP2 in 530 Caucasian VASST patients using an Armitage trend test. HeLa cells were then transfected with either a TNFAIP2 overexpression or control vector for 48 hours. Protein phosphorylation was then measured in cell lysate (KINEXUS KPSS 1.3 Assay). Gene expression in HeLa cells and a literature search for replication of TNFα induced gene expression identified three genes common to all data sets: TNFAIP2, NFKBIA and NFKB1. Genotyping of 13 tagSNPs in the three genes revealed TNFAIP2 rs8176373 to be highly associated with mortality in the VASST cohort of septic shock patients (p=0.0019, Bonferroni corrected p=0.03). Of the additional 68 SNPs nearby, rs8126 was most highly associated with mortality (p= 0.007). Septic shock patients with the GG (homozygous minor) genotype of rs8126 had increased 28-day mortality (relative risk 0.73 (95% CI 0.59–0.82, p=0.0065)). At 24 hours of septic shock, VASST patients of the GG/ AG genotypes have increased plasma CXCL10 compared to those of the AA genotype (n=618, p=0.014). In vitro studies of the over expression of TNFAIP2 in HeLa cells resulted in significant decreases in phosphorylation of MAPK signaling pathway members, of note, phosphorylation of Raf-1 S259 (132% decrease compared to control). We conclude that the G allele of TNFAIP2 rs8126 is associated with increased septic shock mortality, possibly due to altered TNFAIP2 function and/ or increased pro-inflammatory cytokine CXCL10 production. As well TNFAIP2 may influence phosphorylation of the MAPK signaling pathway.

1633T

Significance of the NODAL p.H165R variant in complex cardiovascular malformations: A report of two lethal cases with an asymptomatic parent. *Z. Ammous[1,2], A. Rajadhyaksha[2], P. Jayakar[2].* 1) University of Miami, Miami, FL; 2) Miami Children's Hospital, Miami, FL.

Heterotaxy is a heterogeneous genetic disorder. Mutations in 7 genes (NODAL, ZIC3, CFC1, FOXH1, LEFTY2, GDF1, ACVR2B) involved in NODAL signaling have been proposed to cause heterotaxy and/or congenital heart defects (CHD). These genes play an essential role in establishing left-right patterning during organogenesis. Heterotaxy visceral 5, an autosomal dominant disorder with variable penetrance, is caused by loss of function mutations in the TGFβ-related ligand NODAL gene. Missense, nonsense, in-frame insertion/deletions and splice site mutations have been reported while certain polymorphisms (including H165R) were found to be functionally abnormal but their significance in humans is not completely understood. We report the case of a full term baby girl who presented with respiratory distress shortly after birth and was found to have complex CHD (dextrocardia and total anomalous pulmonary venous return). Ultrasounds revealed heterotaxy with asplenia. She had a complicated course requiring multiple surgeries and eventually death at the age of 4 months due to sepsis and multi-organ failure. Karyotype and chromosomal microarray analysis were normal. A Heterotaxy panel sent to Cincinnati Children's Heart Institute revealed the patient to be homozygous for a common polymorphism, c.494A>G (H165R) in exon 2 of the NODAL gene. Family history was significant for a paternal half-brother who died at the age of 7months with Heterotaxy and asplenia but no molecular testing was available at that time. Paternal targeted mutation analysis confirmed the father, who has been asymptomatic so far, was carrying the same variant in cis configuration. The H165R polymorphism is frequently identified in the population in its heterozygous form and does not cause disease. However, it has been shown by functional analyses to reduce NODAL activity and therefore may modify the risk for CHD or serve as a susceptibility allele in combination with other genetic or environmental factors. The risk of being homozygous for this variant is not known. It has been noted in a severe case of Holoprocencephaly and CHD where the patient was homozygous for H165R in cis position. We suggest that being homozygous for the variant in cis configuration in addition to other modifier genes could attribute to the severe phenotype in our patient and her sibling. The interpretation of this variant may change in the future if similar cases are reported or if these modifying genes could be identified.

Parent of origin effect in HDL levels. *J.S. Lilley[1], I.M. Predazzi[2], W.S. Bush[2], M.F. Linton[3], S.M. Williams[2], S. Fazio[3].* 1) Pediatric Endocrinology, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Division of Cardiology, Vanderbilt University, Nashville, TN.

Even though heritability estimates for lipid traits are high (40–50% for HDL), genetic contributions to lipid expression are complex and are not fully understood. Part of this variability may be due to epigenetic influences such as genomic imprinting; maternal hypercholesterolemia is thought to influence in offspring cardiovascular outcomes even in adult life. Such epigenetic factors can be observed as parent of origin effects within families. To explore this mechanism in lipid traits, we examined natural lipid variation that can be explained by parent of origin effects in the general population. We performed linear regressions in the second and third generations from the Framingham Cohort (n= 9,219 participants) to compare lipid trait correlations between mothers and daughter, mothers and sons, fathers and daughters, and fathers and sons with the goal of identifying sex-specific transmission effects. Models were adjusted for BMI, age, smoking status, treatment, and menopausal status of both parent and offspring. We performed a likelihood ratio test to compare a reduced model (containing offspring and parent covariates only) to a full model that includes parent HDL as a risk factor. As anticipated, we observe that a significant amount of offspring HDL is explained by parent HDL levels. However, we also note that maternal HDL levels explain significantly more variance in daughter HDL compared to other models of other parent/offspring pairs, with the full model showing R2=0.19 versus a reduced model with R2=0.12 (chi2 = 104.9 and p=1.285e-24). By contrast, the relationship between maternal HDL explains only 2% of the son's HDL (LR= 19.74, p<8.872e-6). To investigate the source of this transmission effect, we conducted a transmission disequilibrium test between mothers and daughters only. Variants within several genes show significant transmission distortion (p<1e-6). SLC16A7, previously associated with HDL in genome wide case-control association studies; SH3GL3, previously reported as associated with height and BMI; GLCCI1, induced by glucocorticoids; CSF1, a cytokine that controls the proliferation and differentiation of macrophages; and PSMD1, involved in peptide and MHC peptides processing. Biologically, these results suggest that maternal factors have a strong influence on offspring HDL and that this influence is sex-specific. These findings indicate that for females, maternal lipid levels are an important factor for predicting HDL levels.

Loci on chromosomes 2q12, 6p21 and 13q14 modulate the effect of smoking on carotid intima-media thickness in whites, blacks and Hispanics. *C. Dong[1], L. Wang[2], A. Beecham[2], D. Cabral[1], C.B. Wright[1,3], S.H. Blanton[2], T. Rundek[1,3], H. Zhao[4], R.L. Sacco[1,2,3].* 1) Dept. of Neurology, Univ. of Miami, Miami, FL; 2) Dept. of Human Genetics, Univ. of Miami, Miami, FL; 3) Dept. of Epidemiology and Public Health, Univ. of Miami, Miami, FL; 4) Dept. of Epidemiology and Public Health, Yale Univ. New Haven, CT.

Carotid artery intima-media thickness (IMT) is a recognized marker of atherosclerosis and smoking is a well-known vascular risk factor, but whether genetic variants modulate the smoking effect on IMT is unknown. We performed a genome-wide smoking-by-SNP interaction analysis in 1,010 individuals (15% white, 17% black, 66% Hispanic), who underwent carotid B-mode ultrasonography and genotyping with the Affymetrix 6.0 chip. Smoking was defined as 0, < 20, and ≥20 cigarette pack-years. An additive genetic effect was assumed for each SNP based on the minor allele number. A total of 722,379 SNPs with a minor allele frequency at least 5% were included in the analysis. Multiple linear regression analysis was conducted to test for smoking-by-SNP interaction on the segment-specific IMT while controlling for age, sex, and the top 3 principal components estimated to capture ancestry by EIGENSTRAT. The strongest interactions were found for 5 SNPs on 2q12, 6p21 and 13q14 for IMT in the internal carotid artery (ICA) (interaction p<5.0E-7) but not in the common carotid artery or bifurcation. Two SNPs on 13q14 near or within *RCBTB1* (including rs7331252) achieved a genome-wide significance (beta±se for smoking-SNP interaction: 0.04±0.01 mm; p=1.2E-8; the adjusted means of ICA IMT were similar among GG-carriers with 0.88, 0.88 and 0.87 mm, respectively, for 0, <20, and ≥20 cigarette pack-years, but substantially increased among AA carriers with 0.85, 0.92 and 1.00 mm for 0, <20, and ≥20 cigarette pack-years) in the total cohort and similar effects in whites (0.04±0.02 mm; p=0.06), blacks (0.04±0.01 mm; p=0.001) and Hispanics (0.03±0.01 mm; p=4.6E-6). SNP rs4851822 on 2q12, which is located near *NCK2*, had an interaction of p= 8.4E-8 (-0.04±0.01 mm) in the total cohort and similar effects in whites (-0.04±0.02 mm; p=0.007), blacks (-0.05±0.02 mm; p=0.004) and Hispanics (-0.03±0.01 mm; p=0.002). The other top 2 SNPs, located between *MDGA1* and *ZFAND3*, including rs6908598, had an interaction effect of p=7.4E-8 (0.05±0.01 mm) in the total cohort with similar effects in whites (0.05±0.02 mm; p=0.02) and Hispanics (0.05±0.01 mm; p=4.6E-6) but not in blacks (0.02±0.02 mm; p=0.37). The interaction effects remained very similar after further adjustment for hypertension, diabetes and hypercholesterolemia. Given the consistent findings across race-ethnic groups, further studies are warranted to perform in-depth investigations of functional genetic variants in these regions.

1636T

A Genome-wide Gene-by-environment Scan for Mobile Source Air Pollution in Atherosclerosis and Myocardial Infarction Identifies PIGR and HCN4. *C.K. Ward-Caviness[1,2], L. Neas[3], C. Haynes[2], C. Blach[2], E. Burns[2], K. LaRocque-Abramson[2], E. Dowdy[2], W. Cascio[4], R. Devlin[4], D. Diaz-Sanchez[4], W.E. Kraus[2,3], S.H. Shah[2,3], S.G. Gregory[2], M.L. Miranda[5], E.R. Hauser[2,3].* 1) Computational Biology, Duke University, Durham, NC; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC; 3) Department of Medicine, Duke University Medical Center, Durham, NC; 4) Environmental Protection Agency, Chapel Hill, NC; 5) University of Michigan, Ann Arbor, MI.

Mobile source air pollution (MSAP) is a prevalent environmental exposure with known adverse cardiovascular effects. To investigate the role of genes and genetic variants in the pathological process triggered by MSAP exposure, we performed race stratified gene-environment interaction GWAS (GWAS) using distance from primary residence to the nearest roadway as a proxy for MSAP exposure. We performed GWAS for recent myocardial infarction (MI) and atherosclerosis, using an ordinal measure of atherosclerosis burden (CADindex), in a large cardiac catheterization cohort. To identify possible associations we first identified the 10 strongest gene-environment interaction associations. Among these 10 we removed SNPs not in genes (introns, exons or 3'-UTR) and examined these biologically relevant signals for consistency of direction and replication in separate African-American (AA) and European-American (EA) cohorts. The GWAS for MI among the EA (N = 1647) revealed three strong gene-environment interaction associations: RS1400207 (CNTN4, P = 1.3×10-5), RS2623997 (HCN4, P = 2.0×10-5), and RS925820 (CNTN4, P = 2.4×10-5). Of these RS2623997 was consistent in direction in the AA (P = 0.084, meta-analysis P = 1.6×10-4). As HCN4 is necessary for proper cardiac pacemaker function and associated with sick sinus syndrome 2, it is a strong candidate for a gene involved in MI. For the CADindex GWAS, three of the 10 strongest associations were in genes including RS291096, a synonymous mutation in PIGR in AA. An examination of other SNPs in PIGR revealed multiple SNPs in exons with nominally significant (P < 0.05) p-values for the gene-environment interaction term. Among these was RS291102 a missense mutation identified as probably pathogenic (A -> V, minor allele frequency (MAF) = 0.35, P = 0.0025). No PIGR SNPs replicated in the EA CADindex GWAS, but the direction of association was consistent for RS291096 (meta-analysis P = 0.0016) and RS291102 (meta-analysis P = 0.092). The MAF of RS291102 is 0.033 in the EA, making detection of a gene-environment interaction signal difficult in this cohort. These results show that genetic variants are associated with MI and atherosclerosis burden under exposure to MSAP. Future work will increase the sample size and add gene expression and metabolic profiling to further investigate joint effect of specific genes and MSAP exposure on MI and atherosclerosis.

1637T

Genome-wide association analysis of blood pressure incorporating gene-age interactions in the CHARGE, GBPgen, and ICBP Consortia. *J. Simino, CHARGE, GBPgen, and ICBP Investigators.* Division of Biostatistics, Washington University School of Medicine, St. Louis, MO.

BACKGROUND: Hypertension afflicts 26% of adults worldwide and accounts for 10% of global healthcare expenditures. Massive genome-wide association studies (GWAS) of single nucleotide polymorphism (SNP) main effects have successfully identified ≥50 blood pressure (BP) associated loci, however they collectively explain a small proportion of BP variance. We investigate whether additional loci can be discovered through an analysis of gene-age interactions using 9 studies (N=55,796) from the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium.

METHOD: Each CHARGE study stratified participants into 10-year age bins. GWAS main effects analyses were conducted within each cohort and age bin by regressing systolic (SBP), diastolic (DBP), mean arterial (MAP), and pulse pressure (PP) onto allele dosage, age, age-squared, body-mass-index, gender, and field center (28 analyses per trait). After applying genomic control, we conducted a fixed effects meta-regression of the SNP coefficient onto the median age of participants within each study and age bin. Significant findings using genomic-controlled chi-square tests were replicated in 43,493 participants of European descent and 8,682 Chinese, Indian, and Malay individuals from Singapore.

RESULTS: Three loci reached genome-wide significance (p-value<5×10-8) for previously unassociated BP traits via joint tests of the SNP main effect and SNP-age interaction (2 df). SNPs rs880315 (*CASZ1* intron), rs2004776 (*AGT* intron), and rs7599598 (*FER1L5* missense mutation) were associated with SBP, MAP, and DBP, respectively. Rs7233332 (*RAB31* intron) exhibited no main effect but significantly interacted with age to influence PP. Rs6782531 (*FHIT* intron) displayed a joint main effect and SNP-age interaction on SBP in 46,939 participants aged 40–70 years. Singapore participants aged 40–70 years replicated the main effects of rs2004776 on MAP (p-value=0.003) and rs7599598 on DBP (pvalue=0.005).

CONCLUSION: Age is a convenient surrogate for an array of complex biological and environmental phenomena that influence BP gene expression. Capitalizing on gene-age interactions using GWAS and next-generation sequencing data may enhance the identification of novel genes associated with common complex traits.

1638T

A genome wide association study of carotid intima-medial thickness, a preclinical marker of atherosclerosis. *S.H. Blanton[1,2], A.H. Beecham[1], L. Wang[1], C. Dong[2], D. Cabral[2], B.I. Hudson[2], M. Kiryiya[3], F. Jasmine[3], B. Pierce[3], R. Demmer[3], A. Habibul[3], M. Desvarieux[4], R. Sacco[1,2], T. Rundek[2].* 1) Dept of Human Genetics, Univ Miami, Miami, FL; 2) Dept of Neurology, Univ Miami, Miami, FL; 3) Dept of Health Studies, Univ Chicago, Chicago, IL; 4) Columbia Univ, New York, NY.

Carotid intima-medial thickness (CIMT) is a recognized risk factor for cardiovascular disease. The genetic underpinnings of CIMT are not fully understood. The aim of this study was to identify potential novel risk loci for CIMT by performing a genome-wide association study. CIMT for 1278 individuals from the population-based Northern Manhattan Study (NOMAS;1066) and the Oral Infections and Vascular Disease Epidemiology Study (INVEST;212) was measured by high-resolution B-mode ultrasound and expressed as the total IMT defined as mean of the maximum (IMTm). Other carotid segment-specific IMT phenotypes, bifurcation-BIF, common-CCA and internal carotid artery-CCA, were also examined. Genotyping was done in NOMAS using the Affymetrix SNP array 6.0 and in INVEST using Illumina 330k. With HapMap3 as the reference, IMPUTE2 was used to impute the NOMAS SNPs in INVEST which had not been genotyped, resulting in 598557 high quality SNPs (INFO ;≥ 0.4). SNPs were evaluated using linear regression first in Hispanics (795) and then in Blacks (263) and Whites (220) for replication. The model controlled for age and sex. Additionally, PCA1 and 2 from Eigenstrat were used to control for substructure in Hispanics and PCA1 was used in Blacks and Whites. We observed strong associations (p<1.0×10-5) in Hispanics that replicated (p<0.05) in either Blacks or Whites on chromosomes 3, 4, 14, 15 and 19. Five SNPs in the 4p15.31 region were associated with p<1.0×10-5 for BIFm and IMTm. One SNP, rs12507937, met genome-wide significance in Hispanics (p=4.48×10-8) and replicated in whites (p=0.016) for BIFm. Although no genes are located in this region, previous studies link this locus to type 2 diabetes and cholesterol levels. Interestingly, numerous SNPs identified on chromosome 14 were located in the T cell receptor alpha locus (TRA@). TRA are key genes in the activation of T-cells in the adaptive immune response, and play a role in regulating the inflammatory state of plaque. Lastly, 2 SNPs on chromosome 13 in the integrin beta-like protein (ITGBL1) gene were associated with BIFm in Hispanics alone. The integrin family of proteins is involved in cell adhesion and immune responses and critically involved in the cellular process of atherosclerotic plaque initiation and progression. In conclusion, we have identified several novel gene regions associated with CIMT which may further underpin the role of the adaptive and innate immune response in atherosclerosis.

1639T

Genome-wide association analyses of long-term blood pressure traits. *S.K. Ganesh[1,2], G.B. Ehret[1,3], A. Chakravarti[1] on behalf of the CHARGE-BP and ICBP consortia.* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD 21205; 2) Department of Internal Medicine, Division of Cardiovascular Medicine, University of Michigan Medical Center, Ann Arbor, Michigan 48109; 3) Cardiology, Department of Specialties of Internal Medicine, Geneva University Hospital, Rue Gabrielle-Perret-Gentil 4, 1211 Geneva 14, Switzerland.

Blood pressure (BP) is an important cardiovascular trait, and arterial exposure to high BP is a major, modifiable risk factor for atherosclerotic diseases and cardiovascular mortality. Gene discovery is an important route to understand its mechanisms. BP has significant intra-individual variability and there are well-described sources of errors for noninvasive BP measurements. Most genetic studies utilize single visit traits but these do not correct for variability that occurs over days, months, and years. We conducted a genome-wide association study (GWAS) of four BP traits, systolic (SBP), diastolic (DBP), mean arterial (MAP), and pulse pressure (PP), for the purpose of improved gene discovery by increasing phenotypic accuracy through long-term averaging (LTA) of multiple measurements acquired over years. We also studied the statistical effects of such averaging. We identified 40 trait-variant associations across 20 independent loci associated with these traits (13 SBP, 10 DBP, 12 MAP and 5 PP loci with SNP association at P-value < 5×10-8) in individuals of European ancestry, of which four BP associations are novel. The novel loci include associations of SBP at 2p23 (rs1275988, near KCNK3), DBP at 2q11.2 (rs7599598, in FER1L5), and PP at chromosome 6p21 (rs10948071, near CRIP3) and 7p13 (rs2949837 near IGFBP3). Monte Carlo simulation studies to examine the effect of the averaging approach used here showed ~20% gain in statistical power for detection of associations. Thus, we demonstrate significant enrichment of our discovery findings by using LTA BP traits through improvement of the precision of the BP trait by averaging. We also highlight regions that might contain genes associated with phenotypic variation due to physiologic changes in blood pressure in which LTA does not improve signal. The expression level of genes identified with single-visit BP analysis were compared to those identified with LTA, and we found tissue-specific expression patterns with diurnal variation, suggesting a mechanism for the lack of enrichment seen in some regions with LTA. These discovery findings increase our understanding of the genetic determinants of BP and the implications of the averaging procedure on study design and power. This suggests that, as we enter an era of sequencing for complex diseases and traits, where power may be limited for the detection of rare variants, trait averaging is a useful strategy.

The manifestation of coronary artery disease (CAD) follows a well-choreographed series of events that includes damage of arterial endothelial cells and deposition of lipids in the sub-endothelial layers. Genome-wide association studies (GWAS) of multiple populations with distinctive genetic and lifestyle backgrounds are a crucial step in understanding CAD pathophysiology. We carried out a genome-wide association study of arterial stenosis as measured by cardiac catheterization in 4 741 individuals of Lebanese ancestry. The locus of PHACTR1 showed association with coronary stenosis in a discovery experiment with genotype data from 2 002 individuals (OR= 1.37, P=1.57×10-5). Replication in 2 739 individuals yielded positive results (OR=1.31, P=8.85×10-6), leading to genome-wide significant association in a combined analysis (OR=1.34, P=8.02×10-10). GWAS data imputed with untyped single-nucleotide polymorphisms (SNPs) from the HapMap2 reference panel (for a total of 20 225 SNPs) replicated HNRNPA3P1-CXCL12 association with CAD and identified new significant associations of type 2 diabetes (T2D) genes CDKAL1, ST6GAL1, and PTPRD. In parallel, analysis of 10 candidate SNPs with CAD and/or MI in genotypic and allelic association models using logistic regression identified a protective effect of MTHFD1 against MI, and a positive association of CDKN2A/CDKN2B/ANRIL in the 9p21 locus with MI. Our study provides additional insights into mechanisms and genes underlying CAD/MI and show the potential for new discovery from genetic association studies in the Lebanese population that has an increased susceptibility to CAD.

An assessment of association of blood pressure with DNA variants in the Long Life Family Study and other studies. *A.T. Kraja[1], J.H. Lee[2], R. Straka[3], I.B. Borecki[1], C. Kammerer[4], M.A. Province[1].* 1) Div Statistical Genomics, Dep of Genetics, Washington U, St Louis, MO, USA; 2) Taub Institute, Sergievsky Center, Columbia U., New York, NY, USA; 3) Dep. of Experimental and Clinical Pharmacology, U. of Minnesota, MN, USA; 4) Dep. of Human Genetics, U. Of Pittsburgh Graduate School of Public Health, PA, USA.

The Long Life Family Study (LLFS, N >4,700, with a mean age of 70, gen. 2 with a mean of 90 and gen. 3 of 60, range 24–110 years; stroke prevalence of 3% and diabetes 6%), represents mainly Caucasian families identified for exceptional longevity in the United States and Denmark. Genome wide associations (2.5M SNPs) were performed for blood pressure (BP). The purpose of this work was to better understand different aspects of BP and its associated variants in relation with aging, health, and longevity. Clinical trials average-class constants were used to correct BP traits for anithypertensives' use, based on labels of medications participants presented. Thus up to 17 BP traits were studied. Similar procedures were used in the Family Heart Study for comparing results (N~5,000, with 2.5M `hybrid' SNPs, split into samples with familial history of high risk for CVD and one representing general population). After medication corrections 52% of LLFS subjects and 66% of FHS were classified with hypertension (MCHT). All traits were adjusted and analyzed with standard procedures. Results from samples of LLFS All; gen. 2; and 3; FHS All; with high risk for CVD; and with a general population CVD risk, yielded relatively weak association results. Of interest was rs407724 (MAF=0.4726) of *ROS1*. Only LLFS gen. 3 results were significant for additive effects of this SNP (p=5.9e-08) on MCHT versus ALL (p=1.4e-05), and gen. 2 (p=0.788), The C allele showed a protective effect against high BP. Referring to systolic BP, corrected for medication use (MCsbp), gen. 3 had 685 (C/C) with 132.8 (se=0.9), 1476 (C/T) with 135.0 (0.6), and 850 subjects (T/T) with a mean of 136.8 (0.8) mmHg, thus with almost 2 mmHg decrease for each copy of C allele. In contrast, in gen. 2, 356 subjects (C/C) were with 152.5 (1.5), 730 with 153.7 (1.0) and 435 subjects with a mean of MCsbp of 155.1 (1.3). After excluding married-ins from gen. 3, 524 subjects remained C/C with a mean MCsbp of 131.0 (1.0), 1103 as C/T with a mean of 134.8 (0.7) and 628 T/T with a mean of 136.0 (0.9) mmHg. This finding was not replicated with FHS samples. Yet, *ROS1*, a receptor tyrosine kinase is expressed relatively high in the kidney and intestines; It interacts among others with *PTPN* and *EGFR* genes; One intron-rs172409 is reported in association with heart rate; downstream 0.5M bps, rs654128 is reported to associate with telomere length (p=3.1e-06) and upstream rs281868 ~1M bps is associated with heart rate (p=3.9e-10).

Novel Tissue-Specific Transcriptomic Signatures Revealed by Experimental Endotoxemia in Healthy Human Subjects. *Y. Liu[1], J. Feguson[2], I. Silverman[3], B. Gregory[3], M. Li[1], M. Reilly[2,4].* 1) Department of Biostatistics and Epidemiology; 2) Cardiovascular Institute; 3) Department of Biology; 4) Institute for Diabetes Obesity and Metabolism, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Deregulated activation of innate immunity is a major pathogenic feature of multiple complex diseases including common cardiometabolic diseases such as diet-induced obesity, insulin resistance, type-2 diabetes and atherosclerotic cardiovascular disease. Indeed, inappropriate and sustained tissue-specific inflammatory responses to diet and lifestyle factors in genetically prone individuals may contribute to cardiometabolic disease initiation and clinical complications. However, little is known for the modulation of the transcriptome by inflammatory stress in disease relevant human tissues. Here we applied RNA-Seq during low-dose experimental endotoxemia (LPS) in healthy human subjects to explore unbiased tissue-specific transcriptomic responses that may directly relate to complex disease responses. We utilized adipose and blood from three healthy individuals recruited to the Genetics of Evoked Responses to Niacin and Endotoxemia study who underwent a standardized inpatient endotoxemia protocol. Specifically, we examined LPS modulated tissue-specific gene expression, alternative splicing (AS), and expression of lincRNAs. Our comprehensive analysis revealed a remarkable number of novel tissue-specific transcriptomic signatures during activation of innate immunity in vivo. In total, we identified 587 and 664 differentially expressed genes at 5% FDR level in adipose and blood, respectively, following LPS administration. These genes were further replicated by an independent microarray experiment. Genes up-regulated are highly enriched in immune responses and infection/cardiovascular diseases, whereas those down-regulated are mainly related to oxidative process and mitochondria. We also detected 186 and 47 genes showing differential AS in adipose and blood. By comparing with deep RNA-Seq data of technical replicate samples, we confirmed 75% and 87% of the splicing events in adipose and blood, respectively. Additionally, we detected 14 and 17 differentially expressed lincRNAs in adipose and blood, including linc-TP53, which was differentially expressed in both tissues. At present, we are experimentally validating our findings by qPRC experiments and replicating in obese vs lean individuals. In summary, we have identified multiple levels of tissue-specific transcriptome modulation during induced inflammatory stress, which provide insight into genomic regulation of complex diseases that cannot be detected by analysis of DNA variations alone.

Genome-wide association study for atrial fibrillation in the Japanese population. *K. Ozaki[1], Y. Onouchi[1], N. Kamatani[2], T. Tsunoda[3], M. Kubo[4], Y. Nakamura[5], T. Tanaka[1].* 1) Laboratory for Cardiovascular diseases, RIKEN, Ctr Genomic Med, Yokohama, Japan; 2) Laboratory for Statistical Analysis, RIKEN, Ctr Genomic Med, Yokohama, Japan; 3) Laboratory for Medical Informatics, RIKEN, Ctr Genomic Med, Yokohama, Japan; 4) Laboratory for Genotyping Development, RIKEN, Ctr Genomic Med, Yokohama, Japan; 5) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Atrial fibrillation (AF) is the most common arrhythmia in developing countries including Japan associated with increased morbidity and mortality. AF is an abnormal heart rhythm characterized by rapid and irregular activation of the atria. Through the Genome wide association study (GWAS) from European descent, genetic variants that confer susceptibility to AF have been indicated to be present on several chromosomal loci so far. These studies, however, were conducted in individuals from only European decent. To identify additional susceptibility loci for AF and to increase the understanding of the complex genetic effect on AF, further GWAS of Asian and other ethnic populations are required. To identify novel AF susceptible loci, we conducted a GWAS for AF with Japanese population. The GWAS was genotyped by the Illumina Human610-Quad and Illumina Human Hap550v3 BeadChip platform. We applied stringent quality-control criteria and tested 843 cases and 3,350 controls for approximately 430,000 autosomal SNPs with minor allele frequency of > 0.01. We also assessed population stratification in our study population by comparison to HapMap samples using principal component analyses, and found that these subjects did not show any sign of population stratification. The inflation of test statistics, $\lambda_{\text{genomic control}}$ (λ_{gc}) was 1.03. In this GWAS, the locus corresponding to the SNPs close to *PITX2* on chromosome 4q25, identified previously for AF susceptibility in European desent, satisfied a genome wide significance threshold of $P < 1 \times 10^{-7}$ in this GWAS stage. We are currently conducting the validation analysis with additional 1,646 cases and 17,190 controls for high-ranking SNPs of this GWAS.

Cardiovascular genetics wooooooo. *D. Seo, Z. Liu, N. Sikka, P. Goldschmidt-Clermont, M.A. Pericak-Vance, G.W. Beecham.* University of Miami, Miami, Fl.

Coronary heart disease is the leading cause of death in the United States, with atherosclerosis of the coronary arteries (CAD) being one of the major underlying etiologies. Patients with atherosclerosis are more likely to suffer a myocardial infarction or sudden cardiac death. Though the role of genetics on CAD has been studied in European ancestry populations, its role in Hispanic populations is less clear. To further determine the genetic etiology of CAD, we are performing a genome-wide association study of CAD using a diverse set of cardiac catheterization patients. This study utilizes the Miami Cardiovascular Registry of the University of Miami, Miller School of Medicine. A diverse set of patients were ascertained through local cardiac catheterization labs; the dataset consists of over 65% Hispanic and 15% African American. All 2,000 patients were phenotyped using a research grade read of the coronary angiograms, describing the amount of atherosclerosis in each of the 16 major coronary artery branches. Genotype data were generated using the Affymetrix SNP array 6.0 platform for 900,000 SNPs; an additional dataset using the same samples but genotyped on Illumina's “exome chip” is currently being generated. Extensive quality controls tests were performed to ensure the integrity of the data, including sample filters (gender consistencies, efficiency thresholds, etc), SNP filters (Hardy-Weinberg equilibrium, genotyping efficiency, MAF, etc), and EIGENSTRAT methods to correct for population substructure. We are first testing the dataset for ethnic differences in the architecture of disease; that is: do different populations have different coronary branches affected at different levels? Additionally, we are testing for association between disease and genetics using regression-based methods, including covariates for smoking, cholesterol, age, sex, and vectors describing the population substructure of the samples. We are testing for association both between overall disease burden, and with disease in specific major branches; results will be presented. This study will yield important results, both about the phenotypic differences and similarities between populations, and about underlying genetic etiology of CAD.

Functional Relationship of the COL4A1/COL4A2 Locus on Chromosome 13q34 to Coronary Artery Disease (CAD). *A. Turner, P. Lau, S. Soubeyrand, O. Jarinova, R. McPherson.* University of Ottawa Heart Institute, Ottawa, Ontario, Canada.

The COL4A1 and COL4A2 genes on chromosome 13 have been identified as new loci associated with CAD (p<3×10-8) from the recently published CARDIoGRAM meta analysis (Nature Genetics, 2011). The goal of the current project is to elucidate how variants in the COL4A1 and COL4A2 genes associated with CAD functionally and mechanistically contribute to the CAD phenotype. Type IV collagen triple helices constitute the major structural component of basement membranes, consisting primarily of 2 COL4A1 chains arranged with 1 COL4A2 chain. COL4A1 and COL4A2 also have important functional roles in angiogenesis, and mutations are associated with diverse vascular abnormalities. A follow-up study to CARDIoGRAM with more cases and controls has identified an intronic SNP in COL4A2, rs9515203, as having the greatest CAD association. Bioinformatics analysis using data from the ENCODE project reveals high degrees of histone 3 lysine 27 acetylation in the region near this rs9515203 SNP, a mark often located near active regulatory elements. We therefore hypothesized that the intronic region near rs9515203 behaves as either an enhancer or a repressor. Furthermore, we hypothesized that the rs9515203 SNP, or a SNP linked with rs9515203, may disrupt the function of this regulatory element. ChIP-Seq data from the ENCODE project shows binding of transcription factors such as STAT3 and USF1 to this intronic region. 2 kb of this intronic sequence (containing rs9515203) was cloned into the pGL3-Promoter vector (Promega), in which insertion of functional enhancers leads to upregulation of luciferase expression in vitro. Luciferase assays in HT-1080 cells reveal this intronic sequence acts as an enhancer due to its insertion upregulating pGL3-Promoter activity over threefold relative to controls (p<0.0001, n=3 independent experiments). Currently, using deletion constructs we have narrowed down the functional sequence of this enhancer. Future work entails verifying what protein factors bind this enhancing region and SNP effects using techniques to investigate DNA-protein interactions (ie. DNA pull-down assays, electrophoretic mobility shift assay (EMSA)). Chromosome conformation capture will also be conducted to evaluate whether this enhancer acts locally or distally. These findings are important because misregulation of COL4A1 and COL4A2 could have important consequences relevant to CAD, including effects on basement membrane integrity and angiogenesis.

***De novo* Copy Number Variants in Non-syndromic Left Ventricular Outflow Tract Obstruction.** *L.A. Umana[1], N.A. Hanchard[1], G.A. Zender[2], S.M. Fitzgerald-Butt[2], G. Zapata[1], P. Hernandez[1], M.S. Azamian[1], D.J. Penny[3,4], J.W. Belmont[1,4], K.L. McBride[2].* 1) Department of Human and Molecular Genetics, Baylor College of Medicine, Houston, TX; 2) Center for Molecular and Human Genetics, Nationwide Children's Hospital, Department of Pediatrics, Ohio state University, Columbus, OH; 3) Department of Pediatric Cardiology, Texas Children's Hospital, Houston, TX; 4) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Background: Congenital cardiovascular malformations (CVMs) occur in 5-8/1000 live births. Defects leading to Left Ventricular Outflow Tract Obstruction (LVOTO), most commonly represented by Hypoplastic Left Heart Syndrome (HLHS), Aortic Valve Stenosis (AVS) and Coarctation of the Aorta (CoA), constitute 15–20% of medically significant CVMs, and contribute significantly to CVM-associated morbidity and mortality. Non-syndromic LVOTO is multifactorial in origin, but familial clustering of cases and an increased risk of LVOTO in first degree relatives suggest a significant genetic contribution. We evaluated the incidence of large (> 150 Kb) de novo chromosome copy number variants (CNVs) among a cohort of affected family trios.

Methods and results: Family members were genotyped with ~732,000 SNPs genome-wide using the Illumina OmniExpress SNP microarray chip. CNVpartition and PennCNV software were used to detect copy number variants larger than 150 kb in the affected probands that were not seen in either parent. Called CNVs were confirmed by visual inspection of the logR ratio and B-allele frequency tracks. A total of 16 large de novo autosomal events were observed among the 377 affected probands (4.2%). Observed events ranged in size from 152 Kb to 50.8 Mb and included 10 losses, 2 gains, 2 unbalanced translocations, 1 instance of copy neutral absence of heterozygosity of chromosome 16 and 1 instance of extensive AOH (459 Mb total) consistent with a consanguineous mating. An apparent recurrent deletion of chromosome 14q32.33 was observed in two patients, as were two atypical deletions of chromosome 22q11.2 and two cases with terminal deletions of 11q (Jacobsen syndrome). In 11 of the 16 cases (69%) the cardiac lesion was complex, involving a typical LVOTO lesion in combination with additional cardiac findings.**Conclusions:** These findings suggest that large chromosomal events may contribute to even apparently non-syndromic LVOTO CVMs. In such patients, complex cardiac lesions in particular, may warrant extended cytogenetic work-up. In addition, copy number analysis can identify CVM patients at high risk for non-cardiac complications even if they are not evident in the newborn period.

1647T

Genetic association of CVD-related loci with lipid traits in the Heart Strategies Concentrating on Risk Evaluation (Heart SCORE) study. *XB. WANG[1], S. Reis[2], M.M. Barmada[1], I. Halder[2], F.Y. Demirci[1], M.I. Kamboh[1].* 1) HUMAN GENETICS, University of Pittsburgh, PITTSBURGH, PA., US; 2) Cardiovascular Institute, University of Pittsburgh, Pittsburgh, PA, US.

Cardiovascular disease (CVD) is the leading cause of death worldwide. Plasma levels of total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C) and triglycerides (TG) are significant risk factor for CVD and about 50% of the variation in these four quantitative traits is under genetic control. A recent meta-analysis of 46 published lipid genome-wide association studies has identified 95 loci that explain ~25–30% of the genetic variance for each of the four traits, indicating that additional genetic factors remain to be identified. In this study, we used a novel Illumina CVD BeadChip that contains ~49,000 SNPs in approximately 2,100 candidate genes selected based on their potential role in CVD to test for association with four lipid traits in 464 African American (AA) and 770 White subjects as part of the Heart SCORE study. Forty-nine of the reported 95 genome-wide significant genes were represented on this chip. We observed significant associations (p<0.05) with SNPs in 39 of the 49 genes with strongest associations between HDL-C and CETP/rs7499892 (p=2.56E-10), LDL-C and APOE/rs7412 (p=6.59E-05), TC and ABCA1/rs10991405 (p=9.69E-05), TG and APOB/rs2678379 (p=5.21E-05). In addition to the replication of known loci, we also observed novel suggestive associations between HDL-C and MTNR1A (p=2.62-05), HDL-C and NR1I2 (p=1.56E-05), TG and ADD3 (p=1.67E-05), TC and OSBP2 (p=1.1E-05), HDL-C and GHRL (p=5.24E -06), HDL-C and F2RL1 (p=4.52-05). We are in the process of confirming these novel associations in an independent sample. In conclusion, we have replicated many of the known lipid loci and identified potentially new genes for the four lipid traits using a novel CVD chip.

1648T

Genetic analysis of vascular disease in the Diabetes Heart Study. *A.J. Cox[1, 2], M.C-Y. Ng[2], J. Xu[2], C.D. Langefeld[3], J.J. Carr[4], B.I. Freedman[5], D.W. Bowden[1, 2].* 1) Department of Biochemistry, Wake Forest School of Medicine, Winston Salem, NC; 2) Diabetes Research Center, Wake Forest School of Medicine, Winston Salem, NC; 3) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston Salem, NC; 4) Department of Radiological Sciences, Wake Forest School of Medicine, Winston Salem, NC; 5) Department of Internal Medicine - Nephrology, Wake Forest School of Medicine, Winston Salem, NC.

Understanding genetic risk factors for cardiovascular disease (CVD) in individuals with type 2 diabetes (T2D) may identify biological pathways contributing to the increased risk for macrovascular complications and CVD mortality in T2D. The aim of this study was to examine genetic association signals for vascular disease and associated risk factors in a sample enriched for T2D. A genome-wide association study (GWAS) for vascular disease was performed in 1180 European Americans from 474 families from the Diabetes Heart Study (DHS). Phenotypes of interest included history of CVD (prior event or intervention), coronary artery calcified plaque (CAC) and other known CVD risk factors. Genotyping was completed using the Affymetrix 5.0 Array. Poorly performing SNPs (CR<0.95; Hardy-Weinberg p-value<1×10^{-6}; MAF<0.01) were excluded from analyses. Association analyses were completed using variance components methods implemented in SOLAR v6.3.4. Among the DHS cohort, 84% were T2D affected with disease durations averaging 10.5±7.2 years. Regions on Chr6p13 (lead SNP: rs7341323; *KCNQ5/RIMS1*; p=1.9×10^{-5}) and Chr10p12 (rs10741097; *GPR158*; p=6.5×10^{-6}) were associated with history of CVD. Stratification by smoking status (n=694 current or prior smokers; n=483 non-smokers) demonstrated differential associations with history of CVD, revealing an additional region on Chr12q24 (rs10850155; *LHX5*; p=2.4×10^{-6}) for smokers; Chr6p13 was the most strongly associated region among non-smokers (rs7763575; *KCNQ5/RIMS1*; p=4.9×10^{-7}). Refinement of the CVD history definition to include CAC burden revealed additional associations with regions on Chr9p23 (rs10978059; *PTPRD*; p=5.7×10^{-6}) among smokers and on Chr13q31 (rs1331967; *SLITRK1*; p=1.2×10^{-7}) among non-smokers. For all other risk factors examined, the strongest phenotype association was seen for total Bilirubin concentrations (rs887829; *UGT1A8*; p=8.67×10^{-20}). SNPs from this region were nominally associated with all-cause mortality (p=0.0004–0.04), but not with history of CVD or CAC. This study identified genetic loci associated with vascular disease in a sample of European Americans enriched for T2D. Further fine mapping of these regions is required to more fully characterise and replicate these associations and to identify SNPs which are likely to have impacts on gene function/expression. The potential for a modifying effect of environmental factors, here smoking status, on genetic associations warrants further consideration.

1649T

SNPs associated with plasma triglyceride levels influence response during intensive cardiovascular risk reduction. *D.L. Ellsworth[1], A. Decewicz[1], M. Hicks[1], K.A. Mamula[1], A. Burke[2], M.J. Haberkorn[2], H.L. Patney[1], M.N. Vernalis[3].* 1) Integrative Cardiac Health Program, Windber Research Institute, Windber, PA; 2) Windber Medical Center, Windber, PA; 3) Integrative Cardiac Health Program, Walter Reed National Military Medical Center, Bethesda, MD.

Background: Triglycerides play a fundamental role in development and progression of atherosclerosis. Current guidelines advocate lifestyle change involving diet, physical activity, and weight control for management of hypertriglyceridemic patients as a first step. Recent genome-wide association studies (GWAS) identified single nucleotide polymorphisms (SNPs) associated with plasma triglyceride levels in the general population. We hypothesize that plasma triglycerides may be influenced by genetic composition in addition to lifestyle behaviors. Methods: We examined the influence of genetic variation on variability in triglyceride response in 178 participants who completed a prospective, non-randomized intervention designed to stabilize or reverse progression of cardiovascular disease (CVD) through dietary changes, exercise, and stress reduction. CVD risk factors were assessed at baseline, 12 weeks, and 52 weeks by standard methods. SNPs (n=19) associated with plasma triglycerides were genotyped by TaqMan® allelic discrimination assays. Results: Patients experienced significant improvement (P < 0.05) in CVD risk factors, including weight (-9%), blood pressure (-6%), total cholesterol (-7%), and triglycerides (-9%). Triglyceride response during the program differed significantly (P < 0.05) between genotypes for three SNPs (rs442177, rs3846662, and rs17145738) located close to the following genes: transcriptional activator AF4/FMR2 family member 1 (AFF1), 3-hydroxy-3-methylglutaryl-CoA reductase (HMGCR), which catalyzes the rate-limiting step in cholesterol synthesis, and MLX interacting protein-like (MLXIPL), which controls transcription of genes involved in glycolysis. Discussion: This is the first study to show that individual response to lifestyle modification for CVD risk reduction may be influenced by genetic composition. Genetic variation associated with CVD risk may provide a basis for personalized treatments to optimize cardiovascular health and requires further study.

Sex-specific association of cadherin with high density-lipoprotein cholesterol in the Long Life Study Family. *M.F. Feitosa[1], A.T. Kraja[1], J. Lee[2], K. Christensen[3], J. Wang[1], C. Kammerer[4], M.A. Province[1], I.B. Borecki[1].* 1) Division of Statistical Genomics, Department of Genetics, Washington University School of Medicine, MO; 2) Taub Institute, Columbia University, NY; 3) Institute of Public Health at the University of Southern Denmark, Denmark; 4) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, PA.

It is well known that high levels of high-density lipoprotein (HDL) cholesterol have protective effects on atherosclerosis and cardiovascular disease, with involvement in the prevention of low-density lipoprotein (LDL) oxidation. Studies have suggested sex-specific heritability of lipids. Also, it has been shown that elderly people, especially centenarians, possess high HDL cholesterol levels and low LDL cholesterol levels as compared to septuagenarians. To detect whether loci exhibit sex-specific associations influencing fasting levels of HDL cholesterol, we analyzed men and women separately in the Long Life Family Study (LLFS) which is designed to characterize exceptionally healthy elderly people. For subjects taking lowering-lipid medications, the HDL cholesterol levels were corrected by classes of lowering-lipid medication effects. Levels of HDL cholesterol were adjusted by field centers, age, and principal components using stepwise regression analysis and retaining terms significant at the 5% level. The residuals were calculated separately for men and women. We performed genome-wide association (GW) scans on HDL cholesterol using a mixed model approach, accounting for family structure with the kinship correlations. A total of 4,114 European-American subjects (480 families) was typed using ~2.3 million SNPs (Illumina Omni chip). We identified a strong association between *CDH12* (cadherin 12 type 2, 5p14) variants with HDL cholesterol ($p<5.0\times10^{-8}$) in women but not in men ($p>1.0\times10^{-1}$). Further, we tested if there was an interaction effect between sex and SNP by examining the statistical significance of the main effects and interaction term. Significant evidence was found for sex-specific association with HDL cholesterol (p=0.004, for sex*SNP term). There was no other association at GW significance level for men or women. The *CDH12* gene belongs to the cadherin superfamily that mediate calcium-dependent cell-cell adhesion and cadherins adhesion are regulated by the Wnt signaling pathway. The *CDH12* is expressed in the brain and may play a role in neuronal development. Modest associations of CDH12 variants with total cholesterol in women ($p>1.0\times10^{-5}$) and HDL cholesterol in sex-combined analysis ($p>1.0\times10^{-3}$) were previously found in a meta-GWA study. Our findings suggest that using more homogeneous subgroups in elderly people in LLFS data helped to identify the *CDH12* loci associated with HDL cholesterol in women.

A genome-wide association study identifies KNG1 as a genetic determinant of plasma factor XI level and activated partial thromboplastin time. *JM. Soria[1], M. Sabater-Lleal[2], A. Martinez-Perez[1], A. Buil[3], L. Folkersen[2], JC. Souto[4], M. Bruzelius[2], M. Borrell[4], J. Odeberg[2], S. Silveira[2], P. Eriksson[2], A. Almasy[5], A. Hamsten[2].* 1) Unit of Genomic of Complex Diseases, Hospital de Sant Pau, Barcelona, Barcelona, Spain; 2) Cardiovascular Genetics and Genomics Group, Atherosclerosis Research Unit, Department of Medicine, Karolinska Institutet, Karolinska University Hospital Solna, Stockholm; 3) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 4) Haemostasis and Thrombosis Unit, Department of Hematology, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; 5) Department of Population Genetics. Southwest Foundation for Biomedical Research. San Antonio, TX, USA.

Objective: Elevated plasma levels of coagulation factor XI (FXI) are implicated in the pathogenesis of venous thromboembolism (VTE) and ischemic stroke, and polymorphisms in the F11 gene are associated both with risk of VTE and an elevated plasma FXI level. Methods and Results: Here, we report the first hypothesis-free genome-wide genetic analysis of plasma FXI levels. Two genome-wide significant loci were detected in the family-based Genetic Analysis of Idiopathic Thrombophilia 1 (GAIT-1) cohort: one located in the kininogen 1 gene (KNG1) (rs710446; P=7.98×10-10), and one located in the structural F11 gene (rs4241824; P =1.16×10-8). Both associations were replicated in a second population-based Swedish cohort. A significant effect on KNG1 mRNA expression was also seen for the two most robustly FXI-associated SNPs located in KNG1. Furthermore, both KNG1 SNPs were associated with activated partial thromboplastin time (aPTT), suggesting that FXI may be the main mechanistic pathway by which KNG1 and F11 influence aPTT and risk of thrombosis. Conclusions: These findings contribute to the emerging molecular basis of VTE, and more importantly, help understanding the biological regulation of a phenotype that has proved to have promising therapeutic properties in relation to thrombosis.

Gene Variants are Associated with Soft Lipid-rich Coronary Plaque in African Americans with Replication in European Americans. *L.R. Yanek, B.G. Kral, D. Vaidya, T.F. Moy, L.C. Becker, D.M. Becker.* Medicine, Johns Hopkins University, Baltimore, MD.

Introduction: Genome-wide association studies (GWAS) have identified significant single nucleotide polymorphisms (SNP) for coronary artery calcification (CAC) in European Americans (EA) but not in African Americans (AA). Further, no studies have examined soft lipid-rich plaque, the most important vascular substrate for acute coronary syndromes. New computed tomographic angiography (CTA) technology extends simple CAC measures to allow better discrimination of plaque characteristics and identifies soft lipid rich plaque as “low attenuation plaque” (LAP). We performed a GWAS on LAP volume in healthy AA and EA from families with early-onset acute coronary events. Methods: Traditional risk factors were assessed using standard methods. Coronary artery plaque was assessed using 256 multidetector dual-source CTA. LAP was defined as plaque with density <30 Hounsfield units and volume was quantified using an automated well-validated proprietary method. Genotyping was performed using the Illumina 1Mv1c human array. MACH was used to impute to 2.5 million SNPs in HapMap II. Race-specific mixed models adjusted for age, sex, and two principal components from EIGENSTRAT were run under an additive model to test each SNP-phenotype association. Results: Participants (350 EA, 198 AA) were 58% female, with mean age 51.5 ± 10.8 years. Two SNPs were significant at p<1E-5 in AA, and had nominal replication in EA, in the same direction (Table). Conclusions: This is the first GWAS to report any potentially important genetic signals for coronary plaque in AA, replicated with the same vector and nominal significance in EA, and also the first to report signals for soft lipid rich plaque, an important precursor for acute coronary syndromes.

SNP Chr	Gene	AA MAF (MA)	AA effect	AA p	EA MAF (MA)	EA effect	EA p

Genetic variation for leukocyte telomere length predicts incident coronary heart disease The Framingham Heart Study. *S. Hwang[1], A. Aviv[2], D. Levy[1], M. Mangino[3], S. Hunt[4], A.L. Fitzpatrick[5], J.C. Bis[5], E.S. Smith[6].* 1) The National Heart, Lung, and Blood Institute, The Framingham Heart Study, Framingham, MA 01702; 2) The Center of Human Development and Aging, New Jersey Medical School, UMDNJ, Newark, NJ 07103; 3) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 4) Cardiovascular Genetics Division, Department of Medicine, University of Utah, Salt Lake City, UT84101; 5) Departments of Epidemiology and Global Health, University of Washington, Seattle, WA 98195; 6) Genome Information Sciences at University of California San Diego, 3855 Health Sciences Drive, La Jolla, CA 92093.

Shorter leukocyte telomere length (LTL) correlates with higher cardiovascular disease risk. Whether genetic variation associated with LTL can be applied as a predictor of coronary heart disease (CHD) is unknown. We examined the association between LTL genetic risk score (GRS) derived from 6 SNPs with incident CHD in 4078 Framingham Heart Study participants who were free of CHD at baseline. Polymorphisms associated with LTL were identified through meta-analysis of genome-wide association in six cohorts with a total sample size of 9190 were used to construct a GRS for LTL. We applied proportional hazards regression to test for significant association of the GRS with CHD. Net reclassification index was calculated to characterize the incremental improvement of the GRS for the prediction of CHD above and beyond established CHD risk factors. A total of 324 participants (7.95%) developed CHD after an average 11.3 years of follow-up. Results of proportional hazards regression adjusted for baseline CHD risk factors showed an association of the GRS with CHD (hazards ration 1.1, 95% confidence interval 1.03–1.19, p=0.0068 for each unit of the GRS). Those with highest quartile of the GRS had a 45% increase in risk for CHD compared with those with the lowest quartile (95% CI 8% to 95%). Results of this community-based study suggest a potential role of a GRS for the prediction of CHD. These results warrant further investigation.

Genome-wide association analysis of plasma triglyceride in Korean population. *B. Gombojav[1], D. H. Lee[1], M. K. Lee[1], Y. M. Song[2], K. Lee[3], J. Sung[1].* 1) Complex Diseaseand Genome Epidemiology Branch, Department of Epidemiology and Instituteof Environmentand Health, School of Public Health, Seoul National; 2) Department of Family Medicine, Samsung Medical Center, and Center for Clinical Research, Samsung Biomedical Research Institute, Sung Kyun Kwan University School of Medicine, Seoul, Korea; 3) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Korea.

Background: The metabolic syndrome and associated disorders such as insulin resistance and type 2 diabetes results from calorie excess, physical inactivity and underlying genetic susceptibility. Increased plasma triglycerides are key atherogenic lipid phenotype of the metabolic syndrome. Objective: To identify common genetic variants associated with plasma triglycerides, we did a genome-wide association study. Methods: A total of 537,159 markers were tested for their association with the plasma triglyceride in a GWAS. The GWAS sample consisted of 3,029 healthy individuals from 661 families of the Healthy Twin Study Korea. The most promising markers from the GWAS were subsequently tested in replication samples comprised of 8,834 individuals from the KARE study. Results: We replicate previously reported association of a synonymous SNP (rs651821) in APOA5 (P = 1.0 × 10-10) and identify four novel loci, which associated with plasma triglyceride level: 9q21.13 near GNA14 (rs6560604, P = 3.2 × 10-7); 7p21.3 near ICA1 (rs17144686, P = 3.3 × 10-7); 14q13.1 near AKAP6 (rs2300856, P < 0.0000053); 7p15.1 near CHN2 (rs3793269, P < 0.0000063). Among the four candidate loci, 9q21.13 has been reported to associate with plasma triglyceride and GNA14 controls the activation of phospholipase. Conclusion: We have identified genetic locus harboring common genetic variant that was associated with plasma triglycerides. Further studies are required to replicate these findings and to elucidate the biological mechanisms.

Genome-wide Association Study of Calcific Aortic Valve Disease. *S. Guauque-Olarte[1], M. Lamontagne[1], N. Gaudreault[1], P. Mathieu[1], P. Pibarot[1], Y. Bossé[1,2], D. Messika-Zeitoun[3,4].* 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Laval University, Quebec, Canada; 2) Department of Molecular Medicine, Laval University, Quebec, Canada; 3) Cardiology Department, AP-HP, Bichat Hospital, Paris, France; 4) INSERM U698, University Paris 7, Paris, France.

Calcific aortic valve stenosis (AS) is a life-threatening disease that affects 2% of people older than 65 years. There is currently no medical treatment available. Only a few genetic studies were conducted to uncover the genetic architecture of AS. Some candidate genes have been identified but the causal genes remain to be identified. The objective of this study was to perform a genome-wide survey of susceptibility loci for AS. Cases from Quebec and France were collected independently to perform a genome-wide association study (GWAS) on AS among patients of European ancestry. The genotyping of both Quebec and French cohorts was carried out using the Illumina® HumanOmniExpress-12v1.0 BeadChip. After quality controls, the Quebec cohort consisted of 474 patients who underwent an aortic valve replacement, while the France cohort included 486 patients with at least mild AS confirmed using echocardiography. A control cohort of 3,294 individuals of European ancestry was taken from the Illumina® iControlDB. Two independent GWAS were performed. First using the cases from Quebec and 1,575 Illumina controls, and second using cases from France and 1,576 different Illumina controls. Imputation was performed with IMPUTE2 using SNPs in common between cases and controls. Nearly 6 million genotyped or imputed SNPs were analyzed in both GWAS. Single marker associations were tested using additive logistic regression models in PLINK v1.07. Eight principal components derived from EIGENSTRAT were used as covariates to adjust for population stratification. The genomic inflation factors were 1.0 for both GWAS. A meta-analysis was then performed to identify SNPs robustly associated with AS using the inverse variance meta-analysis implemented in PLINK. The Bonferroni correction was used to adjust for multiple testing. The best genetic association signals were observed on chromosomes 12 and 15. Replication of these susceptibility loci in additional populations is underway. Identifying genes associated with AS is important to find new molecular targets and therapeutic pathways for this frequent and life-threatening disease.

Genetic Variants Explaining Sodium Intake in a Population with Higher Sodium Intake Level: The Healthy Twin Study, Korea. *M. Kho[1], Y.-M. Song[2], K. Lee[3], JE. Lee[4], K. Kim[5], J. Sung[1].* 1) Department of Epidemiology, Institute of Health and Environment, School of Public Health, Seoul National University, Seoul, Korea; 2) Department of Family Medicine, Samsung Medical Center, Center for Clinical Research, Samsung Biomedical Research Institute, Sungkyunkwan University School of Medicine, Seoul, Korea; 3) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Busan, Korea; 4) Department of Food and Nutrition, Sookmyung Women's University, Seoul, Republic of Korea; 5) Department of Statistics, Sookmyung Women's University, Seoul, Republic of Korea.

[BACKGROUND] Excess consumption of salt is an established risk factor of chronic diseases, notably hypertension as well as obesity and stomach cancer. In Asian countries including Korea, where rapid westernization of lifestyle is ongoing, traditional food has been reported to contain higher level of sodium, despite its potential beneficial effects. In our previous study, genetic factor was the most important determinant of sodium intake, with heritability of 0.32. Environmental factors including shared familial environments did not account significant proportion of salt intake. However, limited evidence has been accumulated on the specific variants explaining individual sodium intake. The aim of this study is to identify genetic variants associated with sodium intake through a genome-wide association study (GWAS). [METHOD] This study involved 2,209 healthy individuals from Healthy Twin Study cohort, Korea. We estimated 24 hour urinary sodium excretion from a Half-day urine (HU) sample. HU collection starts around 7 pm of the day before visit, after completely voiding when time record starts. Next morning, before health check, remaining urine was further voided and the time was recorded as final. We estimated 24 hour sodium intake using simple volume-time extrapolation with samples collected more than 8 hours. With samples less than 8 hours duration, we applied the Kawasaki Formula which is developed for estimating 24 hour sodium intake using spot urine. Total calorie was adjusted to correct sodium intake due to food volume. A total of 537,158 markers were tested for their association with the 24 hour sodium intake in GWAS. The association is conducted through Family-based Score Test for Association(FASTA) approach(genABEL). [RESULTS] Several candidates variants reached sufficient or probable genome-wide significance level; p16.2(p=2.35E-07), which harbors genes regulating voltage-gated Na+ channels(VGSCs) and Ca2+/calmodulin kinase in cardiac muscle; p15.33(p=8.78E-06) which harbors genes related to sodium reabsorption process in nephron; q11.21(p=8.30E-06) where genes related to potassium channel. [DISCUSSION & CONCLUSIONS] Although our findings await replications, we suggested a potential interesting genetic locus associated with individual preference to salt intake level. We expect the candidate genetic variants will provide references for future studies regarding sodium intake and its health effects.

Dietary intake of saturated fatty acids modulates the genetic effects on triglyceride concentrations in a Korean genome-wide study. *H. Lee[1], H. Jang[1], M. Go[2], J. Park[1], J. Choi[1], J. Park[1], Y. Ahn[2], B. Han[2], J. Lee[2], J. Song[1].* 1) Center for Biomedical Sciences, NIH Korea, Cheongwon-gun, Chungcheongbuk-do, South Korea; 2) Center for Genome Science, NIH Korea, Cheongwon-gun, Chungcheongbuk-do, South Korea.

Triglyceride is one of the key risk factor for the metabolic syndrome and the increased plasma triglyceride concentrations are influenced by dietary high intake of saturated fatty acid. To explore genetic loci interacting with dietary intake of saturated fatty acids participating in plasma triglyceride level, we analyzed the interaction between Korean genome-wide genotype data from the KARE project (the Affymetrix Genome-Wide Human SNP arrays 5.0) and dietary intake saturated fatty acids from Korean Genome Epidemiology Study (KoGES). We investigated 37 genome-wide significant signals interacting with dietary intake of saturated fatty acids explaining their potential involvement in triglyceride concentrations in Korean population (n = 7495). After the additional adjustment with smoking and alcohol drinking status, dietary intakes, and hyperlipidemic medication status, 1p13.2d (KCND3) and 6q25.1a (LRP11) loci appeared with the highest interaction effect signal (P for interaction < 3.47E-05) and 13q14.11d (EPSTI1), 13q21.1a (OLFM4), and 20p13e (RSPO4) loci ranked marginal interaction effect with dietary saturated fatty acid on plasma triglyceride. When the subjects were separated into two groups according to saturated fatty acid dietary intake level, high and low, KCND3 rs2165987 (1p13.2d) in the group with a high level of dietary saturated fatty acid showed the highest significant interaction with plasma triglyceride (P=0.0035). The triglyceride plasma concentration in the subjects with KCND3 rs2165987 (1p13.2d) genotypes TT (169.9 ±111.0 mg/dL) was higher than TC (152.7±83.7 mg/dL) which was higher than in CC carriers (150.5±85.8 mg/dL) in the subgroup exhibiting a higher dietary intake of saturated fatty acid. In the subgroup exhibiting a lower saturated fatty acid dietary intake, carriers of minor homozygous genotypes of LRP11 rs2342765 (6q25.1a), had lower plasma triglyceride concentrations than those who carry major homozygous genotypes (P= 0.0049. The effect of dietary intake of saturated fatty acid on plasma triglyceride might be varified by the susceptibility of KCND3 and LRP11 genotype.

A GWAS approach in search for modifiers of congenital heart disease in 22q11 microdeletion syndrome. *G.M. Repetto[1,2], C. Vial[1], S. McGhee[3], N.K. Henderson-MacLennan[4], M.L. Guzman[1], M. Palomares[5,6], G. Lay-Son[1,2], K. Espinoza[1], T. Guo[7], B. Morrow[7].* 1) Center for Human Genetics, Clin Alemana- Univ Desarrollo, Santiago, Chile; 2) Hospital Padre Hurtado, Santiago, Chile; 3) Stanford University, Stanford, CA; 4) UCLA, Los Angeles, CA; 5) Fundación Gantz, Santiago, Chile; 6) Hospital Dr Luis Calvo Mackenna, Santiago, Chile; 7) Albert Einstein College of Medicine, NY.

Chromosome 22q11 microdeletion syndrome (del22q11) has an estimated frequency of 1/4000 live births. Most patients share a common 3Mb deletion, but despite molecular similarity, the clinical phenotype shows marked variable expressivity. Approximately 50-70% of patients have congenital heart disease, predominantly involving the cardiac outflow tract. The cause of the incomplete penetrance of this manifestation of the syndrome is unknown. We performed a genome wide association study (GWAS) to search for genetic modifiers of the cardiac phenotype in Chilean patients with del22q11. DNA samples from 112 Chilean patients with del22q11 demonstrated by FISH with TUPLE1 probe (Abbott®), and know cardiac anatomy by ultrasound were analyzed with Affymetrix ® v. 6.0 SNP array. We compared cases with any cardiac or great vessel anomaly (n=59) to controls with normal cardiac or great vessel anatomy by echocardiogram (n=53). The most common cardiac defects in this series were ventricular septal defects and tetralogy of Fallot. After filtering and quality control, genotypes for 728,000 SNPs were analyzed with PLINK v1.07, using Fisher exact test for association. A Bonferroni corrected p value of 1 × 10-7 was considered as evidence of association. Five SNPs in a 100 kb region on chromosome 6q14 showed p values between 1 × 10-6 to 2 × 10-5. Although these results do not fulfill criteria for statistical significance, they point to potential regions of interest. A larger sample size in the GWAS, and sequencing of the region may help identify modifier genes for the cardiac phenotype in del22q11 syndrome. Funded by Fondecyt-Chile Grant #1100131.

Blood pressure (BP) is a heritable determinant of risk for cardiovascular disease. To investigate genetic associations with systolic BP (SBP), diastolic BP (DBP), mean arterial pressure (MAP), and pulse pressure (PP), we genotyped ~50,000 single nucleotide polymorphisms (SNPs) that capture variation in ~2,000 candidate genes for cardiovascular phenotypes in 61,619 individuals of European ancestry from cohort studies in the US and Europe. We identified novel associations between gene HRH1 and SBP and between gene MDM4 and DBP and then replicated these associations in an additional set of 65,866 independent individuals of European ancestry. We also identified associations between a SNP from SOX6 gene and SBP, previously reported to be associated with MAP. We also confirmed nine previously known loci associated with SBP, DBP, MAP, or PP (ADRB1, ATP2B1, SH2B3/ATXN2, CSK, CYP17A1, FURIN, HFE, LSP1, MTHFR) at array-wide significance (P value < 2.4 × 10-6). Modest sex interactions were identified in the MDM4 locus, and findings from eQTL analysis showed associations of SNPs in the MDM4 region with MDM4 expression. Our findings extend our understanding of genes involved in BP regulation, some of which may eventually provide new targets for therapeutic intervention.

Additional variance of serum lipid levels explained by incorporating less significant genetic variants and allelic heterogeneity. *R. Deka[1], G. Zhang[2], R. Karns[1], G. Sun[1], S.R. Indugula[1], H. Cheng[1], D. Havas-Augustin[3], N. Novokmet[3], Z. Durakovic[3], S. Missoni[3], R. Chakraborty[4], P. Rudan[3].* 1) Dept Environmental Hlth, Univ Cincinnati Med Ctr, Cincinnati, OH; 2) Human Genetics Division, Cincinnati Children's Hospital Med Ctr, Cincinnati, OH; 3) Institute for Anthropological Research, Zagreb, Croatia; 4) Institute of Applied Genomics, Univ North Texas Health Science Ctr, Forth Worth, TX.

Serum concentrations of total cholesterol, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, and triglycerides are important heritable risk factors for cardiovascular disease. Large-scale genome-wide association studies (GWAS) have identified many genetic variants robustly associated with serum lipid levels; however, these variants explain only a small proportion of the overall phenotypic variance, leading to the issues of `missing' heritability. In this study we examined two possible sources of missing heritability: first, variants with smaller effects whose associations with the trait failed to reach genome-wide significance and second, allelic heterogeneity due to the effects of multiple variants at a single significant locus. For this purpose, we developed an analytical approach that accounts for local linkage disequilibrium patterns and dissects the allelic heterogeneity of significant loci from summary-level statistics from a meta-analysis of GWAS. We applied this method to the summary results reported by Teslovich et al, *Nature* (2010) and dissected heterogeneous allelic effects of lipids-associated loci identified at various significance levels. In a sample of 1,304 individuals from an island population of the Adriatic coast of Croatia, we further examined the extent of phenotypic variance of serum lipid levels explained by incorporating the effects of both the leading and additional variants of lipids-associated loci. Our results indicate that approximately half of the lipid loci that achieved stringent genome-wide significance (p-value $< 5\times10^{-8}$) showed significant evidence of allelic heterogeneity. In addition, including less significant loci (p-value $< 5\times10^{-5}$) and accounting for effects of allelic heterogeneity substantially improved the variance explained of serum lipid levels in our samples (>50% higher than the variance explained by using only leading SNPs with genome-wide significance). These observations suggest that allelic heterogeneity is common phenomenon in complex traits and an appreciable fraction of SNPs not meeting genome-wide significance might have small but genuine effects. Supported by NIH grants R01 DK069845, P30 ES006096, T32 ES010957.

Background: The presence and severity of coronary artery calcified plaque (CAC) differs markedly between individuals of African and European descent, suggesting that admixture mapping (AM) may be informative for identifying genetic variants associated with subclinical cardiovascular disease (CVD). Methods: AM of CAC was performed in 1,040 unrelated African Americans (AAs) with type 2 diabetes from the African American-Diabetes Heart Study (AA-DHS), Multi-Ethnic Study of Atherosclerosis (MESA), and Family Heart Study (FamHS) using the Illumina custom ancestry informative marker (AIM) panel. All cohorts obtained computed tomography scanning of the coronary arteries using identical protocols. For each AIM, the probability of inheriting 0, 1, and 2 copies of a European-derived allele was determined. Association testing was performed between each AIM using these probabilities and CAC, accounting for global ancestry, age, gender and study. Results: Markers on 1p32.3 in the GLIS1 gene (rs6663966, LOD= 3.7), 1q32.1 near the CHIT1 gene (rs7530895, LOD=3.1), 4q21.2 near PRKG2 (rs1212373, LOD=3.0) and 11q25 in the OPCML gene (rs6590705, LOD=3.4) had statistically significant LOD scores, while markers on 8q22.2 (rs6994682, LOD=2.7), 9p21.2 (rs439314, LOD=2.7), and 13p32.1 (rs7492028, LOD=2.8) manifested suggestive evidence of linkage. These regions were uniformly characterized by higher levels of European ancestry associating with higher level or odds of CAC. Findings were replicated in 1,350 AAs without diabetes and 2,497 EAs with diabetes from MESA and 1,181 EAs with diabetes from the DHS. Conclusions: Fine mapping these regions will likely identify novel genetic variants that contribute to CAC and clarify racial differences in susceptibility to subclinical CVD.

Genome-wide association studies of NMR-based lipoprotein subclasses in African American populations elucidate subfractions affected by SNP variation. *Y. Huang[1], WM. Chen[1], K.L. Keene[1], F. Chen[1], U. Nayak[1], X. Hou[1], I.J. Spruill[3], K.J. Hunt[3], J.K. Fernandes[3], K.H. Lok[2], J. Divers[4], J.C. Mychaleckyj[1], D.L. Kamen[3], W. Post[5], S.S. Rich[1], J.I. Rotter[6], G.S. Gilkeson[3], W.T. Garvey[2], M. Cushman[7], M.M. Sale[1].* 1) University of Virginia, Charlottesville, VA; 2) University of Alabama at Birmingham, Birmingham, AL; 3) Medical University of South Carolina, Charleston, SC; 4) Wake Forest University School of Medicine, Winston-Salem, NC; 5) Johns Hopkins University, Baltimore, MD; 6) Cedars Sinai, Los Angeles, CA; 7) University of Vermont, Burlington, VT.

We conducted a meta-analysis of GWAS scans of NMR measured lipoprotein subclasses in 5,438 African Americans (AA), including 1,491 family-based Gullah AA from the Sea Island Genetic NETwork (SIGNET), 2,370 unrelated AA from the Reasons for Geographic And Racial Differences in Stroke study (REGARDS) and 1,577 unrelated AA from the Multi-Ethnic Study of Atherosclerosis (MESA). We also attempted replication of significant associations discovered in AA in 4,550 non-AA MESA participants. Hapmap 3 imputed autosomal SNPs (r^2>0.3) plus genotyped autosomal SNPs (1,438,463 SNPs in total)were used for meta-analysis of 23 heritable inverse-normal-transformed quantitative lipoprotein traits. A regression-based QTL model for dosage data, adjusting for sex, age, diabetes status, lipid medication status, ancestry principal components and family structure, was applied for every SNP. We identified three putative novel loci in AA. A variant in *CD36* (7q11.2) was significantly associated with NMR lipoprotein traits small VLDL particle concentration (VSP, $P=6.91\times10^{-11}$) and VLDL & chylomicron particle concentration (VLDLCP, $P=1.10\times10^{-8}$), while its association with the total concentration of VLDL & chylomicron triglyceride (NVCTG) was marginal ($P=6.36\times10^{-3}$). Two variants in *DOCK6* (19p13.2) were significantly associated with HDL particle concentration (HDLP, $P=3.34\times10^{-9}$ and $P=3.57\times10^{-9}$) and a variant in *ATRN* (20p13) was associated with large HDL particle concentration (HLP, $P=1.53\times10^{-9}$), while none of them were significantly associated with conventionally-measured total HDL cholesterol (HDL, $P=5.29\times10^{-5}$, 4.37×10^{-4} and 3.86×10^{-4} respectively). No variants in these three genes were replicated in our non-AA samples with European, Asian and Hispanic ancestry. Associations were also found between well-known lipid loci variants and novel lipid subclass traits, such as rs247617 in CETP, which was associated positively with HLP ($P=1.16\times10^{-24}$), HDL mean particle size (HZ, $P=7.63\times10^{-18}$), large LDL particle concentration(LLP, $P=2.05\times10^{-8}$), LDL mean particle size (LZ, $P=4.72\times10^{-13}$), and negatively with small LDL particle concentration (LSP, $P=9.64\times10^{-13}$), besides its previously known association with total HDL concentration. Our study suggests that the additional information provided by NMR lipoprotein subclasses may be able to identify novel lipid loci in African American population, and may also help elucidate the specific lipoprotein subclasses that are impacted by known variants.

Redefining Fibromuscular Dysplasia of the Arteries as a TGF-β Pathway Disorder. *R. Morissette[1], S. Ganesh[2], B. Griswold[1], L. Sloper[1], N. McDonnell[1].* 1) National Institute on Aging, National Institutes of Health, Baltimore, MD; 2) Division of Cardiovascular Medicine, University of Michigan Health System, Ann Arbor, MI.

Fibromuscular dysplasia (FMD) is a disorder involving stenosis, aneurysms, and dissections of predominantly renal and carotid arteries. Other medium sized arteries of the abdomen, intracranial vessels, and coronary arteries may also be involved. The histopathology observed is aberrant extracellular matrix deposition in the arterial wall. The disorder preferentially becomes evident in women in their fourth through sixth decade. Autosomal dominant inheritance with reduced penetrance has been suggested. Although FMD-type histopathology can be seen in a number of genetic disorders, no underlying gene mutation has been identified in the vast majority of patients who have a diagnosis of primary FMD. Clinical examination of FMD subjects from NIA protocol 2003-086 (a screening protocol for hereditary disorders of connective tissue) revealed a high prevalence of joint laxity (as defined by a Beighton score > 5), scoliosis, low bone density, and other stigmata of hereditary connective tissue dysplasias such as pes planus, pectus deformities, and dolicocephaly. Family histories were notable for increased incidence of thoracic and abdominal aneurysms in first-degree male relatives. These clinical findings as well as the extracellular matrix pathology led to the hypothesis that derangement of the TGF-β pathway may play a role in the pathogenesis of FMD. To study the pathway, skin biopsy specimens were obtained from 18 FMD patients and fibroblast lines were established. Secretion of TGF-β1 and TGF-β2 from the FMD fibroblasts was found to be elevated compared to matched controls (p=0.0008 and p<0.0001, respectively) by ELISA. Interestingly, secreted TGF-β3 was not significantly different (p>0.05), suggesting biomarker specificity in FMD pathogenesis. FMD patients also had elevated circulating TGF-β2 in plasma relative to matched controls (p=0.005). Studies are underway to explore the role of TGF-β signaling and other candidate pathways in FMD, as well as formulation and investigation of alternative hypotheses to explain the observed elevation of circulating and secreted TGF-β1 and TGF-β2.

Integrated microRNA and mRNA profiling of the mouse ventricles during development of severe hypertrophic cardiomyopathy and heart failure. *R.D. Bagnall[1], T. Tsoutsman[1,2], R.E. Shephard[1,2], W. Ritchie[3], C. Semsarian[1,2,4].* 1) Agnes Ginges Center for Molecular Cardiology, Centenary Institute, Sydney, NSW, Australia; 2) Sydney Medical School, University of Sydney, NSW, Australia; 3) Department of Bioinformatics, Centenary Institute, Sydney, NSW, Australia; 4) Department of Cardiology, Royal Prince Alfred Hospital, Sydney, NSW, Australia.

Hypertrophic cardiomyopathy (HCM) is a primary disorder of the myocardium characterized by left ventricular hypertrophy, myocyte disarray and interstitial myocardial fibrosis. HCM is caused by autosomal dominant mutations primarily affecting genes encoding proteins of the sarcomere, however, it is less clear how these mutations alter intracellular signaling, leading to cardiac remodeling and hypertrophy. MicroRNAs (miRNAs) are short non-coding RNAs that regulate post-transcriptional gene expression during development and disease. We have used TaqMan Low Density Arrays to measure the expression levels of 335 murine miRNAs in ventricular tissue and determine the miRNA signatures of early- and end-stage HCM in a severe, transgenic mouse model of the disease. Seven miRNAs were dysregulated at an early stage of HCM development. Time-course analysis revealed that decreased expression of miR-1 commences at a pre-disease stage, with a consequent upregulation of target genes causal of cardiac hypertrophy and fibrosis, and thus represents an early disease change. At end-stage HCM, 21 miRNAs were dysregulated to form a cardiac stress signature resembling that of other forms of cardiac hypertrophy, suggesting common responses. Analysis of the mRNA transcriptome using Affymetrix GeneChip Arrays revealed that miRNAs potentially target 19.7% upregulated and 6.7% downregulated mRNAs at end-stage HCM, and regulate mRNAs associated with cardiac hypertrophy, calcium signaling, fibrosis and the Tgf-β signaling pathway. Collectively, these results highlight the regulatory roles of miRNAs in the development and progression of HCM, and shed light on critical miRNA regulated gene networks involved in disease pathogenesis. Furthermore, strategies to maintain miR-1 levels may represent a therapeutic opportunity in HCM.

Novel transcripts and pathways identified in blood one week following implant of continuous-flow left ventricular assist device (CF-LVAD). *J.L. Hall[1], W. Guan[2], A. Mitchell[1], R. Staggs[1], S. Grindle[1], N. Adhikari[1], S. Hozayen[1], P. Eckman[1].* 1) Dept Med, Univ Minnesota, Minneapolis, MN; 2) Dept Biostatistics, School of Public Health, Univ Minnesota, Minneapolis MN.

Introduction: Bleeding, thrombosis and infection are common adverse events following placement of continuous-flow left ventricular assist devices (CF-LVADs). We performed RNA sequencing to identify novel genes and pathways that may be involved. Methods: RNA was extracted from blood samples taken from 9 heart failure patients (8 males) prior to and 7 days after implant of a CF-LVAD. Libraries were sequenced on an Illumina Hiseq2000 and sequences mapped to the human ensembl GRCh37.67 genome assembly using TopHat. Annotations were assigned using the ensembl gene transfer format (GTF) reference. Cufflinks, Cuffmerge and Cuffdiff were used to generate FPKM values. All called gene FPKM values and upper, lower confidence interval bounds were analyzed with a Paired T-test and q-values generated to estimate the false discovery rate. Ingenuity Pathway Analysis was used to investigate pathways. Results: Five of the top ten differentially expressed genes were related to hematopoiesis, neuronal edema, or leukocyte trafficking (carbonic anhydrase I, 7.1 fold up, p< 0.001, q=0.035; alpha hemoglobin stabilizing protein, 6.1 fold up, p 0.002, q=0.043, ABCG2, 4.6 fold up, p< 0.0006 q = 0.02; FAM20A, 4.6 fold up, p 0.0003, q=0.02; CXCL9, 4.0 fold down, p < 0.0006, q=0.03). Of the major pathways represented two involved T cell signaling (CD28 signaling and CTLA4 signaling). Conclusions: To our knowledge this is the first characterization of changes in the human transcriptome in blood one week after LVAD insertion. These findings may represent new pathways for exploration to define mechanisms underlying the adverse events in this patient population.

Activation of TLR signaling in atherosclerosis and ischemic stroke. *C.-C. Huang[1], R. Sieberg[2], G. Feng[2], S. Wang[3], M. Yu[3].* 1) Dept of Preventive Medicine, Northwestern Univ, Chicago, IL; 2) Feinberg School of Medicine, Northwestern University, Chicago, IL; 3) Dept of Biostatistics & Medical Informatics, University of Wisconsin, Madison, WI.

Atherosclerosis is the major cause of cardiovascular diseases (CVD), the leading cause of morbidity and mortality in the United States and the developed world. Early efforts to understand the etiology of atherosclerosis from large population studies have established that atherosclerosis is primarily caused by dys-regulation of lipid metabolism, compounded by the influence of diverse modifiable risk factors such as smoking and hypertension. However, a wealth of recent investigations has revealed that inflammation also plays a central role in atherosclerosis. Compelling evidence shows that inflammation is a key mediator of atherosclerosis, rather than merely a bystander of this disease. Recently, the immune system has been shown to play a critical role in inflammatory response in atherosclerosis. However, the major genetic pathways and their components involved in regulating immune response in atherosclerosis remain to be elucidated. In this work, we perform an integrative analysis of four public available microarray gene expression data sets in human studies. These studies investigated transcriptomic changes in atherosclerosis, ischemic stroke, and acute inflammatory response in peripheral blood, as well as atherosclerotic lesion progression. Data sets are downloaded from NCBI Gene Expression Omnibus (GEO). Analysis on individual data set shows abundant differentially expressed (DE) genes comparing disease phenotype with control samples or advanced lesions with early lesions. Gene expression fold changes or t statistics were calculated for each study. Parallel comparisons of these statistics show striking correlation (Pearson correlation coefficient ρ: 0.56–0.76) across studies. Gene ontology analysis of DE genes identified several enriched immune and inflammatory pathways, including toll-like receptors (TLR), NF-$\kappa\beta$, p38 MAPK, B-cell, and T-cell signaling. More importantly, pathway mata-analysis identified toll-like receptor (TLR) signaling as the most significant pathway. Since TLR pathways play a pivotal role in initiating and shaping innate and adaptive immune responses, our result suggests that activation of TLR signaling promotes atherosclerosis and eventually lead to clinical events such as ischemic stroke.

Genetic insights into Nonalcoholic Fatty Liver Disease from the proteomic analysis of HDL particles. *K. Merath[1], M. Zickus[1], R. Komorowski[2], J. Wallace[3], M. Goldbladtt[3], S. Gawrieh[4], M. Olivier[1].* 1) Physiology, Medical College of Wisconsin, Wauwatosa, WI; 2) Pathology, Medical College of Wisconsin, Wauwatosa, WI; 3) Surgery, Medical College of Wisconsin, Wauwatosa, WI; 4) Medicine/Gastroenterology, Medical College of Wisconsin, Wauwatosa, WI.

Nonalcoholic Fatty Liver disease (NAFLD) defines a spectrum of disease manifestations that are associated with a liver fat content of greater than 5 percent. Obesity, insulin resistance, and dyslipidemia are predisposing factors. In a subset of NAFLD patients, the disease progresses to a state characterized by liver inflammation and fibrosis referred to as nonalcoholic steatohepatitis (NASH). Due to the variability in the development of steatosis and the subsequent variation in the progression of the state of liver disease, it is probable that genetic polymorphisms are a contributing factor. Three GWAS have been reported for NAFLD to date and a number of genetic modifiers have been previously reported. However, the likely complex genetic nature of NAFLD and the progression to NASH has not been fully elucidated. In this study, we are taking an alternative approach to identify potential genetic contributors. One of the characteristic changes in the lipid profile of obese individuals is a shift to smaller, denser HDL particles. Smaller and denser HDL particles are thought to lose their cardioprotective properties and thus are referred to as “dysfunctional” HDL. In previous studies, we have shown that this shift to smaller denser HDL particles correlates with quantitative changes in HDL-associated proteins. We have previously validated a technique of separating the larger HDL2 and the smaller HDL3 particles from human serum by size exclusion chromatography. Using nano-HPLC-ESI-tandem mass spectrometry, the proteomes of the particles can be quantitatively assessed. We characterized differences between the HDL particles of NAFLD and NASH patients and control individuals. All individuals were morbidly obese females of Northern European descent. We selected five representative individuals with NAFLD and age-matched control individuals for a comprehensive proteomic analysis using mass spectrometry. Overall, we identified 319 HDL-associated proteins in our analysis. Across all pairs, we identified a total of 12–17 significantly different protein levels, with 4–11 proteins increased in NAFLD patients. The proteins identified included proteins involved in immune signaling, and members of the complement and the coagulation system. The ultimate goal is to use this proteomic data to identify specific proteins and assess the corresponding gene for variations within our cohort that might contribute to the development of NAFLD and/or to the progression to NASH.

Do variations in genes encoding the argonaute proteins confer risk or protection from cardiovascular disease in Europeans? *I. Predazzi[1], W. Bush[1], S. Williams[1,2].* 1) CHGR, Vanderbilt University, Nashville TN, TN; 2) Dartmouth Medical School, Hanover, NH.

Micro RNAs (miRNAs) are small non-coding RNAs that bind argonaute proteins and regulate post-transcriptional gene expression of specific targets. Many miRNAs have been implicated in the pathogenesis of cardiovascular disease (CVD); however, mechanisms through which miRNAs affect CVD are still unclear. In particular, little is known about how genetic variation in miRNAs and associated genes may affect their function and ultimately disease. We hypothesized that genes encoding proteins that interact with all miRNAs (e.g., Drosha, Dicer-1 and the argonaute proteins) should be conserved across human populations; whereas miRNA sequences that have specific, more limited functions should be less conserved. We assessed the patterns of selection of genes that encode generic miRNA interacting proteins, Drosha, Dicer-1 and the argonaute proteins. We also tested whether regions that encode for miRNA and miRNA targets associated to CVD are subject to population specific patterns of selection, depending on the environment. We found strong signals of selective sweeps in three out of four genes encoding for argonaute proteins (EIF2C1, EIF2C2 and EIF2C3), but only in European samples. Through whole-genome eQTL analysis, we identified SNPs in the genetic regions that regulate expression of these genes and found that these SNPs are most polymorphic in European populations and exhibit large Fst compared to other continental ancestry groups (Fst ~ 0.400). Notably, two of these variants (rs7540413 and rs4026409) have been reported to associate with CAD in a previous genome wide association study. Our data indicate that miRNAs could have population specific expression patterns. Furthermore, SNPs affecting miRNA function could confer risk to disease, and this effect could be different depending on population. Further studies will be necessary to assess the role of these and other genetic variation in miRNA regulation and disease.

Gene expression profiling in peripheral blood cells in patients with myocardial infarction at young age. *T. Zeller[1], C. Müller[1], A. Schillert[2], M.O. Scheinhardt[2], S. Szymczak[2], F. Ojeda[1], C.R. Sinning[1], R.B. Schnabel[1], S. Wilde[1], P.S. Wild[3,4], K.J. Lackner[5], T. Munzel[4], A. Ziegler[2], S. Blankenberg[1].* 1) Clinic for General and Interventional Cardiology, University Heart Center Hamburg, Hamburg, Germany; 2) Institut für medizinische Biometrie und Statistik, Universitätsklinikum Schleswig-Holstein, Campus Lübeck, Maria-Goeppert-Str. 1, 23562 Lübeck, Germany; 3) Center for Thrombosis and Hemostasis, University Medical Center Mainz, Johannes Gutenberg University Mainz, Germany; 4) Department of Medicine 2, University Medical Center Mainz, Johannes Gutenberg University Mainz, Germany; 5) Institute for Clinical Chemistry and Laboratory Medicine, University Medical Center Mainz, Langenbeckstraβe 1, 55131 Mainz, Germany.

Myocardial infarction (MI) is one of the main causes of mortality. It usually is a disease of the middle-aged and elderly and MI in young adults is a rare phenomenon and explanations about the molecular mechanisms of the genetic predisposition of MI at young age remain elusive. Transcriptome analysis by large-scale gene expression profiling is a promising tool to explore disease-related genes and biological pathways. The aim of this study was to identify differentially expressed genes in young MI individuals, to functionally characterize these genes by pathway analysis and to investigate the relation to the underlying pathophysiology. Using Affymetrix GeneChip Human Exon ST1.0 gene expression data we performed linear regression analysis to identify differentially expressed genes between 235 young MI individuals and 419 population-based controls. After adjustment for classical cardiovascular risk factors age, gender, hypertension, smoking, BMI, diabetes, LDL/HDL ratio and principal components we identified 217 genes being differentially expressed in the young MI group. Most significantly deregulated was *GPR15*, an orphan G-protein-coupled receptor ($p = 5.96*10^{-17}$, up-regulation, fold change 1.78). Pathway analysis using the Ingenuity Pathways Analysis tool (IPA) identified several canonical pathways including the pathways of “PPARα/RXRα Activation”, “Role of NFAT in Cardiac Hypertrophy”, and the “P2Y Purigenic Receptor Signaling” Pathway. These analyses revealed key signaling processes (G-protein signaling, including *P2RY2*, *DUSP1*, *GPR107*, *GPR133*, *PRKAG2*, *PIK3CD*, *ADCY2*, *ADCY7*, *GNAL*) and lipid metabolism (including *ABCA1*, *ABCG1*, *FDFT1*, *GALNT2*, *LIPG*) to be affected in MI patients at young age. Expression quantitative trait analysis to investigate the genetic background of differentially expressed genes revealed SNPs surrounding genes involved in lipid metabolism to be associated with expression of those genes, with the strongest association found for the *FDFT1* gene and SNPs rs2740592 ($p = .19*10^{-13}$), rs4839 ($p = 2.96*10^{-13}$), rs1692821 ($p= 6.39*10^{-13}$). This comprehensive transcriptome analysis of circulating peripheral blood cells in patients affected by MI at young age revealed several profoundly changed genes involved in key pathways. Our results provide novel insights in the genetic basis and expand our current understanding of the pathophysiology.

A genetic study of familial intracranial aneurysm in French-Canadian and Inuits through exome sequencing. *S. Zhou[1], L. Xiong[1,2], C. Bourassa[1], M. Bojanowski[3], N. Dupré[4], M. Dubé[5], A. Dionne-Laporte[1], D. Spiegelman[1], E. Henrion[1], O. Diallo[1], P. Dion[1], G. Rouleau[1,6].* 1) Centre of Excellence in Neuroscience of Universite de Montreal(CENUM), CHUM Research Center and the Department of Medicine, Montréal; 2) Centre de recherche Fernand-Seguin, Hopital Louis H. Lafontaine, Montreal; 3) Department of Surgery, Universite de Montreal, Montreal; 4) Department of Neurology, Universite Laval, Quebec; 5) Pharmacogenomics Centre, Montreal Heart Institute, Universite de Montreal, Montreal; 6) Ste-Justine Hospital Research Center, Universite de Montreal, Montreal.

Background: Intracranial Aneurysm (IA) is a localized dilation or ballooning of the cerebral artery; a lesion may lead to a consequence of subarachnoid hemorrhage. The cause of primary IA is mainly unknown except for its genetic origin and co-exist factors such as hypertension and smoking. Moreover, genetic predisposition is even higher in familial IA. **Materials & Methods:** We performed whole exome sequencing in 19 affected individuals from three French-Canadian (FC) and one Quebec Inuit families. Targeted capture was done using the SureSelect Human All Exon 50Mb Kit and was sequenced on Illumina Hiseq 2000. Bioinformatic analytical pipline includes FastQC, BWA, GATK and Annovar were used for QC, alignment, variant calling and annotation, respectively. An in-house algorithm was applied for the family-wide variant segregation analyses and based on a selection of 583 in-house controls. **Results & Conclusions:** The initial goal of this study is to look for rare or unique exonic nonsynonymous variants or indels co-segregating within IA individuals of each family. 30 such variants from the exome data of 3 FC families were selected and were validated in all available family members, from which 7 variants showed a >70% penetrance in a separate family. A missense variant located in gene *NOG* was particularly interesting. The variant P84H was presented in all 5 affected individuals from one family but in none of its unaffected members, and was also absent from more than 700 other in-house exomes and 1000 Genome Database. Six different prediction programs indicated that the variant had an extremely deleterious effect to this single exon gene. However, *NOG* mutations have been implicated to cause severe defects such as multiple synostosis and proximal symphalangism which doesn't include IA as part of their clinical descriptions. Therefore, the contribution of this variant to IA in this family is unknown and need further research. At last, the study of combining genome-wide linkage analysis and exome data of the large Inuit IA pedigree is currently undergoing, as well as the additional sequencing of thirty-two IA affected Inuits. From which we hope they will add more information to the discovery of candidate region of Inuit IA.

Rare variant *APOC3* R19X is associated with cardio-protective profiles in a diverse population-based survey as part of the Population Architecture using Genomics and Epidemiology (PAGE) study. *D.C. Crawford[1,2], L. Dumitrescu[1], R. Goodloe[1], K. Brown-Gentry[1], C. Sutcliffe[1], R. Wiseman[1], P. Baker[1], H.H. Dilks[1,2], J. Boston[1], B. McClellan, Jr[1], P. Mayo[1], M. Allen[1], N. Schnetz-Boutaud[1], J.L. Haines[1,2], T.I. Pollin[3].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 3) Division of Endocrinology, Diabetes and Nutrition, Department of Medicine, University of Maryland School of Medicine, Baltimore, Maryland.

High levels of low-density lipoprotein cholesterol (LDL-C) and triglycerides (TG) and low levels of high-density lipoprotein cholesterol (HDL-C) have long been recognized as risk factors for coronary artery disease (CAD), a leading cause of morbidity and mortality. Approximately 100 common genetic variants have been associated with lipid traits through genome-wide association studies, collectively accounting for <15% of the observed heritability. Multiple large effect rare variants in aggregate may account for much of the "missing heritability" as well as provide better predictors of cardio-risk and cardio-protective profiles in a personalized medicine setting. Indeed, a founder mutation was recently discovered and described as conferring favorable lipid profiles and reduced subclinical disease in a Pennsylvania Amish population, and preliminary data have suggested that this null mutation *APOC3* R19X (rs76353203) is rare in the general population. To better describe the frequency and associated lipid profile in a general population setting, we as part of the Population Architecture using Genomics and Epidemiology (PAGE) study and the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) genotyped rs76353203 in the National Health and Nutrition Examination Surveys (NHANES III, 1999–2002, and 2007–2008). Out of 19,613 participants, we identified 30 participants heterozygous and one homozygous for the 19X allele, for an overall allele frequency of 0.08% in this US-representative survey. Among the three major groups, the 19X allele was observed at a higher frequency among Mexican Americans (0.23%) compared with non-Hispanic whites (0.20%) and non-Hispanic blacks (0.02%). Among fasting adults, the 19X allele was associated with lower ln(TG) (n=5,990; β= -0.55; p = 3.6×10-4) and higher HDL-C (n=8,891; β = 15.65; p = 2.1×10-4) and trended towards lower LDL-C (n=6,502; β= -4.85; p = 0.68) after adjustment for age, sex and race/ethnicity. On average, participants with the 19X allele had approximately half the TG levels (geometric means 65 vs. 141 mg/dL), >20% higher HDL-C levels (geometric means 68 vs. 52 mg/dL), and, although not statistically significant, had lower LDL-C levels compared with RR participants (geometric means 110 vs. 121 mg/dL). Overall, these data demonstrate that *APOC3* R19X exists in the general U.S. population in multiple racial/ethnic groups and that 19X is associated with cardio-protective lipid profiles.

1672T

Resequencing of the Cholesteryl Ester Transfer Protein gene (CETP) in U.S. Whites and African Blacks with extreme HDL-C levels. *D. Pirim[1], F.Y. Demirci[1], X. Wang[1], J.E. Hokanson[2], R.F. Hamman[2], C.H. Bunker[3], C.M. Kammerer[1], M.M. Barmada[1], M.I. Kamboh[1].* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, Colorado School of Public Health, Univ Colorado Denver, Aurora, CO; 3) Epidemiology, GSPH, Univ Pittsburgh, Pittsburgh, PA.

Coronary heart disease (CHD) is a global health problem and the main cause of morbidity and mortality in developed countries. In order to decrease the global burden of CHD across the world, the risk factors for CHD have been investigated by conducting both epidemiological and genetic studies. Genetic findings suggest that *CETP* genetic variation has an impact on the inter-individual variation in CHD risk by affecting the plasma lipid levels. Although several common genetic variants were reported to be associated with *CETP* deficiency and CHD risk, undetermined variations in this gene still stir up considerable research interest. To investigate the role of both common and rare variation in *CETP* in regulating plasma HDL-C levels, we resequenced the entire gene (22kb) and 1kb flanking regions in individuals with HDL-C levels of lower 5th percentile (48 Whites, 47 Blacks) and upper 5th percentile (47 Whites, 48 Blacks), selected from a non-Hispanic White (NHW) U.S. population and an African Black population. We identified a total of 280 variants, of which 45 were present only in NHWs and 157 were present only in Blacks. Out of 280 variants, 136 were common with a minor allele frequency (MAF) ≥0.05. Fourteen variants were located in coding regions, of which 9 were predicted to cause non-synonymous changes. Thirty-six common variants showed significantly different allele frequencies between high and low HDL-C subgroups in at least one ethnic group. The variants that showed most significant MAF distribution between the two subgroups were rs17231506 (p=1.00×10-6) and rs17231520 (p=2.36×10-6) in Whites and Blacks, respectively. These two variants were already reported to be strongly associated with HDL-C levels in different ethnic groups; hence, our data confirmed previous associations. We observed 74 rare or relatively uncommon variants (MAF<0.05) unique to either high or low HDL-C subgroups in at least one ethnic group, suggesting the potential importance of *CETP* rare variation in determination of the HDL-C levels. Our complete sample sets of NHWs (n=623) and Blacks (n=788) were comprehensively genotyped for the rare and common variants identified by resequencing; the results are being analyzed for associations with plasma lipid levels using single-site, haplotype, and burden tests. The results of this comprehensive analysis will help us to better understand the role of both common and rare variants in *CETP* in regulation of plasma HDL-C levels and other lipids.

1673T

Comprehensive evaluation of the effects of *APOE* genetic variation on plasma lipoprotein traits in U.S. Whites and African Blacks. *Z.H. Radwan[1], F.Y. Demirci[1], X. Wang[1], F. Waqar[1], J.E. Hokanson[2], R.F. Hamman[2], C.H. Bunker[3], C.M. Kammerer[1], M.M. Barmada[1], M.I. Kamboh[1].* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, Colorado School of Public Health, Univ Colorado Denver, Aurora, CO; 3) Epidemiology, GSPH, Univ Pittsburgh, Pittsburgh, PA.

Cardiovascular diseases (CVD) continue to be a leading cause of mortality and morbidity worldwide. CVD risk factors are well established and dyslipidemia with high levels of low-density lipoprotein cholesterol (LDL-C) and low levels of high-density lipoprotein cholesterol (HDL-C) is a significant risk factor. Thus, unraveling the genetic determinants of the interindividual variation in plasma lipoprotein levels that modulate the CVD risk has public health importance. Apolipoprotein E (ApoE) has a crucial role in lipoprotein metabolism and its genetic variation was found to have effects on lipoprotein levels and CVD risk. The objective of this study was to identify the common and rare genetic variants of *APOE* through comprehensive resequencing of all exons, introns and 1 kb flanking regions of the gene in 95 individuals with extreme HDL-C levels (upper and lower 5th percentiles), selected from two distinct well-defined epidemiological samples [U.S non-Hispanic Whites (NHWs) and African Blacks], and then evaluate the tagSNPs and all relevant rare variants in entire sample sets (623 NHWs and 788 Blacks) to examine their effects on lipid profiles. Analysis of sequencing data revealed a total of 42 variants (40 substitutions and 2 indels), of which 11 were present in both ethnic groups. In NHWs, 20 variants were observed, of which 4 were located in exons, 2 were indels, and 56.0% had ≥5% minor allele frequency (MAF). In Blacks, out of 32 variants observed, 3 were located in exons, 2 were indels, and 30.0% had ≥5% MAF. In NHWs, 28% of the individuals in the high HDL-C group (13/47) had at least one rare or relatively uncommon variant (MAF<5%) versus 13% in the low HDL-C group (6/48). Similarly in Blacks, 52% of the individuals in the high HDL-C group (25/48) had at least one rare or relatively uncommon variant versus 36% in the low HDL-C group (17/47). Following comprehensive genotyping of the identified variants in entire sample sets, single-site association analysis of variants with MAF≥1% revealed 8 variants in NHWs (MAFs ranging between 0.021 and 0.477) and 9 variants in Blacks (MAFs ranging between 0.017 and 0.366) significantly associated with one or more lipoprotein traits. Haplotype analyses and rare variant burden tests have also been performed. Our findings indicate that APOE genetic variation has a significant role in regulating plasma lipoprotein levels, further supporting the importance of ApoE in lipoprotein metabolism.

Filamin-C: a novel candidate for familial restrictive cardiomyopathy identified by whole-exome sequencing. *M. Tariq, E. Miller, S. Ware.* Division of Molecular Cardiovascular Biology and The Heart Institute, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Restrictive cardiomyopathy (RCM) is a rare and distinct form of cardiomyopathy characterized by normal ventricular chamber dimensions, normal myocardial wall thickness, and preserved systolic function. The abnormal myocardium, however, demonstrates impaired relaxation. RCM accounts for <5% of all cardiomyopathies in the US and Europe. To date, dominant mutations causing RCM (~10% of all cases) have been reported in a small number of sarcomeric or cytoskeletal genes including *DES, ACTC1, TNNI3, TNNT2*, and *MYH7*. In this study, we investigated a large family with multiple affected individuals diagnosed with autosomal dominant isolated RCM. All affected individuals presented in childhood without evidence of myopathy or other extra-cardiac findings. Clinical genetic testing for sarcomeric genes was negative in the proband. To identify the cause of disease in the family, whole-exome sequencing of the proband was undertaken with >30x coverage resulting in 26,065 coding variants. After filtering by comparison to 1000 Genomes and dbSNP135 datasets, 2,913 non-synonymous changes were left. Targeted filtering of these changes for ~300 genes previously implicated in cardiomyopathy or related-phenotypes, heart development, or cardiac function identified 4 heterozygous changes: one each in *MYPN, LDB3, PKP2, FLNC*. After screening 4 affected and 2 unaffected individuals of the family, only *FLNC* (c.C6893T; p.Pro2298Leu) segregated appropriately with the disease-phenotype. Filamin C is an actin crosslinking protein found in skeletal and cardiac muscle and localizes to the z-disk, sarcolemma, and sarcoglycan-related complex. A small number of mutations in the FLNC N-terminal actin binding and rod or dimerization domains have been identified in distal myopathy and myofibrillar myopathy, respectively. The *FLNC* p.Pro2298Leu mutation falls in the immunoglobulin-like repeat of the protein affecting a highly conserved residue, and is predicted to be damaging by 5 different bioinformatic programs. In analogy to the domain-specific phenotypes caused by mutations in related family members such as *FLNA* and *FLNB*, we predict that the *FLNC* p.Pro2298Leu mutation causes isolated RCM without skeletal myopathy. Functional analyses are ongoing. In conclusion, we identified a new candidate for autosomal dominant RCM using whole-exome sequencing. This study extends the current clinical and genetic spectrum of filaminopathies by associating a novel *FLNC* mutation to a distinct phenotype.

Mutations in SMAD3 in a British cohort of thoracic aortic aneurysm and dissection (TAAD) patients. *G. Arno[1], J.A. Aragon-Martin[1], O. Song[1], N.P. Kamali[1], A. Saggar[2], M. Jahangiri[3], A.H. Child[1].* 1) Cardiac and Vascular Sciences, St George's University of London, London, United Kingdom; 2) Clinical Genetics Unit, St George's University of London, Cranmer Terrace, London SW17 0RE, UK; 3) Department of Cardiothoracic Surgery, St. George's Healthcare NHS Trust, London, UK.

Background: Thoracic aortic aneurysm and dissection (TAAD) is a feature of several genetic conditions, such as Marfan (MFS) and Loeys-Dietz (LDS) syndromes. However, there is a growing body of work suggesting that non-syndromic TAAD is also of genetic origin. Recently studies have implicated mutations in *SMAD3* (MIM*603109) as a cause of aneurysm-osteoarthritis syndrome (AOS) and 2% of non-syndromic familial TAAD. AOS is characterised by thoracic aortic aneurysm with a risk of early dissection, aneurysm and tortuosity throughout the arterial tree, joint anomalies with osteoarthritis, osteochondritis dissecans (OCD) and meniscal anomalies. It was the aim of this study to determine the frequency of *SMAD3* mutation in a consecutive series of TAAD patients attending a British MFS cardiac genetics clinic. Diagnosis was based on pedigree, physical examination, echocardiogram, CT and MRI studies and operative reports. **Method:** A total of 87 UK patients (71M:16F, mean age 51±13.1) with known TAAD who did not fulfill the revised Ghent criteria for MFS, and with no demonstrable mutations in *FBN1*, *TGFBR2* or *ACTA2* were recruited to this study. These patients were screened for mutations in all exons of *SMAD3* including intron/exon boundaries by bi-directional sequencing. **Results:** Five novel mutations were identified in 6/87 (6.9%) probands. These mutations comprised: in exon 1, a missense mutation - p.Ile67Ser (c.200T>G) (found in two unrelated probands); in exon 2, a missense mutation - p.Arg90Cys (c.268C>T); in intron 2 - c.401-6G>A - predicted to create a cryptic splice site; in exon 6, a nonsense mutation - p.Tyr238* (c.714C>A); and also in in exon 6, a duplication leading to a frameshift and premature termination codon - p.Arg287Thrfs*24 (c.858dupA). None of the mutations were found in 208 control chromosomes or are reported in any SNP databases. The cryptic splice site mutation found in intron 2 was identified in an affected sibling of the proband, familial screening is ongoing. **Conclusion:** This study supports data from previous studies that link mutations in *SMAD3* with TAAD. Furthermore, our findings suggest it may be a more important cause of aneurysmal disease in our British population than equivalent similar US or European studies.

1676T

Distribution of sarcomere vs. non-sarcomere gene mutations in over 2400 hypertrophic and dilated cardiomyopathy patients. *S. Baxter[1], A. Daly[1], D. Macaya[1], N. Smaoui[1], G. Richard[1], W. Chung[2].* 1) GeneDx, Gaithersburg, MD; 2) Department of Pediatrics, Columbia University Medical Center, New York, New York, USA.

Hypertrophic and dilated cardiomyopathy (HCM/DCM) are primarily disorders of the sarcomere. Rarely, mutations in genes encoding non-sarcomere proteins have been associated with both forms of cardiomyopathy, including non-syndromic (Z-disk genes) and syndromic forms (protein storage and mitochondrial disorders). We assessed 1838 HCM and 630 DCM cases that were sent for clinical diagnostic testing over the course of two years to study the mutation distribution and contribution of genes encoding non-sarcomere proteins to HCM and DCM. The HCM cases were sequenced for 18 genes including 9 sarcomere-encoding genes (ACTC1, MYBPC3, MYH7, MYL2, MYL3, TNNC1, TNNI3, TNNT2, and TPM1) and 9 non-sarcomere-encoding genes (CAV3, GLA, LAMP2, MTTG, MTTI, MTTK, MTTQ, PRKAG2, and TTR). Of the 1838 HCM cases, 38% (n=706) had a positive result and 5% (n=85) had one or more variant of unknown clinical significance (VUS), 4% in sarcomere genes and 1% in non-sarcomere genes. A disease-causing mutation in a sarcomere gene was identified in 677 cases compared to 34 cases with mutations in non-sarcomere-encoding genes, including CAV3 (n=1), GLA (n=9), LAMP2 (n=4), mitochondrial genes (n=5), PRKAG2 (n=9), and TTR (n=6). Five percent (n=84) of all cases had more than one mutation or VUS. The DCM cases were sequenced for 27 genes including 6 sarcomere-encoding genes (ACTC1, MYBPC3, MYH7, TNNI3, TNNT2, and TPM1) and 21 non-sarcomere-encoding genes (DES, LAMP2, LDB3 (ZASP), LMNA, MTND1, MTND5, MTND6, MTTD, MTTH, MTTI, MTTK, MTTL1, MTTL2, MTTM, MTTQ, MTTS1, MTTS2, PLN, SGCD, TAZ, and TTR). Of the 630 DCM cases, 26% (n=165) were positive and 10%(n=65) had VUSs evenly split between sarcomere and non-sarcomere genes. Compared to HCM, DCM has a higher frequency of non-sarcomere mutations among positive cases, 37% (n=61). The majority of pathogenic mutations in non-sarcomere genes were identified in LMNA (n=34) and mitochondrial genes (n=10). Like HCM, 5% (n=33) of the DCM cases also had more than one mutation or VUS. Our data supports the notion that HCM and DCM are predominantly diseases of the sarcomere; however, DCM has a significantly higher prevalence of mutations in non-sarcomere genes ($p<0.001$). Although storage disorders and mitochondrial disorders are relatively rare causes of HCM and DCM, they are important to include in molecular testing panels for prevention, early diagnosis, and management of cardiac and extra-cardiac symptoms.

1677T

Burden of rare sarcomere gene variants in the Framingham and Jackson Heart Study cohorts. *A. G. Bick[1,2], J. Flannick[2,3], K. Ito[1], S. Cheng[4], R. S. Vasan[5,6], M. G. Parfenov[1], D. S. Rare non-synonymous mutations in sarcomere genes cause hypertrophic and dilated cardiomyopathies, dominant disorders that are characterized by cardiac remodeling and dysfunction. To evaluate whether allelic variants in these genes are associated with cardiac morphology and function in the general population, eight sarcomere genes (*ACTC1, MYBPC3, MYH7, MYL2, MYL3, TNNI3, TNNT2, TPM1*) were sequenced in 1,637 individuals from the Framingham Heart Study (FHS) Offspring cohort and 1,963 individuals from the Jackson Heart Study (JHS) cohort; echocardiography was used to assess cardiac structure and function. Amongst the sequenced individuals, 11.2% had one or more rare (MAF<1%) non-synonymous coding variants. The prevalence of rare likely pathogenic sarcomere variants was 0.6%, at least two times higher than previously anticipated. Individuals with rare sarcomere variants had significantly increased mean left ventricular wall thickness (LVWT) of 3% ($p=.01$) and 2% ($p=.05$) in the FHS and JHS cohorts, respectively. Sarcomere gene variants previously identified as pathogenic that were detected here conferred an 8.6% greater LVWT in the FHS cohort ($p=.05$, n=14) but no change in the JHS cohort (n=8). Only 4 out of the 22 individuals carrying likely pathogenic variants had clinical manifestations of HCM implying that pathogenic variants identified in affected individuals may have reduced penetrance when ascertained in the general population. Additionally individuals with the combination of a common variant rs3729799 (*MYBPC3*, p.R1002W) and a second rare *MYBPC3* variant had a 15% decreased LVWT in comparison to individuals with rs3729799 and no rare variant ($p<10^{-5}$) implying that multiple variants may have more effect on cardiac morphology than each alone. Rare sarcomere variants were associated with increase left ventricular dimensions over time and an increased risk for adverse cardiovascular events over a follow-up period of 30 years (hazard ratio: 2.3; 95% confidence interval: [1.2, 4.1]) in the FHS cohort. Our sequence analysis of eight sarcomere protein genes, suggests that analysis of rare variants may potentially contribute to cardiovascular risk assessment in the general population.

Whole-exome sequencing for identification of novel genes and variants underlying the risk of Lonq-QT syndrome. *M. Chaix[1], P. Goyette[1], A. Alikashani[1], F. Latour[1], L. Robb[1], B. Mondesert[1], L. Rivard[1,2], S. Foisy[1], M. Ladouceur[1], R.M. Hamilton[3], M. Talajic[1,2], J.D. Rioux[1,2].* 1) Montreal Heart Institute, Montreal, Canada; 2) Universite de Montreal, faculty of medicine; 3) The Hospital for Sick Children, University of Toronto.

Long QT syndrome (LQTS) is a cardiac disorder characterized by elongation of the cardiac repolarisation characterized on the ECG by an elongation of the QT interval. This syndrome is a cause of sudden cardiac death mostly in young individuals without any medical history. To date, 13 genes have been associated with LQTS risk (LQT1-13), with the majority of cases showing mutations in the LQT1 (KCNQ1), LQT2 (KCNH2) and LQT3 (SCN5A) genes. The different LQTS genes have been associated with differing clinical expression of the disease, and all implicate ion channel complexes (for sodium, potassium and calcium) or accessory proteins interacting with them. High genetic heterogeneity has also been observed in this disease, with several hundred mutations identified in associated loci, many of which being private/familial. Genetic testing of individuals with elevated disease risk (based on the Schwartz's clinical diagnostic score), through sequencing of the most common genes in the clinic identifies causal genetic variants in up to 60–70% of cases, suggesting that additional genes may be involved in this disease. In the current study, we have recruited 24 patients with elevated disease risk for LQTS, but reported negative for mutations in the known LQTS loci in clinical testing, and have used a Next generation sequencing (NGS) whole-exome DNA sequencing approach. We have developed a stepwise analytic approach that focuses on (1) the known LQTS genes, (2) genes in loci identified in genome-wide association studies of QT-interval and sudden cardiac death, (3) known ion channels and accessory proteins, and (4) loci with expression patterns consistent with a role in LQTS; we will also weight any locus showing multiple variants across our different patients. Identification of novel genes implicated with LQTS through this approach will allow a better understanding of the pathophysiologcal mechanism underlying this condition and should improve clinical diagnosis of patients and families that are currently reported as negative for the known LQTS loci.

1679T

A rare genetic mutation (FBLN-4 mutation) found in a patient presenting with diffuse severe aortopathy. *K. Coleman[1], P. Fernhoff[1], S. Shankar[1], C. Hebson[2], M. Clabby[2], B. Kogon[3], B. Loeys[4].* 1) Children's Healthcare of Atlanta, Department of Human Genetics, Emory University, Atlanta, GA; 2) Sibley Heart Center, Children's Healthcare of Atlanta, Atlanta, Ga; 3) Department of Cardiothoracic Surgery, Emory University, Atlanta, Ga; 4) Antwerp University Hospital/University of Antwerp, Antwerp, Belgium.

A 6-month-old female presented with acute onset difficulty breathing progressing to respiratory failure. Chest films showed a large mediastinum; chest MRI eventually detailed a severely dilated aorta from aortic root to aortic hiatus. The patient was diagnosed with RSV bronchiolitis as the etiology of the acute respiratory distress and compression of the main left bronchus by the dilated aorta as the etiology for failure to extubate. She thus required a tracheostomy prior to weaning from mechanical ventilation. The aorta was eventually surgically treated with an “elephant trunk” type ascending aorta repair and plication with reimplantation of the all of the strap vessels. Months after surgical repair, the patient was successfully decannulated and no longer requires any airway support. The eventual plan is a second and hopefully final surgery on her descending aorta to reduce its caliber. Otherwise, during the clinical progression, an ongoing attempt at defining an underlying genetic etiology was undertaken. Specific testing for Loeys-Dietz syndrome (TGFBR2 and TGFBR1) and arterial tortuosity syndrome (SLC2A10) was negative. DNA was sent to Dr. Bart Loeys in Brussels, Belgium for sequencing of the Fibulin-4 (FBLN4) gene that is a member of the fibulin family, a group of extracellular matrix proteins prominently expressed in medial layers of large veins and arteries. The result was a homozygous FBLN4 mutation (p.E126K) in this patient. Both parents who are consanguineous were heterozygous for the same mutation. Mutations in FBLN4 have previously been described in four patients including one patient from Australia with the identical mutation as this patient. This case report thus describes a severe clinical presentation of an extremely rare genetic mutation, which has to date been successfully surgically managed.

1680T

Rare Variants in Notch Pathway Genes Among Individuals with Congenital Heart Defects. *K. McBride[1,2], G. Zender[1], S. Fitzgerald-Butt[1], J. Stemming[1], A. Hooper[1].* 1) Molecular & Human Genetics, Nationwide Children Hospital, Columbus, OH; 2) Dept Pediatrics, College of Medicine, Ohio State University, Columbus, OH.

The Notch pathway is an important signaling system involved in development of the myocardium, valves, and outflow tract of the heart, regulating epithelial to mesenchymal transition (EMT). Mutations in *NOTCH1* were first identified in two families demonstrating autosomal dominant inheritance for aortic valve disease. We subsequently found *NOTCH1* variants among individuals with other apparently sporadic congenital heart defects of the left ventricular outflow tract (LVOT), including aortic valve stenosis, bicuspid aortic valve, coarctation of the aorta, hypoplastic left heart syndrome. These variants caused dysfunction of Notch signaling, leading to downstream effects on EMT. We hypothesized that variation in other genes of the Notch pathway might also cause LVOT defects. Multiple genes of the Notch pathway were screened in over 450 individuals with an LVOT defect, coding for ligand *DLL4*, NOTCH1 intracellular domain cleavage *PSEN1*, transcriptional repressors *HEY1*, *HEY2*, *HEYL*, and effectors of EMT *SNAI1, SNAI2*. Variants causing amino acid substitutions were found in *DLL4* (p.R248Q, p.L622G); *PSEN1* (p.R35Q, p.R358Q, p.Q459K); *HEY1* (p.K249T p.F275L); *HEY2* (p.S12N p.S172P p.P179L p.T228A); *HEYL* (p.R141C p.P173S p.W177C p.F179L); but not in *SNAI1* or *SNAI2*. These variants were not identified in 300 control chromosomes and were absent in the 1000 Genomes database or present at a MAF of <0.001. We used a cell based assay to study the effects of select Hey gene variants on repression of GATA4/6. Hey wild type and mutant expression vectors, GATA4/6 expression vector and ANF promoter luciferase reporter were transfected into HeLa or 293 cells. A statistically significant loss of repression was demonstrated for *HEYL* p.W177C and p.F179L ($p<0.001$ for difference in ANF luciferase activity). In conclusion, we identified a number of rare variants in genes important in the Notch signaling pathway among individuals with an LVOT defect, several of which have demonstrated loss of function.

1681T

TTN Mutations from Exome Sequences of 17 DCM Families: Clinical Implications. *A. Morales[1], N. Norton[1], D. Li[1], E. Rampersaud[2], E. Martin[2], S. Zuchner[2], S. Guo[2], M. Gonzalez[2], R. Hershberger[1].* 1) Cardiovascular Division, Department of Medicine, University of Miami Miller School of Medicine, Miami, FL; 2) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, Florida.

BACKGROUND: Truncating variants in TTN were recently implicated in up to 25% of DCM and 3% of controls. METHODS: To evaluate the role of TTN in a broader genetic background, we analyzed exome data from 17 families (48 cases) in which the proband was found not to carry mutations in 16 known DCM genes. A filtering strategy for segregating, rare (<0.5% controls), and conserved (Phastcons >0.4 or GERP >2) coding or splice site variants in genes with known myocardial expression was followed. TTN variants meeting filtering criteria were confirmed and evaluated in family members by Sanger sequencing. Exome data was also queried for DCM variants meeting all criteria except for segregation. RESULTS: Variants in an average of 28 candidate genes per family were identified (range 1–80). TTN was among the candidates in nine families (7 with truncating, 2 with missense variants). Truncating variants may be more relevant, as the average number of TTN truncating variants in the Exome Sequencing Project (ESP) was 0.014 per individual while the average number of missense variants per individual in our DCM cases and non-DCM ESP exomes was 23. Among the 7 families with truncating variants, 22 of 35 TTN carriers were affected. Median age of onset was 42, ejection fraction 33.5% and left ventricular size 62 mm. In addition to TTN truncations, 2 families had potentially relevant variants that met filtering criteria in SYNE2 and SOS1, respectively. Non-segregating variants in ACTN2, ANKRD1, CRYAB, CSRP3, DMD, DES, LMNA, MYBPC3, MYH6, MYH7, RBM20, TCAP, TMPO, TPM1, and TTN were identified in 6 families. Non-segregating TTN truncating variants were identified in 2 additional families. DISCUSSION: Our data confirm that TTN truncating variants are frequent in DCM. While genetic testing for DCM should encompass as many known genes as possible and clinical exome sequencing is now considered for patients with negative known gene panels, clinicians face increasingly complex issues of testing strategy and variant interpretation. Whole panel testing should be considered in more than one family member, especially with widely disparate ages of onset, clinical presentation or meiotic distance. Missense TTN variants are expected; their relevance remains unknown. Rare, non-segregating variants in TTN and other relevant genes occur. Comprehensive analysis of much greater numbers of DCM exome sequences, ideally in well phenotyped families, will be needed to fully understand DCM genetics.

1682T

A novel Ser33045Ala variant of TTN gene in a family with left ventricular non-compaction and syncope. Is there a linked etiopathogenesis? . *A. Psychogios, A. Marsidi.* Dept Pediatrics, Division of Medical Genetics and Genomic Medicine, East Tennessee Univ/James H Quillen Col Med, Johnson City, TN.

Left ventricular non-compaction (LVNC) is a rare cardiomyopathy defined by ventricular trabeculations resulting in arrhythmia, heart failure, cardioembolic events, and sudden death. Several LVNC genes are reported but the spectrum remains unclear. We report a 28-year old Caucasian female with history of arrhythmia and heart failure secondary to LVNC. Her growth and developmental history are normal. Family history is significant for maternal cardiomyopathy and hypertension, paternal history of syncope and sudden death, and a brother who died of infantile heart disease. **On examination,** she is well developed, thin, without dysmorphic features. **Clinical molecular testing:** Initial sequencing analysis for LVNC at John Welsh Cardiovascular Diagnostic Laboratory, Houston, TX including Taffazin (TAZ, G4.5) gene, Z-band alternatively spliced PDZ motif-containing protein gene (ZASP), and Lamin A/C (LMNA) was normal. Further DNA sequencing of the coding regions and splice sites of 46 cardiomyopathy genes (Pan Cardiomyopathy Panel) at the Laboratory for Molecular Medicine, Center for Personalized Medicine, Harvard Medical School, Cambridge, MA identified two novel variants. A heterozygous c.99133T>G (p. Ser33045Ala) in exon 309 of the TTN gene and a heterozygous c.1159-13C>T in intron 7 of the JUP gene. The Ser33045Ala variant (TTN) has not been reported in the literature nor previously identified. Computational analyses (biochemical amino acid properties, conservation, AlignGVGD, PolyPhen2, and SIFT) did not provide strong support for or against an impact to the protein. This variant has been seen in 0.03% (2/6666) of European American chromosomes in a broad population by the NHLBI Exome Sequencing Project (http://evs.gs.washington.edu/EVS). In addition, over 30 benign TTN gene polymorphisms were identified in our patient. **Conclusion:** A novel Ser33045Ala TTN gene sequence variant is reported in a 28-year-old Caucasian female with LVNC, heart failure, arrhythmia, and family history of syncope and sudden death. The TTN gene role in the pathogenesis of LVNC and/or syncope in this family is unclear. Frequent follow-up and medical therapy for arrhythmias and possible increased risk for syncope were recommended independently of her carrier mutation status. Further studies are needed to clarify the association of TTN gene in the etiopathogenesis of LVNC or syncope.

1683T

Molecular autopsy for sudden death using whole genome sequencing. *M.J. Puckelwartz[1], L. Dellefave-Castillo[1], D. Wolfgeher[1], V. Nelakuditi[2], M.T. Campbell[3], J.R. Golbus[1], E.M. McNally[1,2].* 1) Medicine, University of Chicago, Chicago, IL; 2) Human Genetics, University of Chicago, Chicago, IL; 3) Integrated DNA Technologies, Inc., Coralville, IA.

Sudden, unexpected death in the young is rare and is often attributed to cardiac arrhythmia events. Cardiac arrhythmia may leave few pathological clues, and pathogenic DNA sequence variation in arrhythmia genes may be helpful in identifying the cause of death and providing useful information to family members. Genetic testing for sudden death has focused on genes encoding cardiac ion channels with very limited sensitivity. We applied whole genome sequencing to a young individual with sudden death to examine genes beyond those previously associated with heritable cardiac arrhythmia. A rare variant in RYR1 encoding the ryanodine receptor 1 was identified. RYR1 mutations are associated with malignant hyperthermia, heat stroke, seizures and death. Because the decedent had pre-mortem symptoms attributable to heat intolerance, the RYR1 mutation was concluded to be a primary risk allele. Several variants of high population frequency were also identified that may have had a contributory role because of their predicted pathogenic nature. We conclude that the combination of genetic variants and environmental conditions contributed to sudden death in this individual and that autopsy-derived whole genome analysis should be considered in cases of young unexplained deaths.

1684T

High incidence of *GLA* variants in a non-selected heart disease patient population suggests that the Fabry trait is a common cardiovascular genetic risk factor. *R. Schiffmann[1], S. Forni[1], C. Swift[1], X. Wu[2], D.J. Lockhart[2], M. Chee[3], T. Kitaoka[3], E. Chudin[3], S. Pond[3], N.H. McNeill[1], K. Sims[4], E.R. Benjamin[2], L. Sweetman[1].* 1) Inst Metabolic Disease, Baylor Res Inst, Dallas, TX; 2) Amicus Therapeutics, Cranbury, NJ; 3) Prognosys Biosciences, Inc., La Jolla, CA; 4) Neurogenetics DNA Diagnostic Laboratory, Massachusetts General Hospital, Boston, MA.

We have initiated a large screening research protocol for the Fabry disease biochemical and genetic trait in a non-selected population of patients, age 19–85 years, with any form of cardiac disease with either coronary artery disease, conduction or rhythm abnormalities, cardiomyopathy or valvular defects. We hypothesized that α-galactosidase A deficiency is a genetic risk factor for non-specific cardiovascular complications that occur in the general population. The verification of our hypothesis will confirm the Fabry trait as a potentially modifiable cardiovascular risk factor, allowing for better management and prevention of heart disease. Screening is performed by measuring urinary globotriaosylceramide (Gb_3) in random samples of whole urine using tandem mass spectrometry, measuring α-galactosidase A activity in dried blood spots, and looking for *GLA* gene mutations by parallel sequencing of the whole gene in pooled genomic DNA samples. Individual samples from selected pools are further analyzed by conventional Sanger sequencing. Thus far we studied 1110 unselected consecutive adult patients, age 19–85 years, with a variety of cardiac ailments including coronary artery disease, conduction and rhythm defects, hypertrophic cardiomyopathy and valvular disease. Exonic mutations were confirmed in four female cardiac patients. Intronic variants were confirmed in nine other cardiac patients, eight males and one female, with above normal levels of urinary Gb_3. In four of these nine patients, α-galactosidase A activity ranged from 30–50% of the mean seen in normal controls. We conclude that the general heart disease population contains up to 1% of individuals with exonic *GLA* variants and intronic *GLA* variants associated with elevated urinary Gb_3. Variations in the *GLA* gene may be a relatively common genetic risk factor (the Fabry trait) for all forms of heart disease.

1685T

Exome sequencing identifies homozygous truncation mutations in *MYOM2* in arrhythmogenic ventricular dysplasia/cardiomyopathy. *J. Wang, C. Silverstein, H. Lee, E. Mokhonova, A. Seki, S.P. Taylor, M. Fishbein, M. Spencer, S.F. Nelson.* UCLA, Los Angeles, CA.

Background: Arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) is a genetic disorder of the myocardium characterized by progressive fibrofatty replacement that predisposes to ventricular tachycardia and sudden death. Although it classically affects the right ventricle, left and biventricular forms are increasingly recognized. A mutation in one of the 8 known genes, primarily encoding desmosomal proteins, is found in fewer than half of patients. We identified a family with onset of dilated cardiomyopathy in the 2nd or 3rd decade in four out of four siblings with progression to cardiac transplantation so far in three. Gross and histopathologic examination of the three explanted hearts demonstrated the characteristic fibrofatty replacement of ARVC/D involving predominantly the left ventricle. The family reported a high degree of consanguinity.

Methods: To identify the molecular basis of these findings in the family, exome sequencing was carried out in the index patient at the UCLA Clinical Genomics Center. Exome variants were filtered for rare heterozygous variants and homozygous variants to identify new mutations. Mean oversampling of bases was 163X and at least 95% of the ~33.4 Mb of protein coding sequence defined by RefSeq was read to at least 10X depth.

Results: A single plausible mutational target, a homozygous truncation mutation in *MYOM2*, was identified genome-wide. MYOM2 is a sarcomere structural protein localized to the M-line, and these individuals would thus be predicted to make no functional MYOM2. The mutation was confirmed by Sanger sequencing, and the index patient's siblings' and father's DNA were collected to confirm the mutation. Quantitation of the regions of homozygosity was consistent with a closer than 1st cousin relationship in the subject's parents.

Conclusions: Our findings implicate *MYOM2* as a new gene for ARVD/C and provide new evidence of a critical role for MYOM2 in cardiac sarcomere structure and function. The significance of an MYOM2 truncation mutation in the heterozygous state is to be established.

Replication of Associations from Large Scale Re-sequencing Studies. *D. Waterworth[1], L. Li[2], R. Scott[3], C. Gillson[3], J. Aponte[2], L. Warren[2], M. Nelson[2], M. Ehm[2], N. Wareham[3], S. Chissoe[2].* 1) Gen Div, GlaxoSmithKline, King of Prussia, PA; 2) Genetics, GlaxoSmithKline, Research Triangle Park, NC; 3) MRC Metabolic Unit, Institute of Metabolic Science, Addenbrookes Hospital, Cambridge, UK.

202 drug-target genes were sequenced in 14,002 individuals as part of a drug-repositioning and target validation experiment. In focusing on coding variation it was hoped that we would be able to identify gene-specific functional tool variants that could be utilized in predicting drug efficacy, alternative indications and safety. An abundance of rare, putatively functional, variation was found, providing opportunities for translational research; however large sample sizes will be needed for genotype-phenotype association studies. Some of the most significant associations in the cardiovascular and metabolic disease areas were with low frequency variants and intermediate traits, however it was not known how robust these findings were due to their relatively low power. Therefore we selected the 43 most promising variants from 27 genes (two thirds of the variants with MAF less than 0.05) for the purpose of replicating initial association results. These variants were typed in up to 6 different cohorts (CoLaus, Lolipop, EPIC-Norfolk, Norfolk-T2D, ELY and Fenland) by either Sequenom or Kaspar technologies, up to a total of 39,290 subjects and analyzed for a broad range of cardiovascular and metabolic phenotypes. Eight of the variants could not be designed or failed to generate viable genotypes and many did not replicate with their original trait. However, a low frequency (MAF 0.015) coding variant in GLP1R (A316T) was associated with glucose (p=0.0004), HOMA-B (p=0.0009) and waist (p=0.001), recapitulating the therapeutic effect of the GLP1 agonists, an effect not seen with GWAS SNPs. A common coding variant in MMP9 (Q279R, MAF 0.35), also not covered in GWAS platforms, was consistently associated with HDL-cholesterol (p=2.5e-5) and to a lesser extent triglyceride (p=0.006). A rare novel coding variant T258I also in MMP9 was found to be associated with higher interleukin levels (p=1.07e-6), supporting a finding in the initial study (p=3.4e-6), though not the same interleukin. While following up results identified from sequencing experiments will require large, well phenotyped cohorts, genotyping technologies capable of providing robust data for rare variants as well as analysis methods tailored to rarer variants, the insights obtained from full characterization of drug target genes and their associations with cardiovascular, metabolic and inflammatory phenotypes provide support for existing and future drug development efforts.

Rare Copy Number Variants in Congenital Heart Disease Affecting Gene Structure. *K. Dumas[1], Y. Bouhlal[1], M. McKeon[1], JTC. Shieh[1,2].* 1) Division of Medical Genetics, Department of Pediatrics, University of California San Francisco, San Francisco, CA, USA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA, USA.

Developments in genome-scale technologies have greatly facilitated the discovery of copy number variants (CNVs) in the human genome. Some rare variants may constitute predisposing alleles to diseases of early age onset and may be associated with decreased reproductive fitness. To assess for the presence of such variants in individuals with congenital anomalies, we performed CNV analysis on eleven individuals affected with congenital heart disease, their phenotypically normal parents, and HapMap sample NA10851 using Affymetrix 6.0 genotyping arrays. Replicates of NA10851 revealed 100% concordance of CNV calls above an average of 85 markers. CNVs in the CHD trio samples were stringently called to decrease the likelihood of false positives. Rare CNVs were filtered from common variants using known databases then compared to Decipher. We found five rare CNVs including variants on 13q, Xq, and 10p. The latter two variants were not present in parents, while the rare 13q CNV was inherited. Of particular interest, we noted that some of the CNVs alter gene structure by interrupting exons. We cloned the precise CNV boundary and verified the presence of a novel transcript from 13q that crossed the CNV boundary using RT-PCR. Since this predicted early translation termination, we transfected GFP-tagged truncated or full-length cDNA constructs and found that the truncated protein was also stable in cell culture. These data demonstrate CNVs can create altered transcripts, and some truncated genes may be expressed. Studying these products may help in determining the phenotypic consequences of rare CNVs in congenital anomalies.

1688T

Rare variants in the *APOA5* promoter are associated with a paradoxical HDL-C decrease in response to fenofibric acid therapy. *A. Brautbar[1,2], M. Barbalic[3], F. Chen[3], J. Belmont[4], S. Virani[1], S. Scherer[4], R. Hegele[5], C. Ballantyne[1].* 1) Department of Medicine, Baylor Col Med, Houston, TX; 2) Department of Genetics, Marshfield clinic, Marshfield, WI; 3) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 4) Department of Human Genetics, Baylor College of Medicine, Houston, Texas; 5) Robarts Research Institute, London ON Canada.

Background: The role of rare genetic variants in determining response to lipid modifying therapy is not fully understood. Individuals with mixed dyslipidemia are characterized by elevated triglycerides (TG), depressed high density lipoprotein cholesterol (HDL-C), and high risk for coronary events. Fenofibric acid (FA) is commonly used to treat mixed dyslipidemia by increasing HDL-C and apolipoprotein (apo) A1 (APOA1), decreasing TG, and possibly reducing coronary events. We sought to examine the effect of rare genetic variants in the *APOA5* gene region on plasma HDL-C, APOA1, and TG response to fenofibric acid (FA) and its combination with statins in individuals with mixed dyslipidemia. Methods: The *APOA5* gene region was sequenced in individuals (N=1612) with mixed dyslipidemia participating in a randomized, double-blind, active controlled, clinical trial examining the response to FA and its combination with statins. Student's t-test and rare variant burden tests were used to examine plasma HDL-C, APOA1 and TG response to therapy. Results: Instead of the expected increase in HDL-C and APOA1 following FA therapy, rare variants in the *APOA5* promoter region were associated with a paradoxical decrease in HDL-C and APOA1 levels in response to FA therapy, while rare missense variants were associated with better TG response to the statin-FA combination. Conclusion: Rare variants in the *APOA5* promoter region were associated with paradoxical decreases in HDL-C and APOA1 in response to FA therapy in the mixed dyslipidemia population, while missense variants were associated with improved TG response. Further study is indicated to examine the effect of these rare variants on coronary outcomes in individuals with mixed dyslipidemia receiving FA and its combination with statins.

1689T

***COL4A1* and *COL4A2* mutations cause genetically modifiable hemorrhagic stroke.** *M. Jeanne[1], J. Jorgensen[1], C. Labelle-Dumais[1], Y. Weng[1], W.B. Kauffman[1], M. de Leau[1], S.M. Greenberg[2], J. Rosand[2,3,4], J. Favor[5], D.B. Gould[1].* 1) Departments of Ophthalmology and Anatomy, Institute for Human Genetics, University of California San Francisco, San Francisco, CA; 2) Department of Neurology, Massachusetts General Hospital Boston, MA; 3) Center for Human Genetic Research, Massachusetts General Hospital Boston, MA; 4) Division of Neurocritical Care and Emergency Neurology, Massachusetts General Hospital Boston, MA; 5) Institute of Human Genetics, Helmholtz Zentrum Munchen, Neuherberg, Germany.

Patients with mutations in the collagen type IV alpha 1 gene (*COL4A1*) suffer from a broad spectrum of highly penetrant cerebrovascular diseases (CVDs), including subclinical cerebral microbleeds, leukoaraiosis, infantile porencephaly and fatal intracerebral hemorrhage (ICH). This phenotypic heterogeneity suggests that environmental and other genetic factors may influence pathology expressivity. COL4A1 associates with COL4A2 in heterotrimers before being secreted in the extracellular matrix where they form a network critical for basement membrane stability and function. We recently screened a cohort of patients with non-familial, spontaneous ICH. We identified novel *COL4A1* mutations and importantly, we discovered the first *COL4A2* mutations causing hemorrhagic stroke. Notably, our findings show that *COL4A1* and *COL4A2* mutations could contribute to 5–10% of non-traumatic, sporadic ICHs. We are now using cell biological and genetic approaches to decipher the pathogenic mechanisms underlying the disease. Using a cell-based assay, we found that mutations impair COL4A1 and COL4A2 secretion. We showed that mutant COL4A1 or COL4A2 proteins accumulate within cells where they titrate normal COL4A1 and COL4A2 and can ultimately trigger endoplasmic reticulum stress and the Unfolded Protein Response. Using cerebral magnetic resonance imaging and histological analysis, we determined that the hemorrhage localization and severity were dependent on the position and nature of the mutation in the *Col4a1* or *Col4a2* gene, and also on their genetic context. These findings suggest that allelic heterogeneity and the presence of genetic modifiers contribute to the CVD heterogeneity in human patients. Our ongoing experiments to better understand the cell biology of *COL4A1* and *COL4A2* mutations and the mechanisms of genetic modification could lead to targeted therapeutics to reduce the risk of CVD in patients with *COL4A1* or *COL4A2* mutations.

1690T

Association of 87 traits related to coronary heart disease and rare sequence variants in the ClinSeq™ Study. *H. Sung[1], B. Suktitipat[1], K. Lewis[2], D. Ng[2], S. Gonsalves[2], J.K. Teer[2], N.F. Hansen[3], J.C. Mullikin[3,4], L.G. Biesecker[2], A.F. Wilson[1], NISC Comparative Sequencing Program.* 1) Genometrics Section, Inherited Disease Research Branch, NHGRI, NIH, Baltimore, MD; 2) Genetic Disease Research Branch, NHGRI, NIH, Bethesda, MD; 3) Comparative Genomics Unit, Genome Technology Branch, NHGRI, NIH, Bethesda, MD; 4) National Institutes of Health Intramural Sequencing Center (NISC), NHGRI, Bethesda, MD.

ClinSeq™ is a large scale medical sequencing study designed to investigate associations of rare sequence variants with traits related to coronary heart disease (CHD). The study currently includes 976 non-smoking patients, ages 45 to 65, with normal to severe coronary artery calcification with both traits and whole exome data. More than 200 CHD-related traits were measured at the NIH Clinical Research Center in Bethesda, MD; 87 quantitative traits were selected for the first pass analyses. Whole exome sequencing with two different capture regions was performed at the NIH Intramural Sequencing Center; 387 and 325 individuals were sequenced with the Agilent SureSelect 38 mb and 50 mb capture regions, respectively. Sequence variants (SVs) in common over both capture regions with calling rates > 98% and minor allele frequency (MAF) > 1% were used to check for misspecified population stratification by multidimensional scaling analysis - 635 Caucasians were included in these analyses. The two groups of capture regions were merged, yielding 645,364 SVs. Of these SVs, 68% and 31% had MAFs < 0.01 and < 0.001, respectively. The SVs with MAF < 0.01 were collapsed into a single derived variant for each genomic region defined by hotspot blocks. Collapsed variants were coded as the proportion of the minor allele within each region; common variants were coded as the number of minor alleles (scaled from 0 to 1). Tests of association of each SV with each trait were performed on age- and sex-adjusted traits on the untransformed, log-transformed and Box and Cox transformed data with simple linear regression. Associations between 23 traits and at least one SV were significant over both untransformed and transformed traits after Bonferroni correction (p value < 7.78e-08). Traits and the number of significant SVs (indicated in parentheses) included: coronary calcium score (208), echo right atrium pressure (117), corrected QT interval (38), direct bilirubin level (19), total bilirubin level (18), echo left atrial dimension (16), echo AV peak velocity (11), glucose (10), QT interval (8), echo E/A ratio (8), head circumference (7), platelet count (6) and progesterone (3). Tiled regression implemented in TRAP will be performed to identify the set of independently significant SVs that affect each trait. The genes for the associations will be described at the meeting.

1691T

Exome Sequencing Identifies a Novel Splice Site Mutation in *LMNA* and Multigenic Heterozygosity of Potential Modifiers in a Multi-generation Family with Sick Sinus Syndrome, Dilated Cardiomyopathy and Sudden Cardiac Death. *M.V. Zaragoza, E. Jensen, F. Oh, C.K. Tran, V. Hoang, S. Hakim.* UC Irvine Cardiogenomics Program, Dept of Pediatrics, Division of Genetics & Metabolism, and Dept of Biological Chemistry, University of California, Irvine.

Sick Sinus Syndrome (SSS) is a cardiac arrhythmia caused by abnormal pacing of electrical activity via the sinus node; the defect causes an irregular heart beat leading to an increased risk of cardiac dysfunction (cardiomyopathy) and sudden death. The main goals of this study are to understand the primary genetic mechanism that causes SSS and to identify the secondary factors that may result in clinical variability within a large, multi-generation family. The proband is a 61 year-old male with SSS and a family history of individuals (>10) with atrial flutter, ventricular tachycardia, cardiomyopathy, heart failure and/or sudden death. After our initial Sanger sequencing studies for mutations were negative, we conducted exome sequencing to identify the primary mutation and potential modifiers. We used NimbleGen SeqCap enrichment and Illumina HiSeq paired-end sequencing. This produced 9 Gb of sequencing data of 97 million reads at an average length of 93 bases. Bioinformatics analysis using DNAnexus showed 94% of the reads mapped the reference (hg19) and 98% of the target exons (191,866 of 194,954) were completely sequenced. The average mean read coverage of each exon was 129X (range: 0 to 7108X), and 92% of the exons had mean coverage above 30X. We identified 128,563 unique variants with 108,795 (85%) located in 16,319 genes of 19,056 target genes. To identify candidate mutations, we focused on 2,077 variants located in 237 genes of 283 known arrhythmia, cardiomyopathy or ion channels genes. We filtered the candidates to 41 variants in 33 genes using zygosity, protein impact, database searches and clinical association. We found that half of these variants were real; only 20 variants were validated by Sanger sequencing. We then selected nine confirmed variants with minor allele frequencies (<1%) for extensive family studies of affected and unaffected individuals. These results identified *LMNA* c.357-2A>G, a novel heterozygous splice site mutation as the primary mutation and rare or novel heterozygous variants in *HCN4*, *MYBPC3*, *PKP4*, *TMPO*, *TTN*, *DMPK* and *KCNJ10* as potential modifiers. In conclusion, we used exome sequencing to identify a novel *LMNA* mutation and demonstrated the importance of Sanger validation and extensive family studies to evaluate candidate variants. We also discovered multiple variants in known arrhythmia, cardiomyopathy or ion channels genes that may serve as secondary factors in disease expression.

1692T

Whole-exome sequencing and quantitative analysis of genetic variants associated with blood pressure: the NHLBI Exome Sequencing Project. *S.L. Pulit[1,2], E.S.P. Blood Pressure Project Team[2], The NHLBI Exome Sequencing Project.* 1) Center for Human Genetics Research, Massachusetts General Hospital, Boston, MA, USA; 2) Medical and Population Genetics Program, The Broad Institute, Cambridge, MA, USA.

Background: Hypertension is a highly heritable trait that increases the risk of congestive heart failure, stroke, and other cardiovascular diseases. Rare mutations in salt-handling genes underlie Mendelian hypo- or hypertension syndromes and, for three of these genes, blood pressure (BP) variation at the population level [1]. Genome-wide association studies (GWAS) have implicated 45 common SNPs associated with BP, but these SNPs explain only 1% of the heritability of BP. Low-frequency and rare variants, thus far untested by GWAS, may contribute to the genetic architecture of BP. **Methods:** We exome-sequenced 6,823 European- and African-ancestry samples selected for heart and lung traits. Of these samples, 815 were selected from the top and bottom 1% of the BP distribution measured in 100,000 samples. Another 4,155 samples selected for other traits had available BP measures. We applied sample- and variant-level quality control (QC) including principal component analysis and filtering by Ti/Tv ratio. **Results:** We performed quantitative trait analyses of baseline systolic and diastolic BP (SBP and DBP), adjusted for age, sex, BMI, cohort, and ancestry, on all samples with these measures (N=4,769 after QC). BP measures were imputed in individuals on antihypertensive treatment. Variants with frequency >0.5% were tested individually using linear regression. No exonic variants achieved exome-wide significance ($p<10^{-6}$). The top exonic variant was a missense SNP in *RGS22* (chr8:101011612, MAF=0.008, $p=1.08\times10^{-6}$) associated with DBP. We used permutation-based burden tests to test the aggregate effects of rare variants. No genes achieved significance after multiple-test correction for 18,000 genes ($p<3\times10^{-6}$). Further, we did not replicate 3 genes previously shown to contain rare variants associated with BP (p>0.05). **Conclusions:** Analysis of baseline SBP and DBP using whole-exome data from 4,769 samples failed to identify single mutations or genes influencing BP variation. Our current results could reflect limited power due to sample size [2] or phenotypic variability. To improve power to identify a potential role of rare mutations in BP variation, analysis of long term average BP and imputation in >10,000 individuals with GWAS data are underway. **Citations:** [1] Ji, W., et al. Nat Genetics. 40 (592-9). May 2008. [2] Kryukov, G. et al. PNAS. 106 (3871-6). Feb 2009.

Identification of Novel Genes and Their Mutations Associated with Hypertrophic Cardiomyopathy. *X. Liu, Q. Huang, X. Dai, W. Xie.* Institute of Life Sciences, Nanjing, Jiangsu, China.

Hypertrophic cardiomyopathy (HCM) is a common form of genetic heart muscle disease that occurs in 1 out of 500 people and is also the leading cause of sudden cardiac death in young athletes. HCM is inherited as an autosomal dominant trait and is attributed to mutations in genes that encode for the sarcomere proteins. About 50–60% of patients with a high index of clinical suspicion for HCM will have a mutation identified in at least 1 of 9 sarcomeric genes. So far mutations of over 30 genes are can cause HCM. There are around 20% of HCM without known genetic causes. To identifiy novel HCM associated genes and their mutations, we performed exon sequencing of 20 Chinese HCM samples without mutations in two of the most common HCM genes (MYH7 and MYBPC3). Three of 20 samples did not have any mutation in known HCM associated genes. To further analyze these three samples, we performed a series of filtration analysis to exclude all the common polymorphism and non-coding variants, we retained 30–240 variants per sample. Combined with functional relevance analysis, we identified three novel HCM associated genes for functional study and population analysis.

1694T

Linkage Analysis and Exome Sequencing to Identify Causal Variants for Familial Combined Hyperlipidemia. *A. Mak, C.R Pullinger, M.J. Malloy, P.L.F. Tang, R. Deo, P.Y. Kwok.* Cardiovascular Research Institute, University of California San Francisco, San Francisco, CA.

Familial combined hyperlipidemia (FCH), the most prevalent hyperlipidemia, is a complex metabolic disorder characterized by variable occurrence of high low-density lipoprotein (LDL) and high triglycerides (TG) - a condition that is commonly associated with coronary artery disease (CAD). Over the years, numerous studies have contributed to the elucidation of the genetic basis of FCH, which is still largely unknown. The need to search for additional genetic variants remains due to the highly variable and complex genetic profile specific to each affected family.

Exome sequencing provides a fast and comprehensive study of genetic variants that are associated with FCH. The large number of genetic variants typically detected in a human genome can, however, be overwhelming and makes it difficult to differentiate disease-causing variants from common variants that are not disease-associated. Linkage analysis greatly reduces the search space for disease-causing variants by pinpointing the most-likely chromosomal regions that are associated with disease phenotypes in the family. Using Affymetrix Axiom Custom array, we genotyped 42 individuals from a 60-member family with history of FCH and low levels of high-density lipoprotein (HDL) cholesterol. We identified various chromosomal regions associated with low HDL, high LDL, high TG and obesity in this family. To identify the exact causal variants that were associated with these traits, we performed exome sequencing on five representative family members using the Illumina HiSeq2000 platform with the TruSeq exome enrichment protocol.

The exome data obtained reached a high mean target coverage of 66X with 10X coverage over 90% of the targeted regions. A union set of 35739 exonic / splicing single nucleotide variants and indels were found in the five family members. Among these variants, 1263 non-synonymous, frameshift or stop-gain/loss variants were identified in one or more linkage peaks associated with various lipid phenotypes in the family. This includes variants found in 22 genes related to lipid metabolism and 256 novel variants that possibly represent rare variants responsible for the FCH phenotype. Verification of potential causal variants is underway. The findings from this study will contribute to the understanding of the genetic basis of FCH.

1695T

Exome Sequencing Reveals a Truncation Mutation in the Novex-3 Isoform of TTN that Disrupts Cardiomyocyte Ultrastructure and Segregates with Familial Dilated Cardiomyopathy. *J.L. Theis[1], V.V. Michels[2], S. Middha[3], S. Baheti[3], P.C. Abell Aleff[4], T.M. Olson[1].* 1) Cardiovascular Genetics Laboratory, Mayo Clinic, Rochester, MN; 2) Department of Medical Genetics, Mayo Clinic, Rochester, MN; 3) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 4) Department of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN.

Dilated cardiomyopathy (DCM) is a heritable, genetically heterogeneous disorder characterized by progressive heart failure. The molecular and cellular pathobiology of DCM remains unknown in a majority of cases. Massively parallel sequencing and comparative variant filtering in well-characterized families enable discovery of novel, unsuspected genetic underpinnings of DCM.

Echocardiography in 15 members of a three-generation family revealed 6 with DCM, which segregated as an autosomal dominant trait. Whole-exome sequencing was performed in 3 affected 2nd–3rd degree relatives using the Agilent Sure Select Capture Kit (50 Mb) and the Illumina HiSeq 2000. An iterative bioinformatics process was used to filter >40,000 annotated SNVs (single nucleotide variants) and INDELs (insertion-deletion variants) for novel, non-synonymous, shared variants, culminating in identification of 7 candidates. A sole heterozygous mutation in TTN, encoding the giant protein titin, segregated with DCM. The mutation deleted a conserved base pair within an alternatively-spliced exon unique to the novex-3 isoform of titin. The N-terminal 3454 amino acids of the novex-3 isoform are 97% identical to the N2A and N2B isoforms, but the C-terminus is made up of a single distinct exon encoding 2150 amino acids. The resultant frameshift mutation truncated 758 amino acids of the 5604-residue full-length protein, causing loss of an obscurin binding domain as well as two phosphorylation sites. Electron microscopy of cardiac biopsy tissue from an affected family member revealed marked myofibrillar dissolution in multiple cardiomyocytes with complete absence of the classic sarcomeric structure.

Comparative analysis of exome sequences from non-nuclear affected family members is a powerful strategy to discover pathogenic mutations. While truncating mutations in *TTN* are relatively common in DCM, none have been reported to disrupt novex-3, a short isoform thought to play a minor role in myocardial physiology. Moreover, the impact of *TTN* mutations on cardiomyocyte ultrastructure in human DCM has not been described. Our findings implicate a central role for the unique novex-3 isoform in sarcomere assembly and stability. Genetic testing platforms for DCM should include the novex-3 encoding exon of *TTN*.

Challenges in interpreting secondary variants from massively parallel sequencing, perspectives from the ClinSeq[™ study. *D. Ng[1], J.J. Johnston[1], K.L. Lewis[1], S.G. Gonsalves[1], L.N. Singh[1], L.C. Peller[1], J.K. Teer[1,2], J.C. Mullikin[2,3], L.G. Biesecker[1,2].* 1) Genetic Disease Research Branch, NHGRI, NIH, Bethesda, MD; 2) NIH Intramural Sequencing Center, NHGRI, NIH, Bethesda, MD; 3) Genome Technology Branch, NHGRI, NIH, Bethesda, MD.

Massively parallel sequencing (MPS) has been used successfully to identify the genetic cause of rare disease (primary findings). MPS also generates incidental disease susceptibility variants (secondary findings). Interpreting secondary findings in asymptomatic individuals is a challenge as there is no consensus on the analysis and return of incidental genetic results. As part of our ongoing endeavor to study secondary variants, we selected 22 arrhythmia-associated and 41 cardiomyopathy-associated genes for analysis and present our findings. Methods: 572 whole exome sequences were annotated for variants in 63 genes with an algorithm that filtered results based on genotype quality, allele frequency, mutation type, and information in locus-specific databases. Variants were assigned pathologic scores ranging from 0–5 (0=poor genotype quality, 1=not pathogenic, 2=likely not pathogenic, 3=uncertain, 4=likely pathogenic, 5=pathogenic). Results: Seven arrhythmia-associated variants were designated likely pathogenic and three variants were pathogenic (KCNE1 p.Thr10Met, p.Arg98Trp; KCNH2 p.Arg3-12Cys). Two individuals had prolonged QTc interval (male with SCN4B p.Ser206Leu and female with SCN3B p.Leu10Pro). Three participants had relatives who died suddenly and one had a relative who died in infancy of unknown cause. There were 20 likely pathogenic and 3 definitely pathogenic (MYBPC3 IVS+1G>A; MYH7 p.Arg787Cys; PLN p.Leu39X) cardiomyopathy-associated variants. Among these 23 participants, 16 had abnormal ECG (sinus bradycardia n=13, premature ventricular contractions n=2, supraventricular contractions n=1). Echocardiogram showed one participant with a borderline thickened septum. Family history showed relatives with cardiomyopathy (n=1), congestive heart failure (n=5) and cardiac arrhythmia (n=11). Conclusion: We identified 6 asymptomatic individuals with pathogenic variants associated with Long QT syndrome (LQTS n=3), hypertrophic cardiomyopathy (HCM n=2) and dilated cardiomyopathy (DCM n=1). The incidence of these cardiac-associated variants in the ClinSeqTM cohort exceeds the estimated population frequency of LQTS (1/2500), HCM (1/500) and DCM (1/7500). The elevated incidence may be due to self-selection, false positives, or underestimation of the incidence of these disease phenotypes. Further family and functional studies are underway to address the pathogenicity, penetrance and medical management of secondary variants identified through MPS.

1697T

An intronic mutation affecting pre-mRNA splicing in the COL3A1 gene as novel mechanisms causing vascular Ehlres-Danlos syndrome. *A. Watanabe[1,2], B.T. Naing[1], M. Sasaki[2], K. Akutsu[3], S. Kosaihira[4], A. Gemma[4], T. Shimada[1,2].* 1) Dept Biochem & Molec Biol, Nippon Med Sch, Tokyo, Japan; 2) Div Clinical Genetics, Nippon Med Sch Hosp, Tokyo, JAPAN;; 3) Div Intensive and Cardiac Care Unit, Nippon Med Sch Hosp, Tokyo, Japan; 4) Div Pulmonary med, Infectious dis, and Oncology, Dept Internal Med, Nippon Med Sch, Tokyo,.

Vascular type of Ehlers-Danlos syndrome (vEDS), also known as EDS type IV (MIM#130050), is a life-threatening autosomal dominant inherited disorder connective tissue mainly caused by mutations in type III collagen, *COL3A1* gene. vEDS is usually caused by mutations in single amino acid substitutions for glycine in the GLY-X-Y repeat of the triple helical region or invariant splice sites. Recently, premature translation termination mutations are reported affecting nonsense-mediated mRNA decay of mutated allele. Here, we described a 35 y/o male with clinical features and family history of vEDS and characterized the functional consequences of an intronic *COL3A1* mutation. The coding regions and flanking intronic bases of the *COL3A1* gene were screened by high resolution melting curve method using genomic DNA. The patient is a heterozygote for a variant with IVS15 -10 A>G in genomic DNA. By RNA/cDNA sequencing analysis from fibroblast, this variant generated a new acceptor site within intron 15, causing the insertion of a 9-bp intronic sequence between exon 15 and 16 (c.996_997insTTTTTTCAG), and resulting in-frame three amino acids insertion. Consistent with this finding, minigene splicing assays demonstrated that this variant is sufficient to create a cryptic splice site and cause the observed 9-bp insertion. This is the first report of creation of a splice site by an intronic single nucleotide change in vEDS. Intronic mutations may be responsible for vEDS in some families with otherwise negative mutation screening of *COL3A1*.

Impaired basement membrane function causes dilated cardiomyopathy in Marfan syndrome. *J.R. Cook[1], L. Carta[1], L. Benard[1], E.R. Chemaly[1], E. Chiu[1], T. Hampton[2], N. Clayton[3], C. Nelson[3], B. Wentworth[3], R.J. Hajjar[1], F. Ramirez[1].* 1) Pharmacology & Systems Therapeutics, Mount Sinai School of Medicine, New York, NY; 2) Neuroscience Discovery Core, Mouse Specifics, Inc., Framingham, MA; 3) Genzyme Corporation, Framingham, MA.

Contrary to the general view that cardiomyopathy in Marfan syndrome (MFS) is a secondary complication of arterial and/or valvular disease, some clinical findings have suggested intrinsic myocardial insufficiency. Our characterization of mice with early onset of progressively severe MFS ($Fbn1^{mgR/mgR}$ mice) supports this hypothesis. First, histological and physiological analyses demonstrated that $Fbn1^{mgR/mgR}$ mice display dilated cardiomyopathy (DCM) prior to the emergence of aortic aneurysm and valvular regurgitation. Second, conditional Fbn1 inactivation in cardiomyocytes, but not in the ascending aorta or cardiac valves, was associated with DCM. Even though fibrillin-1 regulates TGFβ bioavailability, additional experiments excluded involvement of promiscuous TGFβ activity in DCM progression by showing unremarkable Smad2/3 signaling in fibrillin-1 deficient hearts and unabated myocardial dysfunction in $Fbn1^{mgR/mgR}$ mice systemically treated with the pan-TGFβ neutralizing antibody 1D11. Furthermore, normal cardiac size and function were noted in $Fbn1^{mgR/mgR}$ mice that were treated with the angiotensin type I (AT1) receptor antagonist losartan or those lacking the AT1 receptor. Collectively, the data imply that basement membrane-associated fibrillin-1 assemblies protect the mammalian heart against DCM by providing structural support for cardiomyocyte contraction. More generally, our study suggests that monitoring myocardial insufficiency should become standard care in MFS and that losartan treatment is an effective therapy to restore cardiac function in afflicted patients.

Oxidative stress as a modifier of cardiovascular disease in a mouse model of Williams Beuren Syndrome. *B. Kozel[1], L. Ye[1], R. Knutsen[2].* 1) Gen & Genomic Med, Washington Univ Sch Med, St. Louis, MO; 2) Cell Biology and Physiology, Washington Univ Sch Med, St Louis, MO.

Introduction: Elastin haploinsufficiency causes the cardiovascular complications associated with Williams-Beuren syndrome (WBS) and isolated supravalvular aortic stenosis. However, severity of vascular disease ranges broadly in this population. Using the Eln+/− mouse, we sought to identify the source of this variability. Previous investigation showed that crossing the C57Bl/6 Eln+/− to 129×1/SvJ increased hypertension and decreased vascular compliance. Conversely, the DBA/2J-crossed Eln+/−s were protected from the pathologic changes associated with elastin insufficiency. Methods/Results: Quantitative trait locus (QTL) analysis performed on F2 intercrosses revealed a largely additive effect of the 129×1 background on the severity of Eln+/− vascular disease. Highly significant peaks for blood pressure (BP) or vascular stiffness (VS) were identified on chromosomes 1 (BP, LOD 9.7), 9 (VS, LOD 8.7), and 5 (BP and VS, LOD 4.5). In the C57 Eln+/−×DBA F2s, the modifier effect was epistatic. Peaks on chromosomes 14 (VS, LOD 4.7) and 5 (BP, LOD 7.6) were identified only in the Eln+/− and a peak on chromosome 2 (VS, LOD 5.6) mainly affected Eln+/+s. Bioinformatic analysis of the QTL peaks revealed multiple genes affecting oxidative stress, including both the NADPH oxidase (NOX) and nitric oxidase synthase (NOS) pathways. Preliminary Eln+/−; Ncf1+/− (a member of the NOX2 complex) and Eln+/−; Nos1+/− double mutant studies show opposite modifying effects on elastin mediated vascular disease, with Ncf1 haploinsufficiency being protective and Nos1 deficiency causing more severe disease. Conclusions: QTL analysis successfully identified genes that modulate the severity of vascular disease in elastin insufficient mice. Follow-up studies with elastin modifier double mutants suggest that the balance and type of reactive oxygen species generated markedly affect the vascular phenotype of these animals. These initial results are promising and may suggest rational therapies for the treatment of vascular disease in individuals with WBS.

The National Registry of Genetically Triggered Thoracic Aortic Aneurysms (GenTAC): registry progress and research successes. *C. Maslen, GenTAC Consortium.* Cardiovascular Med, Oregon Hlth & Sci Univ, Portland, OR.

Funded by the National Institutes of Health, the GenTAC Registry is a multicenter, longitudinal, observational cohort study of patients with conditions involving genetically triggered thoracic aortic aneurysm and/or dissection (TAAD). GenTAC was established to provide a biospecimen inventory and bioinformatics infrastructure that will enable research to advance the clinical management of such patients. Primary diagnoses include Marfan syndrome, bicuspid valve with aneurysm and/or a family history of aneurysm, idiopathic TAAD in patients < 50 years of age, Turner syndrome, familial TAAD, other congenital heart disease with TAAD, Ehlers-Danlos syndrome, and Loeys-Dietz syndrome. To date GenTAC has recruited 2826 subjects, with a final goal of 4000 registrants. Initial analyses of GenTAC data/specimens have included studies of genetic causes for aortic syndromes via gene sequencing, SNP, CNV and genome-wide association studies, potential usefulness of TGF-β blood levels as prognostic or therapeutic marker in Marfan subjects, surgical approaches/outcomes for ascending aortic conditions and gender differences in TAAD. Other studies in progress include cross-sectional and longitudinal data regarding phenotype-genotype correlations of disease risk factors, features, treatment, and outcomes, and analysis of imaging methods/integration of imaging findings with clinical and genetic data. GenTAC phenotyping and imaging cores have been established to facilitate these inquiries. The GenTAC Registry is a resource for anyone in the scientific community interested in advancing our understanding of genetically mediated TAAs and their causes, diagnosis, and optimal treatment. Investigators interested in utilizing GenTAC for ancillary studies should contact the registry at gentac-registry@rti.org or apply at http://gentac.rti.org.

Association of CRP gene variation in Asian Indian Takayasu's arteritis patients. *K. Shah[1], D. Danda[2], R. Shah[2], S. Prasanna[3], P. Chandna[4], R. Chopra[4], S. Danda[1].* 1) Clinical Genetics Unit, Christian Medical College, Vellore, India; 2) Department of Clinical Immunology and Rheumatology,Christian Medical College, Vellore, India; 3) Department of Biostatistics, Christian Medical College, Vellore, India; 4) AceProbe Technologies (India) Pvt. Ltd., B-8, Namdhari Chambers, Karol Bagh, NewDelhi, India.

BACKGROUND: Takayasu's arteritis (TA) is a rare, systemic inflammatory disease, typically involving the aorta and its main branches where cell-mediated autoimmunity has been strongly implicated in its pathogenesis. CRP gene polymorphisms are associated with serum C-reactive protein (CRP) concentrations and may play a role in pathogenesis of Takayasu's arteritis. The association of CRP gene polymorphism with Takayasu's arteritis is being reported for the first time. METHODS: SNP genotyping was done with Sequenom iPlexTM Gold Assay and MALDI-TOF platform for 54 TA patients and 100 controls (Indian population). Four single nucleotide polymorphisms (SNPs) from the CRP gene (rs1205, rs1417938, rs3093058 and rs1800947) were evaluated. Single nucleotide polymorphisms in MCP-1, IL-23R, MMP-2, MMP-9, IL-10, IL-18, IL-12RB2, CD-24 and ICAM-1 were also investigated. Statistical analysis was done using the PLINK software. RESULTS: Detected frequencies of heterozygous genotype rs1205 were 53% (53/100) in control group and 22.3% (11/54) in TA group (P = 0.0001, odds ratio: 0.2, 95% CI: 0.09, .45). rs1417938, rs1800947 and rs3093059 genotyping did not show significant association. Rest of the studied polymormphisms also did not show significant association with takayasu's arteritis. CONCLUSIONS: This is a pilot study from India, first time looking at association of various gene polymorphisms in takayasu's arteritis. A significant association between heterozygous genotype rs1205 in the CRP gene and TA was revealed which decreased the risk of TA. No significant association of rs1417938, rs3093058, and rs1800947 polymorphisms in the CRP gene was found in our study population. The current results suggest that CRP polymorphisms may play a major role in pathogenesis of TA patients. Our results for the first time show an association between CRP gene polymorphisms and TA.

1702T

Cardiomyopathy as an emerging phenotype in Hereditary Inclusion Body Myopathy (HIBM). *S. Siebel[1], S. McGehee[2], A. Brofferio[2], C. Ciccone[1], M. Huizing[1], L. Medne[3], R. Finkel[3], J. McKew[4], W.A. Gahl[1], N. Carrillo-Carrasco[4].* 1) National Human Genome Research Institute, NIH, Bethesda, MD; 2) National Heart, Lung and Blood Institute, NIH, Bethesda, MD; 3) Children's Hospital of Philadelphia, Philadelphia, PA; 4) Therapeutics for Rare and Neglected Diseases (TRND), National Center for Advancing Translational Sciences (NCATS), NIH, Bethesda, MD.

Background: HIBM is an autosomal recessive neuromuscular disorder presenting during early adulthood with slowly progressive muscle weakness and atrophy. It is caused by GNE mutations in either the epimerase or kinase domains of this enzyme of sialic acid biosynthesis. More than 60, mainly missense, mutations have been described in different ethnic groups. The complete phenotypic characterization of HIBM is ongoing. **Case report**: We describe a 37-year-old patient with HIBM and cardiomyopathy, evaluated under the Natural History Study of HIBM (CT.gov: NCT01417533). She is a compound heterozygote for missense mutations in exon 4 and exon 11 (p.V216A/p.A631V), affecting both the epimerase and kinase domains. Prior to her evaluation she denied any cardiac symptoms, but screening cardiac evaluation detected an arrhythmia with Holter monitoring; an echocardiogram showed global left ventricular hypokinesis with a reduced ejection fraction of 40%. A follow-up echocardiogram, while the patient was managed with a low-dose AT1 subtype angiotensin II receptor antagonist, showed an ejection fraction of 46%, global left ventricular hypokinesis and paradoxical septal motion. Cardiac stress MRI showed no evidence of ischemic disease. Her 29 year-old sister diagnosed with HIBM had a normal echocardiogram. **Conclusion:** We describe cardiomyopathy in a patient with HIBM and no other apparent predisposition to heart disease. The association of cardiomyopathy and HIBM remains to be established. The only other case report of dilated cardiomyopathy in HIBM was recently described in two siblings who were compound heterozygous for mutations in the kinase domain (p.F528C/A631V) (Chai, 2011). One of the mutations, p. A631V, was present in our current patient. In a recent study, cardiac myocytes derived from murine Gne-/- KO embryonic stem cells showed early degradation and a rapid decrease in their beating capacity, suggesting GNE may be an important factor in the development of cardiac tissue (Krentsis, 2011). Our case further supports the association between cardiomyopathy and HIBM, raises the possibility of a genotype-phenotype correlation and highlights the evolving and variable phenotype of HIBM. These data are encouraging to continue the systematic clinical evaluation and follow up of this patient group and the study of the role of GNE in cardiac development.

1703T

Role of the Pro12Ala, G972R, G1057D polymorphism of the PPAR-γ 2, IRS1 and IRS2 genes in type 2 diabetes and Coronary Artery Disease. *S. Vats, K. Matharoo, V. sambyal, A.J.S Bhanwer.* Human Genetics, Guru Nanak Dev University, Amritsar, India.

Diabetes mellitus (DM) is a metabolic disorder of multiple aetiology characterized by chronic hyperglycemia with disturbances ofcarbohydrate,fat and lipid metabolism resulting from defects in insulin secretion, insulin action or both. Diabetic subjects have 2 to 4 fold increased risk of the most common and life threatening cardiovascular complication; coronary artery disease (CAD) as compared to non diabetic subjects. As insulin resistance characterizes T2D, obesity and cardiovascular diseases, genes involved in the insulin resistance pathway can be the important candidate genes for CAD also. Insulin receptor substrates (IRS) are the important mediators of insulin signalling and have an important role in insulin resistance. Insulin stimulated tyrosine phosphorylation of insulin receptor substrate 1(IRS1) and insulin receptor substrate 2 (IRS2) is promoted by Peroxisome proliferator-activated receptor-gamma (PPARγ), hence all of them plays a major role in insulin resistance. In the present study, association of PPARγ Pro12Ala, G972R of IRS1 and G1057D of IRS2 polymorphisms in T2D and CAD patients of Punjabi population (North India) was investigated in 444 subjects divided into four groups: 122 healthy controls, 103 T2D+CAD, 117 T2D only and 102 CAD only patients. Binary logistic regression was applied to test the association of risk factors with T2D, T2D+CAD and CAD only after adjusting for age, sex and BMI. The minor allele (G) frequency for Pro12ala polymorphism was observed to be 11.5%, 12%, 6.9% and 4.6% in controls, T2D+CAD, CAD only and T2D only group respectively. In case of G972R polymorphism the minor allele (A) frequency for G972R polymorphism was observed to be 4.9%, 3.4%, 5.9 % and 4.3% in controls, T2D+CAD, CAD only and T2D only group respectively. 33.2%, 34.0%, 34.3% and 32.9% was found out to be the frequency of D allele in controls, T2D+CAD, CAD only and T2D group respectively. In case of Pro12Ala statistically significant difference ($p<0.05$) was observed in the allele frequencies of T2D patients with controls (Odds ratio : 3.014 (1.38–6.96) The allelic and genotypic frequencies of G972R and G1057D were found to be nonsignificant in all the groups($p>0.05$). For Pro12Ala, CC homozygotes appeared more likely to develop T2D than GG (Ala) carriers. Thus G allele may be protective for T2D patients of Punjabi population in the absence of CAD.

Genetic causes of cardiomyopathy in pediatric transplant recipients. *L. Zahavich, A. Al-Maawali, A. Dipchand, C. Manlhiot, S. Bowdin.* The Hospital for Sick Children, Toronto, Canada.

Background: Cardiomyopathies are a heterogeneous group of disorders. There are many different etiologies including myocarditis, familial isolated cardiomyopathy, neuromuscular disorders, inborn errors of metabolism and malformation syndromes. In children, cardiomyopathy is associated with a high degree of mortality and morbidity. Death within 2 years or requirement for heart transplant is seen in about 40% of children. Pre transplant risk factors and different etiologies have a major impact on prognosis. With advances in genetic investigations and availability of testing, the number of patients with genetic diagnoses will continue to expand. However, underlying genetic diagnoses may impact patient eligibility for heart transplantation. Objectives: To describe the genetic aetiology of cardiomyopathy in pediatric heart transplant recipients. Methods: We retrospectively reviewed the clinical phenotypes and results of cardiomyopathy gene panel testing in pediatric heart transplant recipients with cardiomyopathy, during the period of 2001–2012. Results: A total of 92 children have received heart transplants at the Hospital for Sick Children. Of these, 34 (36.9%) were excluded due death prior to 2001, transfer to another centre, anthracycline- related cardiomyopathy or other non-genetic etiology. Of the 58 remaining patients, 4 (6.9%) were diagnosed with hypertrophic cardiomyopathy, 42 (72.4%) with dilated cardiomyopathy, 10 (17.2%) with restrictive cardiomyopathy and 2 (3.4%) with other. A total of 20 (34.5%) patients had not undergone genetic testing to date and the results of testing for 3 (5.1%) patients were pending. Of the 35 who underwent genetic testing, 2 (5.7%) were diagnosed with a metabolic disease, 5 (14.3%) had a neuromuscular disorder and 8 (22.9%) patients were found to have a mutation in one of the 8 sarcomeric genes. As well, 8 (22.8%) of patients had variants of unknown significance and 12 (34.3%) had negative cardiomyopathy panels. Conclusions: Preliminary results suggest that about one third of our cohort of pediatric heart transplant patients have “idiopathic” cardiomyopathy. However, with the rapid increase in knowledge regarding genetic causes of cardiomyopathy, this number is likely to decrease. At present, all patients with confirmed genetic etiology of their cardiomyopathy are living, however, studies are ongoing to assess the clinical course and outcomes in transplant recipients with genetically caused cardiomyopathies.

1705T

Is your mother or father's family history more important when assessing your risk of having high blood pressure: Studies in humans and mice. *C.L. Chiu, C.T. Morgan, S.J. Lupton, S. Lujic, J.M. Lind.* University of Western Sydney, School of Medicine, Australia.

Background High blood pressure (HBP) is caused by a combination of environmental and genetic factors. A family history of disease is known to increase an individual's risk of having HBP. The contribution of paternal versus maternal effect is poorly understood. We aimed to determine the contribution of maternal versus paternal family history of HBP towards the risk for having HBP in humans. Animal models were also used to study parent of origin influences of angiogenic molecules implicated in HBP. **Methods** Self-reported data from 220,711 individuals recruited from the 45 and Up Study, Australia, were included in the study. Family history was stratified according to whether your father, mother, both, or neither parents had HBP. Relative risks (RR) and 99% confidence intervals were estimated using generalised linear models, adjusting for demographic and lifestyle factors. Total RNA was extracted from heart tissue of two homozygous mouse strains, A/J (AJ) and 129×1/SvJ (129) and the F1 of their reciprocal cross (n=8 males and n=8 females per group). Expression of *Vegfa* and *Hif1a* were measured using qPCR. GLM was used to compare expression differences within both the parental and F1 hybrid groups. **Results** Paternal and maternal family history of HBP was associated with an elevated risk of having HBP, when compared to no family history (RR, 99% CI: paternal 1.83, 1.79–1.87; maternal 1.79, 1.75–1.83; both 2.42, 2.36–2.47). Paternal family history of HBP was associated with a significantly increased risk of having HBP for males, compared to maternal family history (1.20, 1.14–1.27). This association was not observed in females. Within mice, *Vegfa* expression was 1.45 fold higher in male AJ compared to male 129 parentals. *Vegfa* experssion was 1.72 fold higher in F1 males with an AJ father, compared with F1 males with a 129 father; and 1.32 fold higher in females with an AJ father compared with females with a 129 father. *Hif1a* expression was 1.35 fold higher in male AJ compared to male 129 parentals, and 1.33 fold higher in male F1 with an AJ father compared to male F1 with a 129 father. **Conclusions** Males with a paternal family history had 20% increased risk of having HBP compared to males with a maternal family history. In mice, genes involved in angiogenesis that were elevated in male parents were shown to be elevated in the F1 offspring of these males. The sex of the patient and parent should be considered when assessing an individual's risk of having HBP.

Analysis of Variations from Exome Sequence Data with Subclinical Cardiovascular Disease in the Diabetes Heart Study. *J. Adams[1,2,3], A. Cox[2,3,4], B. Freedman[5], J. Carr[6], D. Bowden[2,3,4].* 1) Molecular Genetics and Genomics, Wake Forest School of Medicine, Winston Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 5) Department of Internal Medicine - Nephrology, Wake Forest School of Medicine, Winston-Salem, NC; 6) Department of Radiologic Sciences, Wake Forest School of Medicine, Winston-Salem, NC.

An estimated 8% of the US population is affected by diabetes with 95% of these cases being type 2 diabetes (T2D). Diabetes is a major risk factor for cardiovascular disease (CVD). Up to 65% of T2D individuals die due to vascular disease events. Identification of heritable risk factors for CVD and other complications of T2D are important to help understand individual disease risk. A recent GWAS in the CHARGE consortium identified loci associated with coronary artery calcification (CAC) and myocardial infarction. A meta-analysis of GWAS also from CHARGE identified several loci associated with carotid intima media thickness (IMT) and plaque. CAC and IMT are clinically relevant measures of subclinical CVD. In this study SNPs from exome sequencing were selected in the top hit genes from the CHARGE GWAS and meta-analysis using the NHLBI ESP-GO database. The aim of this study was to examine the association of rare coding SNPs with measures of subclinical CVD in a sample enriched for T2D. 28 SNPs from 14 genes were determined in 1208 European Americans from 474 families in the Diabetes Heart Study. Measures of subclinical CVD included CAC, carotid artery and abdominal aortic calcified plaque (CarCP and AaCP respectively), determined by CT scanning, and carotid IMT, determined by B-mode ultrasound. Additional risk factors including blood lipid levels were also analyzed. Average minor allele frequency for the genotyped SNPs was 0.030 (0.00040–0.16). Three SNPs were significantly associated with CVD risk factors: rs3135506 (Ser19Trp) in *APOA5* was associated with increased triglycerides (TG) (p=5×10-5), decreased concentrations of LDL (p= 0.00070), and HDL (p=0.0054). Also in the *APOA5*, rs651821 (5' UTR), was associated with increased TG concentration (p=0.00080) where as rs13832449 (splice donor) in *APOC3* was associated with decreased TG concentrations (p=0.0015). In addition, several other SNPs including rs45456595 (*CDKN2A*, Gly63Arg), rs5128 (*APOC3*, 3' utr), and rs 72650673 (*SH2B3*, Gly400Lys) were nominally associated (at p<0.010) with history of CVD, subclinical CVD, or CVD risk factors. While we were not able to replicate the associations with CAC and IMT, we did find that the genes identified in the CHARGE consortium GWAS and meta-analysis contain additional variants associated with CVD risk factors in individuals with T2D.

1707T

Common familial effects on ischemic stroke and myocardial infarction: A Swedish national cohort study. *K. Kasiman[1,2], C. Lundholm[1], S. Sandin[1], N. Malki[1], P. Sparén[1], E. Ingelsson[1].* 1) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 2) Saw Swee Hock School of Public Health, National University of Singapore, Singapore.

Introduction: Recent genome-wide association analyses suggest some overlap of genetic determinants of ischemic stroke (IS) and myocardial infarction (MI). This study aimed to assess shared familial risk between IS and MI in a large population-wide cohort study. Methods: Study participants free of IS and MI were identified through linkage with their affected siblings extracted from the Swedish Hospital Discharge and Cause of Death Registers between 1987 and 2007, forming an exposed sib-pair. The Swedish Multi-Generation Register was used to match each exposed sib-pair, by birth year of both siblings and calendar period, to up to five unexposed sib-pair. Stratified Cox regression analyses were used to assess familial risk of incident MI and IS in those exposed to having a sibling with IS and MI, respectively, compared to unexposed. Results: A total of 31,659 exposed and 143,728 unexposed to siblings with IS, and a total of 62,766 exposed and 265,974 unexposed to siblings with MI were included in the analyses. The overall risk of incident MI when exposed to having a sibling with IS was significantly increased (RR, 1.44; 95% CI, 1.34–1.55, p<0.001) to a similar extent to risk of incident IS when exposed to having a sibling with MI (RR, 1.41; 95% CI, 1.32–1.50, p<0.001). The familial risks were higher among full siblings in both groups (RR for MI, 1.46; 95% CI, 1.35–1.58, p<0.001; and RR for IS, 1.40; 95% CI, 1.30–1.40, p<0.001) compared to half siblings (RR for MI, 1.29; 95% CI, 1.05–1.59, p<0.001; and RR for IS, 1.38; 95% CI, 1.16–1.65, p<0.001). Conclusion: Our large, population-wide study indicates that there is a considerable overlap of familial risk between ischemic stroke and myocardial infarction. The sources of this overlap should be evaluated using other study designs.

Jervell and Lange-Nielson Syndrome: Homozygous missense mutation in KCNQ1 in a Turkish family. *S. Temel[1], O. Bostan[2], H. Cangul[3], E. Cil[2].* 1) Department of Medical Genetics, Faculty of Medicine, University of Uludag, Bursa, Turkey; 2) Department of Pediatric Cardiology, Faculty of Medicine, University of Uludag, Bursa, Turkey; 3) 3University of Birmingham, Department of Medical and Molecular Genetics, School of Clinical and Experimental Medicine.

Long QT syndrome is one of the most common cardiac ion channel disease which its morbidity and mortality rate can be lessened with an early diagnosis and proper treatment. It is a cardiac repolarization abnormality that is characterized by prolonged OT interval and propensity for ventricular tachycardia (VT) of the torsades de pointes type are the charecteristics of the disease. This syndrome represent high risk of presyncope, syncope, cardiac arrest and sudden death. Jervell and Lange-Nielson syndrome (JLNS) is one of the inherited form of long QT syndromes. It is inherited recessively and characterized by profound sensorineural deafness and prolongation of the OT interval, thus representing abnormal ventricular repolarizasiton. JLNS has been shown to occur due to homozygous and copmpound heterozygous mutations in KCNQ1 or KCNE1. There was one clinical report on JLNS in Turkey; however, it was not confirmed by a molecular study. We identified a homozygous mutation in KCNQ1 in a 3.5-yr-old female child with JLNS, who visited the hospital due to recurrent syncope and seizures and had congenital sensorineural deafness. Her electrocardiogram revealed a markedly prolonged QT interval. The sequence analysis of the proband revealed the presence of homozygous missence mutation (c.728G>A, p.R243H). Heterozygous mutation in KCNQ1 was identified on the maternal, paternal and sister side. Even if with a high dose β-blocker therapy the patient has twice VT attacks, because of this reason the implanted cardiac defibrillator (ICD) was planned and implanted. We suggest early genetic diagnosis for proper management of the disease and genetic counseling.

1709T

Genetic Risk Profiles For Incident Coronary Heart Disease Using a 28 SNP Marker Panel In Four Prospective Cohorts. *E. Tikkanen[1,2], A.S. Havulinna[2], A. Palotie[1,3,4,5], V. Salomaa[2], S. Ripatti[1,2,3].* 1) Institute for Molecular Medicine Finland FIMM, Helsinki, Finland; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) Wellcome Trust Sanger Institute, Hinxton, UK; 4) Department of Medical Genetics, Haartman Institute, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 5) Broad Institute, Cambridge, USA.

Genome-wide association studies have identified several single-nucleotide polymorphisms (SNPs) associated with coronary heart disease (CHD). The clinical and practical utility of these findings in prediction of CHD has been under debate. We tested 28 genetic variants in four Finnish prospective cohorts (N=24,124). During the median follow-up time of 11 years (IQR 8.75–14.25 years), we observed 1552 (6%) cardiovascular disease events (1093 CHD events). We compared the associations of previously reported 13-SNP genetic risk score and our novel 28-SNP score using Cox proportional hazards model and tested how well the scores predict future CHD events over traditional risk factors and family history of CHD. We found that the genetic risk scores were strongly associated with incident cardiovascular events after adjusting for traditional risk factors. The 28-SNP risk score was more strongly associated with CVD events than the 13-SNP score, particularly in individuals with high genetic risk load, thus showing evidence for non-linear relationship to risk. Subjects in the highest 10% of GRS had 2.1-fold (95% CI 1.68–2.56) increased risk for coronary heart disease in the 28-SNP score and 1.6 (95% CI 1.26–1.91) in the 13-SNP score, when compared with the subjects in the middle 20% of the GRS distribution. The 28-SNP score improved discrimination of CHD cases above traditional risk factors and 13-SNP score, when a non-linear form of genetic effects was allowed in the risk model (AUC difference = 0.4%, P=0.009). We conclude that the genetic risk score based on 28 CHD SNPs could help to identify individuals at high genetic risk for the first CHD event, but the accumulation of genetic risk alleles may not increase the CHD risk linearly. The more accurate classification of subjects using the GRS, particularly for high risk individuals, may have potential for better targeting intervention strategies, but the clinical utility of the genetic risk score needs to be further tested.

1710T

Vascular Stiffness in a Healthy High Risk African American Population is Modified by the Extent of European Admixture. *D. Vaidya, R.A. Mathias, L.R. Yanek, L.C. Becker, D.M. Becker.* Medicine, Johns Hopkins University, Baltimore, MD.

Background: Compared to European Americans (EA), African-Americans (AA) have stiffer peripheral vessels, reflected in reduced carotid distensibility coefficient (DC). To determine whether this racial difference may be genetically determined, we examined the extent to which the variance in carotid distensibility in AA could be explained by EA admixture either at a global or local at genomic level. **Methods**: We examined data from 344 AA, 62% women, aged 25–76 years, enrolled in a large study (GeneSTAR) of apparently healthy people with a family history of early-onset coronary artery disease. DC was assessed using 2D ultrasound, calculated as 2*(fractional change in diameter from diastole to systole)/(systolic -diastolic blood pressure). By its calculation DC is inherently corrected for blood pressure levels. EA admixture was determined using a panel of 50,000 ancestry informative markers (deCODE Genetics), and local ancestry was calculated on Illumina Human 1M genomewide SNP panel using LAMP. Associations of log-transformed DC were tested using mixed model regressions adjusted for age, sex, sex*age interaction and within-family correlations. LAMP models were adjusted for population stratification PCAs derived from the Illumina 1M SNPs (EIGENSTRAT). **Results**: The median [interquartile range] of the DC was 0.0017 [0.0012–0.0024] $mmHg^{-1}$. Every 10% incremental level of EA admixture was associated with 5% higher DC (95% CI: 1% to 9%, p= 0.005), reflecting more distensibility, and less stiffness. In genomewide local ancestry analysis adjusted for sex, age, sex*age interaction, population stratification PCAs and within-family correlations, of 2756 genome segments in local ancestry LD, the highest association for local ancestry was found in Chromosome 8, positions 8.3M to 10M (Build 37.3), p=0.0012. On adjusting for local ancestry in this region, population stratification PCA1 representing global Caucasian ancestry was no longer significantly associated with DC (p=0.93). **Conclusions**: The racial difference in arterial distensibility between AA and EA is likely to have a basis in genetic admixture. We have identified a candidate region on chromosome 8 that may be responsible for this global admixture association.

1711T

A Dutch founder mutation in the cardiac regulatory light chain (MYL2). *I.P.C. Krapels[1], G.R.F. Claes[1], M.B. Hoos[1], Y.E.G. Barrois[1], J-W. Sels[2], A.T.J.M. Helderman-van den Enden[1], P.G.A. Volders[3], H.J.M. Smeets[1], A. Van den Wijngaard[1].* 1) Clinical Genetics, Maastricht University Medical Center, Maastricht, Netherlands; 2) Cardiology, Catharina Hospital, Eindhoven, The Netherlands; 3) Cardiology, Maastricht University Medical Center, Maastricht, The Netherlands.

Hypertrophic cardiomyopathy (HCM) is a common disease defined as left ventricular hypertrophy in the absence of other cardiac or systemic disease explaining the hypertrophy with an estimated prevalence is 0.2% in the general population. HCM is most often inherited; genetic causes of HCM are merely found in the sarcomeric genes. In approximately 60% of patients an autosomal dominant mutation is identified. Most of the reported mutations are distinct and unique for each family. In addition, clinical heterogeneity and incomplete penetrance are observed in families with a mutation. Sometimes, sudden cardiac death can be the first manifestation of the disease. We report on a novel Dutch founder mutation in MYL2, a gene that is rarely mutated in HCM (less than 1% of identified HCM mutations). We identified a p.Glu22Lys (c.64G>A) mutation in 10 different HCM families of which 3 large pedigrees. We show that the MYL2 p.Glu22Lys mutation is actually a founder mutation which probably originated 450 years ago in the region around the city of Eindhoven in the South-East of the Netherlands. The availability of clinical cardiologic data of multiple MYL2 mutation carriers in these families gives a better understanding of the clinical phenotype and risk stratification for this mutation. Our data show that MYL2 mutation carriers usually have a benign disease course with low penetrance, no sudden cardiac deaths, moderate left ventricular hypertrophy and late disease onset in the 5th or 6th decade of life. However, when an additional risk factor is present like hypertension or another mutation, the disease penetrance is higher with an earlier onset.

1712T

Genome-wide DNA methylation profiling in myocardial infarction. *A. Russo[1,2], G. Fiorito[1], S. Guarrera[1], C. Di Gaetano[1,2], F. Ricceri[1,2], F. Rosa[1], A. Allione[1], F. Voglino[1], L. Iacoviello[3], M.C. Giurdanella[4], R. Tumino[4], S. Grioni[5], V. Krogh[5], A. Mattiello[6], S. Panico[6], P. Vineis[1,7], C. Sacerdote[1,8], G. Matullo[1,2].* 1) Human Genetics Foundation, Turin, Turin, Italy; 2) Genetics, Biology and Biochemistry Department, University of Torino, Torino, Italy; 3) Fondazione di Ricerca e Cura "Giovanni Paolo II", Catholic University, Campobasso, Italy; 4) Cancer Registry and Histopathology Unit, "Civile-M.P. Arezzo" Hospital, ASP7, Ragusa, Italy; 5) Department of Preventive and Predictive Medicine, Epidemiology and Prevention Unit, Fondazione IRCSS Istituto Nazionale dei Tumori, Milano, Italy; 6) Department of Clinical and Experimental Medicine, Federico II University, Napoli, Italy; 7) Epidemiology and Public Health, Imperial College London, UK; 8) Cancer Epidemiology, CPO-Piemonte, Torino, Italy.

Methylation of cytosine bases in DNA CpG islands is an important epigenetic regulation mechanism in the organ development and differentiation, aging and several diseases, ranging from neurological and autoimmune disorders to cancer. To investigate the role of differential methylation on the onset of myocardial infarction (MI), we examined the methylation levels of more than 450K CpG sites in 129 cases and 129 matched controls belonging to the Italian section of the European Perspective Investigation into Cancer and Nutrition (EPIC) cohort. EPIC healthy volunteers were recruited between 1994–98 and followed up for cancers or other diseases; blood and other biological samples were stored in liquid nitrogen until use. For the CpG methylation level assessment we used the HumanMethylation450 BeadChip from Illumina Inc. (San Diego, CA, USA). Data were quality checked, normalized, and analyzed according to standard procedures using the R statistical environment (Bioconductor's open source Methylumi package). To account for sex specific methylation and risk profiles, logistic regression analyses were conducted separately for males (95 matched pairs) and females (34 matched pairs). All analyses were corrected by matching variables (age, season and center of recruitment) and cardiovascular risk factors when significantly different between cases and controls (smoke, BMI, waist/hip ratio). In males, the most differentially methylated CpG site between cases and controls was found on chromosome 1 (p=8.12*10-6) in a gene encoding for a zinc finger protein with transcriptional repression function. The following CpG significant signal (p=2.11*10-5) resides in the gene-body region of a gene (Chr. 8) involved in the lipid metabolism supporting its possible involvement in the onset of MI. In females, no CpG signal reached the statistical significance of 10-5, possibly due also to the limited sample size. The present results suggest to further investigate the blood methylation profiles in a larger number of subjects in independent cohorts.

1713T

Common cardiovascular disease risk factors are associated with mitochondrial DNA levels. *S. Mitchell[1], K. Brown-Gentry[1], M. Allen[1], L. Hunt[2], P. Mayo[1], N. Schnetz-Boutaud[1], D.C. Crawford[1], D.G. Murdock[1].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN.

Mitochondria are the primary energy producers of the cell and are essential for cellular metabolism. They are unique organelles in that they maintain their own DNA separate from the nuclear genome. Maintenance and expression of mitochondrial DNA (mtDNA) are essential for mitochondrial fitness; decreased mtDNA levels have been linked to mitochondrial dysfunction. Various classes of disease have been associated with mitochondrial dysfunction including neurodegenerative disorders, cancer, diabetes, and cardiovascular disease (CVD). Cardiovascular phenotypes, such as cardiomyopathy and cardiac dysrhythmias, are commonly observed in diseases resulting from mtDNA point mutations or deletions. The different roles mitochondria play in normal cardiac function, and exactly how mitochondrial dysfunction contributes to CVD, have not been fully elucidated. In the present study, we determined mtDNA levels in more than 6,000 samples from three populations (non-Hispanic Whites (NHW), non-Hispanic Blacks (NHB), and Mexican Americans (MA)) from the National Health and Nutrition Examination Surveys (NHANES) 1999–2002 and examined the relationship between mtDNA levels and common CVD risk factors. Using quantitative real-time PCR, mtDNA levels (mitochondrial genome equivalents, or MGEs) were determined as a ratio of expression of the mitochondrial ND5 and nuclear RNASEP genes. Linear regression was performed to examine the relationship between MGEs and known CVD risk factors.Preliminary analysis revealed the mean MGEs were similar across populations: 249, 247, and 252 in NHW, NHB, and MA, respectively. Low density lipoprotein was significantly associated with mtDNA levels in MA, while high density lipoprotein was significantly associated in NHW. Additionally, GWAS-identified variants associated with lipid profiles were also significantly associated with mtDNA levels in all three populations. Further conditional analysis is required to facilitate elucidation of the link between common CVD risk factors, such as lipid profile and genetic variants, and mtDNA levels and how this relationship contributes to the pathological mechanisms of CVD. Results of this study may identify factors influencing mtDNA maintenance and reveal novel phenotype associations with mtDNA levels, both of which are likely critical to uncovering the role mitochondrial dysfunction plays in the etiology of CVD.

1714T

Assessing change in quality of life in patients participating in Additional KIF6 Risk Offers Better Adherence to Statins (AKROBATS) trial. *HR. Superko[1], SL. Charland[2], BC. Agatep[2], V. Herrera[2], M. Ryvkin[2], BJ. Schrader[2], J. Shabbeer[3], JJ. Devlin[1], EJ. Stanek[2].* 1) Celera Corporation, Alameda, CA.,; 2) Medco Research Institute, LLC/an Express Scripts Company, Bethesda, MD; 3) Celera Corporation, currently with Ariosa Diagnostics Inc., San Jose, CA.

Background: Few studies have prospectively evaluated the psychosocial and behavioral impact of genetic testing, and there remains some concern about potential negative effects. We evaluated the effect of providing kinesin-like protein 6 (KIF6) genotype results directly to the patient on health-related quality of life (QOL). Methods: Patients (N=647) new to statin therapy enrolled in the AKROBATS trial completed a validated QOL questionnaire (SF-12v2) at baseline and were then provided an interpretation of their KIF6 results. The SF-12v2 was completed again after 6 months of follow-up; it yields 3 summary scores: Physical Component Summary (PCS) which incorporates physical functioning and pain, Mental Component Summary (MCS), and a utility score (SF-6D). Categorical and continuous variables were analyzed using chi-squared and t-tests, respectively (significance at p<0.05). Multivariate analysis was used to evaluate the relationship between KIF6 carrier status and QOL scores. Results: Carriers (N=423) and non-carriers (N=224) did not differ significantly by age (60±12 vs 61±11 years), sex (48% vs 42% males), Deyo-Charlson score (0.59±1.10 vs 0.66±1.18), or BMI (30.5±6.7 vs 30.6±7.0 kg/m2). Non-carriers were more likely to be white (86% vs 88%, p<0.001), while carriers were prescribed simvastatin more often (46% vs 38%, p=0.046). At baseline, KIF6 carrier and non-carriers did not differ by any QOL score: PCS (46.5±10.9 vs 45.8±11.0), MCS (54.0±8.4 vs 54.5±8.6), and SF-6D (0.79±0.13 vs 0.79±0.14), respectively. After adjusting for age, sex, race, income, BMI, statin adherence, concomitant diseases, medications, education, and baseline QOL scores there were no differences between carriers and non-carriers after 6 months: PCS (47.5; 95% CI, 46.8–48.2 vs 47.11; 95% CI, 46.2–48.1); MCS (53.9; 95% CI, 53.2–54.6 vs 54.5; 95% CI, 53.5–55.4); and, SF-6D (0.80; 95% CI, 0.79–0.81 vs 0.80; 95% CI 0.79–0.82). Conclusion: Patients' quality of life remained stable over 6 months and was unaffected by knowledge of their KIF6 carrier status. As genetic testing advances in clinical practice, it is important to fully understand the physical and mental effect of informing patients of their genetic makeup and potential drug response or disease risks.

Heritability of John Henryism, and Correlation Between John Henryism and Hypertension in the Jackson Heart Study. *S.G. Buxbaum[1], P. Goel[1], W. White[2], M. Gregoski[3], S.H. Dunn[4].* 1) Jackson Heart Study, Jackson State Univ, Jackson, MS; 2) Tougaloo College; 3) Medical University of South Carolina; 4) University of Pittsburgh.

Purpose: The John Henryism Scale of Active Coping is measured in the Jackson Heart Study, a cohort of African Americans in the Jackson, MS area. The purpose of this study is to assess the heritability of John Henryism (JH) and to determine whether or not it is correlated with hypertension. The null hypothesis for this study was twofold: 1) John Henryism is not associated with hypertension; 2) John Henryism is not genetic. The initial data set comprised 4,567 participants who answered questions in the third JHS annual follow-up questionnaire and 64.5% are women. **Method**: After recoding the JH survey responses, a score was created by summing the values. Spearman correlations between JH and both hypertension and age were determined. Heritability of the JH score within the family subset, excluding singletons (N= 1040), was determined using S.A.G.E. and SOLAR, with adjustment for hypertension and age. **Results**: 3,987 participants answered all 12 questions in the John Henryism questionnaire. Among these, the correlation between JH and hypertension was not significant (p-value = 0.39). However, JH *is* inversely correlated with age (r= -0.12, p < 0.0001). The heritability of John Henryism was 10% with adjustment for hypertension and 9% with further adjustment for age, and not quite statistically significant (p=0.07). **Conclusion**: Unlike a previous study, we did not find strong evidence of heritability of John Henryism. This study failed to reject the null hypotheses at an α level of .05. However, together with previous findings of significant heritability, the results are suggestive. Imputation of missing JH questionnaire responses will be done using STATA; this will increase the number of relative pairs in the analysis and may affect our heritability estimate.

Assessment of health information technology tools use among cancer genetic counselors. *M. Doerr[1], T. Vu[2], C. Eng[1].* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 2) Cancer Genetics Program, Carilion Clinic, Roanoke, VA.

Purpose: Survey to establish baseline descriptive data regarding the use of health information technology (HIT) within cancer genetic counseling practice. This survey is a joint project of the Familial Cancer Risk Counseling Special Interest Group (Cancer SIG), Practice Issues Sub-Committee and the Health Information Technology Special Interest Group (Health IT SIG) of the National Society of Genetic Counselors (NSGC). This project was awarded an NSGC Cancer SIG Grant Award in March 2012. Methods: The survey was developed by the authors in conjunction with members of the Health IT and Cancer SIGs. The survey was reviewed and approved by the Cleveland Clinic Institutional Review Board (CCF12-365). The survey is hosted by Survey Monkey, and was publicized through eBlast May 1, 2012. It will remain open for a period of six (6) weeks; results in this abstract are therefore preliminary. Results: As of May 11, 2011, there are 121 respondents. Demographics are consistent with NSGC Professional Status Survey (PSS) 2012 for sex, age, race, and work setting for clinical counselors. At this time, Region IV is overrepresented and Region III is underrepresented in the respondent pool compared with the PSS. 61.7% of respondents sole area of clinical practice is cancer genetics. Among all respondents, 80% agreed/strongly agreed that HIT will improve their efficiency and two-thirds of respondents agreed/strongly agreed that HIT will improve their ability to implement new/different practice models. More than three-quarters of cancer genetic counselor respondents report using an electronic medical record (EMR) in their practice. Of those using an EMR, 79.8% maintain a separate patient database and 57.8% keep shadow charts which contain information not archived in the EMR. The majority (70%) are not satisfied with how family history information is maintained in the EMR. Conclusions: Although HIT use is widespread among cancer genetic counselors, satisfaction with EMR features lags.

1717W

Behavior and food-related concerns in children with Smith-Magenis syndrome are similar to Prader-Willi syndrome. *L.V. Barton[1], T.P. York[1], S.H. Elsea[1, 2].* 1) Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA; 2) Pediatrics, Virginia Commonwealth University, Richmond, VA.

Smith-Magenis syndrome (SMS) is a complex genetic disorder associated with intellectual disability (ID), sleep disturbances and early-onset obesity. Problem behaviors are commonly reported and may be more characteristic of SMS than physical findings, but few reports have examined changes in behaviors across development and how those behaviors influence weight gain. Parents and guardians (n=81) of children with SMS were surveyed to assess problem behaviors and food-related concerns. The Food-Related Problems Questionnaire (FRPQ) revealed significant positive correlations between age and total score and for each subscale, including preoccupation with food, impaired satiety, and composite negative behavior (CNB). SMS mean scores on the FRPQ subscales were compared to two reference populations: adults with general ID and adults with Prader-Willi syndrome (PWS), a syndrome with almost universal early-onset obesity. SMS mean scores were more similar to PWS than ID in the subscales of preoccupation and CNB, as well as the total FRPQ score. The Behavior Problems Inventory (BPI) showed SMS mean scores that were significantly increased relative to the ID reference population, indicating a higher frequency and increased severity of behavior problems in SMS. BPI data show that total behaviors do not increase with age; however, many negative behaviors including destroying things and head hitting and were consistently reported across all ages. Data show a clear increase in food-related concerns with age, with problems reported in SMS more similar to those seen in PWS than general ID. While a description of the behaviors seen in SMS is useful, identification of similarities between SMS and PWS may be especially helpful in developing more effective therapies, particularly for excessive weight. Previous reports have noted excessive weight in both SMS and PWS, but these data are the first to examine the behaviors associated with the weight gain in both syndromes. Similarities identified between SMS and PWS with regard to food-related problems suggest that treatments for obesity in PWS may serve individuals with SMS. For persons with PWS, avoiding obesity is possible if a diet routine is utilized that addresses food-related behaviors before they manifest, typically in the toddler years. These data suggest that a different approach may need to be taken with children with SMS regarding long-term outcomes and therapies to include routines effective for individuals with PWS.

1718W

Genetic counseling future in historicist Middle East culture. *A. Haghighatfard, M. Mahdavi.* Islamic Azad university, tehran, Iran.

Genetic counseling is a process of communication and education that considering expression and transference of genetic disorders . Achieving to this communication is depended to knowledge about culture and traditions of society and psychological situation of consultant. This article is an inspection about social reactions against genetic counseling as a new branch of medical science in historic and historicist middle east societies and their own culture. Public beliefe to “paternal big family”and “god willing destiny”are two major challenges of genetic counseling in middle east. In case of paternal big family middle east people especially arab tribes of persian gulf region believe that familial marriage especially children of two brothers makes stable and honorable family . for example familial marriage rate in Saudi Arabia and Kuwait are 12 times more than north America .even in some arab tribes marriage of a girl needs her cousin's permission. in the other case religious belief to god willing destiny that is based on some Quran sentences (also mentioned in Torah) made kind of religious historicism. In this ideology called “taghdir”, no person can predict about illness or healthy of newborn child; because it is part of god's desigens and theology . Now middle east geneticist are facing with public distrust about genetic counseling ; especially in old generation. Also increasing rate of recessive genetic disorders patients and deacreasing the gene pool diversity . in the absence of state programs for public education, “perceived personal control” has a completely different definition from west societies. It seem so spiritual influence of pioneer muslim clerics and their “Fatwa” (religious decree) could help to improve people's trust to genetic counseling. Beacause for muslims, the only thing that is more important from traditions is religious obligations.

1719W

Pre-conception genetic counseling awareness in a post-secondary educational institute. *A. NEOGI, A. MAHESH, D. JALALUDDIN SHARIFF.* BITS-PILANI DUBAI, Dubai, United Arab Emirates.

Genetic Counseling research has been carried out in several domains and the common target groups for such studies involve known patient families, genetic counselors and the consumer public. Young adults can contribute significantly to studies on health during the preconception stages where existence of known or unknown genetic conditions can affect conception, the pregnancy and the baby itself. Since preconception healthcare can be offered to any individual with reproductive potential, educational institutes have been identified as potential centers for awareness study target groups. Hypertension, diabetes, thyroid disease, obesity and polycystic ovary disorder are common disorders in the Middle East and India that have a significant effect on pregnancy. The study involves discussions with medical professionals. Information brochures have been designed and distributed to clinics and educational institutes. Health is the main focus for the clinic information sheet, whereas for college, both health and career aspects are included. To thoroughly assess the understanding of Genetic Counseling, a standard questionnaire is made based on a rating system (-10, 0, 10) and higher points indicate the presence and/or knowledge of a genetic condition/symptom either in the immediate family or relatives and friends. This is correlated with a checklist of the role of genetic counseling and corresponding points in this indicate the level of understanding of this role. Personal interviews and electronic surveys are carried out for the largely Indian female population of BITS-Dubai. A case study was done based on personal interview results. The results envisaged a generalized increase in awareness about preconception healthcare and genetic counseling for the few common disorders. Preliminary analysis shows no relationship between age of the individual and willingness to take a survey or go through a personal interview. Among the faculty, women above the age of 30 who are aware of the possible presence of a genetic condition are hesitant to consult a genetic counselor because of fear of information overload and lack of ability to manage symptoms in a current pregnancy. Part of this reluctance is attributed to them having incorrect information regarding testing options and unclear understanding of the role of a genetic counselor. However, the majority of the faculty agrees that there needs to be more awareness regarding genetic conditions and the impact on health.

Genetic Counseling in India - Challenges in a Developing Country. *R. Puri, U. Kotecha, R. Saxena, J. Verma, S. Movva, S. Kohli, I.C. Verma.* Center of Medical Genetics, Sir Ganga Ram Hospital, New Delhi, INDIA.

Genetic counseling in India has a different perspective as compared with the West. Firstly, the average physician has limited training for diagnosis of genetic disorders. Secondly counseling is mostly sought during pregnancy to ensure a normal fetus. Geneticists have to make a primary diagnosis in the absence of the proband, limited availability of medical documents and absence of DNA sample. From a tertiary care genetic center, we illustrate this challenge through three representative cases. A fourth gravida came at 8 weeks gestation for prenatal diagnosis. Her third born boy was well till 3 months age, after which he developed intractable seizures and neuroregression. Parents had noted increased tone, unexplained fever and irritability. He died at 3 years without a diagnosis. No medical documents except a CT Scan report of cerebral atrophy were available. Krabbe disease was suspected. As there was no DNA of the child, the parents were tested for the common 30 kb deletion, and were found to be positive. This confirmed Krabbe disease, making prenatal diagnosis possible. A consanguineous couple had lost two previous children with immune deficiency but no specific diagnosis. In the last child, though immunologic studies were done, diagnosis of the type of immune disorder was not made. A possibility of ADA deficiency was kept on review of the available data and molecular studies had to be done on the parents to confirm this and provide help in the next pregnancy. In the third case, a fourth gravida was referred for prenatal diagnosis at 12 weeks gestation. All 3 children had failure to thrive and neuroregression after 4 months age. Evaluation and bone marrow biopsy in the third child suggested a storage disorder. No confirmatory tests were done. In the absence of a cost effective strategy to establish a diagnosis for the family, a chorionic villus sampling was done after appropriate counseling. Enzyme analysis for GM1, Gaucher and Niemann Pick disease showed deficient activity of beta galactosidase. This not only confirmed GM1 gangliosidosis in the family but also prevented the birth of a fourth affected child. The challenge of counseling in India lies in a diagnosis to be established without examination of the proband and with no medical records, as these are usually disposed by the family after the death of the child. Molecular studies in the parents enable to confirm the diagnosis of the disorder and help to provide prenatal diagnosis.

1721W

A novel GLI2 mutation and discordant holoprosencephaly phenotypes in monozygotic twins. *C. Quindipan[1], M. Van Hirtum-Das[2], S. Saitta[1,3].* 1) Medical Genetics Institute, Los Angeles, CA; 2) Huntington Medical Foundation, Pasadena, CA; 3) Cedars-Sinai Medical Center, Los Angeles, CA.

Holoprosencephaly (HPE) is a developmental anomaly of the forebrain and midface affecting approximately 1:10,000 live births with widely variable features. Chromosomal aneuploidies account for 25–50% of cases, while 18–25% of HPE cases result from a single gene disorder. There are both autosomal recessive and dominant forms of HPE. We report 19-month-old monozygotic twins in which Twin A presents with single central incisor, microcephaly, hypotelorism, and normal development. Brain MRI performed at 14 months of age was normal. Twin B has significant global developmental delay, single central incisor, microcephaly, hypotelorism, failure to thrive, diabetes insipidus with dysgenesis of the corpus callosum and abnormality of the posterior pituitary noted on brain MRI. IVF was utilized in the pregnancy and a single embryo was implanted. Monozygosity was further confirmed by SNP microarray (LabCorp), which showed no pathogenic CNVs, no evidence of uniparental disomy, and excluded long contiguous regions of homozygosity. Molecular analysis of a panel of genes associated with HPE available on a clinical basis: SHH, GLI2, PTCH1, TGIF1, SIX3, and ZIC2, was performed revealing that both twins were heterozygous for a previously unreported C1573T missense mutation in GLI2 (Prevention Genetics). The reported mutation results in an amino acid substitution of Arginine to Tryptophan (R525W). The arginine residue is conserved among non-human primates with the substitution predicted to be pathogenic using PolyPhen-2. Subsequent parental analyses revealed that the father also carries the same GLI2 mutation. He is not affected with cognitive impairment nor does he have a single central incisor or other clinical features. A brain MRI has not been performed on him. He did not report any history of developmental delay or cognitive impairment, and his family history was unremarkable for clinical manifestations of HPE or stillbirths. Overall, we report a novel GLI2 missense mutation in monozygotic twins with discordant phenotypes and in their apparently unaffected father. We cannot exclude the possibility of an additional gene or epigenetic change that may explain the findings in this family that may require further whole exome and/or methylation analysis. There is wide clinical variability in this disorder, complicating recurrence risk counseling. Approximately 1/3 of individuals with microform HPE will have subclinical manifestations.

1722W

Furnishing appropriate information on mitochondrial diseases to patients and their families. *Y. Sato, Y. Goto.* National Center of Neurology and Psychiatry, Kodaira, Japan.

We've been doing genetic counseling for families who have patients with mitochondrial diseases. We clarified problems in the genetic counseling, and developed solutions for some of them. During the period from 2004 to 2011, a total of 38 clients received our genetic counseling. Approximately eighty percent of them were recommended to visit our hospital by their doctors. The clinical diagnoses included mitochondrial disease without particular category (n=13), Leigh syndrome (n=10), mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (n=6), pyruvate dehydrogenase complex deficiency disease (n=6), chronic progressive external ophthalmoplegia (n=1), myoclonic epilepsy with ragged-red fibers (n=1) and Pearson disease (n=1). Most of them were concerned about heredity, causes, symptoms, diagnoses and treatments of the diseases. Some consulted us about their genetic testing, family planning and information sharing among their families. We provided various kinds of information and discussed clients' concerns. We recognized some characteristics of genetic counseling for mitochondrial diseases. First, neither healthcare professionals nor families have enough knowledge about diseases. Second, the explanations about genetics are hard to understand because of their complexity. Third, the results of genetic testing are less useful to expect the risk of occurrence and recurrence. Fourth, patients' mothers and her families often feel guilty due to maternal inheritance. It was suggested that appropriate supports according to clients' understandings and situations are needed. For providing information relating to the diseases, we developed the handbook. It contains explanation and illustration in every page, and consists of totally six parts: basic knowledge, diagnoses, symptoms, treatments, social resources and genetics. We expect that healthcare professionals can explain using illustrations, and families can understand using explanations. In addition, we will provide information on the web and hold seminars for healthcare professionals periodically. We also plan to obtain feedback from users and make use of it towards revisions of the handbook.

1723W

A special thalassemia case with probable uniparental disomy. *Y. ZHANG[1,2], J. WU[1], M.Q. MAI[1], A.H. YIN[1,2], H.K. DING[1,2], D.Q. QIN[1], Q.Y. DU[1], J.Q. LIANG[1].* 1) Prenatal Diagnosis Center & Genetic Disease Diagnosis and Treatment Center, Guangdong Women and Children Hospital, Guangzhou, Guangdong, China; 2) Maternal and Children Metabolic-Genetic Disease Key Laboratory of Guangdong Women and Children Hospital.

Background: Frequently occurs in South China, beta thalassemia is a kind of autosome recessive disease which can be diagnosis by gene analysis with many methods. Prenatal diagnosis is feasible if parents' genotype were known. 17 mutants in beta hemoglobin gene and two kinds of large deletion in beta gene cluster are mostly found in Chinese. Objective: The pregnant woman wanted to know the fetus's genotype of beta thalassemia, for she once gave birth to a boy with severe bata thalassemia, who needed blood transfusion regularly to suatain life from 2 years old. and prenatal diagnosis was subjected. Methods: The parent and proband's peripheral blood was first used to extract the genome DNA and to inspect beta hemoglobin gene(HBB) with PCR-RDB (reverse dot blotting). Then Gap-PCR was used to investigate if SEA-HPFH or Gγ+(Aγδβ)0 exist in the parent and proband. Also, gene sequencing was used to inspect the potential scare mutants in HBB. Furthermore, the fetus' genotype was detected with amniotic fluid. Finally, STS markers were used to analysis the strange genetic phenomenon in the family. Results: The mother was a carrier whose genotype was βCD41–42/βA, paternal genotype wasβA/βA, and the fetus' genotype was the same with that of the mother's. However, PCR-RDB and DNA sequencing show the CD41–42 homozygote for the proband(βCD41–42/βCD41–42), SEA-HPFH or Gγ+(Aγδβ)0 was not found in all of them, which contradicts Mendel's genetics. With informed consent for diagnostic genetic testing, paternity testing was carried out and the result was unexclusive. With four STS markers around CD41–42 in beta hemoglobin gene, we found the probalble uniparental disomy in the proband. Conclusion: The fetus was a carrier with CD41–42 homozygote in beta hemoglobin gene; if the proband was uniparental disomy or de novo mutant in beta hemoglobin gene needs further research.

Understanding the Needs of Parents of Children with a Genetic Diagnosis - can it improve clinical practice? *L. Bryson, J. Dunlop, A. Anderson, J. Berg.* University of Dundee, Ninewells Hospital, Dundee, Angus, United Kingdom.

There has been a very rapid increase in our ability to diagnose genetic conditions in children, using technology such as Next Generation Sequencing and array CGH. Very little is known about the impact of such diagnoses on parents, and the parents' need for support following testing. We, therefore, used a qualitative methodology to explore the effect of diagnosis on parents and identify areas in which additional support would be most useful. Semi structured interviews were undertaken with the parents of 11 children with a confirmed genetic diagnosis causing developmental delay and additional syndromic features. All patients were identified and recruited with ethical approval and consent from within NHS Tayside. The interviews were transcribed and analysed using framework analysis(1). Four main themes were identified from the transcripts: the reaction to having a genetic diagnosis; the support which was available; how parents felt they were managed by the healthcare team and how a genetic diagnosis affects the family. Within each theme, there were multiple sub-themes highlighting both positive and negative effects on the family. A key point that emerged was that parents felt there was a lack of signposting to support, especially before and immediately after diagnosis, and that provision of appropriate information and structured follow up would improve parents' experiences. Our results have allowed us to design a questionnaire, for both geneticists and paediatricians, to ascertain how often key themes are appropriately dealt with during consultations, and to propose a new framework for clinical follow up of parents with a child with a new genetic diagnosis. 1. Pope C, Ziebland S, Mays N. Analysing qualitative data. BMJ. 2000 January 8, 2000;320(7227):114-6.

A diagnostic assay for predicting medullary cystic kidney disease type 1 (MCKD1). *B. Blumenstiel[1], M. DeFelice[1], A. Kirby[1,2], A. Gnirke[1], A. Bleyer[3], S. Gabriel[1], M. Daly[1,2].* 1) Broad Institute of Harvard and MIT, Cambridge, MA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 3) Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, NC.

Medullary cystic kidney disease type 1 (MCKD1) is a rare autosomal dominant disorder which manifests as a slow deterioration in kidney function typically becoming symptomatic in the second to third decade in life. Disease progression ultimately results in the need for dialysis and/or kidney transplantation several decades post diagnosis. Until recently, decisive diagnosis of MCKD1 has been hampered by several factors including variable age of onset and symptom variability. A very recent study (Kirby et. al. pending publication) has implicated a single base (+C) frameshift insertion in a variable nucleotide tandem repeat (VNTR) region of the MUC1 gene located on Chromosome 1 as the causal mutation for the disorder. Interrogating and detecting a rare, single insertion event in a high-copy tandem repeat region posed a unique set of challenges. Due to the high wild-type: mutant allelic ratio (~100:1), high GC composition of the repeat (>80%) and variable positioning of the insertion within the VNTR region, many standard commercial genotyping protocols were not feasible. Exacerbating this challenge was the unique nature of the mutation being a single insertion event creating an eight base cytosine homopolymer (8C) against a high-copy background of wild-type (7C) repeats. Here we describe a novel and robust diagnostic assay for detecting the presence of a single mutated copy of a GC-rich 60-baseVNTR sequence in order to positively verify the causal variant as well as identify carrier patients prior to symptom development. We developed a probe-extension assay capable of detecting a single mutant copy within the predominantly wild-type VNTR using selective restriction digestion of wild-type copies and analyte detection by MALDI-TOF mass spectrometry. By genotyping 62 phenotypically affected and 79 unaffected relatives from collected families, we observed perfect segregation of the mutant allele with the disease phenotype. Additional genotyping of over 500 unrelated controls from HapMap CEU, Japanese, Chinese, Yoruba and Tuscan HapMap3 populations showed no evidence of the +C insertion event arising in the larger global population.

1726W

Studding the importance of common α-deletions among β-thalassemia minor individuals in an Iranian population based on their frequencies and CBC indexes. *A. Moosavi[1,2,3], M. Karimipoor[1], S. Zeinali[1], B. ZarbakhshH[1].* 1) Molecular Medicine Department, Pasteur Institute of Iran, Tehran, Iran; 2) Biochemistry.,Tarbiat Moallem University of Tehran,Tehran,Iran; 3) Karaj thalassemia screening center, Alborz Medical University,Karaj,Alborz,Iran.

Beta-thalassemia (thal) is the most common inherited monogenic recessive disorder in IRAN. In the screening carriers an important challenge is co-inheritance of α-deletions. The pathogenesis of thalassemia depends on alpha/beta chain ratio changes, so we can suppose that alpha deletions as a secondary modifier factor can result in misdiagnosis in the screening of beta-thal carriers. In this study the frequency of common alpha deletions in beta thalassemia carriers was determined. The study includes families referred from different primary health care center with hypochromic anemia [MCV<80fl; MCH<27pg] and A2> 3.5. After providing informed consent,genomic DNA was extracted from peripheral blood by salting out method and proteinase K. Allele-specific PCR was exploited for common β-mutations. Then common alpha deletions (-α3.7, -α4.2, -α20.5 and - MED)were screened by multiplex gap PCR in samples with β-mutations.At the end Multiplex polymerase chain reaction (m-PCR) assay was used to detect the $\alpha\alpha\alpha^{anti3.7}$ triplication and $\alpha\alpha\alpha\alpha^{anti3.7}$ quadruplicate in cases that we had co-inheritance of α-deletion in beta thalassemia carriers. **Among 227 β-thalassemia minor individuals we found α-thal mutations in 43 cases: 37 heterozygote -α3.7 (16.3%), 5 homo -α3.7 (2.2%)and 1 -MED (0.44%).There was not any $\alpha\alpha\alpha^{anti3.7}$ triplication and $\alpha\alpha\alpha\alpha^{anti3.7}$ quadruplicate in these samples.** The results show high prevalence of co-inheritance of alpha-thal and beta-thal in our selected population and comparing CBC indexes in these person shows low changes in these cases. Therefore it is highly recommended that physicians and genetic counselors involved in the screening program of beta thalassemia major in the country consider this phenomenon.

1727W

Genomic data interpretation challenges: healthy older relatives as super controls. *M.S. Naslavsky, R.C.M. Pavanello, N.C.V. Lourenço, A. Cerqueira, M. Lazar, M. Vainzof, D. Schlesinger, M. Zatz.* Human Genome Research Center, Biosciences Institute, University of Sao Paulo. Sao Paulo - SP, Brazil.

With the improvement of whole-genome sequencing and genotyping technologies at affordable costs, an increasing body of data from human populations is emerging. However, the interpretation of such a large flow of information represents a great challenge. Since the identification of rare variants is rising in number with large whole-genome and exome sequencing studies, assessing the pathogenicity of novel mutations/variants and their impact in health is of utmost importance. It was recently observed that many genetic variants once predicted to be deleterious were in fact present in healthy individuals. As an example, we recently ascertained a 44-year father of a 10-year-old daughter with bilateral coloboma and hearing loss, in whom a whole-genome CGH revealed a deletion of exons 38–44 in the dystrophin gene. This mutation, which was not found in almost 1000 Duchenne/Becker patients screened in our Center, was inherited from her asymptomatic father, who was further clinically and molecularly evaluated for prognosis and genetic counseling (GC). To assess whether the present case represents a rare case of non-penetrance, and aiming to obtain more information for prognosis and GC, we analyzed healthy older relatives. Mutation analysis revealed that his mother, brother and 56-year-old maternal uncle also carry the 38–44 deletion, suggesting it an unlikely cause of muscle weakness at least in this family. In short, in addition to population-based studies, keeping DNA from older relatives may turn into a valuable source of information. This is particularly relevant regarding the variability of specific mutations penetrance under influence of distinct genetic backgrounds and environmental factors.

Assessment of cascade testing in families of carriers identified through newborn screening for cystic fibrosis in western Brittany, France. *C. Ferec[1,2,3,4], I. Dugueperoux[1,2,3,4], M.-P. Audrezet[1,2,3,4], P. Parent[5], V. Scotet[1,3,4].* 1) Inserm, U1078, Brest, F-29200, France; 2) C.H.R.U. Brest, Hôpital Morvan, Laboratoire de Génétique Moléculaire, Brest, F-29200, France; 3) Etablissement Français du Sang (EFS) - Bretagne, Brest, F-29200, France; 4) Université de Bretagne Occidentale, Faculté de Médecine et des Sciences de la Santé, Brest, F-29200, France; 5) C.H.R.U. Brest, Hôpital Morvan, Service de Génétique Médicale, Brest, F-29200, France.

Objectives: DNA-based newborn screening (NBS) for cystic fibrosis (CF; {OMIM#219700}) aims to early detect affected children. However, it also leads to the unwanted but inevitable detection of some healthy carrier newborns (i.e. having only one CFTR mutation). If being a carrier has no influence on the development of the newborn, the knowledge of that status is nonetheless important. It provides opportunity for the parents and relatives to know their genetic status regarding CF, as they can benefit from cascade carrier testing. The aim of the study was to measure the use of cascade testing in families of carrier children identified through NBS in an area where CF is frequent (western Brittany, France) and where NBS is implemented for over 20 years. Methods: We reviewed all the carriers identified by NBS in the district of Finistère since the introduction of the IRT/DNA strategy (1991). In parallel, we recorded the genetic tests made in those families in the sole genetic laboratory of our area, over the 1991–2010 period. Results: Among the 200 378 newborns screened over that period, 199 (0.1%) from 195 families, were identified as CF carriers. To date, 148 families (75.4%) have required carrier testing at least once, and 374 genetic tests were performed (mean number/family: 2.5; range: [1–8]). Testing was mainly used by the parents (77.4% of the tests performed and 95.9% of the parental couples tested) and uncles/aunts (13.7% of the genetic tests done). Overall, family testing identified 183 CF carriers and evidenced 5 new 1-in-4 risk couples. Of them 4 requested prenatal diagnosis 5 times. One affected pregnancy was diagnosed and terminated. Almost all the tested couples (151/156 i.e. 96.8%) could be reassured about their genetic status and about the risk of having a child with a disease that remains severe and life limiting, despite important improvements in the management over the past decades. Moreover, considering the CF incidence observed over that time (1/2 569) and the deducted carrier rate (1/26), we estimated that NBS detected only 2.6% of all the expected carriers born over the 1991–2010 period, and only 1.9% of those born since NBS was enlarged to the whole country in 2002, which had led to a change in strategy. Carriers detected by NBS appeared to be well managed in our area and cascade testing, that prevents birth of other CF children in families, seems relatively active. Study approved by our local ethical committee.

1729W

NextGen sequencing of *HEXA*: A more sensitive assay. *J. Hoffman[1], M. Umbarger[2], C. Kennedy[2], B. Bishop[2], P. Saunders[2], G. Porreca[2], E. Strovel[3], M. Blitzer[3], J. Douyard[1], J. Davies[2], S. Hallam[2], V. Greger[2], C. Towne[2].* 1) Division of Genetics, Department of Pediatrics, Tufts Medical Center, Boston, MA; 2) Good Start Genetics, Cambridge, MA; 3) Division of Genetics, Department of Pediatrics, University of MD School of Medicine, Baltimore, MD.

Tay-Sachs disease (TSD), an autosomal recessive neurodegenerative disease, serves as the prototype for ethnic based carrier screening. With a carrier rate of approximately 1 in 25 in Ashkenazi Jews (AJs) and French Canadians, use of highly sensitive methodology is critical in screening for this disease. *HEXA* enzyme analysis has long been considered the gold standard for TSD screening, detecting roughly 98% of carriers from all ethnic backgrounds. Due to poor enzyme stability and effects of certain medications and/or pregnancy on serum enzyme analysis, this method has significant limitations. DNA mutation screening for TSD is widely available, with sensitivity of 89–96% for carriers of AJ descent, but much lower for other ethnicities. We proposed NextGen sequencing (NGS), a rapid and efficient methodology, along with genotyping for the common 7.6kb *HEXA* deletion as a possible screening method for TSD. 74 blood samples and questionnaires were collected at a family conference for TSD and related diseases. Results of serum *HEXA* analysis (enzyme) and NGS + 7.6kb del analysis were compared. Mutations were confirmed with Sanger sequencing. 51/74 participants (69%) had positive enzyme results (46 carriers, 5 with late-onset TSD). 42/51 enzyme positives had a pathogenic mutation, detected via NGS +7.6kb del analysis. 7/ 51 were found to have a previously reported VUS, 1/51 had a novel VUS, and 1/51 had the *HEXA* pseudoallele (false positive enzyme). 2 of the enzyme-negative individuals had the B1 pathogenic allele (not detectable via enzyme). 7/74 (10%) had enzyme-inconclusive results; 4 had no reported family history of TSD and negative NGS + 7.6kb del analysis, 2 were obligate carriers with previously reported mutations, and 1 had a VUS. Overall, NGS + 7.6kb del screening of *HEXA* found a pathogenic mutation, pseudoallele, or VUS in 100% of the enzyme-positive or obligate carrier/enzyme-inconclusive samples, detected 2 carriers that would have been missed by enzyme alone, and detected mutations in 7/51 (14%) which would have been missed using common mutation panels. The VUSs require further laboratory and pedigree analysis to prove pathogenicity. Our data suggest that NextGen sequencing in combination with enzyme may be used as an efficient screening technology for people of all backgrounds, and will provide a more sensitive test than enzyme alone or a mutation panel with enzyme.

1730W

No association between ATXN2 (SCA2) CAG repeat expansion and amyotrophic lateral sclerosis /parkinsonism-dementia complex of the Kii Peninsula, Japan. *H. Tomiyama[1,2], C. Yamashita[1], R. Sasaki[3], Y. Li[4], M. Funayama[1,4], N. Hattori[1,2,4], S. Kuzuhara[5], Y. Kokubo[3].* 1) Department of Neurology, Juntendo University School of Medicine, Tokyo, Japan; 2) Department of Neuroscience for Neurodegenerative Disorders, Juntendo University School of Medicine, Tokyo, Japan; 3) Department of Neurology, Mie University School of Medicine, Tsu, Japan; 4) Research Institute for Diseases of Old Age, Graduate School of Medicine, Juntendo University, Tokyo, Japan; 5) Department of Medical Welfare, the Faculty of Health Science, Suzuka University of Medical Science, Suzuka, Japan.

Objectives. To clarify the genetic background of amyotrophic lateral sclerosis (ALS)/parkinsonism-dementia complex (PDC) of the Kii peninsula, Japan (Kii ALS/PDC). Backgrounds. Etiology and pathogenesis of amyotrophic lateral sclerosis / parkinsonism-dementia complex (ALS/PDC) of Guam and the Kii peninsula remain unclear. Intermediate CAG repeat expansions of ATXN2 (SCA2) have been detected in autosomal dominant parkinsonism. Recently, intermediate CAG repeat expansions of ATXN2 were also recognized as a predisposing factor for ALS. Methods. In 12 patients with pathologically diagnosed Kii ALS/PDC, we performed fragment analysis for PCR products and determined the lengths of CAG repeat expansions of ATXN2. Results. CAG repeat lengths of ATXN2 were normal (22 repeats) in all 12 patients with Kii ALS/PDC. Conclusions. No abnormal CAG repeat expansions of ATXN2 were found in patients with Kii ALS/PDC. Combined with our previous study, we have found no causative mutations in the reported major causative or susceptible genes (25 genes) related to ALS, frontotemporal lober degeneration, parkinsonism, synucleinopathy, TDP-43 proteinopathy, and tauopathy. However, familial clustering and lack of any environment factors suggest that unidentified genetic factors cause Kii ALS/PDC. ALS/PDC warrants exome or whole genome sequencing and other genetic approaches.

Assigning disease liability of mutations in the CFTR gene improves detection rate of CF carrier screening. *K.R. Siklosi[1], P.R. Sosnay[2,3], F. Van Goor[4], K. Kaniecki[1], M. Corey[6,7], A.S. Romalho[13,14], M.D. Amaral[13,14], R. Dorfman[8], R. Karchin[9], M.H. Lewis[10], H. Yu[4], J. Zielenski[8], J.M. Rommens[8,11], C. Castellani[5], C.M. Penland[12], G.R. Cutting[1,2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Medicine, Johns Hopkins University, Baltimore, MD; 3) Perdana University Graduate School of Medicine, Serdang, Malaysia; 4) Vertex Pharmaceuticals Incorporated, San Diego, CA; 5) Cystic Fibrosis Center, Azienda Ospedaliera Universitaria Integrata, Verona, Italy; 6) Child Evaluative Health Sciences, The Hospital for Sick Children, Toronto, ON, Canada; 7) Dalla Lana School of Public Health, University of Toronto, ON, Canada; 8) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada; 9) Department of Biomedical Engineering, Institute for Computational Medicine, Johns Hopkins University, Baltimore, MD; 10) Genetics and Public Policy Center, Berman Institute for Bioethics, Johns Hopkins University, Baltimore, MD; 11) Department of Molecular Genetics, University of Toronto, ON, Canada; 12) Cystic Fibrosis Foundation, Bethesda, MD; 13) University of Lisboa, Faculty of Sciences, Centre for Biodiversity, Functional and Integrative Genomics (BioFIG), Lisboa, Portugal; 14) Department of Genetics, National Institute of Health, Lisboa, Portugal.

Testing for CF carrier status is commonly performed in the US. The American College of Medical Genetics (ACMG) recommends a screening panel of 23 CFTR mutations of ≥0.1 frequency in CF patients. The panel detects approximately 85% of Caucasian CF carriers and fewer of other ethnicities. Optimal screening would detect ≥95% of carriers so that couples in whom one tests positive and the other negative have a residual risk for having a child with CF that is below their population risk. Improving CF carrier detection rate to ≥95% requires a larger set of mutations of known prevalence and disease liability. The Clinical and Functional Translation of CFTR (CFTR2) project was initiated to define clinical consequences and disease liability of CFTR mutations. The CFTR2 database contains 39,545 patients from the US and Europe. Patients in the database harbor 1,045 unique CFTR mutations, 160 of which occur at a frequency of ≥0.01 and together account for 97% of the identified CF alleles; these underwent further analysis. Mutations were evaluated by clinical, functional and penetrance analysis. The mean sweat chloride concentrations of patients bearing the mutation in question in trans with a severe ACMG mutation was used for clinical verification. Analysis of CFTR function was performed by measuring short-circuit chloride current in cell lines expressing missense mutant CFTR. Mutations introducing a premature termination codon were classified as functionally deleterious. Penetrance was evaluated by genotyping fertile fathers of CF patients who are expected to carry a deleterious CFTR mutation and a “healthy” CFTR gene. The presence of another CFTR mutation in the “healthy” gene indicated that the mutation may have reduced penetrance or no deleterious effect on CFTR function. Of the 160 mutations, 122 were deemed CF-causing based on 1) mean sweat chloride concentration ≥60 mEq/L (146/159 mutations with sweat chloride measurements available); 2) experimental evidence of CFTR dysfunction (120/138 tested mutations); and 3) not observed in trans with an ACMG mutation in the fathers (144/160 mutations). The remaining mutations were deemed as mutations of varying clinical consequence (15) and non CF-causing (6) while 17 mutations continue to be analyzed. Summary information for mutations in the list of 160 is included on the CFTR2 website (www.cftr2.org). The 122 mutations verified as CF-causing to date attains a 95% sensitivity for CF carrier detection.

1732W

Mutational screening of C9ORF72, SOD1, TARDBP and FUS genes in an ALS cohort from the North-Eastern part of Italy. *C. Bertolin[1], J. Agostini[2], C. D'Ascenzo[2], F. Boaretto[1], C. Salvoro[1], C. Angelini[2], E. Pegoraro[2], G. Sorarù[2], ML. Mostacciuolo[1].* 1) Laboratory of Human Genetics, Department of Biology, University of Padova, Italy; 2) Department of Neurosciences, University of Padova, Italy.

Background: Mutations in C9ORF72, SOD1, TARDBP and FUS genes appear as the most common genetic cause of familial (FALS) and sporadic (SALS) forms of ALS. Objectives: To assess the frequency of ALS genes mutations in a large cohort of ALS patients referred to the ALS Clinic of the University of Padova. Most of the patients are Italian (about 98%) and originating from the North-Eastern regions (about 85%). Methods: Overall we investigated 327 patients, 39 with reported family history (FALS) and 288 sporadic/isolated cases (SALS). We performed Sanger sequencing of all coding exons of SOD1 and FUS genes and two exons of TARDBP (exon 4 and 6) in all ALS patients. Moreover, with a two-step repeat primer PCR, we searched for the expanded GGGGCC hexanucleotide repeats in the C9ORF72 gene, recently associated with the disease. Results: 14 pathogenic missense mutations were found in 14 unrelated patients: 6 SOD1 (3 in FALS and 3 in SALS), 5 TARDBP (1 in FALS and 4 in SALS) and 3 FUS (1 FALS and 2 SALS). All the mutations but one have already been reported: a novel TARDBP mutation was identified in exon 4. Expanded repeats in C9ORF72 were found in 19 patients (7 FALS and 12 in SALS). From a clinical point of view, we could observe a shorter disease lifespan and an increased dementia comorbidity in carriers of the expanded C9ORF72 hexanucleotide repeats (25% vs 7% of overall sample, p=0.0009). Conclusions: This study is the first mutation screening of the most frequently mutated genes involved in ALS (SOD1, FUS, TARDBP and C9ORF72) performed in an Italian North-East cohort of patients. Overall, our screening identified the molecular causes of ALS in the 30% of FALS and in the 7% of SALS patients. As already reported by other studies C9ORF72 and SOD1 are the most common mutated genes but, in our sample, mutation frequencies are lower if compared with those reported in other Italian ALS cohorts [Chiò et al., Brain. 135:784–93 (2012)]. Recently, other studies pointed out to a relevant correlation among population origins and gene-specific mutation frequencies. In that view, our results could be very useful to direct the genetic test in ALS patients.

1733W

Cree Leukoencephalopathy and Cree Encephalitis Carrier Screening Program: Lived Experiences of Carrier and Non-Carrier Couples. *J. Le Clerc-Blain[1,2,3], H. Denoncourt[4], A. Richter[1,2,3], A.M. Laberge[1,2,3].* 1) Medical Genetics Division, CHU Sainte-Justine, Montreal, Quebec, Canada; 2) Dept of Pediatrics, Université de Montréal, Montréal, Québec, Canada; 3) CHU Sainte-Justine Research Center, Montréal, Québec, Canada; 4) Cree Board of Health and Social Services of James Bay, Chisasibi, Quebec, Canada.

STATEMENT OF PURPOSE: Cree leukoencephalopathy (CLE) and Cree encephalitis (CE) are severe neurodegenerative autosomal recessive conditions with carrier rates of 1/10 and 1/30, (respectively) in the James Bay Cree communities of Northern Quebec, Canada. Since 2006 a regional public health educational and screening program informs the population about CE/CLE and offers carrier screening starting at 14 years of age. OBJECTIVES of this study are to describe the lived experience of couples who participated in the CE/CLE carrier screening program and to assess their level of satisfaction with the program. METHODOLOGY: In collaboration with the local parents' committee (Eeyou Awash Foundation), we took a phenomenological approach to evaluate the lived experience of couples who have gone through the CE/CLE carrier screening program. Nineteen adults recruited in two Cree communities took part in semi-structured interviews that were audio-recorded, transcribed verbatim and coded with QDA Miner. Transcripts were analyzed to extract elements describing the underlying essence of the participants' experience. RESULTS: All participants had previous direct or indirect contact with a child affected by CE/CLE. Most expressed concern over the impact that carrier status identification may have on their family's future generations. Half of the participants had not discussed the screening process or their own results with family members but wondered about the mutation origin in their family. Participants emphasized the importance of having access to prenatal diagnosis and a minority spontaneously expressed interest in preimplantation genetic diagnosis. They articulated the importance of being able to know the foetus' status, thus allowing pregnancy decisions. However, couples were ambivalent about the decision to undergo medical termination of pregnancy. All participants expressed their appreciation of the program and its importance for the community, emphasizing the need to increase its visibility. CONCLUSION: Few studies have focused on population screening participants' experience. The experience of individuals who participated in the CE/CLE carrier screening program reflects the general satisfaction of participants and the importance of the program for the community. This knowledge will allow the improvement of the program as well as serving as a model for development of other population screening programs, particularly in other Canadian First Nation communities.

Diagnostic Exome Sequencing in Movement Disorders. *E.J. Kamsteeg[1], C.F.H.A. Gilissen[1], K. Neveling[1], H.J.E. de Reuver[1], B.P.C. van de Warrenburg[2], M.A.A.P. Willemsen[3], S. Vermeer[1], H.G. Brunner[1], M.R. Nelen[1], H. Scheffer[1].* 1) Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 2) Neurology, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 3) Pediatric Neurology, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

Exome sequencing has a great potential in genetic diagnostics, particularly if used for heterogeneous diseases. Sanger sequencing strategies in these heterogeneous diseases are known to have a low diagnostic yield per gene tested. We now have implemented a routine diagnostic exome sequencing workflow for several highly heterogeneous diseases using disease(group)-specific gene filters. Here, the experiences of diagnostic exome sequencing in 50 patients with a movement disorder are reported. Our strategy is to sequence the `whole' exome independent of the diagnostic question, and afterwards apply masking filters for specific disease groups. Over 150 genes are represented in the list of movement disorders, which include forms of ataxia, hereditary spastic paraplegia (HSP) and dystonia. An in-house designed interface was built to display only the sequence variants in those genes, and to prioritize or further select putative pathogenic variants. Using this interface, in the order of 500 sequence variants are typically detected in the genes of the movement disorders list. Subsequent selection based on several parameters, such as frequencies, conservation, type of mutation etc., allows the reduction of variants to about 10 putatively pathogenic variants. The results of a cohort of 50 patients will be presented. QC, cases, and pitfalls will be discussed. With the analysis still ongoing, the movement disorders gene package analysis is expected to provide a molecular diagnosis in ~15% of the patients. So far, mutations were detected in the KIF5A (SPG10) in a large family with a dominant form of HSP, C10orf2/TWINKLE in a patient with an isolated complicated form of ataxia, and KIAA0415 (SPG48) in two siblings with HSP. The results so far indicate that exome sequencing tests are appropriate to identify the underlying molecular defects in movement disorders. Also, some mutations were unexpected, which may imply that the clinical spectra of several disorders may widen now exome sequencing has become diagnostically available.

1735W

Whole exome sequencing as an approach to the diagnosis of the ataxic patients. *Y. Yang[1], M. Vatta[1], Z. Niu[1], Y. Ding[2], H. Sun[1], M. Scheel[2], N. Saada[2], W. Liu[2], M. Wang[2], D.P. Sexton[2], A.C. Hawes[2], M.N. Bainbridge[2], P.A. Pham[2], J.G. Reid[2], D.M. Muzny[2], A.A. Braxton[1], P.A. Ward[1], T.M. Balmakund[3], W.K. Chung[4], A. Willis[1], S.E. Plon[1,5], J.R. Lupski[1], R.A. Gibbs[2], A.L. Beaudet[1], C.M. Eng[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Arkansas Children'ts Hospital Little Rock, AR; 4) Columbia Univ, Div Molec Gen New York, NY; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

The diagnosis of the patient with suspected hereditary ataxia includes a long list of some common and some very rare conditions that have significant overlap and few distinguishing features. We have recently diagnosed two patients with Autosomal Recessive Spastic Ataxia of Charlevoix-Saguenay (ARSACS, MIM 270550) by whole exome sequencing (WES) testing on a clinical basis. ARSACS is a rare genetic disorder characterized by progressive spasticity and horizontal gaze nystagmus, distal muscle wasting and sensorimotor neuropathy, and dysarthria. A sibling has similar phenotype. The first patient is a 16 year old female with a history of cerebellar atrophy and mild spinal cord atrophy, increased tone in the hamstrings and distal lower extremities, demyelinating changes on EMG, ataxic gait and chronic headaches. WES testing identified two heterozygous novel deleterious mutations in the *SACS* gene, a c.6434T>A (p.L2145X) nonsense mutation and a c.2938_2939del (p.M980fs) frameshift mutation. Sanger sequencing confirmed mutations in the proband and found that the father is a carrier for the c.6434T>A (p.L2145X) mutation and the mother carries the c.2938_2939del (p.M980fs) mutation, indicating that the mutations were in trans-configuration in the proband. The second patient is a 4.4 year old female born to consanguineous parents in the Middle East. The patient presented with delayed motor milestones, spastic ataxia, abnormal gait, and a mild white matter abnormality. A homozygous c.11637_11638delAG (p.R3879fs) frameshift mutation in the *SACS* gene was detected by WES in this patient and confirmed by Sanger sequencing; both parents were found to be heterozygous for this novel mutation. Clinical correlation of the both patients's presentations was felt to be consistent with an ARSACS diagnosis. Both patients had previously gone through extensive workups without a definitive diagnosis. Because of the rarity of the ARSACS disease (less than 400 confirmed cases so far), the phenotypic overlap with other ataxia disorders, and the exclusion of the *SACS* gene from current ataxia gene testing panels, diagnosis of ARSACS can be elusive and costly, a challenge faced by most rare genetic disorders. The diagnosis of ARSACS in these patients demonstrates the potential benefit of WES as a diagnostic approach to patients with previously unsolved rare disorders. Our findings may help determine genotype-phenotype relationships and provide information for enhanced genetic counseling.

A Retrospective Genetic Analysis of Cases Reported using an XLMR/XLID Next-Generation Sequencing Panel. *M. Parra, S. Mexal, R. Hoiness, K. Waller, I. Lu, C. Gau, J.A. Neidich, J. Wei.* Ambry Genetics, Aliso Viejo, CA.

X-linked mental retardation or X-linked intellectual disability (XLMR/XLID) is a phenotypically and genetically heterogenous disorder that occurs at a prevalence of 1/1000 males. Excluding the CGG repeat expansions in the 5' untranslated region of FMR1 that are associated with Fragile X syndrome, XLMR/XLID has yet to show any major mutational hotspots. At least 90 genes on the X chromosome have been associated with XLMR/XLID, accounting for 10–40% of cases, depending on the inheritance pattern (i.e. sporadic or passed on from obligate female carriers). This study provides a retrospective genetic analysis of the approximately 800 cases reported using the Ambry XLMR Next Gen Sequencing Panel™ since March 2010. This panel is a comprehensive gene sequencing assay for 81 genes associated with X-linked intellectual disability (nonsyndromic and syndromic). Herein we report the mutations identified to date across all cases, as well as in our collection of approximately 380 family studies. Also discussed are variants reclassified as polymorphisms following further family study investigation. Finally, we highlight a case study of a NS-XLMR family, wherein a novel variant in HUWE1 (HECT, UBA and WWE domain containing 1, E3 ubiquitin protein ligase) was found to segregate with the disease in a large family with non-syndromic intellectual disability. Overall we demonstrate here the power of family studies in assisting in reclassification of variants and defining mutations.

Principles and Informatic Infrastructure for Implementing Diagnostic Next-Generation Sequencing for Genetically Heterogeneous Conditions. *S. Topper, V. Nelakuditi, C. Tan, A. Reeder, D. Del Gaudio, S. Das.* Human Genetics, University of Chicago, Chicago, IL.

The diagnosis of many genetic conditions is complicated by extensive genetic heterogeneity. Phenotypically indistinguishable forms of Intellectual Disability, for example, can be caused by mutations in any one of about 100 known genes, each one of which accounts for a very small percentage of patient cases. In many cases a highly parallelized sequencing approach is a more effective and efficient diagnostic strategy than serial single gene sequencing. But handling the large amount of data generated, while maintaining the essential clinical standards developed in low-throughput tests, can present substantial challenges for the diagnostic lab. Here we present an enumeration of those standards as applied to large-panel, next-generation sequencing (NGS) diagnostic testing, a web-based tool to assist in meeting those standards, and data from validation samples for a set of diagnostic tests. These principles are intended to ensure reliable test results that can be successfully integrated into a diagnostic strategy, especially in the likely case of a negative result, an outcome that is still expected in more than 50% of patient samples. The principles are: 1)Data must be processed and evaluated efficiently and reproducibly; 2)Target regions of essential genes must be evaluated completely; 3)Identified mutations must be confirmed by an orthogonal technology; and 4)Pathogenicity of each identified variant must be evaluated independently and in the context of the patient's entire data set. To ensure that these standards are met we developed a database and web-based interface to facilitate a teamwork approach to sample tracking, variant interpretation, annotated data storage, and integrating NGS and Sanger data. In this tool, an `Overview' module presents data quality statistics, a summary of missed regions in the target genes, and sample tracking information. A `Confirmation' module consists of an interface for coordinating Sanger sequencing of NGS data gaps, variants that must be confirmed, and provides a method for integrating Sanger data into the data set. An `Interpretation' module provides an interface for presenting annotation information, tracking variant review status, maintaining notes, and linking to the data sets of other patients with the same sequence change. Using this system we have evaluated data from 50 validation samples, in some cases identifying pathogenic mutations in samples for which no molecular diagnosis had previously been found.

Clinical Characterization of Patients Undergoing Molecular Testing for Ehlers Danlos Syndrome at The Hospital For Sick Children in Toronto, Canada: Five Year Experience. *L. Dupuis, M.A. Qoqandi, P. Kannu, L. Fishman, D. Chitayat, S. Bowdin, R. Mendoza-Londono.* Division of Clinical & Metabolic Genetics, The Hospital for Sick Children and University of Toronto, Toronto, ON, Canada.

Introduction: Ehlers-Danlos Syndromes (EDS) is a heterogeneous group of disorders. Molecular testing is only available for a small subset of patients with this clinical diagnosis. The reported yield for molecular testing for mutations in the Collagen V gene in patients that meet criteria for classic EDS is 50%. On average our genetics service evaluates four patients per month with presumed diagnosis of EDS. **Objectives:** To determine the frequency of detectable molecular alterations in patients with clinical diagnosis of EDS investigated by genetic testing and explore the genotype-phenotype correlations with regards to diagnostic yield. **Materials and Methods:** Retrospective chart review of patients undergoing molecular testing between 2007 and 2012. Data collected included basic demographics, anthropometric, Beighton score and clinical findings associated with EDS. Descriptive statistics were calculated from the cohort of index patients. **Results:** A total of 52 individuals from 31 index families underwent molecular testing in the 5 year period. Of these 55% were female (17/31), 45% male (14/31). Average age at evaluation was 18 years (SD 12.5). The average Beighton score (BS) was 5.33 (SD 2.1). Mutations were identified in 29% (9/31) of the subjects. Of these seven mutations affected the Collagen V genes, and one each in Collagen I (*COL1A2*c.304C>T,p.Pro102Ser) and Collagen III (*COL3A1* c.2044G>A,Glu682Lys). Mutations found in Collagen V included one missense mutation (*COL5A1* c.1303 C>G Pro435Ala), one nonsense mutation (*COL5A1* c.1123G>T, Glu375Term), one frameshift mutation (*COL5A1* c.2771delG), one exonic deletion (2.85 kb deletion between IVS1 and IVS2 in *COL5A1*) and 3 splicing mutations (*COL5A2* IVS23+5A>G, *COL5A1* IVS34+4T>C and *COL5A1* IVS54+5C>T). **Conclusions:** In our experience the diagnostic yield for molecular testing in patients with EDS appears to be lower than the one reported in the literature. Detailed clinical characterization of these patients may allow clinicians to perform more targeted genetic testing. Identification of subgroups of patients with consistent phenotypes will facilitate the identification of additional genes responsible for this heterogeneous disorder.

1739W

Detection of oipA using PCR method can help to the diagnosis of *Helicobacter pylori* in the dyspeptic patients. *L. Salimzadeh[1], N. Bagheri[2], F. Azadegan[3], Gh. Rahimian[4], A. Taghikhani[4], M. Hashemzadeh[4], H. Shirzad[4].* 1) Department of Immunology, Molecular Research Center, Shahrekord University of Me, Shahrekord, Iran; 2) MSc of Immunology, Molecular Research Center, Shahrekord University of Medical Sciences; 3) MSc Genetic, Cellular and Molecular Reserch Center, Shahrekord University of Medical Sciences; 4) Cell and Molecular Research Center, Shahrekord University of Medical Sciences.

Background and Aim: Helicobacter pylori has been strongly associated with chronic gastritis, gastric and duodenal ulcers, and it is a important risk factor for gastric cancer. Major virulence factors of H. pylori have been described: the cytotoxin-associated gene product (CagA) and the adhesion proteins BabA2, iceA1, iceA2 and the secretory protein, OipA. H.pylori culture is difficult and CLO test gives various false positive and false negative results. Availability of PCR method for detection of bacterial DNA in biopsy specimens using specific primers implies that detection of one frequent virulence factor can help to the diagnosis H.Pylori. Because of many reports about geographic diversity of the prevalence of H. pylori virulence factors, the second aim of this work was to find their frequency in dyspeptic patients of Shahrekord area of Iran. Methods: Gastric biopsy specimens were taken from 438 patients with gastroduodenal problems during endoscopy. Firstly CLO test and PCR using housekeeping genes, glmM and16srRNA was done. After that, samples that were positive at least for two of mentioned testes were selected and PCR analysis of virulence factors was performed. Results: In this study 189 patients were infected with strains of H.Pylori that at least in two mentioned tests (CLO test, glmM and 16srRNA) were positive. Further PCR analysis of virulence factors showed that the frequency of oipA, iceA1, iceA2, cagA and babA2 were 93.7%, 83.1%, 69.8%, 57.7 % and 38.6%, respectively. Conclusion: In conclusion our results indicated that the oipA virulence factor has most association with CLO test and PCR analysis of H.Pylori housekeeping genes. Therefore oipA can be used as an appropriate auxiliary marker in the molecular diagnosis of H.Pylori infection.

Connecting family branches through recurrent BRCA mutations. *A. Toland[1], M. O'Connor[2], L. Senter[2,3].* 1) MVIMG/Human Cancer Gen, Ohio State Univ, Columbus, OH; 2) Clinical Cancer Gen, OSU, Columbus, OH; 3) Div Hum Genetics, OSU, Columbus, OH.

Mutational analysis of BRCA1 and BRCA2 has been clinically available since the mid 1990's. To date thousands of individuals have undergone genetic testing of these genes due to personal or family history of breast and ovarian cancer. The Ohio State University Clinical Cancer Genetics program has identified over 390 families with a pathogenic mutation in BRCA1 or BRCA2. All but 10 of the probands resided in the state of Ohio. In our patient cohort we identified 256 different deleterious BRCA mutations of which many are unique. However, excluding the Ashkenazi Jewish founder mutations, we observed 8 deleterious mutations 6 or more times in ostensibly unrelated families. These include BRCA1 mutations C61G (8 families), 3875del4 (7 families), 2800delAA (8 families) and Exon13ins6kb (6 families), and BRCA2 mutations 5910C>G (10 families), 7297delCT (6 families) and 6503delTT (6 families). Some of these are likely due to common distant ancestors or mutational hotspots. We reviewed all 51 pedigrees for these families and based on the information provided, no common ancestor could be identified. We observed another 17 mutations 3–5 times. We compared these mutations to the mutations collected worldwide by CIMBA and identified 9 mutations that were not reported as the most frequent. We hypothesized that some of the rarer recurrent mutations observed in our population may be due to different branches of the same family being tested independently without knowledge of previous testing in their family. To test this hypothesis, we examined 57 pedigrees with shared mutations to look for shared reported family medical history or surnames. In 4 of the 9 groups of pedigrees with mutations in common, links were made despite the fact that individuals were not aware that another branch of their family had been tested. Three of these were related through a more distant relative with a shared surname, but one family had first cousins who were tested without knowledge of the other. It is possible that more of our families with shared mutations are related. As more individuals undergo genetic testing based on family history, we propose that this phenomenon will become more common. It is important to obtain release of genetic information from mutation-positive individuals to their family members for testing purposes. In practice, it would be most efficient and cost effective for genetic counselors to try to link pedigrees prior to testing but this is not always possible.

1741W

Low prevalence of large genomic rearrangements in BRCA1/2 found in at-risk Southern California population. *T. Hoffman[1], M. Alvarado[2].* 1) Medical Genetics, Southern California Kaiser Permanente, Anaheim, CA; 2) Medical Genetics, Southern California Kaiser Permanente, Pasadena, CA.

Large genomic rearrangements appear to represent a small but significant percentage of the overall mutation burden found in the BRCA1/2 genes, and initial data suggests the prevalence of large rearrangements appears to vary somewhat depending on ethnicity. In May 2012, NCCN guidelines were revised to include a recommendation to perform rearrangement studies in all individuals undergoing DNA testing for BRCA1/2. To determine the prevalence of large genomic rearrangements in BRCA1/2 in an ethnically diverse Southern California testing population, we included rearrangement studies ("BART") in all patients undergoing BRCA1/2 testing over a 6 month period with a mutation probability of 10% or higher on at least one of the probability models included in the CancerGene software platform. Patients with a mutation probability below 10% who were felt to be candidates for BRCA1/2 testing were offered standard BRCA1/2 testing without BART testing. Our testing population was comprised of individuals of Western/Northern European (~40%), Latin American/Caribbean (~25%), Asian (~10%), African American (~10%), Ashkenazi (~3%), and Middle Eastern (~3%) ancestry. Among patients tested with comprehensive BRCA1/2 analysis without BART, we found a deleterious sequence mutation in 7.7% (40 individuals out of 520). Among individuals whom BART testing was performed, we found a large genomic rearrangement in 1.6% (3 individuals out of 180). Two of the three individuals found to have a large genomic rearrangement did not meet the "Myriad criteria" typically used by the testing lab to determine when to perform BART testing. Thus, large rearrangements represented about 7% of our total mutation burden. We also retrospectively reviewed our department's cumulative experience with BART testing over a longer period (~5 years) during which rearrangement studies were performed in a nonsystematic fashion due to heightened concern for a lesion in BRCA1/2. We found that the number of large rearrangements identified in cases that did not meet the "Myriad criteria" was low. Furthermore, large rearrangements accounted for ~7% of BRCA1/2 mutations in our patients of Latin American/Caribbean heritage, ~6% in African Americans, ~5% in Western/Northern Europeans, ~2% in Asians and 0% in those of Ashkenazi Jewish heritage. Further data may help identify a more efficient testing strategy to find large rearrangements rather than offering BART studies to all individuals undergoing BRCA1/2 testing.

Clinical whole exome sequencing for the diagnosis of Mendelian disorders: program design, implementation, and first year reporting experience. *C.M. Eng[1], D. Muzny[2], J. Reid[2], M. Bainbridge[2], P. Pham[2], M.R. Bekheirnia[1], J. Beuten[1], M. Hardison[1], Z. Niu[1], R. Person[1], M. Vatta[1], F. Xia[1], A. Hawes[2], M. Wang[1,2], Y. Ding[1,2], H. Sun[1], M. Scheel[1,2], N. Saada[1,2], W. Liu[1,2], A. Braxton[1], P. Ward[1], A. Willis[1], J. Wiszniewska[1], S.E. Plon[1,3], J.R. Lupski[1], A.L. Beaudet[1], R.A. Gibbs[2], Y. Yang[1].* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Next generation massively parallel sequencing technologies have entered the clinical arena as a new approach to the molecular characterization of challenging patient phenotypes. In October 2011, the Baylor Human Genome Sequencing Center (HGSC) and the Baylor Medical Genetics Laboratories developed and implemented a CAP/CLIA whole exome sequencing (WES) service with clinical interpretation of variant alleles. WES is performed to a mean depth of >100X coverage >95% target bases greater than 20X coverage), in parallel with a dense SNP array for quality control (SNP concordance to genotype >99.8%) and for detection of copy number variation and regions of absence of heterozygosity, annotation of variants, clinical interpretation, and validation of significant findings by an orthologous method (currently Sanger sequencing). Reporting is done in two phases: a focused report which consists of mutations and variants related to the patient's clinical phenotype, mutations in medically actionable genes, mutations in genes for recessive disorders consistent with carrier status, and selected pharmacogenetic traits. An expanded report includes mutations and variants in genes unrelated to the indication for testing including mutations in genes with no current association with a disease phenotype. To date, 194 samples have been submitted for clinical testing, of which 85% are from pediatric-age patients. The majority of probands have complex neurological phenotypes and had extensive prior genetic testing that has not yielded a specific etiologic diagnosis. Of the first 60 WES datasets analyzed, 16 positive results (27%) consistent with the patient's described phenotype were detected,including mutations in: ARID1B (2 unrelated cases), CASK, CBL, FGFR1/FGF8, GLB1, HIBCH, MECP2, NDUFV1, PTPN11, RBM10, SACS (2 unrelated cases), SMC1A, SYNGAP1, and WDR19. Twenty-three mutant alleles (7 previously reported) in these genes were detected including 7 frameshifts, 3 nonsense, 3 splice site, and 10 missense. In addition to these diagnostic findings, medically actionable variants identified included those causing G-6-PD, Marfan syndrome, and arrthymogenic right ventricular dysplasia. We demonstrate the clinical utility of WES as a diagnostic modality with an initial yield of 27% of previously undiagnosed patients having definitive positive findings as well as early evidence of WES as a cost effective and efficient diagnostic approach for patients and families.

Diagnostic Yield of Single Nucleotide Polymorphism Array Based Genotyping is Equivalent to Metaphase Cytogenetics for Turner Syndrome. *S.K. Prakash[1], D.C. Guo[1], C.L. Maslen[2], M. Silberbach[2], D.M. Milewicz[1], C.A. Bondy[3], GenTAC Investigators.* 1) University of Texas Health Science Center at Houston, Houston, TX; 2) Oregon Health & Science University, Portland, OR; 3) National Institute of Child Health and Human Development, Bethesda, MD.

Turner syndrome (TS) is a developmental disorder caused by partial or complete monosomy for the X chromosome in 1:2500 females. Metaphase karyotype analysis has been the gold standard for diagnosis of TS but is expensive and lacks molecular resolution. We hypothesized that single nucleotide polymorphism (SNP) array genotyping can provide superior resolution in comparison to karyotyping at a lower cost to facilitate rapid diagnosis and genotype-phenotype correlations in TS. We genotyped 183 adult TS patients (European American, average age 32) using 733,000 SNP markers. All cases met diagnostic criteria for TS based on karyotypes (61%) and/or characteristic physical features including short stature, premature ovarian failure and congenital cardiovascular defects such as bicuspid aortic valves (36%) or coarctation (16%). DNA copy number and percent mosaicism were calculated using intensity and B allele frequency values for 18,239 SNPs along the length of the X chromosome. The SNP array results confirmed the diagnosis of TS in 100% of cases. We identified a single X chromosome (45,X) in 11 cases and mosaic 45,X and 46,X,X or 46,X,Y cell lines in 15 cases. Arrays successfully detected Y chromosomal material in all 6 cases. In 58 additional cases (31%), other mosaic cell lines were present including isochromosomes (14%), rings (5%) and Xp deletions (11%). Our array-based models of X chromosome structure were compatible with karyotypes in 98 of 111 of cases with available data (88%). The principal limitations of SNP data were inability to detect X;autosome translocations (3 cases) and discrepancies in mosaic findings for aberrations that are present in fewer than 10% of cells (8 cases). However, we also identified 4 low abundance mosaic cell lines and 13 large copy number variants in 16 different individuals that were not detected by karyotyping. Our data is the first systematic comparison between the two methods and supports the utility of SNP array genotyping to address clinical and research questions in TS.

1744W

High resolution copy number profiling of the X chromosome in clinical diagnosis. *SA. Yatsenko[1,2], S. Madan-Khetarpal[3], U. Surti[1,2], A. Rajkovic[1,2].* 1) OB/GYN & Reproductive Sci, Univ Pittsburgh, Magee-Womens Hosp., Pittsburgh, PA; 2) Department of Pathology University of Pittsburgh, PA; 3) Department of Medical Genetics, Children's Hospital of Pittsburgh of UPMC, PA.

Whole genome array comparative hybridization (aCGH) has become the first tier test in the clinical diagnosis of patients with intellectual disabilities and congenital anomalies. Copy number variations (CNVs) involving sex chromosomes account for approximately 20% of the overall detected genomic imbalances. The human X chromosome contains a significant number of genes implicated in congenital and metabolic disorders, intellectual disability, disorders of sexual development (DSD), and infertility. However in routine diagnostics by aCGH, small X chromosome deletions and duplications involving an individual gene have remained beyond the detection resolution. To identify intragenic, pathogenic and benign CNVs, we designed a custom high-resolution chromosome X microarray. This microarray contains 180,000 oligonucleotide probes to detect abnormalities, DNA gains and losses, with an average 3–5 kb resolution within the entire X chromosome including pseudoautosomal regions PAR1 and PAR2, and an enhanced 500–2,000 bp resolution for each X-chromosome specific gene, as well as probes for 208 autosomal genes implicated in DSD and ovarian insufficiency. Using this microarray we studied 36 male and 31 female individuals with suspected or known X-linked conditions. Overall we detected 147 copy number changes involving the X chromosome, 16 changes were interpreted as pathogenic, 12 CNVs were of unclear clinical significance, and 119 were considered to be benign CNVs. Pathogenic gains and losses ranging from 16 kb to 19.8 Mb in size were identified in eight patients. These imbalances include heterozygous and hemizygous deletions involving genes *IDS*, *STS*, *DAX1*, *BMP15*, and *POU3F4* which are associated with Hunter syndrome, X-linked ichthyosis, DSD, premature ovarian failure, nonsyndromic deafness, respectively. In addition we characterized large chromosome abnormalities in two patients with an extra mosaic derivative chromosome X and a complex chromosome X rearrangement. We detected 62 recurrent benign CNVs (35 gains and 27 losses) seen in at least two male individuals out of 36 studied. These benign CNVs vary from 475 bp to 251 kb in size, and only ~10% of them involve gene coding regions. The application of high-resolution chromosome X array-CGH for clinical diagnosis brings significant advantages in detection of intragenic aberrations beyond the resolution of clinically available routine aCGH analysis in families with known or suspected X-linked conditions.

1745W

MLPA-based strategy for discrete CNV genotyping: CNV-miRNAs as an example. *M. Marcinkowska[1,2], P. Kozlowski[1,2].* 1) Institute of Bioorganic Chemistry, Polish Academy of Sciences, Poznan, Poland; 2) European Centre of Bioinformatics and genomics, Poznan, Poland.

Copy number variation (CNV) in the human genome has become well recognized in recent years. CNVs are genomic regions spanning roughly 1 kb to 1 Mb that show variable numbers of copies in compared genomes. It has been estimated that common CNVs account for about 10% of the human genome, covering hundreds of genes, regulatory sequences and other functional genetic elements. Although substantial progress in genome wide CNV analysis has been recently made there is still need for inexpensive locus specific method allowing discrete (with integer resolution) genotyping of selected CNVs in large number of samples. Such method would greatly facilitate association studies of CNVs with various phenotypes. Recently we have developed multiplex MLPA-based strategy that allows discrete genotyping of almost any CNV. Multiplexed CNVs can be selected either based on localization (e.g. proximity to association signal) or based on prior knowledge about their relation to investigated problem. As a proof-of-concept we developed two MLPA assays covering 17 candidate CNVs that overlap with human miRNA genes (CNV-miRNAs). With the use of developed assays we analyzed 96 samples from three HapMap populations CEU, CHB and YRI and we confirmed polymorphism in 8 out of 17 (47%) candidate CNVs. Among identified polymorphisms were both simple bi-allelic polymorphisms and complex multi-allelic polymorphisms containing up to 9 copies of investigated region. Extensive quality control testing, including (i) reproducibility analysis, (ii) comparison with previously published results and (iii) analysis of agreement with Mendelian inheritance and Hardy-Weinberg equilibrium confirmed very high quality of our results. Almost all polymorphic CNV-miRNAs showed substantial differences in terms of genotypes/alleles frequency and distribution in three human populations. It may suggest that these CNV-miRNAs are functional polymorphisms modifying phenotypes that undergo different selective pressure in various human populations. Summarizing, we have developed and validated the strategy for discrete genotyping of CNVs in complex genomes. The main advantages of this strategy include simplicity of the assay design, flexibility in terms of selection of genomic region and low cost (~$5/sample and <$1/genotype). These advantages make presented strategy attractive for large scale genotyping of individual CNVs required in association studies. Acknowledgement: MNiSW N N302-278937 and NCN 2011/01/B/NZ502773.

Turkish Medical Students Perceived Genetic Counseling Style and the Use of Hypothetical Genetic Testing Across 5 Psychiatric and 3 Non-Psychiatric Disorders. *D. Kinney[1], E.A. Ergul[2], K. Munir[1], O. Kutuk[1], F. Topuz[1], A. Kanik[1].* 1) Boston Children's Hospital, BOSTON, MA., USA; 2) Massachusetts General Hospital, Boston, MA, USA.

Introduction: Through the advances in genetics, genetic testing has become increasingly relevant to health care. Consumption of these tests is still with debate for psychiatric disorders. The purpose of this study is to evaluate medical students' perceived genetic counseling style as well as the use of predictive genetic tests for 5 psychiatric and 3 non-psychiatric disorders in Turkey. Methods: 206 medical students in Turkey were given questionnaires during class hours. Student response rate was 95%. Results: Students (57%male) were with mean age of 22.77(sd=1.66). Overall 50% of males and 30% of females were in favor of nondirective approach. Except Down syndrome, ADHD and schizophrenia, significant gender difference is observed in counseling style. In autism, 96% of females versus 83%males chose the non-directive counseling (p=0.004) while it was 96% females versus 85% males in Huntington (p=0.008).Higher proportion of males(37%) advised to terminate the pregnancy than females(21%) in CF p=0.049, and in antisocial behavior (4%males versus 15%females, p=0.032). Paradoxically, rate of males advising continuation in CF was also higher(38%) than females,p=0.019. Both in FragileX and Huntington, proportion of males choosing continuation of pregnancy over other counseling styles was higher than females (29% males versus 12% females, p=0.019) in CF and (43% males and 20% females, p=0.005) in Huntington. For hypothetical use of predictive genetic testing, 60% of students approved the test for prenatal population screening in autism, schizophrenia and Huntington whereas 10–15% of students refused the use of this test for any reason. 71% students agreed to use it to identify asymptomatic children with family history of Huntington while 44% students approved it for prenatal population screening for antisocial behavior. Conclusion: Medical students varied greatly in attitudes toward genetic testing and counseling. Most notably, most male students and sizable minorities of female students took directive approaches to genetic counseling, advising pregnant women to either abort or terminate their pregnancy (depending on a particular student's opinion). This approach conflicts with NSGC guidelines, which recommend counselors take a non-directive approach. Turkish Medical school curricula might consider educating students about NSGC guidelines, and discuss ethical issues involved.

Non-optical massive parallel DNA sequencing of BRCA1 and BRCA2 genes: towards the diagnostic setting. *J.L. Costa[1], S. Sousa[1], R. Fernandes[1], L. Cirnes[1], J.C. Machado[1,2].* 1) IPATIMUP Diagnostics, Institute of Molecular Pathology and Immunology of the University of Porto, Porto, Portugal; 2) Medical Faculty of the University of Porto, Porto, Portugal.

The recent developments of bench top massive parallel sequencers have created new avenues for basic research. However, their implementation in a clinical diagnostic setting remains largely unexplored. In this work we present an optimized work-flow to bring this technology into the genetic diagnostic setting. The breast cancer susceptibility genes- BRCA1 and BRCA2 were used in this assay due to their size, polymorphic character, and lack of mutation hot spots. A total of 40 cases were used and divided into: i) training set with 20 cases with sequences previously determined by Sanger method; ii) validation set of 20 cases of unknown genetic diagnosis whose sequences were determined in parallel using an Ion Torrent Personal Genome Machine (PGM) and an ABI 3130 Genetic Analyzer. Genomic DNA was isolated and the two genes amplified using an in house developed multiplex PCR covering all exons and exon-intron boundaries in a total of 77 amplicons. The various steps of the PGM protocol were optimized to maximize coverage and sensitivity. Barcoding was used to increase the number of cases analyzed per chip. PGM sequencing was analyzed using SeqMan NGen3 and Sanger sequencing using Mutation Surveyor. The training set was used to determine optimal sequencing and analysis conditions for data generated using the PGM. The average PGM run consisted of 340000 reads corresponding to a total of 33 Mbp with the 314 chip, and 2500000 reads corresponding to a total of 150000 Mbp with the 316 chip. To detect all variants known to be present in the training set the variant prioritization was defined using the filters: variant quality score>50, depth of coverage >30x and SNP percentage >30%. These conditions were later used in the validation set. At this stage sequence analysis was carried out blind. The sample by sample comparison showed that all 189 variants detected by Sanger sequencing were also detected by the PGM. However, the PGM sequencing resulted in additional systematic calls. These were found to be false positives lowering the specificity of the methodology. This reduction is tolerated as part of the compromise between the higher capacity and scalability for reducing turn-around-time for diagnosis and the screening nature of this methodology that involves the confirmation of all variants called by the PGM using Sanger sequencing. This work demonstrates the potential for mutational screening of BRCA1 and BRCA2 using the PGM in parallel with Sanger sequencing.

Identifying the genetic cause of primary immunodeficiency diseases (PID): Development of a next generation sequencing (NGS) approach for routine diagnostics. *S.C. Drury[1], C. Bacchelli[2], S. Bibi[1], F. McKay[1], L. Jenkins[1], H.B. Gaspar[3], C.M. Cale[3], K.C. Gilmour[3], N.J. Lench[1].* 1) NE Thames Regional Genetics Laboratory, Great Ormond Street Hospital, London, London, United Kingdom; 2) GOSgene, UCL Institute of Child Health, 30 Guilford Street, London, United Kingdom; 3) Department of Immunology, Great Ormond Street Hospital NHS Foundation Trust, London, United Kingdom.

Primary immune deficiency diseases (PID) are a heterogeneous group of inherited diseases characterised by variable genetic immune defects, conferring susceptibility to recurrent infection. Though rare, these disorders are chronic and debilitating. Many patients present with similar clinical and laboratory findings and a number of genes are often sequenced sequentially before identifying the molecular defect. This can be time and resource intensive. Due to the rarity of many PID, mutation analysis at DNA level by sequencing is not routinely available. The objective of this study was to develop a robust, time and cost effective NGS method for identifying genetic defects in PID patients as part of a clinical diagnostic service. The aim is to increase the number of PID genes analysed and expedite diagnosis. 35 known PID genes were targeted using the Agilent SureSelect^{TM} Target Enrichment System. In a pilot experiment, DNA capture libraries were prepared from 10 patients, representing 15 known mutations (in *FAS*, *CD40L*, *IL7RA*, *JAK3*, *IL2RG*, *RAG1*, *ADA*, *SAP*, *PRF1* and *RAG2*) from 10 different PID genes and sequenced on the Roche GS Junior and Illumina MiSeq platforms. Data analysis was performed using NextGene (SoftGenetics) software. Using the Roche GS Junior coverage of the known mutations was less than the required minimum of 30x (0x–28x) and included a number of homopolymer errors that made the data difficult to interpret. Results obtained using the Illumina MiSeq demonstrated comprehensive coverage (151x–371x) and simple detection of all known mutations. Preliminary results suggest targeted resequencing using MiSeq will provide a fast and cost effective method for routine screening and characterisation of the genetic basis causing PID. We are also comparing the efficiencies of target capture and sequence coverage using the additional methods of Agilent HaloPlex Target Enrichment and whole exome sequencing (n=10 patients) for the same panel of genes. This will help us develop the most efficient and cost-effective strategy for comprehensive mutation identification for primary immunodeficiencies.

Exome sequencing analysis for diagnostics. *C. Gilissen, M. Nelen, K. Neveling, R. de Reuver, L.E. Vissers, N. Wieskamp, H.G. Yntema, J. de Ligt, M. Rosario, H.G. Brunner, H. Scheffer, J.A. Veltman.* Human Genetics, Radboud University Nijmegen Medical Center, Nijmegen, Netherlands.

Exome sequencing has great potential in genetic diagnostics, particularly if used for strong heterogeneous diseases were diagnostic yield is currently low. The analysis and interpretation of exome data in diagnostics has specific challenges with respect to quality control, the possibility of incidental findings, and allowing for easy and flexible interpretation. We have implemented a routine diagnostic exome sequencing analysis pipeline that addresses these issues. We have set up pre-defined disease gene packages for seven heterogeneous disorders: Blindness (144 genes), Deafness (98 genes), Movement disorders (152 genes), Oncogenetics (115 genes), OXPHOS diseases (207 genes) and Intellectual Disability (ID) (440 genes). Samples are automatically checked for 1) pre-defined quality control criteria such as enrichment, coverage of the respective disease genes, and concordance with known polymorphisms; 2) matching gender based on sequence coverage and the patient database; 3) Concordance of 12 polymorphisms measured by pyro-sequencing. A diagnostic-oriented graphical user interface automatically limits genetic findings to the relevant genomic loci for a disease, and allows interpretation using predefined filter schemes. In the case of ID samples we sequence the healthy parents and automatically apply an additional de novo analysis; the results of which are combined in the user interface and result in a single overview of potential mutations in known ID genes as well as probable de novo candidates. To date more than 150 patients have been analyzed using this analysis resulting in an average of 487, 397, 388, 288 and 301 variants within the disease gene packages and on average only 11, 6, 7, 6, 4 rare non-synonymous variants for respectively Blindness, Deafness, Movement disorders, Oncogenetics, OXPHOS diseases. In conclusion we have designed and implemented an analysis for exome sequencing based genetic diagnosis of genetically heterogeneous disorders, that allows standardized interpretation and minimizes the risk of incidental findings.

Detection and mapping the breakpoints of heteroplasmic mtDNA deletions by massively parallel sequencing. *F.-Y. Li, H. Cui, D. Gonzalez, J. Wang, V. Zhang, L.-J. Wong.* Molec & Human Gen, Baylor College Med, Houston, TX.

Background: Large Mitochondrial DNA (mtDNA) deletions have been found to be associated with human diseases including Kearns-Sayre syndrome (KSS), Pearson syndrome, diabetes and hearing loss, myopathy, and progressive external ophthalmoplegia (PEO). Inherited mtDNA multiple deletions are usually secondary due to primary mutations in nuclear genes involved in the maintenance of mtDNA integrity. Regardless of the primary molecular defects, the resultant clinical phenotype may be similar among patients with single or multiple mtDNA deletions. The current methods including Southern blot analysis and PCR/Sanger sequencing detect deletions without being able to map the breakpoints. Objective: To develop an analytical algorithm to map deletion breakpoints from sequence reads data generated from massively parallel sequencing (MPS). Method: The entire mitochondrial genome was amplified with one pair of primer followed by MPS analysis, which provides a deep coverage of >20,000X. With the deep and uniform sequence coverage, a deletion can be easily detected. The unmapped sequence reads were re-aligned to the reference sequence to detect the match with half of the read length. Results: Two exemplary clinical cases: one with a single large heteroplasmic deletion, and the other with multiple deletions were studied. In the first case, a blood specimen from a 10 year old boy affected with encephalopathy, exercise intolerance, easy fatigability, and sensorineural hearing loss was analyzed. A heteroplasmic single large deletion of 7,797 bp (m.7638_15434) was detected. In the second case, a muscle sample from a 70 year old man with myopathy was evaluated. Multiple deletions were identified. The deletion breakpoints of both cases were clearly mapped using our analytical algorithm. The single deletion was confirmed by Southern blot and PCR/Sanger sequence analysis of the breakpoints. In the mutiple deletions case, at least 16 out of 23 junction sequences that were mapped by the algorithms have been confirmed by PCR/Sanger sequencing. Conclusion: These cases demonstrate the utility of MPS analysis in the comprehensive diagnosis of mitochondrial DNA disorders, particularly the simultanious detection and mapping of mtDNA deletions.

Three novel AGL mutations in glycogen storage disease type III in Tunisian families. *A. MILI[1, 2], O. MAMAI[2], I. BEN CHARFEDDINE[2], A. AMARA[2], S. PAGLIARANI[3], S. LUCCHIARI[3], A. SAAD[2], K. LIMEM[1], M. GRIBAA[2].* 1) Biochemistry Department, Faculty of Medicine, Sousse, Tunisia; 2) Laboratory of Cytogenetics, Molecular Genetic and Human Reproduction Biology, Farhat University Hached Hospital, Ibn ElJazzar Street, 4000 Sousse, Tunisia; 3) 3Dino Ferrari Center, Department of Neurological Sciences, University of Milan, Fondazione I.R.C.C.S. Ospedale Maggiore Policlinico, Mangialli, Regina Elena, Milan, Italy.

Glycogen-storage disease type III (GSD III) is an autosomal recessive inborn error of metabolism caused by mutations in the glycogen debranching enzyme amylo-1,6-glucosidase gene, which is located on chromosome 1p21.2. GSD III is characterized by the storage of structurally abnormal glycogen, termed limit dextrin, in both skeletal and cardiac muscle and/or liver, with great variability in resultant organ dysfunction. The spectrum of AGL gene mutations in GSD III patients depends on ethnic group. The most prevalent mutations have been reported in the North African Jewish population and in an isolate such as the Faroe Islands. Here, we present the molecular and biochemical analysis of 25 Tunisian GSD III patients. Molecular analysis revealed three novel mutations: a nonsense (Tyr1148X) and two deletions (3033_3036del AATT and 3216–3217del GA) and five known mutations: three nonsense (R864X, W1327X, W255X), a missense (R524H) and a acceptor splice site mutation IVS32-12A>G.In adition, Two high frequency mutations The discovery of this founder mutation in center east of Tunisia is great importance since a test based on haplotype analysis and sequencing live Will Be Utilized to determined carrier status and prenatal diagnosis, genetic counseling for Improving Malthus GSD III in Tunisia. In addition, the discovery of two mutations at high frequency which shows the presence of a founder effect which is of great importance as a test based on haplotype analysis and direct sequencing will be used to determine carrier status and prenatal diagnosis, improving genetic counseling for GSD III Tunisia. This is the first report of screening for mutations of AGL gene in the Tunisian population.

1752W

Multiplex PCR assay for detection of the 2 most common mutations in the profilaggrin gene (FLG) involved in ichthyosis vulgaris. *G. Pont-Kingdon[1,3], L. Hubley[1], E.E. Baldwin[2], E. Lyon[1,3].* 1) Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) ARUP Laboratories, Salt Lake City, UT; 3) Pathology Department, University of Utah, Salt Lake City, Utah.

Filaggrin is a major protein involved in the formation of the cytoskeleton of the cornified layer of the skin, establishing a barrier that prevents entry of allergens and microbes through the skin, regulates pH, prevents water loss, and possibly provides UV protection. In 2006, McLean's group reported that null mutations in the gene encoding profilaggrin (FLG) are responsible for ichthyosis vulgaris (IV), a common skin condition characterized by dry and scaly skin. IV has an incidence of 1/400-1/250 in the Caucasian population, but has been described in all ethnic groups. Additional research has shown an association between FLG-null mutations and atopic dermatitis (AD), asthma associated with AD, allergic rhinitis, some food allergies, keratosis pilaris, and palmar hyperlinearity. The FLG gene is located on chromosome 1q21 within the epidermal differentiation complex. It is approximately 25 kb long, has 3 exons and contains 10–12 tandem repeats that are each 972 nucleotides long. These repeats show nearly identical nucleotide sequence. Each repeat encodes the 324 amino acid monomer of the filaggrin protein. We designed a hybridization probe assay to detect the two most common mutations in FLG found in Caucasians of European descent: p.R501X (c.1501C>A) and c.2282del4. Both mutations are found in FLG-unit 1. This assay is multiplexed and uses two primer sets with each primer being specific for FLG-unit 1. Appropriate PCR conditions were achieved for the specific amplification of FLG-unit 1. The test was validated using 113 samples with various genotypes verified by Sanger sequencing. Genotypes obtained by melting curve analysis corresponded completely to genotypes observed by sequencing. Variation in the assay, obtained by melting temperature analysis of triplicates (within run) and five independent replicates (between) was less than 0.25° C. This assay should detect in a single reaction up to 80% of individuals of Caucasian descent harboring an FLG mutation.

***GeneReviews*™ as a source of medically actionable information for coincidentally diagnosed disorders.** *M.P. Adam, C.R. Dolan, A.R. Amemiya, M. Espeseth, T.D. Bird, K. Stephens, R.A. Pagon.* University of Washington, Seattle, WA.

PROBLEM: The clinical use of whole-exome sequencing (WES) to identify the genetic basis of undiagnosed findings in a patient will inevitably identify "coincidental findings" (i.e., pathogenic mutations in genes not relevant to the features that prompted testing by WES). Some have advocated sharing with patients and their health care providers coincidental findings so that patients can benefit from relevant medically actionable information. HYPOTHESIS: *GeneReviews*, an expert-authored, peer-reviewed resource developed and maintained at the University of Washington and freely available at www.genetests.org, can be used to determine if medically actionable information exists for a coincidentally diagnosed disorder. METHODS: First, we defined medically actionable information as that which addresses: (1) the evaluations (laboratory studies, imaging studies, or specialty referrals excluding medical genetics referral) needed to determine the presence and extent of manifestations of a disorder; (2) disease-specific treatment; (3) primary prevention; and/or (4) contraindicated agents/circumstances. Second, 276 of the existing 555 *GeneReviews* chapters were reviewed. We included only those that deal with disorders that could be coincidentally diagnosed by WES by eliminating chapters that deal with phenotype-based overviews (7), disorders diagnosed exclusively at birth (63), and disorders for which the genetic basis is unknown (1) or not detectable by WES (e.g., repeat expansions or microdeletion syndromes) (18). As a result, 187 chapters (representing 365 genes) were included in this study. FINDINGS: (1) Further evaluations (including laboratory studies, imaging studies, and specialty referrals) were recommended to determine the extent of manifestations in 162 disorders; (2) disease-specific treatment existed for 64 disorders; (3) primary prevention existed for 63 disorders; and (4) contraindicated agents/circumstances were identified for 123 disorders. Of the 187 *GeneReviews* chapters meeting criteria for inclusion in this study, 176 were found to have information considered to be medically actionable. CONCLUSION: As WES and whole-genome sequencing move into mainstream medicine, *GeneReviews* will be useful for identifying those coincidentally diagnosed disorders for which medically actionable information exists and for clinicians caring for patients with these disorders.

1754W

Comprehensive diagnostic hearing loss testing on a single platform: The OtoGenome test. *SS. Amr[1, 2], TJ. Pugh[1, 2], E. Duffy[1], L. Farwell[1], S. Gowrisankar[1], A. Lovelette-Hernandez[1], BH. Funke[1], HL. Rehm[1].* 1) Laboratory for Molecular Medicine, Partners Healthcare Center for Personalized Genetic Medicine, Cambridge, MA; 2) Harvard Medical School Molecular Genetics Training Program, Boston, MA, United States.

To date, the detection of the genetic cause of hearing loss has been challenging due the large number of responsible genes, many of which, have not been available for clinical testing. To solve this problem, we have developed the OtoGenome Test, a next-gen sequencing (NGS) assay that covers all 73 known genes for nonsyndromic hearing loss, Usher, Pendred, and Jervell Lange-Nielsen syndromes. The test utilizes molecular barcoding and Agilent in-solution hybrid capture followed by NGS on the Illumina HiSeq. Molecular barcoding allows for pooling of up to 10 samples in a single capture reaction, which reduces test cost. For sequence alignment and variant detection, our in-house informatics pipeline performs read alignment and variant detection using BWA followed by GATK. In addition, a novel copy number variant (CNV) tool has been developed to detect CNVs. For validation, we selected 61 patient samples with known variants to assess analytical performance. Average read depth was 854 reads providing robust variant detection. All known variants were detected including 77 substitutions, 26 indels ranging in size from 1 to 21 bp, and 8 CNVs at 6 different loci. We selected 10 additional cases that had previously tested negative or inconclusive by our OtoChip test (covering 19 genes), to enable a preliminary estimate of clinical sensitivity of the additional 54 genes. This approach allowed us to identify biallelic variants in 3 out of 10 samples (3 CNVs, 1 indel, and 1 missense variant), and monoallelic pathogenic frameshift variants in two samples. The total number of clinically significant variants identified in this cohort is 3 CNVs, 5 indels, and 12 single base substitutions. The detection rate of the OtoGenome is expected to surpass our current OtoChip detection rate, which detects a biallelic cause of hearing loss in approximately 18% of cases based upon data from over 325 cases. The OtoGenome test is expected to increase detection of biallelic cause of hearing loss to as high as 70%.

Allele drop out and *MECP2* genetic testing. *E. Bettella, R. Polli, E. Leonardi, A. Murgia.* Pediatrics, University of Padua, Padua, Italy.

Allele drop out (ADO) leads to the preferential amplification of one allele, in a heterozygous individual, due a series of reasons among which the occurrence of sequence mismatch within a primer-binding site or a complex DNA motif. The drop out can cause false results during PCR amplification and be responsible of potential misdiagnosis. Recent evidences suggest that DNA sequences that fold in particularly complex secondary structures can hamper DNA replication and transcription and, if altered by mutations, may be responsible of ADO events in PCR amplification. An example of these genomic DNA motifs are repetitive guanine-rich sequences, known as G-quadruplexes, on one stand and the complementary cytosine-rich sequences on the opposite strand, known as i-motifs. We report a case of ADO by which two previously unreported in cis de novo mutations in exon 4 of the *MECP2* gene (c.1137delC and c.1151_1201del50) were detected as seemingly homozygous in a girl with Rett syndrome. Both mutations are located in the *MECP2* WW binding domain and fall in a "frameshift cluster" region where a number of other small deletions have been reported in literature. Under the assumption of ADO, we and adjusted the primer set and the PCR conditions so that we could distinguish two alleles and confirm the presence of a wild type allele. This report confirms that allele drop out is a definite technical risk in *MECP2* molecular analysis; failure in allele amplification may occur in particular for exon 4, due to the complexity of its sequence.

Screening for and Identification of Pathogenic Mutations in Patients with Inherited Retinal Degenerations (IRDs) Using Targeted Enrichment and Next Generation Sequencing. *M.B. Consugar[1], Z.D. Fonseca-Kelly[1], E.M. Place[1], E. Au[1], S.M. Harper[2], X. Gai[3], E.L. Berson[2], E.A. Pierce[1,2].* 1) Ocular Genomics Institute, Department of Ophthalmology, Massachusetts Eye and Ear Infirmary and Harvard Medical School, Boston, MA, 02114; 2) Berman-Gund Laboratory, Department of Ophthalmology, Harvard Medical School and Massachusetts Eye and Ear Infirmary, Boston, MA, 02114; 3) Department of Molecular Pharmacology and Therapeutics, Loyola University Health Sciences Division, Maywood, IL, 60153.

Inherited Retinal Degenerations (IRDs) are a major cause of vision loss, affecting the photoreceptor cells and pigment epithelium of the retina. Complicating matters, the light-sensitive outer segments of photoreceptor cells are modified primary cilia, and many IRDs are genetically heterogeneous and can be associated with other cilia disorders. To date, mutations in 186 genes have been linked to IRDs, yet account for only 50% of clinically diagnosed cases. Although part of the low diagnostic rate can be attributed to unidentified disease genes, another contributing factor is how IRD patients are genetically tested. Because a majority of diagnostic laboratories perform gene-, exon- and/or mutation-specific testing based on clinical diagnoses, de novo mutations and mutations in genetically heterogeneous genes can result in missed genetic diagnoses. Next-generation sequencing (NGS), combined with targeted enrichment, has become an attractive method for mutation screening in a fraction of the time associated Sanger sequencing. In order to increase the fidelity of IRD genetic diagnoses, we designed a SureSelect targeted exon + UTR enrichment library specific to the 186 known, as well as another 20 candidate IRD disease genes. Following capture, samples were sequenced on an Illumina MiSeq, with average per sample coverage metrics for a 10-sample multiplexed, 2 × 110 bp paired-end run, being: 95x mean Depth-of-Coverage (DoC); 99.5% coverage at 1x DoC; 97.0% at 10x DoC; 93.9% at 20x DoC. To date, 54 probands clinically diagnosed with autosomal recessive Retinitis Pigmentosa (arRP) or Leber Congenital Amaurosis (LCA) have been screened for pathogenic IRD mutations using our targeted enrichment/NGS method. We were able to assign likely genetic diagnoses to 21 patients (~39%), including one case where we identified mutations in two genes likely responsible for the patient's vision and hearing loss, respectively. These results demonstrate the feasibility and advantages of this approach for genetic diagnostic testing of IRD patients. An important advantage of testing for mutations in all IRD disease genes is identifying pathogenic mutations in genes not typically associated with patient phenotypes. Further, identification of patients without mutations in known IRD disease genes could facilitate novel IRD disease gene discovery research. Finally, accurate genetic diagnoses could facilitate application of gene-based therapies to prevent further vision loss.

1757W

Validation of Whole Exome Sequencing assay for clinic service at Baylor College of Medicine. *Y. Ding[1], D.M. Muzny[1], J.G. Reid[1], M. Wang[1], Y. Han[1], H. Dinh[1], D.P. Sexton[1], M.N. Bainbridge[1], A.C. Hawes[1], P. Pham[1], B. Yin[1], D.P.C Ng[2], C.J. Buhay[1], J. Wiszniewska[2], M. Scheel[1], N. Saada[1], W. Liu[1], H. Sun[2], R.A. Gibbs[1], A.L. Beaudet[2], C.M. Eng[2], Y. Yang[2].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX 77030; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030.

The Whole Genome Laboratory (WGL) at Baylor College of Medicine (BCM) is a joint venture of the Human Genome Sequencing Center (HGSC) and the Medical Genetics Laboratory (MGL) at BCM to provide genetic testing by high quality next generation sequencing (NGS). The whole exome sequencing (WES) utilizing capture probe set VCRome 2.1 (HGSC exome design) coupled with Illumina Barcoded Paired-End NGS on the Genome Analyzer II/HiSeq platform has been successfully developed and validated as the initial clinical service at WGL. This lab is currently a CLIA (the Clinical Laboratory Improvement Amendments of 1988)-registered and CAP (College of American Pathologists)-accredited clinical laboratory. The validation processes included platform (Ilumina GAII and Hiseq 2000) validations followed by WES assay validation. Eleven samples with known point mutations and small insertions or deletions (indels) previously identified by Sanger sequencing were included in the assay validation. Two independent parallel runs were performed for inter-run reproducibility assessment. Illumina high density SNP assay was performed in each run for sample identification and quality control purposes. Sequencing data was analyzed through the Mercury analysis pipeline developed at HGSC. Our validation results showed that the capture specificity was ~70% and 95% of the target bases were covered 20X or higher. A concordance of about 99% between WES and SNP array data was achieved. About 70% of the VCRome 2.1 genes (approximately 200,000) were fully covered and 85% were covered at least 95%. Overall, WES sensitivity and specificity were 100% and 98% respectively for point mutations, and 85% and 27% respectively for indels. The low specificity for indels was caused by the less stringent quality filtering criteria applied to the short read NGS data in an effort to maximize the sensitivity of the indel calls. A reproducibility rate of about 98% on two parallel runs was achieved. Our results have indicated that our WES assay has good reproducibility, high sensitivity and specificity for point mutation detections. WES in combination with the Sanger sequencing can achieve a specificity of 100% for point mutations and indels. Through targeted capture and high throughput sequencing technologies, WES represents a cost-effective and robust NGS approach to detect variants in the coding regions of the human genome.

1758W

Advancing from targeted resequencing to whole exome sequencing for improving the molecular diagnosis of congenital disorders of glycosylation. *M.A. Jones[1], B.G. NG[2], P. He[2], M.E. Losfeld[2], S. Bhide[1], D. Rhodenizer[1], E.L.H. Chin[1], M. He[1], H.H. Freeze[2], M.R. Hegde[1].* 1) Emory Genetics Laboratory, Atlanta GA; 2) Sanford Burnham Medical Research Institute, La Jolla CA.

Congenital disorders of glycosylation (CDG) are comprised of over 30 autosomal recessive disorders caused by deficient N-glycosylation. Approximately 20% of patients do not survive beyond five years of age due to widespread organ dysfunction. A diagnosis of CDG is based on abnormal glycosylation of transferrin but this method cannot identify the specific gene defect. In 2010 Emory Genetics Laboratory introduced molecular testing for 25 CDG genes including single gene testing and next generation sequencing (NGS) panels. A total of 118 patients have been referred for testing. Disease causing mutations have been identified in several genes including PMM2, COG1, COG8 and ATP6VOA2. Mutations identified in the gene ALG1 are the most common in patients referred for testing. To date, molecular diagnostic testing identified the likely gene defect in only 10% of individuals. This is likely due to patients having mutations in new genes. In the research setting we are using a combined biochemical and whole exome sequencing (WES) approach for a collection of 39 patients that remain without a molecular diagnosis to identify the causative gene. Our WES analysis pipeline focuses on a library of 250 glycosylation associated genes. Through WES we have identified mutations in two previously unknown genes. We identified one patient with mutations in DDOST and five patients with CHIME syndrome, which has clinical features similar to SRD5A3-CDG that had mutations in PIGL. We will summarize the results of WES for the remaining 33 patients currently under analysis. We will also discuss the clinical utility of WES for diagnostics and our approach to addressing incidental findings in a severe pediatric disorder.

1759W

A novel splice site variant (IVS44-3T>C) in *COL3A1* results in small amounts of exon skipping and complicates genetic counseling in a family with features of hypermobility Ehlers-Danlos syndrome. *D.F. Leistritz[1], U. Schwarze[1], D. Sarroza[1], P.D. Steele[2], C. Boni[2], B.A. Salbert[2], P.H. Byers[1].* 1) University of Washington, Seattle, WA; 2) Geisinger Medical Center, Danville, PA.

In fibrillar collagen genes the -3 position of splice acceptor sites is almost always C or T, rarely A, and never G. We studied a 25-year old woman with multiple joint dislocations and hypermobility and found that she had a sequence variant in one *COL3A1* allele: c.3202-3T>C, IVS44-3T>C. The T at this position is conserved in 25 of 38 vertebrate species and 12 have C in this site. It is not known to be polymorphic or variable in humans. To our surprise, analysis of splicing in her cultured fibroblasts demonstrated that in about 5-10% of *COL3A1* transcripts exon 45 was skipped. This skip results in a small amount of proα1(III) chains that lack 18 amino acid residues from the main triple helical domain. About 15% of type III procollagen molecules would be abnormal if 5% of the chains lacked the 18 amino acids, but we could not detect these molecules during gel electrophoresis. Ehlers-Danlos syndrome type IV, the vascular type, results from mutations in which all of the products of one allele are abnormal. This means that 85% of the type III homotrimers have an abnormal structure. We have identified mosaicism for a *COL3A1* mutation such that about 10% of alleles or more are altered. These individuals are generally not symptomatic and do not have hypermobility. However, mosaicism results in discontinuous patches in which the altered allele is expressed. In contrast, we expect that in this family most cells would have the abnormal splicing pattern. We identified 5 additional members with the variant, all of whom had a similar clinical picture to that seen in the proband. There is one unrelated family with a heterozygous mutation in *COL3A1* that was found to have only joint hypermobility. The underlying basis of hypermobility is not known in most individuals. These findings raise the possibility that certain classes of mutations in *COL3A1* could explain the clinical findings in a small subset of families. In addition, the production of a small amount of abnormal product—enough to potentially lessen the integrity of tissues, but not enough to be disease causing—creates uncertainty and complicates genetic counseling for the proband and those relatives identified with the same *COL3A1* sequence alteration.

1760W

A DNA-based method for detecting homologous blood doping. *I. Manokhina, J.L. Rupert.* School of Human Kinetics, University of British Columbia, Vancouver, BC, Canada.

Homologous (or allogenic) blood doping, in which blood is transferred from a donor to a recipient athlete, is an easy, inexpensive and rapid way to increase the oxygen carrying capacity of blood and therefore endurance performance; however, the method can be detrimental to health and is prohibited by doping control authorities. Current tests to detect homologous blood doping are based on cell surface markers. We propose that a DNA-based test centered on the allele-specific amplification of common insertion-deletion polymorphisms would be more convenient and less expensive than protein-based tests. Methods: We adapted and optimized a highly sensitive allele-specific qPCR test panel of nine polymorphic insertion/deletion markers. Mixed DNA samples prepared from blood dilutions ranging from 1/10 to 1/10,000) were used to determine the sensitivity of the assay. These ratios simulate cases of doping with 500 ml of either whole blood or 90% - 99.9% leucodepleted blood. The informativeness of the assay was tested using blood mixtures from 12 unrelated individuals and determining what percent of the 132 potential combinations could be detected by one or more of the 9 markers. Preliminary tests of the specificity of the assay were done using DNA samples from specific populations who have the potential to be natural chimeras, including mothers (n=7) and dizygotic twins (n=2). Results: The sensitivity of the assay based on detection limit for the secondary blood cell population was found to be in the range of 1/1000-1/10000 dilution for all studied markers. The informativeness of the assay, calculated by the ratio of potentially detectable `informative' blood mixtures to all the blood samples obtained (132), was 99.2%. Amplification of potential chimeric samples from mothers and dizygotic twins did not reveal specific alternative PCR products, suggesting that the secondary cell populations, if they exist, do not reach the threshold of assay detection. Conclusion: We propose that a DNA-based test for homologous blood doping could detect homologous doping even if the doper used blood from which 99% of the leukocytes had been removed. Such a test could supplement or replace the current protein-based tests. Even if the test was not routinely applied, the knowledge that DNA can be stored and evaluated using this method long after the sample was taken would be a major disincentive to athletes considering homologous blood doping.

Identification of *ARID1B* mutations in intellectual disability/Coffin-Siris patients by clinical whole exome sequencing analysis. *Z. Niu[1], M. Vatta[1], A. Willis[1], Y. Ding[2], H. Sun[1], M. Scheel[2], N. Saada[2], W. Liu[2], M. Wang[2], D.P. Sexton[2], A.C. Hawes[2], M.N. Brainbridge[2], P. Pham[2], J.G. Reid[2], D.M. Muzny[2], P.A. Ward[1], A.A. Braxton[1], A. Scheuerle[3], M.K. Koenig[4], S.E. Plon[5], J.R. Lupski[1], R.A. Gibbs[2], A.L. Beaudet[1], Y. Yang[1], C.M. Eng[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Tesserae Genetics, Dallas, TX; 4) Dept. of Pediatrics, Division of Child and Adolescent Neurology, The University of Texas Medical School at Houston, Houston, TX; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Molecular diagnosis of developmental disability, especially for the autosomal dominant type, faces multiple challenges of a fast-growing number of causative genes and a substantial involvement of *de novo* genetic defects. Recent efforts using whole genome or whole exome sequencing have significantly accelerated mutation discovery in developmental disability by screening large amounts of genomic sequence simultaneously at a reasonable cost. Supported by these considerations, clinical whole exome sequencing (WES) analysis provides a favorable diagnostic approach to identify the etiological factors of developmental disability in particular for difficult cases where multiple lines of testing have not identified the causative gene.

Here, we discuss two cases of unrelated patients with developmental disability, where prior comprehensive aCGH array and single gene tests failed to identify an underlying genetic cause. Both patients presented with motor and speech delay, hirsutism, and facial dysmorphism including low and posteriorly rotated ears, downslanting palpebral fissures, and mild coarsening of the facial features. Patient one displayed profound intellectual disability and is non-verbal, while patient two can speak three word phrases and read at first grade level. Brain imaging results were normal for these two patients. Clinical WES analysis performed in the Baylor Genetics Laboratory identified heterozygous loss-of-function mutations in the *ARID1B* gene: a nonsense (p.Q1190X) mutation in patient one and an exon/intron boundary disruption (c.2981_2986+7del13) in patient two. Sanger sequencing analysis on the parental samples demonstrated that these two mutations arose *de novo*. *ARID1B* (also known as *BAF250B*), is a component of SWI/SNF nucleosome remodeling complex. Disease causing mutations in SWI/SNF complex genes (*ARID1A, ARID1B, SMARCB1, SMARCA4, SMARCA2 and SMARCE1*) have been recently discovered in intellectual disability/Coffin-Siris patients (PMID: 22405089, 22426308 and 22426309). To date, most of *ARID1B* mutations in intellectual disability/Coffin-Siris patients are *de novo*. Clinical correlation of both patients' presentations was consistent with an *ARID1B* diagnosis.

In summary, clinical WES analysis identified *de novo ARID1B* mutations consistent with the patients' clinical phenotype.

National Institutes of Health (NIH) Genetic Testing Registry. *W.S. Rubinstein[1], D. Maglott[1], B.L. Kattman[1], A. Malheiro[1], J. Lee[1], M. Ovetsky[1], V. Hem[1], G. Song[1], V. Gorelenkov[1], C. Fomous[2], J. Ostell[1].* 1) National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD; 2) Office of the Director, National Institutes of Health, Bethesda, MD.

The NIH Genetic Testing Registry (GTR, www.ncbi.nlm.nih.gov/gtr), an online tool designed to help clinicians navigate the landscape of genetic tests, was unveiled by NIH Director Dr. Francis Collins on Rare Disease Day (February 29, 2012). The GTR arose from the 2008 recommendation by the Secretary's Advisory Committee on Genetics, Health and Society (SACGHS) that called for a publicly available, Web-based registry to enhance the transparency of genetic testing and assist efforts in reviewing the clinical validity of laboratory tests. The GTR was developed by the National Center for Biotechnology Information (NCBI) under the oversight of the NIH Office of the Director and with extensive input from health care providers, researchers, testing labs, patients, and other stakeholders. The GTR contains information about biochemical, cytogenetic, and molecular tests for Mendelian disorders and drug responses. Submissions, which NCBI began accepting in the spring of 2012, are voluntary. The test content is a combination of fully registered tests submitted to GTR, information displayed from the GeneTests Laboratory Directory, and information supplemented by NCBI. *GeneReviews* and GeneClinics are accessible through the GTR and will remain available after the GeneTests Laboratory Directory is phased out in 2013. Fully registered GTR tests are identified by a unique GTR accession and version number and have a detailed description provided by the lab. Test providers are responsible for the content and quality of the data they submit. NIH requires submitters to agree to a code of conduct which includes providing information that is accurate and not misleading. GTR users are requested to report any breaches of the code of conduct. Test information is presented alongside well-vetted publications and resources (e.g., practice guidelines) assembled by NCBI, which enables the professional community to identify information gaps and to focus their efforts accordingly. The accessioning of well-described genetic tests facilitates formal evaluation by professionals and publication of these assessments. NCBI has encouraged the American Society of Human Genetics, American College of Medical Genetics and Genomics, Association for Molecular Pathology, and National Society of Genetic Counselors to publish evaluations of the tests in the GTR. Professional evaluations can be displayed in the GTR as with other important publications and would fulfill the charge articulated by SACGHS.

EuroGentest Clinical Utility Gene Cards - progress and perspectives. *J. Schmidtke, A. Dierking.* Dept Human Gen, Medizinische Hochschule, Hannover 61, Germany.

CUGCs are disease-specific guidelines for the clinically validated use of genetic testing. Each CUGC is authored and peer-reviewed by international experts and published by the European Journal of Human Genetics (EJHG). CUGCs are a work package within EuroGentest, a EU-funded project for the harmonization of genetic testing. Based on the ACCE framework (Analytic validity, Clinical validity, Clinical utility and Ethical, legal and social issues) the CUGCs are dealing with the risks and benefits of genetic test application. Besides analytical and clinical validity, the clinical utility is a significant aspect to define. It is of importance to evaluate a genetic test in the context of the clinical setting and to realize that the laboratory test is only one component of the overall intervention. Due to their concise format CUGCs offer quick guidance to all stakeholders, including clinicians, clinical geneticists, referrers, service providers and payers. All documents are freely available on the websites of EuroGentest, the EJHG, the European Society of Human Genetics and Orphanet and will be revised annually. The analysis of the EJHG download rates shows that between 600 and 1,500 downloads, with an average above 1,000, were counted per gene card and year. Until the end of 2013 at least 300 CUGCs are planned, so far 65 guidelines are published and about 130 are in progress. The first set of CUGC updates is already submitted to the journal and will be published soon. Hampering factors are for example the limited number of experts in the field of rare diseases and the long process from author invitation to completed review. Nevertheless, the current progress and the feedback from the scientific community are positive.

Mutation Screening of Genes Causing Inherited Immunodeficiency and Bone Marrow Failure using Next-Generation Sequencing. *T.A. Sivakumaran, A. Husami, D. Kissell, K. Zhang.* Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Advancements in high throughput sequencing, also known as Next-generation sequencing (NGS), have facilitated the discovery of new disease genes and also the transformation of routine clinical diagnosis of genetic disease. Targeted resequencing using NGS technology offers a unique opportunity to screen for mutations in multiple genes, in parallel, causing heterogeneous genetic disease at lower cost and time. Several recent studies have shown NGS an efficient tool for mutation screening in the diagnostic laboratories. In this study, we evaluated the performance of NGS in detecting the DNA sequence variants in 124 genes causing inherited immunodeficiency and bone marrow failure. Sequence covering the coding, the flanking intronic and regulatory regions of these genes were enriched using RainDance microdroplet PCR and then sequenced on the Illumina HiSeq 2000 sequencer. The raw sequence reads from each sample were subjected to the molecular genetics laboratory's (MGL) NGS analysis pipeline: (1) quality filtering of raw reads, (2) mapping of high quality reads to the Human reference sequence and detecting sequence variants using NextGENe software, (3) finding target bases with < 40x coverage, (4) identifying potential true sequence variants using MGL criteria and (5) confirmation of variants with Sanger sequencing. An average of about 30 million 50 bp reads, ranging from 15,708,900 - 51,719,428, were generated in 21 deidentified samples that were previously screened for mutations in one or more of these genes in the MGL. About 89–95% of the raw sequence reads met our quality criteria in all 21 samples and about 70% of quality-filtered reads aligned to target genes. Of the 591 kb target sequence covering coding and 20 bp of flanking intronic regions, about 97.5% of bases had greater than 40x coverage. In the preliminary analyses of thirteen samples, NextGENE software detected a total of 4720 sequence variants and about 50% of which were classified as potentially true based on MGL criteria. Comparison of NGS results with the available Sanger sequencing results showed about 100% concordance. The results of this study will be presented. In summary, we anticipate that the NGS-based mutation screening of these genes would simplify the genetic workup of an individual with immunodeficiency or bone marrow failure, enabling the effective clinical management of patients and their families.

1765W

Mutation analysis of the SOX2 and OTX2 genes in 235 patients with developmental eye disorders. *N. Smaoui, B. Williams, S. Aradhya, S. Bale, S. Suchi, G. Richard.* GeneDx, Gaithersburg, MD.

Microphthalmia and anophthalmia (MAC) are rare congenital developmental eye disorders, with a prevalence of approximately of 0.5–1.5 per 10.000 birth. MAC can be either isolated or syndromic and is genetically heterogeneous with different modes of inheritance. At least 9 genes are known to cause MAC including SOX2, OTX2, VSX2 (CHX10), PAX6, CHD7, BCOR, RAX, PITX3, and STRA6. SOX2 mutations are most common and are found in up to 20% of MAC. We report mutation analysis of the SOX2 and OTX2 genes in a large cohort of patients with MAC and various developmental eye disorders. Sequence analysis of the SOX2 gene was performed for 235 patients, and additional deletion/duplication testing by exon-level array CGH was completed on 66 samples. Sequence analysis was positive in 13% of samples, while 2 out of 66 sequencing-negative cases had a deletion of the entire SOX2 gene (3%). Most common were mutations introducing a premature stop codon (84%). Two mutations (c.70_89del20 and Y160X) were recurrent, each identified in 16% of unrelated cases. The phenotype was very variable, including isolated unilateral or bilateral MAC, or MAC associated with other developmental eye disorders or systemic malformations. In one familial case, microphthalmia and ocular coloboma was reported in the proband while the father presented with isolated ocular coloboma. Sequence analysis of the OTX2 gene was positive in 4 out 66 (6%) samples that tested negative for a SOX2 mutation. Deletion/duplication analysis of the OTX2 was performed on 39 samples and identified a deletion of the entire OTX2 in one sample (2.6%). OTX2 mutations were associated with isolated MAC only. Our study confirms that SOX2 mutations are the most common genetic cause of syndromic or non-syndromic MAC. The lower rate of whole SOX2 gene deletions (3% in this study versus 10% in the literature) is likely due to prior testing of many patients by genome-wide array CGH, which can identify genomic deletions of the gene locus. Based on our experience and due to the extreme phenotypic and genotypic variability of the developmental eye disorders, mutation analysis of the SOX2 gene should be considered first for molecular diagnosis of these disorders.

1766W

Digitizing clinical genetic literature: a comprehensive, accurate and scalable approach. *M. Sommargren, Locus Development, Inc.* Locus Development, San Francisco, CA.

A major challenge in bringing personalized medicine to the clinic is capturing published genetic information in a scalable and highly accurate manner. We have digitized over 19,000 clinically relevant genetic variants for over 300 conditions in a framework that enables automated interpretation of a patient's genetic data. Our approach combines manual literature curation by genetic experts with commercially available and custom Locus Development software. The result is a clinical-grade annotated database of genetic variants that captures information about mutation pathogenicity and condition risk models. This is a significant improvement over databases that merely list previously observed variants without confirming mapping, effect, and pathogenicity. We follow ACMG reporting recommendations for genetic variants, but we include a new category for variants observed in patients but with uncertain pathogenicity. We have developed pathogenicity criteria to standardize the treatment of reported and novel variants. We employ concise language to report risk conferred by variants that follow autosomal, X-linked, or condition-specific risk models. Our curation-ahead-of-time approach has several advantages over the traditional sequence-and-interpret method of delivering genetic information to patients: (i) it is scalable, (ii) it enables more comprehensive, concise, and accurate test results, and (iii) it improves turnaround time through automated report generation. We will present practical lessons from the curation of these 300 conditions, such as the types and prevalence of reporting errors in the literature, the challenge of defining conditions in an automated way, and the consistent handling of variants of unknown pathogenicity.

1767W

Estimated variant rate for a next-generation sequencing panel of 13 genes associated with hereditary colon cancer. *AJ. Stuenkel, SL. Tandy, JD. Siegfried.* Ambry Genetics, Aliso Viejo, CA., USA.

Next generation sequencing (NGS) is an emerging technology with numerous advantages over traditional sequencing techniques. The movement of NGS panels into the clinical setting provides clinicians and patients with a rapid method of capturing sequence data from multiple genes at a fraction of the cost compared to Sanger sequencing. Numerous factors influence the adoption of NGS technology in the clinic, including an anticipated increased frequency of genetic variants of unknown significance compared to single-gene tests. Recently, the first targeted NGS panels for cancer predisposition became commercially available. One such panel, ColoNextTM, targets sequence data from 13 genes associated with hereditary gastrointestinal and other malignancies. To provide clinicians and patients with estimated variant rates for the ColoNext panel, variant data was compiled from clinical testing of the 13 genes (APC, BMPR1A, CDH1, CHEK2, MLH1, MSH2, MSH6, MUTYH, PMS2, PTEN, SMAD4, STK11, and TP53). Overall, gene-specific variant rates range from 1.65% (SMAD4) to 12.43% (PMS2) with an average of 5.70%. However, when a three-tier variant classification system (suspected benign, unknown significance, suspected pathogenic) is applied, the rate of variants classified as being of unknown significance ranges from less than 1% to 4% (average of 2.04%) per gene. Based on available data, initial variant rates for the ColoNext panel are estimated as follows: frequency of at least one variant (any classification) is approximately 80%, although the majority of these variants are anticipated to be classified as suspected benign or suspected pathogenic. Continued analysis of variant rates from NGS panels will assist clinicians in test selection and allow for appropriate pre- and post-test counseling for patients pursuing these novel clinical diagnostic tests.

1768W

Simple and accurate assays for targeting *CFTR* mutations of specific geographic/ethnic origins by PCR allelic discrimination: still a place for targeted tools. *C. Vasseur[1], A. LeFloch[1], B. Costes[1], A. deBecdelièvre[1], T. Casals[2], C. Costa[1], M. Goossens[1], E. Girodon[1].* 1) Genetics, GH Henri Mondor, APHP and Inserm U955, Creteil, France; 2) Human Molecular Genetics Group-IDIBELL, Barcelona, Spain.

The search for cystic fibrosis (CF) causing mutations with a frequency above 1% depending on the geographic/ethnic origins of individuals has been proposed as a European recommendation (Dequeker et al., Hum Mutat 2009). This is commonly achieved by using a standard kit and, depending on the ethnicities, additional sequencing to the search for specific mutations. For the latter, identification of variants of unknown significance (UVs) is a major concern. It makes genetic counseling delicate, in particular when the UVs are found in CF carriers' partners and in case of fetal bowel anomalies. Hence, we believe that there is still a place for tests focused on specific mutations, even in view of the advent of next generation sequencing (NGS). First, NGS is far from being readily accessible to diagnostic laboratories, and second, and more importantly, it would even worsen the situation by increasing the detection of UVs. Therefore, we developed simple assays targeted on 6 geographic origins (Italy, Spain, Portugal, Turkey, North Africa and Black Africa). They contain 3 to 8 mutations. The assays are based on probe hydrolysis during PCR and fluorescence detection (custom TaqMan® SNP genotyping). Homozygous and heterozygous mutant controls were generated for each mutation, from cloned PCR products or by directed mutagenesis. Validation was done on blinded series of DNA representative of different genotypes and on prospective series of patients' DNAs to be tested in routine analysis. The results were compared to Sanger sequencing. The assays fulfilled the validation requirements in terms of sensitivity, specificity and robustness. They are simple and rapid to implement in diagnostic practice and simplify genetic counseling in the context of heterogeneous populations.

1769W

The CLARITY Challenge: Children's Leadership Award for the Reliable Interpretation and appropriate Transmission of Your genomic information. *C.A. Brownstein[1,4], E.T. DeChene[3], K.C. Flannery[2], S.W. Kong[2], M.C. Connolly[3], I.S. Kohane[1,2], A.H. Beggs[3,4], D.M. Margulies[1,4].* 1) Division of Genetics and Program in Genomics, Gene Partnership, Boston Children's Hospital, Boston, MA; 2) Harvard Medical School Center for Biomedical Informatics and Children's Hospital Informatics Program, Boston, MA; 3) Division of Genetics and Program in Genomics, The Manton Center for Orphan Disease Research, Boston Children's Hospital, Boston, MA; 4) Harvard Medical School, Boston, MA.

Introduction: Despite rapid progress in the speed and performance of next-generation sequencing, there has not been a dramatic advancement in the application of sequencing's insights to everyday patient care. Before personalized genomic medicine can be adopted at scale, several hurdles must be addressed: 1. Conflicting gene variant annotations and classifications in non-standardized databases 2. Inconsistent or non-specific sequencing results and non-interoperable processes 3. Lack of standards concerning individual privacy and data access 4. Results that are not clear or useful to doctors, genetic counselors and patients. The Boston Children's Hospital CLARITY competition is a step forward in creating standardized methods for analyzing, interpreting, reporting and, using genomic information in a clinical setting. Methods: Three families identified by The Manton Center for Orphan Disease Research at Boston Children's have clinical manifestations and pedigrees that suggest a genetic basis for their disorders. Two families have probands with a neuromuscular condition, and the third family has a proband with an autosomal dominant cardiac condition. The genomes and/or exomes of the family members were sequenced and provide the starting point of the Challenge. Participants are tasked with producing an analysis, interpretation, and report suitable for use in a clinical situation. Competitors will be evaluated on 1) the methods by which they analyze and interpret the genome sequences and 2) the ability of the competitors to synthesize the genomic data and produce clinically meaningful reports with actionable results for participants' physicians. The judges are a diverse group of well-respected individuals from the medical and technology industries. Results: 40 teams from academic and commercial entities submitted applications. 33 teams were selected to participate in the challenge. 29 teams signed the participant agreement and accessed the data. Two teams decided not to sign the participant agreement and withdrew from the competition. Contest entries are due in September, and the winner will be announced at the 2012 ASHG annual meeting. Discussion: The CLARITY contest is an international competition to identify and publicize the best practices in clinical genome interpretation and data delivery. Bringing together the best elements of competing pipelines will allow for the development of clear, consistent methods for applying genomic insights to patient care.

1770W

What is a clinical grade genome? *F. De La Vega[1,2], A. Russell[1], M.A. Morales[2], C.D. Bustamante[2], M.G. Reese[1].* 1) Omicia, Inc., Emeryville, CA; 2) Department of Genetics, Stanford University, Stanford, CA.

The precipitous fall in the cost of sequencing spurred by innovations in high-throughout sequencing (HTS) platforms is bringing the use of human exome and genome sequencing closer to the clinic. An important question is whether current sequencing protocols provide data that meets clinical standards of quality. Evaluation of clinical tests requires establishment of analytical validity, with assessment of the false positive/negative rates for the specific conditions/variants being tested. While false positive variant calls can be evaluated through experimental validation, false negatives are more difficult to assess, in particular in the lack of a genome gold standard. Ajay et al. (Genome Res, 2011) studied the performance of HTS on genome-wide coverage, consensus calling, and quality values of calls, suggesting a significant false negative rate. Here we propose to score the known disease variants, e.g. from the HGMD database, in terms of genotype call accuracy, to asses the clinical grade of a HTS genome. To evaluate our metric we analyze a diverse data set: (1) two whole-genome trios of Puerto Rican and Yoruban origin sequenced by Complete Genomics (CGI); (2) the deeply sequenced sample of Ajay et al.; (3) a sample sequenced with both CGI and Illumina technologies by Lam et al., Nat Biotech, 2011; and (4) an exome obtained through the 23andMe Exome Pilot sequenced to ~80X. To eliminate the variance due to bioinformatics pipelines, and to perform joint variant calling in the trios, we realigned and called all the data with the RTG Investigator software. We note that the hg19 reference genome includes 37 HGMD disease alleles that are not reported in variant files unless there is an heterozygote at such positions. We observe an average 2% to 4% false negative for HGMD disease alleles at minimum coverage depth of 6x and 20x, respectively, which corresponds to the depth needed to achieve ~99% genotyping accuracy. We also study the variance in scores among the genomes analyzed, the differences between whole-genome and exome assays, different call quality value cut-offs, and the impact of average sequencing depth, sequencing platform, and joint pedigree variant calling. Our results provide guidance for establishing the analytical validity of HTS exomes and genomes for clinical applications and suggest improved metrics to assess their clinical grade.

1771W

The mutation type and effect of variants underlying human genetic diseases. *J. Westbrook, Y. Kobayashi, Locus Development, Inc.* Locus Development, Inc., San Francisco, CA.

To develop clinically useful interpretations of genomic data, Locus Development Inc. has analyzed published data on the genetic basis of human diseases. At the time of writing, we have curated 18,298 variants associated with 277 genetic diseases from peer-reviewed scientific publications. We critically assessed the pathogenicity of each variant based on its predicted impact on amino acid sequence, experimental data on its functional impact, linkage data from affected families and the known inheritance pattern of the associated disease. The assembled data provides insight into the types of variants underlying genetic disorders. In terms of mutation type, 69.46% of variants were single nucleotide substitutions. The remaining 30.54% of variants were insertions, deletions, duplications or expansions of varying sizes. Deletions large enough to be considered copy number variants were reported for 36.4% of the included genes. In terms of the variants' effects, we found that 39.31% caused frameshifts or introduced premature stop codons in the encoded protein, while 6.20% disrupted canonical splice sites. Splice site variants were biased towards donor splice sites (55.0% donor versus 45.0% acceptor, chi-squared goodness of fit test, $p < 0.001$). In the case of variants with less catastrophic effects on the protein sequence (missense, in-frame, silent, and non-coding variants), we searched for additional evidence supporting their pathogenicity. We found experimental or linkage data indicating that 19% percent of 368 in-frame and 20.15% percent of 8,368 missense variants were pathogenic. We also describe a theoretical framework for determining the likelihood that a missense variant is pathogenic based on its frequency in the population and the occurrence of the associated disease. In addition to variants affecting protein sequence or canonical splice sites, we found evidence that 32 silent and 45 non-coding variants cause genetic disorders. With ever-increasing amounts of human sequence data, careful analysis and curation will be required to separate neutral from pathogenic variants.

1772W

Application of next-generation sequencing technology in the study of mitochondrial diseases. *Y. Ma[1], Y. Cao[1], Z. Chen[2], H. Pan[1], Y. Qi[1].* 1) Central Lab, Peking Univ First Hosp, Beijing, Beijing, China; 2) Department of Human Genetics, UCLA School of Medicine, ULCA Medical Center, Los Angeles,, USA.

Mitochondrial disorders are the most common group of metabolic disorders, with an estimated prevalence of 1 in 5,000. Mitochondrial disorders may present with any symptom, in any organ, at any age and with any mode of inheritance. Mitochondrial disorders can originate from mutations of mtDNA (contains 37 genes, 2 rRNAs and 22 tRNA) and about 1,500 nuclear genes. Many of the mutations in mitochondrial DNA are heterozygosis, therefore, while mtDNA could easily be sequenced by traditional Sanger methods, this technology is inadequate to detect some mtDNA mutations that occur in a small fraction of the total mtDNA molecules. Therefore, we propose to find the mutation in entire mtDNA genome and nuclear genes by next-generation sequencing. 11 mitochondrial encephalomyopathy patients without common mtDNA mutations were collected, mitochondrial genome and all exons of 13 related nuclear genes (including 12 genes encoding complex I and POLG1 gene) were amplified and then sequencing by Illumina sequencing technology. Sequencing data from 11 mitochondrial encephalomyopathies patients showed 6.5×108bp could be called, and 7.7×106bp could be mapped on the reference (89.4%;). After pasting the quality filter, 892 single nucleotide variants (SNV) were detected totally. C11777A mutation in mtDNA was detected in one patient, then it was verified by PCR-RFLP and Sanger sequencing, and it was also found in her mother. This patient was a 10 years old girl, and she was diagnosed as MELAS (mitochondrial encephalopathy, lactic-acidosis and stroke-like episodes syndrome) in clinical. The patient was examined because of left-hand resting tremor, hemi-paresis, and migraine. Elevated lactate levels were measured in the blood. MRI examination showed hyper intense lesions in frontal and parietal lobe and in cerebellar hemisphere. The ratio of C11777A of the girl is 30% in her blood, and 57.3% in her urine. The ratio of C11777A of her mother is 34% in urine, and this mutation could not be detected in her mother's blood. The next- generation sequencing technology has a broad application prospects on detection of pathogenic mutations both in mitochondrial genome and related nuclear genes. C11777A mutation is recognized as a widely seen mutation according to Leigh syndrome, 4 individuals are reported in the PubMed, and we first found the relationship between C11777A mutation and MELAS.

1773W

A combined next generation sequencing and exon-level aCGH diagnostic gene panel for severe developmental delay and epilepsy phenotypes. *N.J. Lench[1], H. Moody[1], A. McTague[2], E. Meyer[2], S. Drury[1], S. Fielding[1], R. Palmer[1], M.A. Kurian[2], R.H. Scott[1].* 1) Regional Genetics Service, Great Ormond Street Hospital for Children, London, United Kingdom; 2) Neurosciences Unit, UCL Institute of Child Health, London, United Kingdom.

Background: A large number of children present with a variety of overlapping severe developmental delay and/or early-onset seizure phenotypes. The number of causative genes continues to grow. In some cases, the phenotype is recognisable and targeted genetic testing is available for a limited number of genes. However, in many cases there is difficulty in defining the phenotype, gene testing is not available and/or does not include copy number analysis. **Objective:** To significantly improve the diagnostic yield in patients with complex developmental delay/epilepsy phenotypes using a combined approach of high-resolution exon-level oligonucleotide microarrays and next generation sequencing. **Method:** 29 genes known to cause developmental delay/epilepsy phenotypes including MECP2, CDKL5, FOXG1, UBE3A, SIP1/ZEB2, TCF4, NRXN1, CNTNAP2, MEF2C, SLC16A2, EHMT1, ATRX, ARX, SCN1A, STXBP1, PCDH19, PLCB1, ARHGEF2, KCNQ2, were chosen for analysis. In order to detect intra-genic insertions/deletions we designed a custom 12plex Nimblegen 135k oligonucleotide microarray. Comprehensive gene sequencing covering all coding exons and intron/exon splice sites was performed using the Haloplex Target Enrichment system (Agilent) in conjunction with the Illumina MiSeq platform. **Results:** DNA samples from 48 children with severe developmental delay and/or early onset seizures of unknown cause were analysed. All had tested negative by routine genome-wide microarray analysis using the Nimblegen CGX-12 135k genome wide array (effective resolution ~200kb). The custom microarray generated high quality and reproducible data with a resolution of ~500bp within target regions. It identified two individuals with likely pathogenic copy number changes - a 3kb deletion including the 3' portion of MECP2 exon 4 and a 50kb gain encompassing exons 6–11 of the CDKL5 gene. Both were confirmed by MLPA and follow up in parental samples indicated that the mutations had arisen *de novo*, confirming likely pathogenicity. We also report the results of our sequencing analysis including the identification of a previously reported pathogenic point mutation in MECP2. **Conclusion:** Our data demonstrate the improved diagnostic yield of this combined approach which offers a cost-effective and efficient method for mutation testing that will improve diagnosis in these challenging and complex phenotypes.

1774W

High-throughput Mutation Screening in Patients with Inherited Retinal Dystrophies. *X. Wang[1], A. Turner[1], M. Brooks[2], H. Rajasimha[2], K. Johnson[3], Y. Fann[3], A. Swaroop[2].* 1) OGVFB, NEI/NIH, Bethesda, MD; 2) NNRL, NEI/NIH, Bethesda, MD; 3) ITBP, NINDS/NIH, Besthesda, MD.

Retinal dystrophy (RD) is a broad group of hereditary disorders with heterogeneous genotypes and phenotypes. More than two hundred genes or loci have been identified as responsible for a variety of retinal dystrophies (RDs). Current available genetic testing for these diseases is complicated, time-consuming, and expensive. It is very important to develop a high-throughput genetic screening tool which can be cost-effective and reliable in mutation identification in RD patients, especially in patients with uninformative family history and/or difficulty in differential diagnosis. We recently developed an assay to detect sequence alterations in genes involved in inherited RDs. In this assay, we developed a primer library which targeted 3071 amplicons from 2078 exons of 184 genes that are involved in retinal function and/or retinal development. We were able to amplify the target regions using the RainDance PCR enrichment method and sequenced the products using next generation sequencing by Illumina's GAIIx. In a pilot study, we have analyzed 16 samples from patients with Retinitis pigmentosa. Preliminary bioinformatic analysis indicated that this procedure was able to cover 99% of target sequence with an average in depth of reads at 245 per base. Data mining identified previously reported mutations in a variety of genes responsible for Retinitis pigmentosa in this cohort of patients. As an example, we were able to identify and validate through Sanger sequencing two *C2orf71* gene mutations in an isolated ARRP patient. The *C2orf71* gene is a newly discovered ARRP gene and would have been very unlikely selected as a target gene if we used a traditional Sanger sequencing algorithmic strategy to study ARRP genes on this patient. These results indicate that this assay is capable to screen for mutations in RP patients, especially in simplex cases with high sensitivity and efficiency, and with a powerful potential in clinical application.

1775W

Predictive Testing for Neurodegenerative Conditions is Often Not Predictive. *C.L. Goldsmith, D.A. Dyment, K.M. Boycott.* Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

Predictive testing for adult-onset neurodegenerative conditions is an integral part of a Neurogenetics specialty clinic and comprises approximately 1/4 of our patient referrals. To better understand our predictive patient population we performed a retrospective 5-year review of patients referred for pre-symptomatic testing for Huntington disease (HD), Familial Alzheimer disease (FAD), Frontotemporal Dementia (FTD), and CADASIL. The vast majority of patients were referred for predictive testing for Huntington disease (n =65 of 73). The average age at referral for HD predictive testing was 33 with a range of 17 to 69 years, and there was a marked skewed gender ratio (3F:1M). Surprisingly, of the 65 patients, 12 (18%) were clearly symptomatic at the time of the initial consultation in the Neurogenetics Clinic. In addition, predictive testing was urgently requested in the context of an ongoing pregnancy in 5 (7%) of the HD referrals. Of the 65 individuals who sought predictive testing for HD, only 7 did not proceed with testing. Of those who proceeded with predictive tests for HD, the number who received positive results was close to the expected 50% (26/58). We conclude that the request for predictive testing during pregnancy in our HD cohort likely reflects, in part, the high incidence of HD compared to other neurodegenerative conditions in the population. The most concerning trend that we saw in our HD cohort was the number of individuals who are referred for predictive testing who are already symptomatic. This may be explained by the fact that the majority of these referrals are coming from health care providers who may be less familiar with the symptomology of HD compared with a neurologist or neuropsychiatrist specialized in the field.

Facioscapulohumeral muscular dystrophy (FSHD) is a common hereditary myopathy causally linked to reduced numbers (≤ 8) of 3.3 kilobase D4Z4 tandem repeats at 4q35. However, since individuals carrying D4Z4 reduced alleles and no FSHD and patients with FSHD and no short allele have been observed additional markers have been proposed to support an FSHD molecular diagnosis. In particular a reduction in the number of D4Z4 elements combined with the 4A(159/161/168)PAS haplotype (which provides the possibility of expressing DUX4) is currently used as the genetic signature uniquely associated with FSHD. Here, we analyzed these DNA elements in more than 800 Italian and Brazilian samples of normal individuals unrelated to any FSHD patients. We find that 3% of healthy subjects carry alleles with reduced number (4–8) of D4Z4 repeats on chromosome 4q and one third of these alleles, 1.3%;, occur in combination with the 4A161PAS haplotype. We also systematically characterized the 4q35 haplotype in 253 unrelated FSHD patients. We find that only 127 of them (50.1%) carry alleles with 1–8 D4Z4 repeats associated with 4A161PAS, whereas the remaining FSHD probands carry different haplotypes or alleles with greater number of D4Z4 repeats. The present study shows that the current genetic signature of FSHD is a common polymorphism and only half of FSHD probands carry this molecular signature. Our results suggest that the genetic basis of FSHD, which is remarkably heterogeneous, should be revisited since this has important implications for genetic counseling and prenatal diagnosis of at-risk families.

Identification of a Common Pan-Ethnic Haplotype Enriched on SMN1 Duplication Alleles Improves the Detection of Silent (2+0) SMA Carriers and Significantly Modifies Residual Risk Estimates. *M. Luo[1], L. Liu[1], I. Peter[1], J. Zhu[1], S.A. Scott[1], G. Zhao[1], C. Eversley[2], R. Kornreich[1], R.J. Desnick[1], L. Edelmann[1].* 1) Dept Gen & Genomic Sci, Mount Sinai Sch Med, One Gustave L. Levy Pl., New York, NY; 2) Northwestern Reproductive Genetics, Inc. 680 North Lake Shore Drive, Suite 1230, Chicago, IL.

Spinal muscular atrophy (SMA) is a common autosomal recessive neuromuscular disorder, and mutations in the *SMN1* gene on 5q13.2 generally involve *SMN1* copy number loss by either deletion or gene conversion events with the highly homologous nearby gene, *SMN2*. Consequently, carrier screening must be performed using dosage sensitive methods that can distinguish between *SMN1* and *SMN2*. The carrier frequency for SMA has been reported to range from 1 in 35 to 1 in 117 depending on ethnicity; however, detection rates vary from 71–94% due to the inability to identify individuals that are silent 2+0 SMA carriers with two copies of *SMN1* on one chromosome 5 and zero copies on the other. We hypothesized that the identification of deletion/duplication founder alleles might provide a general approach to identify silent carriers and improve carrier detection in various ethnic/racial groups. Founder alleles were initially investigated in the Ashkenazi Jewish (AJ) population by microsatellite analysis of a region spanning 3.8 Mb surrounding the *SMN1* locus. A major duplication-specific founder haplotype was identified in AJ individuals with 3 copies of *SMN1*. Haplotype positive duplication alleles were sequenced by both Sanger sequencing of *SMN1* exon 7 through exon 8 and by Next Generation sequencing of the entire *SMN1* gene. Importantly, two tightly-linked polymorphisms in *SMN1*, g.27134T>G in intron 7 and g.27706_27707delAT in exon 8, were detected on the haplotype positive alleles but not in 351 AJ individuals with two *SMN1* copies, making the haplotype highly specific for duplication alleles in this population. The presence of the polymorphisms was further investigated in various ethnicities including African Americans (AA), Hispanics (HI), Asians (AS) and Europeans (EU). In the AS population, the polymorphisms were specific to a subset of duplications, but absent in individuals with 1 or 2 copies of *SMN1*. In the AA, HI and EU populations, the polymorphisms were much more frequent in individuals with *SMN1* duplications than those with 1 or 2 *SMN1* copies. Therefore, identification of these polymorphisms in AJ or AS individuals with 2 copies of *SMN1* is diagnostic of a silent 2+0 SMA carrier, while in AA, HI and EU individuals it significantly increases residual risk. Conversely, the absence of the polymorphisms in all populations significantly decreases residual risk of being an SMA carrier.

1778W

Multiplexing test for molecular diagnosis of skeletal dysplasia (by CGC mutation panel). *P. Tavares[1], A. Lopes[2], L. Lameiras[2], L. Dias[1], J. Sá[2], A. Palmeiro[2], P. Rendeiro[1].* 1) CGC Genetics, Newark, NJ; 2) CGC Genetics, Porto, Portugal.

Introduction: Osteochondrodysplasias, also known as Skeletal Dysplasias (SD) account for more than 450 different genetic diseases with bone involvement but variable clinical characteristics, whose diagnosis is based on clinical examination, radiological findings, histo-pathological and molecular analysis. They represent around 5%; of genetic diseases of the newborn and are a major cause of problems for families and patients. Genetic testing improves clinical diagnosis and is essential for a differential diagnosis. The molecular characterization of genes responsible for SD, is extremely important for establishing a precise diagnostic evaluation, namely during the prenatal period. Here we report our experience using this custom methodology. Method: We developed a multiplex mutation panel (CGC Mutation Panel) that tests 49 point mutations identified in the 6 main genes involved in severe SD: FGFR3, COL2A1, SLC26A2, CRTAP, LEPRE1 and SOX9. With this approach it is possible to achieve a molecular diagnostics of the most frequent and severe forms of SD. Results: We tested 132 cases (48 amniotic fluids, 24 peripheral bloods, 36 DNA samples, 16 cell cultures, 6 CVS, 1 Umbilical cord blood, 1 paraffin block, and 1 tissue sample from a kidney fetal biopsy; one case was tested by CVS and fetal biopsy, confirming the previous result) and 22 had a positive result. 18 cases were positive for heterozygous mutations in FGFR3 gene (8 cases with c.742C>T (p.Arg248-Cys) mutation, 4 cases with the c.1138G>A (p.Gly380Arg) mutation, 3 cases with the c.1118A>G (p.Tyr373Cys) mutation, 2 cases with the c.1948A>G (p.Lys650Glu) mutation and 1 case with the c.2420G>C (p.Term807Ser) mutation), 3 cases with mutations on SLC26A2 gene (2 cases with c.835C>T (p.Arg279Trp) mutation in homozygous and 1 cases with both c.532C>T (p.Arg178Stop) and c.835C>T (p.Arg279Trp) mutations in heterozygous, and 1 case with a homozygous mutation IVS1+2C>A in CRTAP gene. Conclusion: The multiplex mutation panel detects the most common mutations drastically reducing turnaround time (one week after DNA extraction), maintaining accuracy and liability. Results are independent from the type of sample. Faster molecular diagnostic is achieved, allowing early decision-making process in patient management and conduct, being particularly relevant in prenatal situations and future pregnancies.

A combination of panel and exome sequencing to identify novel human retinitis pigmentosa genes. *F. Wang[1], H. Wang[1], J. Zaneveld[1], K. Zhang[2], R. Koenekoop[3], G. Silvestri[4], N. Solanki[1], J. Cheng[1], I. Lopez[3], H. Ren[3], D. Simpson[4], R. Chen[1].* 1) Human Genome Sequencing Center, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Institute for Genomic Medicine and Shiley Eye Center, University of California, San Diego, CA, USA; 3) McGill Ocular Genetics Laboratory, McGill University Health Centre, Montreal, Quebec H3H 1P3, Canada; 4) Centre for Vision and Vascular Science, Royal Victoria Hospital, Queen's University Belfast, Belfast, N Ireland, UK.

Retinitis Pigmentosa (RP) is the most common form of retinal degeneration affecting 1 in 4,000 people worldwide (Hamel, C. 2006). RP is a genetically heterogeneous disease known to be caused by mutations in over 50 genes with multiple forms of inheritance. Although RP has been widely studied, causative mutations cannot be found in known RP genes in half of all people affected with the disease. In order to better understand the genetic causes of RP, we examined 106 well-characterized RP patient families, including 33 families with multiple affected members. In order to enrich for patients with novel causative loci, we developed a custom RP capture panel that, along with Next Generation Sequencing, allows rapid screening for patients lacking mutations in known RP genes and other retinal disease genes. A total of 106 RP patients (one affected member per RP family) have been screened with our custom RP capture panel. Variants were called by our in-house variants calling, filtering and annotation pipeline. Sanger sequencing and segregation tests (where available) were performed to validate the results. So far, our analysis indicates 42 patients lacked causative mutations within 163 known retinal disease genes. These patients are likely enriched for novel RP genes and loci. In this enriched cohort, we will use whole exome sequencing in combination with system-wide bioinformatics, biostatistics, and functional analysis in order to identify novel RP genes and loci with the goal of improving molecular diagnosis and treatment of RP.

Evaluation of *BRCA1* mutations in patients with family history of breast cancer. *S. Rummel[1], C. D. Shriver[2], R. E. Ellsworth[3].* 1) Clinical Breast Care Project, Windber Research Institute, Windber, PA., USA; 2) Clinical Breast Care Project, Walter Reed National Military Medical Center, Bethesda, MD USA; 3) Clinical Breast Care Project, Henry M Jackson Foundation, Windber, PA USA.

Background: Identification of BRCA1 allowed screening of high-risk patients for causative mutations. Current criteria used to identify patients for genetic testing include family history of early-onset breast cancer with or without a family history of ovarian and/or male breast cancer, or a personal history of breast cancer at an early age. Here, we determined the prevalence of BRCA1 mutations in a cohort of female invasive breast cancer patients with a significant family history. Methods: The Clinical Breast Care Project database was queried to identify all female patients with significant family histories defined as being diagnosed <35 years, diagnosed <50 years with at least one primary family member with breast and/or ovarian cancer, or diagnosed <50 years with at least two secondary family members from the same parental branch from two generations diagnosed with breast and/or ovarian cancer. Genomic DNA was isolated from blood and exonic regions of the BRCA1 genes were amplified and sequenced on an ABI3730xl. Sequence data was analyzed using Sequencher 4.10.1. Results: Of the 115 women with significant family histories, three had known deleterious BRCA2 mutations and one had a mutation p53 with a family history of Li-Fraumeni syndrome; these patients were excluded from further analyses. The most common (49%) group of women with significantly family histories are those diagnosed between 35–50 years with a single primary family member with either pre- or post-menopausal breast or ovarian cancer. Luminal A was the most common tumor subtype (52%), followed by triple negative (32%), luminal B (12%) and HER2-enriched (4%). Of the eleven causative mutations detected, all were in patients with triple negative tumors: three diagnosed <35 years, six diagnosed 36–50 years with at least one primary relative with breast cancer and two diagnosed 36–50 with at least two secondary family members with breast cancer. Conclusion: Presence of causative BRCA1 mutations did not segregate with early age of onset or number of relatives with breast cancer. Rather, only patients with triple negative breast disease harbored BRCA1 mutations. These results have important genetic counseling and risk reduction implications as the association between BRCA1 mutations and triple negative breast cancer suggest tumor subtype may be added to the current criteria used to identify patients who should be offered testing for BRCA1 mutations.

1781W

Measuring clinician satisfaction with disclosure of genetic susceptibility test results: Findings from the REVEAL Study. *S.L. Everhart[1, 3], B.M Wood[2], K. Valverde[1], L. Medne[3], J.S. Roberts[4], C.A. Chen[5], K.D. Christensen[4], R.C. Green[6], The REVEAL Study group.* 1) Acradia University, Glenside PA; 2) University of Pennsylvania, Philadelphia PA; 3) Children's Hospital of Philadelphia, Philadelphia PA; 4) University of Michigan School of Public Health; 5) Boston University; 6) Harvard Medical School.

Clinician satisfaction has been shown to correlate with patient satisfaction thus measuring satisfaction can improve healthcare outcomes. Development of a reliable scale to measure clinician satisfaction with disclosing genetic risk information for common diseases will help practitioners and researchers identify best practices for communicating susceptibility test results. This paper describes the psychometric properties of a satisfaction scale used by four physicians and five genetic counselors after disclosing risk estimates to 280 first degree relatives of Alzheimer disease patients in a multi-centered trial. A confirmatory factor analysis (CFA) was performed to validate whether four previously found factors associated with clinician satisfaction in primary care were the same for genetic susceptibility testing. Data was then analyzed with an exploratory factor analysis. A 19-item scale was identified with a 4-factor structure assessing satisfaction with (1) the interpersonal connection between the clinician and patient, (2) the process of obtaining patient information, (3) the intensity of patient demands, and (4) perception of patients' needs and understanding. Each identified factor had an Eigenvalue greater than one and was found to be internally consistent with Cronbach alphas of 0.90, 0.76, 0.83, and 0.75 respectively. Contrary to the CFA of primary care office visits, appropriate use of time fell out of the analysis in the measure of genetic susceptibility testing . This scale can be useful in determining the satisfaction of clinicians in Alzheimer's disease susceptibility testing and related assessment procedures. As discovery of risk factor genes is ever increasing, this study can act as a foundation for future studies of clinician satisfaction when disclosing genetic susceptibility results.

1782W

Reactions to Direct-to-Consumer BRCA Test Results. *U. Francke[1, 2], C. Dijamco[1], A.K. Kiefer[1], N. Eriksson[1], J.Y. Tung[1], J.L. Mountain[1].* 1) 23andMe Inc, Mountain View, CA; 2) Dept Genetics, Stanford Univ Med Ctr, Stanford, CA.

Direct-to-consumer (DTC) genetic health reports provided online include low-effect disease risk information based on published genome-wide association studies, carrier status for recessive disorders, variants affecting drug response and a few high-impact Mendelian dominant mutations. Concerns expressed in the literature and position statements by medical societies postulate that genetic information should not be provided DTC because consumers will misunderstand it, positive test results will cause panic and inappropriate actions, and negative test results will lead to inappropriate actions such as foregoing cancer screening. To assess these claims, we carried out semi-structured interviews, collecting empirical data on the harms and benefits experienced by consumers in response to the most actionable test with proven clinical utility currently available DTC: for 3 mutations relatively common among women with Ashkenazi Jewish ancestry that predispose to hereditary breast and ovarian cancer (HBOC): BRCA1 185delAG and 5382insC, BRCA2 6174delT. 32 mutation-positive and 31 mutation-negative participants, matched for age, sex and ancestry, were asked about their emotional response to the report, with whom they shared the data, and the actions they have taken or plan to take. 59% of cases and 35% of controls were unaware at the time of purchase that the 23andMe service includes testing for mutations predisposing to HBOC. In each group of 16 males (M) and 16 females (F), 6 carried a BRCA1 and 10 a BRCA2 mutation. 4F had been diagnosed with HBOC, and 5F and 2M had prior knowledge of their mutation status. Of 10F and 14M who learned for the first time that they carried a BRCA mutation, 6F and 4M stated they were completely surprised. No participants recalled their mutation status incorrectly. Asked to rate their emotional response, no cases were extremely upset, 3F/1M were moderately upset, 3F/6M were somewhat upset, 8F/8M were neutral and 1F/1M were relieved. Of 31 controls, 7F/8M felt neutral and 11F/5M relieved. Results were shared most often with family and friends, followed by genetic counselors and primary care physicians who initiated repeat testing and specialist follow-up. Non-carrier controls did not report actions such as foregoing cancer screening. We were struck by the snowball effect within families leading to identification of many additional mutation carriers, and the burden expressed by male carriers realizing the risk for sisters and daughters.

Targeted gene capture of BRCA1 using short, explicitly non-gene-specific, peptide nucleic acid baits. *SV. Tavtigian[1], K. Tao[1], R. Bell[1], J. Rosenthal[1], W. Kohlmann[2].* 1) Oncological Sciences, Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 2) High Risk Cancer Clinics, Huntsman Cancer Institute, University of Utah, Salt Lake City, UT.

Introduction. Some implementation of massively parallel sequencing will eventually almost certainly replace capillary-based Sanger sequencing for clinical mutation screening. Because targeted capture protocols are, for limited genes sets, considerably less expensive than whole genome sequencing, these are likely to make their large-scale clinical debut first (e.g., Ambry Genetics' Next-gen Cancer Panels). However, testing of some important susceptibility genes by this strategy is precluded by existing composition of matter patent claims. Purpose. As a naïve strategy to circumvent such patent claims, we examined the suitability of biotinylated 14-mer peptide nucleic acid (PNA) baits for targeted capture of selected sequences prior to massively parallel sequencing. Methods. Biotinylated 14-mer PNA baits were prepared for exon 2 and the 3' end of exon 11 of BRCA1. Baits were selected explicitly to perfectly match two or more sequences in the human genome. Following initial studies of hybridization temperature, their capture efficiency was compared to that of an Agilent targeted capture reagent (designed to capture the coding exons of 28 known and candidate breast and colon cancer susceptibility genes) by Q-PCR. The 14-mer PNA baits and Agilent baits were then used in parallel to capture DNA from libraries made from carriers of a known mutation in BRCA1 exon 2 (187delAG) and two mutations located near the 3' end of BRCA1 exon 11 (p.E1250X and p.Q1313X). The enriched libraries were then sequenced on an Illumina HiSeq2000. Results. At a hybridization temperature of 57° and bait concentrations between 10 nM and 100 nM, 14-mer PNA baits achieved capture efficiencies equivalent to those of the Agilent reagent. Moreover, sequencing of libraries captured under these conditions easily found the known mutations. Conclusion. Biotinylated 14-mer peptide nucleic acid baits could be used for targeted capture in preparation for massively parallel sequencing. Because these baits are less than 15 bp long and can be designed explicitly to target genomic sequences in addition to their primary gene target, they may provide a strategy to circumvent composition of matter claims in certain 1990s-era gene patents.

1784W

Predictive testing for idiopathic scoliosis: Are orthopedic surgeons and pediatricians ready and willing? *A.M. Laberge[1,2,3], A. Moreau[3,4,5].* 1) Dept of Pediatrics, Faculty of Medicine, Université de Montréal, Montreal, Canada; 2) Medical Genetics Division, CHU Sainte-Justine, Montreal, Canada; 3) CHU Sainte-Justine Research Center, Montreal, Canada; 4) Dept of Biochemistry, Faculty of Medicine, Université de Montréal, Montreal, Canada; 5) Department of Stomatology, Faculty of Dentistry, Université de Montreal.

STATEMENT OF PURPOSE: This study is part of a larger project on the genetics of pediatric scoliosis whose goal is to identify genetic and biochemical markers of adolescent idiopathic scoliosis (AIS) and develop a test that could be used to categorize patients into different risk groups. Our purpose is to explore the attitudes of orthopedic surgeons and general pediatricians towards the clinical use of a predictive test for AIS. OBJECTIVES: 1) Identify potential barriers for the use of a predictive test for AIS by clinicians. 2) Identify the needs of clinicians prior to test implementation. METHODOLOGY: Focus groups were conducted with orthopedic surgeons from centers across Canada (1) and general pediatricians (3) in three different centers across Quebec. Sessions were audiotaped. Content analysis was performed. RESULTS: In both groups, there was more interest in the use of a predictive test for AIS as a prognostic test than a susceptibility test. The main barrier is the reluctance of clinicians to guide patient management based on a test result if it goes against their clinical risk assessment: the test will need to have very high positive and negative predictive values for them to trust its results. Also, high cost could be a deterrent, unless it is found to have major impact on patient outcomes. When asked about what information the test report should provide, orthopedic surgeons and general pediatricians disagree about the format of risk estimates (quantitative vs qualitative), the level of detail required in test interpretation and the inclusion of recommendations. Both groups emphasized the need for clear evidence-based algorithms that integrate other known risk factors to guide patient management in different clinical scenarios. Clinicians disagreed about who the target population should be and had different perceptions of what is a high risk of scoliosis. Clinicians expressed concerns about submitting children and adolescents to the risks of unnecessary surveillance or inversely to falsely reassure some families based on test results. CONCLUSION: Orthopedic surgeons and general pediatricians are interested in a predictive test for AIS, but have different views on how it should be integrated in their practice. Many barriers and needs need to be addressed, especially the need for clear evidence of clinical utility. The focus group with orthopedic surgeons was conducted in collaboration with the Canadian Paediatric Spinal Deformities Study Group.

1785W

***Myocilin* genetic screening in severe glaucoma cases and cascade testing in the Australian and New Zealand Registry of Advanced Glaucoma.** *E. Souzeau[1], K.P. Burdon[1], B. Usher-Ridge[1], A. Dubowsky[2], J.E. Craig[1].* 1) Flinders University, Adelaide, SA, Australia; 2) Institute of Medical and Veterinary Science, Flinders Medical Centre, Adelaide, SA, Australia.

Purpose: Glaucoma is the leading cause of irreversible blindness worldwide and affects 3% of the Australian population over the age of 50. The early stages are asymptomatic and it is estimated that half of the cases are undiagnosed. Glaucoma is treatable, and severe vision loss can usually be prevented if diagnosis is made at an early stage. *Myocilin* mutations are identified in 2-4% of primary open-angle glaucoma (POAG) cases, the most common type of glaucoma, and are inherited in an autosomal dominant fashion with high penetrance. Genetic testing to identify asymptomatic at risk individuals is a promising strategy to reduce the prevalence of glaucoma blindness. **Methods:** POAG cases with severe visual field loss were recruited through the Australian and New Zealand Registry of Advanced Glaucoma. Clinical information and blood were collected from participants. Cases were tested for *Myocilin* mutations by direct sequencing and results were provided back to the participants. Predictive genetic testing was made available for relatives of participants found to carry a *Myocilin* mutation. **Results:** Over 1100 participants with severe vision loss from POAG were recruited. The prevalence of *Myocilin* mutations was significantly higher in the cohort with severe vision loss (4.2%) than in a comparative cohort of non-severe cases (1.6%, p=0.02). The mutation detection rate was also higher in individuals with young age at diagnosis, higher intraocular pressure, and strong family history of POAG. Cascade testing was requested by 55 relatives, of whom 29 were found to carry the familial mutation. Twenty-three reported being unaffected, and 91% of them had never seen an ophthalmologist before being tested. The strongest motivations for undertaking predictive genetic testing were to take appropriate interventions and to provide information to children. Individuals who chose to have predictive testing perceived strong benefits, either medical or emotional, in being tested. **Conclusions:** *Myocilin* mutations are more prevalent in phenotypically selected POAG cases. Their identification in glaucoma affected individuals provides the subsequent opportunity to screen their at-risk relatives, and to reduce glaucoma blindness through early management and intervention. Understanding the motivations of individuals undergoing predictive genetic testing helps clinicians and genetic counselors to addressing the relevant issues and providing adequate support to their patients.

1786W

Parental Awareness, Attitudes, and Experiences of Genetic Testing in Autism Spectrum Disorders. *A. Rupchock[1], M. Cuccaro[1], M. Alessandri[2], J.M. Lee[1].* 1) University of Miami, Miller School of Medicine, John P. Hussman Institute for Human Genomics, Miami, FL; 2) University of Miami, Department of Psychology, Coral Gables, FL.

Autism spectrum disorders (ASDs) are one of the most prevalent neurodevelopmental disorders. Studies suggest that up to 20% of individuals with autism have an underlying genetic etiology to account for their autism, and many professional organizations are recommending chromosomal microarrays as a first tier test. Despite these recommendations there has been little research into the psychosocial needs, expectations and experiences of parents whose children receive genetic testing (GT). The aim of this study was to explore the attitudes, beliefs and experiences of GT among parents of children with autism. Key informant interviews were conducted with parents of children with an ASD recruited through a comprehensive outreach and support program serving people with autism and related disabilities. Eight semi-structured interviews were conducted and digitally recorded. The interviews surveyed thoughts and emotions about GT, reasons for pursuing or not pursuing GT, and the general implications of GT. The data were manually coded by two independent researchers and a final consensus was reached. Half of the respondents reported that their child has undergone GT. Three key themes emerged across almost all respondents: seeking answers or a “cure” for ASD, family planning options, and utilizing GT as a means to tailor treatment. Another prominent theme was the confusion about GT and its benefits. The utilization of genetic testing appeared to rely on professional guidance (e.g. “it was never offered to me”). Regarding the utilization of microarrays, several themes emerged: potential usefulness in treatment, assisting in early diagnosis, concerns over access to and cost of GT, genetic discrimination (e.g. labeling with autism for life, information used to deny service), and concerns about use as a screening tool in pregnancy. By eliciting parental attitudes and experiences with GT, we were able to identify several key themes which may be used to inform future research on this topic.

Genetic Testing in Autism: Parental Attitudes and Expectations. *M. Cuccaro[1,2], K. Czape[1,2], J.M. Lee[1,2], A. Rupchock[1,2], E. Bendik[1,2], M. Alessandri[3], S. Hahn[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, 1501 NW 10th Avenue, Miami, FL 33136; 2) John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, 1501 NW 10th Avenue, Miami, FL 33136; 3) Department of Psychology, University of Miami, Coral Gables, FL 33124.

Clinical practice guidelines now stipulate that genetic testing, including chromosomal microarray testing (CMA), be offered as a first-tier test for children suspected of having an autism spectrum disorder (ASD. The enthusiasm in such applying genomic technologies to ASD is offset by concerns about the potential psychosocial and experiential impact of such testing on parents of children with ASD. To assess possible concerns and attitudes about use of genetic testing in ASD, we surveyed parents of children with ASD about their knowledge of, experiences with, and expectations for genetic testing in ASD. Developed by clinical psychologists and genetic counselors familiar with ASD, a 54-item University of Miami IRB approved survey, was electronically sent to the Center for Autism and Related Disabilities (CARD) client registries. Participants were restricted to parents who were a part of one of three CARD registries in Florida as of January 2012. We received completed surveys from 397 parents of individuals with ASD (80% White; 52% Hispanic). The majority of respondents agree that genetic testing is useful in healthcare (89%) and are interested in finding out if genetic factors are the cause of their child's ASD (84%). Although nearly all parents were familiar with the terms “chromosomes” and “genes”, fewer were familiar with “chromosomal microarray” (CMA). In contrast to the 6–8% empiric recurrence risk typically quoted for ASD, the median risk estimation by parents was 50%. A number of respondents stated that their child had been tested for Fragile X syndrome (35%); far fewer had karyotype (13%) or CMA (14%). Among those who had CMA, 68% stated they still have questions or don't understand the test result. Interestingly, 76% of parents reported that their treating physicians did not refer them to or discuss genetic services. Tests were most often ordered by neurologists (68%). and few had ever been referred to a geneticist (21%). Surprisingly, nearly half of the respondents (49%) were not sure if their child would benefit from seeing a geneticist. The most common barrier to genetic testing cited was cost and/or insurance issues (64%). Overall, these preliminary data show that only a small subset of children with ASD are offered comprehensive genetic testing and referral to genetics services as recommended by practice guidelines. Our data support the need for enhancing parental knowledge of and access to genetic testing and clinical genetics services.

Underestimated intimate issues after bilateral prophylactic mastectomy with breast reconstruction in healthy BRCA mutation carriers. *A. Tibben[1,7], J. Gopie[1], C. Seynaeve[3], M. Ter Kuile[4], M. Menke-Pluymers[5], R. Timman[6], M. Mureau[2].* 1) Clinical Genetics, Leiden University Medical Centre, Leiden, Netherlands; 2) Department of Plastic and Reconstructive Surgery, Erasmus University Medical Center, Rotterdam, the Netherlands; 3) Department of Medical Oncology, Family Cancer Clinic, Erasmus University Medical Center-Daniel den Hoed Cancer Center, Rotterdam, the Netherlands; 4) Department of Psychosomatic Gynaecology and Sexology, Leiden University Medical Center, Leiden, The Netherlands; 5) Department of Surgical Oncology, Family Cancer Clinic, Erasmus University Medical Center-Daniel den Hoed Cancer Center, Rotterdam, the Netherlands; 6) Department of Medical Psychology and Psychotherapy, Erasmus University Medical Center, Rotterdam, The Netherlands; 7) Department of Clinical Genetics, Erasmus University Medical Center, Rotterdam, The Netherlands.

Purpose: Decision-making regarding bilateral prophylactic mastectomy and breast reconstruction (BPM-IBR) for healthy BRCA1/2 mutation carriers is not easy and the outcome can be potentially burdensome for the intimate relationship. Therefore, in the current analysis, the impact on body image, sexual and partner relationship satisfaction was prospectively investigated in women opting for BPM-IBR. Patients and Methods: Fifty healthy women undergoing BPM-IBR completed questionnaires at baseline (T0), and most were followed-up 6 months (T1) and after finalized breast reconstruction (median 21 months, range 12–35) (T2). If a statistically significantly change in time was detected with paired t-tests, the outcome was predicted using linear regression analysis. Results: Sexual and partner relationship satisfaction did not significantly change in time. Body image was significantly less positive at T1. After the breast reconstruction process, 39% of the women reported that their breasts felt not pleasantly, 31% was not satisfied with their breast appearance and 23% felt embarrassed for their naked body. Both before and after BPM-IBR, about 30% of women indicated they felt uncomfortable when touched by their partner. An improved body image was predicted by less preoperative cancer distress, a better body image preoperatively, and no severe complications of surgery. Conclusion: BPM-IBR was associated with adverse impact on body image and intimacy, although satisfaction with the overall sexual and partner relationship did not significantly change in time. The psychosocial impact of BPM-IBR in unaffected women should not be underestimated. Therefore, psychological support should ideally be integrated both before and after BPM-IBR for respective women.

Risk of peripartum acute aortic dissection in women with ACTA2 mutations. *E. Regalado, D. Guo, D. Milewicz.* Internal Medicine, University of Texas Health Science Center Houston, Houston, TX.

Pregnancy is an important risk factor for acute aortic dissection in women with a genetic predisposition to thoracic aortic disease, but there is a paucity of data except for women with Marfan syndrome. We performed a retrospective study of 53 women with ACTA2 mutations who had 137 pregnancies past the 24 weeks of gestation to assess the risk of aortic dissection related to ACTA2 mutations. Only 8 (6%) of these pregnancies were complicated by an acute aortic dissection. Eight women (age range, 29–43 years) carrying 6 missense ACTA2 mutations (1 R39C, 1 R39H, 1 M49V, 3 R149C, 1 G275A, and 1 S302A) suffered either a Type A aortic dissection (6 women) or a Type B aortic dissection (2 women) as early as 28 weeks of gestation and up to 2 weeks postpartum. Type A dissection was lethal in three women, while four women underwent successful emergency repair of the aorta and one woman with Type B dissection was medically treated. Aortic imaging at the time of dissection was available in two women and indicated the maximal ascending aortic diameter to be 37 and 39 mm. Five of these women including one with a Type B dissection were noted to have preeclampsia or a history of hypertension but were not on blood pressure medication prior to the dissection. While a preconceptional aortic diameter of 40 mm or less is generally considered to carry a low risk of aortic dissection during pregnancy, we report here at least 2 women with ACTA2 mutations who had dissection with minimal aortic dilatation and 2 women who had Type B dissections that are usually not predicted by aortic diameter. These findings emphasize the need to counsel women with ACTA2 mutations about the risk of aortic dissection during pregnancy as well as the risk to offspring and reproductive options. In women with ACTA2 mutations who proceed with pregnancy, careful management of blood pressure should be done, especially during the third trimester and a month after delivery, along with imaging of the thoracic aorta.

1790W

Translational impact of VEGFA variants on the prediction and follow-up of ocular complications in pseudoxanthoma elasticum. *E. De Vilder[1], MJ. Hosen[1], LM. Martin[2], BP. Leroy[1,3], JM. Ebran[4], PJ. Coucke[1], A. De Paepe[1], OM. Vanakker[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Department of Dermatology, CHU Angers, France; 3) Department of Ophthalmology, Ghent University Hospital, Belgium; 4) Department of Ophthalmology, CHU Angers, France.

Among the phenotypic characteristics of pseudoxanthoma elasticum (PXE), a rare ectopic mineralisation disease affecting skin, eyes and cardiovascular system, the ocular complications (neovascularisation, subretinal haemorrhage and vision loss) result in important morbidity. In the absence of genotype-phenotype correlations with the causal gene ABCC6, it has been suggested that variants in the VEGFA gene, encoding vascular endothelial growth factor, may influence the ocular phenotype. The aim of this study was to evaluate the clinical usefulness of such VEGFA variants in PXE counseling and ophthalmological follow-up. The VEGFA coding region, introns and promotor were analysed in 66 molecularly confirmed PXE patients with mild, respectively severe retinopathy. Three categorizing methods were applied to define severe retinopathy: i) visual acuity (VA) <10/10, ii) VA < 5/10 (legal blindness) and iii) VA <5/10 and/or multiple anti-VEGF injections. Significant association of 4 VEGFA SNPs with severe retinopathy was found only when using the third categorizing method which also takes into account anti-VEGF treatment, even with (near) normal VA. As such, the identification of these SNPs in a patient does not necessarily imply vision loss with significant impact on activities of daily living but rather an increased necessity for anti-VEGF treatment. This subgroup of patients might thus benefit from a more strict follow-up, emphasizing the importance of regular self-testing, and a more pro-active initiation and duration of anti-VEGF treatment. Whether this will eventually change the outcome will have to be evaluated prospectively.

1791W

Familial occurrence and associated symptoms in a population of individuals with non-syndromic craniosynostosis. *J. Greenwood[1], S. Boyadjiev[2], K. Osann[1], P. Flodman[1], V. Kimonis[1].* 1) Division of Genetics, Department of Pediatrics, University of California, Irvine, Irvine, CA; 2) Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento, CA.

Craniosynostosis (CS) is a common cranial malformation occurring in approximately 1 per 2,000 live births. The majority occurs as an isolated defect (non-syndromic), and is hypothesized to be a multifactorial trait with heterogeneous genetic and environmental factors. It is believed that each of the five suture categories (sagittal, coronal, metopic, lambdoid, and complex) denotes a distinct disease, each with varying associated phenotypes and occurrence risks. This large-scale study was the first to analyze familial occurrence and phenotype associations by suture type in a specific subset of all mutation negative (FGFR1–3 and TWIST) non-syndromic CS patients. We analyzed the family histories of 647 patients and the symptoms of 186 patients with identified idiopathic non-syndromic CS. The incidence of CS in first-degree relatives and suture specific phenotypes were evaluated. We found a significantly increased incidence ratio for CS in first-degree relatives (SIR=56) compared to expected based on general population rates. An increased incidence ratio was observed for all suture categories except mutation-negative coronal CS. We observed occurrence rates in relatives of patients to be highest in metopic CS (5.3%), followed by complex CS (3.3%), sagittal CS (3.0%), lambdoid CS (1.4%), and coronal CS (0.4%). There was a significantly higher occurrence in siblings (4.8%) than in parents (1.9%), and in male relatives (4.2%) than in female relatives (1.7%) of affected patients (p=0.002, p=0.009). In comparisons of phenotypes by suture type, patients with complex CS, not surprisingly, had the highest frequency of reported symptoms while sagittal had the lowest frequencies (p=0.016). Ear infections (p=0.026), palate abnormalities (p=0.003), and hearing problems (p=0.002) were significantly more common in complex CS patients compared to all other patients. Chronic fatigue was more common in sagittal CS (p=0.010); coronal CS patients had increased frequency of visual problems (p=0.002); and metopic CS patients noted increased frequency of chronic nasal congestion (p=0.046) and cough (p=0.002). Our data suggest a likely genetic component in non-syndromic CS which appears to be suture-specific. The incidence of CS in first-degree relatives is higher than expected based on general population rates and differs by suture type, gender, and relationship of relative. Additionally, the phenotype of each suture synostosis exhibits both unique and shared features.

Personalized risk prediction in a population-based Biobank: the Estonian experience. *K. Fischer[1], K. Läll[2], L. Leitsalu-Moynihan[1], P.C. Ng[1], T. Haller[1], T. Esko[1], A. Metspalu[1,3].* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Institute of Mathematical Statistics, University of Tartu, Estonia; 3) Institute of Molecular and Cell Biology, University of Tartu, Estonia.

Estonian Genome Centre, University of Tartu (EGCUT), has collected DNA, plasma samples and extensive phenotypes on about 52000 volunteer participants. In coming years, EGCUT will provide feedback to the participants on their predicted genetic and environmental risks, with the pilot project starting in fall 2012. In this presentation we discuss advantages and limitations of such personalized predictions, based on the results of statistical modeling of the EGCUT data. We concentrate on five diseases and medical conditions: hypertension, type 2 diabetes, glaucoma, lactose intolerance and celiac disease. The individual risk of each condition has two components: genetic and environmental. We estimate the two components separately from different data sources. The genetic component estimates are based on recent large-scale meta-analyses of genome-wide association studies, where a risk score can be formed from the effects of the top hits. The environmental component is based on established risk factors that are additionally validated in the EGCUT cohort. The proportions of the two components of the risk are different for the five conditions. We will propose graphical methods for communication of the individual risk and its components to participants. In addition, we validate the risk predictions using follow-up data for a subset of the cohort. Here we mainly focus on the question, how much does the genetic component improve the risk prediction, when the environmental risk factors have already been taken into account. While comparing prediction models that use a different number of genetic markers, we demonstrate that a genetic risk score is always a stronger predictor of the medical condition than any of the individual markers alone. Still, for hypertension and type II diabetes, the effect of modifiable/environmental risk factors is substantially larger than the genetic risk. For glaucoma, age is a strongest predictor, but for given age group, genetic risk score will clearly differentiate high- and low-risk individuals. For lactose intolerance and celiac disease, genetic risk score has strongest predictive value. Here we show that as these conditions are under-diagnosed in the Estonian population, direct validation of the prognostic models is complicated. We discuss some indirect validation methods (such as associations with nutrition data and related diagnoses) and illustrate their applicability in the EGCUT cohort.

1793W

Acquired Thrombophilias; The Reproductive Geneticist's Dilemma. *T. Goldwaser[1,2], K. Bajaj[1,2,3], S. Klugman[1,2].* 1) Montefiore Medical Center, Bronx, NY; 2) Albert Einstein College of Medicine, Bronx, NY; 3) North Bronx Health Network, Bronx, NY.

Our Reproductive Genetics Division within the Department of Obstetrics and Gynecology plays a crucial supportive role in identifying patients at risk for inherited diseases. There are certain circumstances when the role of the Geneticist extends beyond genetic disorders. Acquired thrombophilias may be one such circumstance. When working in a busy, urban setting, a history of a remote thrombotic event may not be uncovered in the routine prenatal visit. Additionally, a history of recurrent pregnancy loss (RPL) may not routinely prompt a referral to a Maternal Fetal Medicine or Reproductive Endocrine specialist. When a history of RPL is elicited during a genetics session, testing for the inherited thrombophilias (IT) has been offered. Practice guidelines published in 2011 by the American College of Obstetrics and Gynecology support testing for acquired antiphospholipid antibodies (APLA) for RPL and do not support testing for IT. Current ACMG guidelines, last updated in 2006, state that testing for Factor V Leiden mutations may be considered for RPL. This seeming conflict is a call to Genetics professionals to review current practices and indeed order appropriate testing in the case of RPL. A geneticist working within an obstetrics department is well positioned to test patients for APLA. This additional testing affords the opportunity to alert the OB team that a patient may be a candidate for treatment in cases of RPL or to prevent thrombosis during/immediately after pregnancy. There is strong evidence that aspirin and heparin use improve the live birth rate in patients with APLA and RPL. Meta-analysis and retrospective cohort studies found similar benefits in cases of IT, forming the basis of the current ACMG guidelines. This testing strategy will prevent missed opportunities and ensure safer outcomes for obstetric patients by alerting prenatal care providers of patients at risk. We propose that our Reproductive Genetics department begin testing for both IT and APLA. We present a stepwise testing and counseling protocol for patients with RPL and thrombosis based on a review of the current literature. This protocol can be a useful tool to any Geneticist taking care of obstetric patients.

Family history and risk assessment in black South African women with breast cancer. *T. Wainstein[1, 2], C. van Wyk[1, 2], A. Krause[1, 2].* 1) Human Genetics, School of Pathology, University of the Witwatersrand, Johannesburg, Gauteng, South Africa; 2) National Health Laboratory Service, South Africa.

Black South African women who have breast cancer are generally diagnosed at a younger age, have more aggressive disease and a poorer prognosis compared to their white counterparts. There is little research regarding inheritance of breast cancer in black South Africans. This study aimed to investigate family history and inheritance of breast cancer in black South African women and evaluate the use and consistency of risk assessment models. A retrospective, file-based analysis of 45 black women diagnosed with breast cancer before the age of 50, was undertaken. Probands were ascertained from the weekly Genetic Counseling Clinic held at the Breast Clinic, Chris Hani Baragwanath Hospital, Johannesburg, South Africa. The probands' personal and family history was analysed. Results indicated that there were few affected women with significant cancer histories (4/45; 9%). Results also suggested that age at diagnosis may not be an appropriate predictor of inherited breast cancer risk in this population. A significant proportion of this sample may have sporadic rather than inherited breast cancer. Three risk assessment tools, (the Claus model, the Tyrer-Cuzick model and the Manchester Scoring System) were evaluated. These showed some degree of consistency, yet each had unique advantages and disadvantages. These tools were designed from data on populations of predominantly European origin; applicability to non-white populations' has not been validated. The true value for this population can only be established once molecular genetic analysis has been performed. This study highlights the necessity of molecular genetic screening in this population to delineate individuals who are truly at increased risk of developing inherited breast cancer. This would clarify which individuals would benefit from cancer risk assessments and various cancer prevention and reduction strategies. Information obtained from this study will direct future research in the South African Black population concerning genetic counseling and testing for inherited breast cancers.

Support for patients with Young-Simpson syndrome, their families and other peoples concerned - Study of patients and family group meetings. *Y. Yamanouchi[1], T. Nishikawa[2], K. Enomoto[2], N. Furuya[2], S. Mizuno[3], T. Kondo[4], M. Adachi[5], K. Muroya[5], M. Masuno[1], K. Kurosawa[2].* 1) Genetic Counselig Program, Kawasaki University of Medical w, Kurashiki, Japan; 2) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Pediatrics, Central Hospital, Aichi Human Service Center, Kasugai, Aichi, Japan; 4) Division of Developmental Disabilities, The Misakaenosono Mutsumi Developmental, Medical and Welfare Center, Isahaya, Japan; 5) Division of Endocrinology and Metabolism, Kanagawa Children's Medical Center, Yokohama, Japan.

Young-Simpson syndrome (YSS) is a rare disorder with only seven cases reported in Japan. Obtaining information about this disorder is thus difficult, and the patients, their families and other people concerned tend to be isolated, with no opportunity to meet those affected by the same disorder. We conducted a survey to determine the efficacy of patient and family group sessions in providing support to these patients and families.We held two “YSS patient and family group sessions” (February 2011 and November 2011, with five families participating in each session) organized by our research team. Doctors and researchers, as well as two certified genetic counselors, attended these sessions. The participants said that they would like to continue having such sessions in the future. They enjoyed meeting other patients and families affected by the same disorder, as they had been trying to obtain medical information about research and treatments. The families actively socialized during the information-exchange time. On the other hand, they also commented on how difficult it is to receive proper medical care in their districts. The participants expressed their concerns that when they visit their otolaryngology (ENT) clinics for conditions such as the common cold, the doctors are not aware of their disorder. This may be because YSS is a pleiotropic disorder characterized by skeletal, endocrine, and neurological abnormalities, and few doctors are aware of it. Creating an information card with details of the disorder, medications to avoid, and contact information for doctors with specialized knowledge of this disorder, as well as allowing families to present it to health care staff will likely enable them to receive necessary medical care. These family group sessions were useful as a form of peer counseling, during which the patients and their families were able to discuss their concerns and worries with each other. It was also an opportunity for them to obtain the latest information about this rare disorder, which was otherwise not readily available. It is essential to have support from various health care professionals, such as specialized doctors who are experienced in managing this particular disorder or medical genetics specialists.

1796W

Duplications Xq28 are questionable for genetic counselling. *C. Costa[1,2], A. Briand[1,2], C. Rothschild[3], E. Bieth[4], J. Melki[5], C. Metay[1,2], M. Goossens[1,2].* 1) AP-HP, CHU Henri Mondor, UF de Génétique, Creteil, France; 2) Inserm et Université Paris 12, U955, Créteil, France; 3) AP-HP, Hôpital Necker, Centre de Traitement des Hémophiles, Paris, France; 4) Hôpital Purpan, Génétique Médicale, Toulouse, France; 5) UMR 788, Inserm et Université Paris 11, Kremlin Bicêtre, France.

Today patients with intellectual disability (ID) are commonly explored by CGH-Array to search for chromosomal microdeletion or microduplication. Recently an Xq28 duplication involving F8 gene in 3 patients with isolated (ID) has been reported (El Hattab AW, J Med Genet 2011). We here describe other Xq28 duplications involving F8 gene in patients presenting two different phenotypes, (ID) or haemophilia A (HA), and we discuss the mechanism of these rearrangements and the difficulties of interpretation for genetic counseling. Severe haemophilia A is frequently caused by inversions involving intronic sequence of the F8 gene (int22h1) and one of two remote, distal copies (int22h2 and int22h3). The inversed orientation of the 2 distal copies suggests that interchromosomal recombination should produce more deletions and duplications than inversion rearrangement. Reciproqual deletion and duplication of F8 gene have been suggested. Though several F8 gene deletions have been described, the few duplication reported are most of the time associated with moderate haemophilia and concern only a small part of the gene. The patients were investigated by CGH-array and further analyzed by MLPA targeted on F8 gene or conversely according to their phenotype. The analysis revealed a telomeric duplication that covers about 0.5Mb, affects several genes and part of the F8 gene from the int22h1 copy to a locus lying between the distal int22h2 and int22h3. These observations seems to support the hypothesis of interchromosomal recombination involving these repeat copies. We propose a mechanism for rearrangement and we underlie the apparently conservation of one F8 gene copy in haemophiliac patients. However the identification of this same duplication in patients with ID without low factor VIII levels and conversely in severe HA patients without ID is questionable. Indeed this same Xq28 duplication involving F8 gene is associated with i)isolated ID or isolated HA, ii)severe form of haemophilia, contrary to the initial hypothesis that F8 gene duplication has no consequences, which then do not justify prenatal diagnosis. These data are important and must be taking account for genetic counselling. Indeed, this is of particular interest when such duplication is identified in pregnant woman with low factor VIII level suggesting of haemophilia carrier and no family history of the disease or conversely in woman with history of ID.

Surname Leakage from Personal Genomes. *Y. Erlich[1], M. Gymrek[1,2], D. Golan[3], E. Halprein[4,5,7], A.L. McGuire[6].* 1) Whitehead Institute for Biomedical Research, Cambridge, MA; 2) Harvard-MIT Division of Health Sciences and Technology, MIT, Cambridge, MA 02139; 3) Department of Statistics and Operations Research, Tel Aviv University, Tel Aviv 69978, Israel; 4) School of Computer Science, Tel Aviv University, Tel Aviv 69978, Israel; 5) Department of Molecular Microbiology and Biotechnology, Tel-Aviv University, Tel Aviv 69978, Israel; 6) Center for Medical Ethics and Health Policy, Baylor College of Medicine, Houston, TX 77030; 7) The International Computer Science Institute, Berkeley, CA 94704.

Sharing sequencing results without identifiers has become a common practice in genomics. Here, we report that surnames can be recovered from these sequencing datasets. Our approach relies on bioinformatic profiling of short tandem repeats on the Y-chromosome and querying massive Web 2.0 genealogical databases. We demonstrate the feasibility of the technique by recovering the surname `Venter' from Craig Venter's genome. We also find that short read datasets are amenable for surname recovery. Applying this technique to more than 1,000 US males shows a success rate of 13%-16%. Surname leakage can lead to a complete breach of anonymity - in most cases, the combination of a recovered surname with minimal demographic information narrows the identity of the target to a handful of individuals. We combine surname recovery with a simple Google search to fully expose the identity of a large HapMap pedigree. We will discuss the implications of surname leakage and suggest policy guidelines to mitigate the risk.

Optional Enrollment into Access Controlled Genomic Databases: Decision making in Hispanics versus non-Hispanics. *S. Scollon[1], S. Gutierrez[1], A.L. McGuire[2], S. Hicks[3], S.E. Plon[1].* 1) Department of Pediatrics, Texas Children's Cancer Center, Baylor College of Medicine, Houston, TX; 2) Center for Medical Ethics and Health Policy, Baylor College of Medicine, Houston, TX; 3) Department of Statistics, Rice University, Houston, TX.

Background: With the growth of genomic-scale data from research studies there is an increasing request for participants to consent to the deposition of data into databases. Prior studies suggest most are generally willing to share data, but few studies have evaluated decisions in the context of family-based studies, ethnic variation, or parental willingness to have children re-contacted at age 18 for continued data sharing. Methods: We examined the response over a 2-1/2 year period at one center of adults - primarily parents of childhood cancer patients or young adult survivors - being enrolled into a cancer susceptibility research study which includes genome-scale sequencing. Informed consent was obtained in an individual session over approximately 45 minutes. Each adult subject was asked permission to deposit their own genetic information into controlled access scientific databases and to have their child contacted at the age of 18 for consent. Self-described ethnicity and race was recorded. We tested the hypothesis that consent to deposit data or be recontacted may differ among Hispanic and non-Hispanic adults using a Fisher's exact test. Results: A total of 52 adult participants were enrolled with 56% self identified as non-Hispanic and 44% as Hispanic. Ninety percent (19/21) of Hispanic and 74% (23/31) of non-Hispanic adults agreed to have their genomic information included in databases. Of 41 childhood cancer patients 88% of parents (95% of Hispanic and 81% of non-Hispanic) consented to have their child contacted at the age of 18. Both tests failed to reject the null hypothesis that there was no difference between Hispanics and non-Hispanics in either measure (p= 0.1739, p=0.3433). Conclusion: This study found no significant difference between Hispanics and non-Hispanics who consented to participate in this genetic study with genome scale sequencing in data sharing decisions or permission for re-consent of children at age 18. Overall, even when deposition of data into databases is optional, the majority of adults (81%) agreed to have their genome-scale data included within a database and to have their child recontacted at age 18 (88%) to discuss data deposition. This work is supported by grant U01HG006485 to SEP.

Development of institutional genomic research infrastructure in an academic pediatric hospital setting to enable large-scale enrollment, education and discovery. *C.M. Clinton[1], S.K. Savage[1], C.A. Brownstein[1], I.A. Holm[1,2], D.M. Margulies[1,2,3,4], W.A. Wolf[1].* 1) Program in Genomics, Boston Children's Hospital, Boston, MA; 2) Department of Pediatrics, Harvard Medical School, Boston, MA; 3) Division of Developmental Medicine, Boston Children's Hospital, Boston, MA; 4) Center for Biomedical Informatics, Harvard Medical School, Boston, MA.

Our objective is to develop an institutional genomic research infrastructure that couples a pediatric Biobank with a new genomic translational research initiative at Boston Children's Hospital to accomplish large scale data sharing and promote discovery. This initiative called the Research Connection, follows the Informed Cohort proposed participant engagement paradigm that was originally described in 2007 by Kohane et al, focusing on an educational, opt-in consenting model that includes the option of individual genetic results return while maximizing the use and potential for the data. Our proposed design includes a tiered consenting structure that allows the participant to engage to the level of their comfort, from sample donation, to participant engagement and general feedback, and finally to individual genetic results return and the potential of enrolling in clinical services. One main driver of this opt-in, full consent model is the proposed changes to the Common Rule and its potential impact on banked clinical samples. The first tier revolves around the creation of a protocol and consent form for the Biobank that will allow for simplified enrollment around the donation of already obtained clinical discard samples and linkage with electronic medical record data. This effort is coupled with a comprehensive education campaign, including web-based education, geared toward both patients and providers to allow for rapid integration of this new initiative into a complex academic environment. The second tier includes participant engagement that allows enrollees to use a web-based platform to allow for Biobank executed contact with enrollees to support investigator needs. The third tier includes an educational and preference setting process for enrollees to be eligible for return of individual genetic research results. Separate research and clinical seed projects also feed into our research infrastructure by including consent form provisions that allow for a de-identified copy of genomic data to be included in a variant database as well as the option to donate project specific data to the Biobank for use in other Biobank-approved studies. We argue that creating a comprehensive, inclusive consenting architecture with appropriate program governance at the launch of a genomics initiative maximizes the return on invested time and funds to benefit the broad academic community, and most importantly respects the autonomy of the pediatric patient population.

A proposal: a family driven social network model for clinical data sharing and research in intellectual deficiencies and other neurodevelopmental disorders with specific genetic causes. *JL. Mandel[1,2,3], JS. Beckmann[4,5].* 1) IGBMC, Illkirch CU Strasbourg, France; 2) CHU Strasbourg, France; 3) College de France, Paris; 4) Genetique Medicale CHUV Lausanne, Switzerland; 5) Dpt Medical Genetics, UNIL Lausanne, Switzerland.

CGH array has led to a rapidly growing number of genetic diagnoses in patients with intellectual deficiency (ID) associated or not to autism, and this will soon be amplified by detection of mutation in ID-related genes with use of high -throughput sequencing. This will be useful for genetic counseling (when penetrance is known to be high). But the extraordinary genetic heterogeneity of ID will render extremely difficult the determination, for each specific cause (recurrent CNV or mutated gene), of genotype-phenotype correlations and natural history, the estimation of penetrance and expressivity variation, and the organization of clinical trials, except for the most frequent causes (see recent work on 16p11.2 deletion or duplication). Symptomatic treatments will be proposed, with little chance to evaluate whether their efficacy depends on the specific genetic cause. It will be difficult to motivate busy MDs to establish and maintain the wide-ranging databases required for such studies. We wish to propose as an alternative ID databases organised in a social network model, whereby most clinical information would be entered by the family of the patient. Recent papers from 23andMe or PatientsLikeMe have shown that such data can be the basis of useful research. Contacts between families affected by the same genetic cause could be established in an initially anonymous way as for Relative finder in 23andMe, creating gene or CNV specific micro-networks to which interested professionals could be associated, akin to disease specific patients associations. Anonymised data could be accessible to professionals for specific projects approved by a comity composed of health or research professionals and of families representatives. Concerned families could then decide to take part or not in such projects.

Turkish Medical Students Attitude Towards the Ethics of Genetic Testing and Genetic Information Disclosure in Fragile X Syndrome, Breast Cancer and Huntington Disease. *E.A. Ergul[1], I. Gun[2].* 1) MGH, Boston, MA; 2) Erciyes University Public Health, Turkey.

Introduction: There has been ongoing debate for whether patients with positive genetic test results or physicians who holds this information for their patients should disclose the information to the family members. The same debate appears when western ethics guidelines for minority testing is introduced to oriental cultures. The purpose of this study is twofold: To investigate Turkish medical students' attitude toward genetic information disclosure among physicians and patients for Fragile X Syndrome, Breast Cancer and Huntington Disease, as well as their attitude towards the use of NSGC guidelines for minority testing. Method: 188 Turkish Medical Students in Erciyes University is anonymously surveyed. Survey response rate was 97%. Results: Students (57 % male) were with the mean age of 24.43 (sd= 1.73). Over 80 % of students approved the information disclosure to parents and off-springs but it was only 47 % for siblings and relatives across the 3 disorders. About 30 % of students were indecisive for siblings and relatives. More than half of the students thought it is not their responsibility to give a notice to a colleague if patient refuses to disclose. For minority testing for cystic fibrosis, 78 % of students approved the testing and 50 % students did not agree with NSGC guidelines. For Huntington, more 57 % approved the minority testing and was against the guidelines. Conclusion: Medical students in Turkey with presumed oriental culture orientation approved the genetic information disclosure for parents and off-springs but they were not decisive for siblings and relatives. More than half of the Turkish medical students approved the minority testing for two specific genetic disorders (Huntington and Cystic Fibrosis) and they refused the NSGC minority testing guidelines. Medical curricula in Turkey should cover both the NSGC guidelines and cultural orientations in Turkey.

1802F

Hope and hype in sight: multi-stakeholder perspectives on ocular gene therapy. *S. Benjaminy[1], T. Bubela[1], M. Bieber[1], I. MacDonald[2].* 1) Public Health Sciences, University of Alberta, Edmonton, Alberta, Canada; 2) Ophthalmology, University of Alberta, Edmonton, Alberta, Canada.

Nascent ocular gene therapy (GT) clinical trials are raising patient hopes for a treatment for choroideremia (CHM)—a degenerative retinopathy leading to blindness. GT trials raise the practical necessity of communicating about the risks and benefits with patients in light of a perceived `cure'while avoiding the sensationalism that has historically undermined this field of translational medicine. We hypothesize that patients in the context of a potential treatment will differentially interpret communications about GT in response to media sensationalism. We examined communications about ocular GT in two contexts: (1) word frequency analysis surveying tone of GT coverage in US, UK and Canadian newspapers (1990–2010) (nUS=5438; nUK=1522; nCA= 948) using search algorithms that captured GT synonyms in Lexis Nexis and Factiva databases; and (2) analysis of clinical communications about a CHM GT clinical trial. We conducted semi-structured interviews with 20 CHM patients and 14 clinicians responsible for their care about expected therapeutic benefits, perceived risks, and timeline for clinical implementation. We analyzed interviews using a grounded theoretical approach. Media representations of ocular GT described a range of outcome goals including finding a CHM cure. On the other hand, clinicians emphasized that the goal of early-phase GT trials is better described in terms of a treatment rather than a cure. Patient expectations were more conservative than experts estimated, centering on a hope that CHM GT will halt the progression of vision loss rather than reverse it. While clinicians believed that patients were predominantly concerned with gaining access to GT rather than ensuring its safety, our analysis revealed salient patient worries about GT safety (ex. risk of accelerating vision loss). Interviews revealed discrepancies between patient and clinician timeline expectations for clinical implementation of CHM GT, illuminating patient urgency to access GT within the therapeutic window of opportunity. Our findings about conservative patient visual benefit expectations and safety concerns suggest that patients are well-informed and process media representations critically to avoid sensationalism about CHM GT. Nevertheless differences remain between patient perspectives and clinician understanding. Bridging this gap will promote responsible communications about CHM GT and facilitate the translation of this biotechnology.

1803W

Social and ethical implications of families' experiences of pediatric genetics: Key findings from a UK qualitative study exploring families' expectations, their responses to diagnosis and their approach to managing the uncertainties of genetic investigations. *J. McLaughlin[1], M. Wright[2], E. K. Clavering[1], E. Haimes[1].* 1) Policy, Ethics and Life Sciences Research Centre, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom; 2) Northern Genetic Service, Newcastle Hospitals Foundation Trust.

Statement of purpose. In the UK children with neurodevelopmental problems with no clear explanation are often referred - usually by paediatricians - to National Health Service (NHS) genetic services. That referral will lead to consultations where the normal procedure is to take a full medical and family history, examine the physical features of the child and from this to come to a differential diagnosis. Samples may be taken for chromosome and/or DNA analysis. Little is known about the perspectives of families or their experiences of the multiple aspects of genetic investigation and diagnosis. This is increasingly important to consider in the light of new diagnostic technologies - e.g. Array-CGH analysis - which bring with them increasing ethical challenges of understanding and sharing findings of uncertain significance for the child's future development and life expectancy. How does a parent or child make sense of a diagnosis which is so rare and new it is a sequence of numbers and letters rather than providing `a name'? This presentation will explore the lessons that can be learnt from a study of families referred to a NHS genetic service using multiple different diagnostic technologies. Methods Used. The study is a qualitative 3 year study funded by the Economic and Social Research Council which followed 26 families for up to 2 years during their time being seen by a genetic service via interviews and observations of clinic consultations. Summary of results. The presentation explores how families find the long duration sometimes involved in genetic investigations difficult and unexpected; how diagnostic findings may not mean the same thing to families and geneticists; and how the fact that any genetic diagnosis is uncertain about what it can predict about a child's future is both challenging and enabling. Understanding families' responses, and how they are linked to the expectations they have when they first enter a genetic clinic, is important for provision of the correct support throughout, from the initial proposal to refer to the genetic service, through to support at the post-investigations stage.

1804F

Driving research forward, but in what direction? Scientist perspectives on goals and groups invested in autism genetic research. *L.C. Milner, M.K. Cho.* Center for Biomedical Ethics, Stanford University, Stanford, CA.

In the past decade, autism spectrum disorders (ASDs) have shifted from relative obscurity into one of the most prominent issues in American healthcare. The presence of ASDs in public and political discourses results from multiple factors, including a sharp increase in prevalence rates (current estimates of ASDs populations suggest that ≥1% of children lie on the ASD spectrum) and the emergence of a formidable ASD advocacy movement instrumental in raising public awareness about ASDs and promoting research efforts. The rise of ASD in both public and research arenas suggests it as an important area of focus for future research efforts. ASD is considered to be primarily biological in origin, a position reflected in current research efforts focusing heavily on genetic contributions to ASDs. Both federal and nonprofit sources have contributed sizable funding and research resource (e.g., genebanks) efforts to promote ASD genetic research. Despite these highly collaborative efforts, the ultimate goals of ASD genetic research remain ambiguous, as do the expectations and motivations of groups participating in this type of research. Considering the investments of researchers, funders and participants in this endeavor, two questions arise: what values are represented in ASD genetic research produced, and whose values do they represent? To explore these issues, we interviewed genetic researchers studying ASD. In these interviews, we assessed researcher goals and motivations, as wells their impressions of funding agencies and participant groups directly involved in their research projects. Data drawn from these interviews suggest that researchers hold a wide variety of goals for research outcomes, from broad and social (e.g., better understand ASD to reduce stigma) to explicit and clinical (e.g., develop ASD biomarkers for screening). When discussing other groups involved in research, most researchers emphasized specific funders and families as `driving research forward' through their deep commitment to and involvement in research efforts. However, researcher impressions of the motivations and expectations of these groups varied substantially, accentuating the diverse and indeterminate nature of collective goals for ASD genetic research. Future work is needed to understand how these goals and motivations differ between stakeholder groups, as well as how these differences can be effectively addressed within the broader ASD research community.

Experiential process of securing free prior informed consent for genetics research from an indigenous population in the Philippines. *C.D. Padilla[1,2,5], A.L. Sur[2], M.T. Guia-Padilla[3], M. Baluyot[1], E.M. Cutiongco - de la Paz[1,2,5], S. Padilla[3,4].* 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila; 2) Department of Pediatrics, College of Medicine, University of the Philippines Manila; 3) Anthrowatch Philippines; 4) Department of Behavioral Sciences, College of Arts and Sciences, University of the Philippines Manila; 5) Philippine Genome Center, University of the Philippines System.

Introduction: Of the 110 ethno-linguistic groups in the Philippines, 35 are Negritos who are known by various names, i.e., Agta and Atta in North Luzon; Aeta, Ayta, Alta and Arta in Zambales and Central Luzon; Dumagats in Sierra Madre; Ati or Ata in Panay-Negros; Ata and Abiyan in Bicol, Batak in Palawan; Mamanwa and Ata Manobo in Mindanao; Iraya Mangyan in Mindoro and Remontado in Sibuyan Island, Romblon. Negritos are most vulnerable to extinction due to intermarriage with other ethnic groups, assimilation to mainstream culture and death due to illnesses. The conduct of genomic research needs approval from the National Commission on Indigenous Populations (NCIP), a government agency mandated to protect the interest of the indigenous peoples (IPs). An ongoing project on genomic diversity entailed a 2-year process in securing consent from NCIP which prompted the preparation of modules. **Objective**: To present the experiential account of developing a culturally sensitive protocol of securing free prior informed consent (FPIC) for a genetics research from the IPs. **Methodology**: 1) Consultation with NCIP; 2) identification of a social development organization and other major players that deal directly with IPs; 3) development of culturally sensitive modules in securing FPIC; 4) pilot testing of modules among lay and IPs; and 5) use of the protocol in orienting major players. **Results and Discussion**: After a series of consultations with NCIP and non-government organizations dealing with IPs (AnthroWatch and Koalisyon ng mga Katutubong Samahan ng Pilipinas), the protocol which was developed included inputs from the IPs. The 2-hour module utilizes picture analysis, lecture and interactive method in the orientation. The module includes: 1) Introduction of participants; 2) Warm- Up Exercise: Binukid “body parts” song which aims to arouse their curiosity on the topic; 3) What are the parts of the body? - participants are asked on their concepts of different parts of the bodies; 4) Guessing game, an interactive activity that demonstrates that important body parts are always not visible to the eyes, i.e., chromosomes, genes and DNA. The signing of FPIC by the Tribal Council and the IP participants (signature/thumbmark) ends the module. **Conclusion**: Genomic research on IPs require a special process for FPIC. Although a tedious process, the presented protocol is a model procedure that can be used by researchers involving genomic research.

1806F

The essential ethical considerations for using human genome sequencing as a diagnostic tool in clinical medicine. *A.D. Zellers.* Institute for Consultative Bioethics, Pittsburgh, PA.

In a few years it may cost patients only a few hundred dollars to have their genome sequenced. Genetic information provides valuable diagnostic information. However, the ethical implications of genome sequencing bring to light some important considerations for the use of genetic information in health care. This presentation will address three central ethical issues that health care practitioners and providers must consider when deciding whether to adopt human genome sequencing as a diagnostic tool or how to use it if it is adopted. The first ethical consideration surrounds the type of information a sequenced genome provides. The patient will be provided with information about their genetic health, which can be very useful in helping the person determine how to conduct their life. However, there are no therapies to addresses many of these genetic problems. Currently, there are no gene-transfer therapies available in Western medicine. Patients will be provided with potentially devastating information and have no medical means or available therapies to address their condition. The second ethical consideration revolves around risk probabilities and interpreting the information revealed. Take for example an individual who has their genome sequenced and is told they have a 10% chance of developing Alzheimer's disease. What does that 10% actually represent? Is it a 1 in 10 chances, or perhaps a 1 in 10 chance if a series of other genetic factors are expressed? The answer is unclear and it is difficult to describe the true value of genetic probabilities to patients. The ethical considerations surrounding risk probabilities must be explored. The final ethical consideration addressed in this presentation pertains to the family members of those individuals who have their genome sequenced. Since families share genetic material, the results of one individual's test will have implications for others in the family, particularly for biological siblings and children. When genetic information is being discussed the familial implications must be considered as well as the privacy of both the patient and family members. Privacy, confidentiality and family dynamics must be considered when using genetic information in diagnostics.The purpose of this presentation is to clarify and begin analyzing these ethical concerns and lay the groundwork for further meaningful discourse on the appropriate use of genome sequencing in clinical medicine.

1807W

The evaluation of low template, degraded and mixed DNA profiles in forensic science. *D. Balding.* Inst Gen, Univ College London, London, United Kingdom.

The genotyping of forensic short tandem repeat loci has been developed over the past decade so that it can successfully be employed with only tens of picograms of DNA, corresponding to the DNA from a few cells. The resulting profiles are subject to many stochastic phenomena, including allelic drop-out and drop-in (sporadic contamination), exaggerated stutter peaks and other artefacts. Problems with the handling and interpretation of such complex and noisy evidence has generated controversy, including scathing criticisms by judges, for example in an important Northern Ireland terrorist bombing case, and by academic commentators, for example the report on the DNA evidence in the Italian case of Knox and Sollecito. The incredible power of low template DNA evidence to link someone with a crime-scene based on only touch or even breath has made it compelling to prosecution authorities in many countries, yet the problem of how to convey its evidential value fairly to courts has still not been adequately resolved. I will describe recent progress in developing adequate probability models of degradation, drop-out and drop-in, in handling appropriately the parameters of these models and in formulating hypotheses for a fair assessment of evidential weight. I will also describe the implementation of these developments in the *likeLTD* software for evaluating low-template DNA profile evidence. This R software is freely available at https://sites.google.com/site/baldingstatisticalgenetics/software and is being used in court cases in the UK and US.

1808F

Legal considerations regarding participant privacy in the genomic era of research on the African continent. *G.E.B. Wright[1], P. Koornhof[2], N. Tiffin[1].* 1) South African National Bioinformatics Institute, University of the Western Cape, Cape Town, South Africa; 2) Dept of Mercantile Law, University of the Western Cape, Cape Town, South Africa.

Rapid advances in next generation sequencing (NGS) are making medical genomic research more readily accessible and affordable, including the sequencing of patient genomes and exomes in order to elucidate genetic factors underlying disease. Over the next five years, the Human Heredity and Health in Africa (H3Africa) Initiative (www.h3africa.org), funded by the Wellcome Trust (UK) and the National Institutes of Health Human Health (USA), will contribute greatly towards sequencing of numerous African patient genomes and exomes by NGS. Funding agencies and journals often require submission of genomic data from research participants to databases that allow open or controlled data access for all investigators. Access to such genotype-phenotype and pedigree data, however, needs careful control in order to prevent identification of individuals or families. This is particularly the case in Africa, where many researchers and their patients are inexperienced in the ethical issues accompanying whole genome and exome research; and where an historical unidirectional flow of samples and data out of Africa has created a sense of exploitation and distrust. In the current study, we analyzed the implications of the anticipated surge of NGS data in Africa and the subsequent data sharing concepts on the protection of privacy of research subjects. We performed a retrospective analysis of the informed consent process for the continent and the rest-of-the-world and examined relevant legislation, both current and proposed. We investigated the following: (i) issues pertaining to informed consent, including a lack of guidelines for performing culturally-sensitive NGS research in Africa and poor availability of suitable informed consent documents; and (ii) issues pertaining to data security and subject privacy whilst practicing data sharing, including difficulties in conveying the implications of such concepts to research participants in resource limited settings. We conclude that, in order to meet the unique requirements of performing NGS-related research in African populations, novel approaches to the informed consent process are required. This will help to avoid infringement of privacy of individual subjects as well as to ensure that informed consent adheres to acceptable data protection levels with regard to use and transfer of such information.

Insurance Coverage of Preventive Services for Individuals with Genetic Predispositions to Cancer. *A. Prince.* Cancer Legal Resource Center, Los Angeles, CA.

Advances in genomic medicine bring great promise of personalizing patient care and saving patients' lives. Only with access to preventive services and knowledge about the consequences of genetic predispositions can an individual make informed medical decisions which may vastly improve treatment options and health outcomes. For many people, getting complete access to preventive services is difficult, if not impossible. For this reason, the Cancer Legal Resource Center (CLRC) and Facing Our Risk of Cancer Empowered (FORCE) created a survey for individuals with genetic predispositions to cancer in order to measure insurance coverage of preventive services. This presentation or poster will summarize the results from the survey to show current trends in insurance coverage for preventive services. Between June 2011 and October 2011, 232 individuals participated in this survey. The survey reflects a national audience. The vast majority (93.3%) of those completing the survey had a family history of breast, ovarian, or colon cancer. Additionally, 92.8% had taken a genetic test for cancer. Of those surveyed, 86.2% had a BRCA1 or BRCA2 mutation and 6.5% had other hereditary cancer mutations. Of those individuals who requested services from their insurers, 82.7% had genetic testing covered, 87.2% had preventive screenings covered, 83.9% had prophylactic surgery covered, and 83.3% had chemoprevention covered. Through ongoing survey analysis, we are finding that certain subgroups of individuals are more likely to have insurance coverage of preventive services than others. We are comparing insurance coverage of these preventive services with other collected information, such as state, age, income level, cancer diagnosis, type of insurance coverage, and participation in appeals processes. If an insurance company denies an individual coverage for a preventive service, the best recourse for the individual may be to appeal the denial. Therefore, this presentation will also cover information on appeals processes in insurance.

1810F

The implementation and impact of student athlete sickle cell trait screening: a survey of Division I California universities. *L. Mar[1], N. Lovick[1], C. Hartshorne[2], M. Treadwell[2], J. Youngblom[1].* 1) California State University, Stanislaus, Turlock, CA; 2) Children's Hospital & Research Center Oakland, Oakland, CA.

Background: In 2010, the National Collegiate Athletic Association (NCAA) mandated sickle cell trait (SCT) testing of all incoming Division I student athletes. Although typically a benign condition, under extreme conditions, SCT has been associated with an increased risk for exercise-related sudden death. NCAA protocol states that athletes be tested for SCT, show proof of prior testing, or waive out of screening. Not included in the mandate are standardized guidelines for schools to follow. Purpose: The aim of this study was to investigate the mandate's impact and implementation at California Division I universities. Methods: Athletic trainers from each of the 24 California Division I universities were invited to participate in an online survey which included questions on demographics, trainer perspective, and the education, testing, and management of student athletes. Data analysis was performed with Chi-square and Fisher's exact tests. Nine post-survey telephone interviews were also conducted. Results: Forty athletic trainers from thirteen of the 24 universities (54%) completed the survey. The majority (92.9%) felt that SCT screening was beneficial and 81% felt that there were no associated risks with the screening. A minority of trainers reported being informed of the impact of SCT on family planning (35.7%). Similarly, a minority of respondents (26.8%) reported that athletes were educated on the impact of SCT on family planning. Less than half (38.1%) reported students receiving pre-test counseling, while 64.3% reported students receiving post-test counseling, primarily by team physicians and/or trainers. Trainers reported differences in the management of athletes with and without SCT. Statistical differences were found between trainers representing public and private universities. Interviews highlighted the divergence of university practices, with few universities mandating that athletes undergo testing. Conclusion: Results of the study revealed a variety of practices being followed, with inconsistencies in the education and counseling of athletes. Trainers and athletes may benefit from more well-rounded educational and counseling resources. This study illustrates the importance of standardizing practices and the potential role for genetic counselors in promoting the education, autonomy, and informed decision-making of student athletes surrounding the issue of SCT testing.

1811W

Direct to consumer genetic testing: What information for which consent? *J. Atia, E. Rial-Sebbag, V. Anastosova, A. Cambon-Thomsen, F. Taboulet.* Inserm and Université de Toulouse III Paul Sabatier, UMR 1027, Toulouse.

Direct to consumer genetic testing (DTC-GT) is a recent phenomenon that poses new ethical and legal issues. It could be considered as a hybrid enterprise between medical practice and purely commercial ventures which is carried around the world via internet. This new context requires an adaptation of the concept of informed consent within the scope of consumer law. Traditionally, informed consent is the process by which a consumer can be actively involved in the commercial ventures. The true informed consent depends on the information that service provider make available for consumers. This professional's duty to inform is controversial concerning websites that offer DTC-GT. Indeed, the information available on the websites makes one believe that the genetic results give the power to control consumer's health and indirectly their life. Nevertheless, after the analysis of some DCT-GT consent forms, it is clear that the results of the test have only informational purpose and, in most of the cases, no clinical validity or utility. Thus, we question whether or not, the information available on some of DTC-GT websites really inform the consumer about the purpose of the test, the risks related to the results and their data protection. Moreover, the companies develop genetic research studies while information about the future use of the samples and associated data is generally missing. Our non- exhaustive search, completed in May 2012, involved 62 websites offering online genetic testing. First, we selected among them those websites proposing DTC-GT with a medical purpose and had a freely available consent form (3) and we analyse the information they provided. . Secondly, we observed if this information corresponded to norms and good practices in consumer and medical law. In conclusion, we make some proposals referring to the report for the management of direct to consumer genetic testing prepared by the Human Genetics Commission and Scientific Technology Options Assessment - STOA.

1812F

Genetic discrimination and the relevance of the United Nations Convention on the Rights of Persons with Disabilities. *A. de Paor.* Centre Disability Law & Policy, Natl Univ Ireland, Galway, Galway, Ireland.

In an age of genetic wizardry, genetic testing is a double- edged sword. With the success of the Human Genome Project, rapid advances in gene discovery and personalised medicine, genetic information is becoming widely available. However, the deluge of genetic information also raises ethical, social and legal issues that can not only threaten advancing science, but can also result in the discriminatory use of genetic information, and violation of genetic privacy. If this information is too widely available it exposes putative persons with disabilities (which, with the aging process, includes most of us) to overt and covert discrimination. In looking towards regulation of genetic discrimination at European Union level, the United Nations Convention on the Rights of Persons with Disabilities (UN CRPD) is of relevance and gives added impetus to the argument that EU level regulation of this area is both preferable and necessary. The UN CRPD prohibits discrimination in a range of fields including employment. The Convention commits the EU to higher standards of non- discrimination with respect to persons with disabilities. The EU ratified the Convention in December 2010 (the first time the EU has ratified an international human rights treaty). There is now a responsibility on the European Institutions to reflect on the case for some form of legislative or other response to the issue of genetic discrimination. This may be a unique opportunity to take a proactive approach towards regulating genetic information for EU citizens in the 21st century. A concerted, uniform approach by the EU would contribute towards guaranteeing fundamental rights and principles, ensuring the effective operation of the internal market and ensuring against any potential obstacles to the realization of these rights. Such an approach is welcomed, not only from a legal perspective, but also from a political and social perspective, and may succeed in facilitating the further advancement of genetic science, and eliminate any fears of genetic discrimination that may prevent individuals from undergoing genetic testing for the benefit of their health. Any EU legislation in the field of genetic discrimination could be regarded as proactive implementation of the Convention. This paper will discuss the need for appropriate regulation of genetic information in light of advancing science, and the relevance of the UN CRPD in working towards regulation at EU level.

1813W

Representing the Indigenous Community: Researcher and Physician voices spark debate over Newborn Screening of CPT1A in Alaska Native and First Nations populations. *N. Garrison.* Stanford Center for Biomedical Ethics, Stanford University, Stanford, CA.

A gene variant present in some Alaska Native (AN) and First Nations (FN) populations has been identified as a potential contributor to infant death and other health problems; however, a lack of consensus exists on the health effects of the variant. AN and FN populations have a high prevalence of the P479L variant of carnitine palmitoyltransferase 1A (CPT1A). CPT1A is involved in oxidation of long-chain fatty acids, important for energy metabolism. Previously, 20 mutations in CPT1A have been associated with reduced enzyme function and reduced energy metabolism in other populations. Anecdotal evidence suggests that 2 copies of P479L are associated with reduced energy metabolism, seizures, and sudden infant death. However, concerns have been raised about the validity of the P479L variant association with sudden infant death: studies to date have involved small numbers, and it is unclear whether an association, if present, is causal. This genetic trait occurs in >50% of most northern indigenous coastal communities; however, 98% of these individuals show no symptoms. With the 2002 adoption of Tandem Mass Spectrometry in expanded newborn screening (NBS), CPT1A was included on the list of conditions and disorders for screening in Oregon and Alaska, but not Washington or British Columbia (BC). A community conversation with AN and FN populations in 2011 sparked debate over the utility of NBS for the CPT1A trait and its impact on the community. Alaskan public health efforts brought attention to the P479L association with decreased energy metabolism and sudden infant death to AN families and local health aid workers. In response, FN parents in BC questioned why newborns in their communities were not screened. Through interviews with physicians, researchers, NBS experts, and policy makers (some of whom are indigenous), I identified a range of opinions about NBS of CPT1A and the interpretation of biomedical research results for the community. This presentation traces the history of CPT1A research, explores NBS policy development, examines community concerns, and highlights views influenced by different health care systems in the US and Canada. While some respondents argue that lives could be saved through identification with NBS, others argue that harms (i.e. over-medicalization, stigma, and undue stress) outweigh any potential benefits. This study provides a deeper understanding of engaging responsible research practices from the laboratory to the community.

1814F

Next Generation Sequencing of Pluripotent Stem Cell Lines: Ethical, Social and Policy Considerations. *R. Isasi.* Centre of Genomics and Policy, McGill University, Montreal, PQ, Canada.

Stem-cell genomics promises to improve our ability to prevent and treat disease by providing cells for organ transplantation and cell therapies. It will also enable the creation of successful model systems for drug discovery and contribute to the understanding of the processes of human cell differentiation for the treatment of several diseases including cancer. For instance, the use of next-generation sequencing (NGS) technologies in induced pluripotent stem cell (iPSCs) lines is expected to greatly contribute to the development of new testing methods for drug efficacy, toxicity and safety for individuals, thereby expediting progress towards personalized medicine. The challenges posed by stem-cell `omics' efforts are not constrained only to scientific hurdles, the field is also confronted by an array of ethical, social and policy concerns as pertains for example, informed consent, feedback of incidental findings, privacy and the governance of research. While, some of these concerns are not completely new, the old answers might not suffice given the scale of challenges. NGS methods are now routinely applied to iPSCs lines, allowing fine, detailed, genotypic information of the cell lines at high resolution. Given that such iPSCs are (often) derived from living individuals - including paediatric populations - are contemporary mechanisms for protecting the autonomy, privacy and confidentiality of donors sufficient? Are current governance procedures adequate? In an era of stem-cell genomics what is the appropriate role for regulatory bodies? This presentation will provide an overview of some key ethical issues surrounding applying next generation sequencing techniques to stem cell research. Issues surrounding informed consent, privacy and confidentiality, data security,feedback of research results and governance of research will be addressed.

1815W

Research Policy of the "Genome Science" Project in Japan. *J. Minari[1], T. Shirai[2], G. Yoshizawa[1], K. Okada[1], N. Yamamoto[1], K. Kato[1,3,4].* 1) Biomedical Ethics and Public Policy, Osaka University, Osaka, Japan; 2) Research Administration Office, Kyoto University, Kyoto, Japan; 3) Institute for Research in Humanities, Kyoto University, Kyoto, Japan; 4) Institute for Integrated Cell-Material Science (iCeMS), Kyoto University, Kyoto, Japan.

A new large-scale project, "Genome Science," started in Japan in 2010. It is 5-year project funded by the Ministry of Education, Culture, Sports, Science and Technology (MEXT). The aim of the project is to support the genome researchers requiring the advanced data. The project has three support programs: "Large-Scale Genome Information Production Program;" "Medical Genome Science Program;" and "Bioinformatics Analysis Program." These programs provide the integrated services of high-throughput DNA sequencing, gene expression profiling, epigenetic profiling, metagenome analysis and/or bioinformatic analysis. Among them, "Medical Genome Science Program" involves the use of human specimens and sequencing of the whole genome and/or the exome, and thus has to take into account various ethical, legal and social implications (ELSI). Our unit called "Research Unit for the ELSI of Genomics" is a part of the project. It was created to establish the governance of the human genome research. The research governance refers to a mechanism of scientific research conducted within the social context. We address ELSI of human genome research in the project under that vision. As the first step, we have designed a model informed consent document used in "Medical Genome Science Program". This process involved policy making of personal genome research, and naturally requires the consideration of key issues such as data sharing, return of results, withdrawal of consent, biobanking and the use of previously collected samples. To deal with these issues, we examined and analyzed the current situation in Japan, by collecting and comparing the informed consent documents utilized in Japan. Referring to these documents, we made the draft of our informed consent document through repeated discussion from multifaceted perspectives with executive members of the project. Currently, we are trying to share the policy of the informed consent document with other large genome projects in Japan. In the next stage, we are focusing on data sharing and release policy. Through the project, we accelerate the deposit of personal genomic data to national database in Japan such as DNA Data Bank of Japan (DDBJ) and National Bioscience Database Center (NBDC). This presentation will highlight our policy of informed consent and data sharing, experienced in "Genome Science" project.

1816F

Cultural Influences on Genetic Testing in East Asia. *H. Numabe[1, 2].* 1) Department of Mecial Ethics and Medical Genetics, Kyoto University Graduate School of Medicine, Kyoto, Kyoto, Japan; 2) Department of Clinical Genetics, Kyoto University Hospital, Kyoto, Kyoto, Japan.

In East Asian countries such as Japan, Korea, and China, genetic testing has been carried out using similar methods with accuracy comparable to western countries. However, the implementation of testing is influenced by various factors such as population policy, economic situation, and the medical system of each government, as well as the bioethical view of each individual. Especially, culture plays a substantial role in genetic medicine and reproductive medicine. It is thus imperative to take cultural influence into consideration when giving genetic counseling and genetic testing to patients and clients in Japan and in the rest of East Asia. We made the questionnaire survey of Japanese university students on genetic diagnoses, and reported the result at the ASHG Meeting in 2008. The questionnaire was consist of properties of the student, considerations to spiritual matters, acceptability of an artificial abortion, the time of the beginning of human life, and considerations to various genetic testing. In Japan, cceptability of genetic testing correlates closely with student's recognition of the time of the beginning of human life. Students who recognize the life start from the fertilization or within 15 days after fertilization are not acceptable to prenatal and pre-implantation tests. On the other hand, students who recognize the life start after 22 weeks of gestational age or after birth are acceptable to them. Acceptability of an artificial abortion has a similar tendency, but over 50% of students who recognize the life start from the fertilization or within 15 days after fertilization are acceptable to an artificial abortion. We planned the similar questionnaire survey in other East Asian countries. We make an interim report.

1817W

The Need for an ELSI Watch of Epigenetic Information. *E. Rial-Sebbag, A. Soulier, C. Delpierre.* UMR U 1027, Inserm, Université de Toulouse - Université Paul Sabatier Toulouse III, 37 allées Jules Guesde, 31073 Toulouse Cedex - France.

All questions relating to the various uses of Genetics at large have been envisaged with regards to their ethical, legal and social issues (ELSI) in particular for the production and utilization of genetics information. This information is usually seen as sensitive by law and requires a particular ethical and legal framework. Known about since the 60's, epigenetics is an innovative field of studies. It bridges the gap between two complementary influences on individual traits and characteristics: environment and genetics. New scientific findings indeed reveal how medical treatments, but also diet and behavior, can affect the expression of genes, that is to say the development and the health of an individual and also of his offspring. Depending on these characteristics it should have been easier to define and analyze the ELSI challenges of epigenetic information in the same way as genetic information. In this paper we make the hypothesis that this position cannot be relevant to this innovative field. Although these two sets of information can be considered as health and sensitive data with a strong familial impact and shared ELSI implications, we will discuss in this paper the following aspects which are totally different with regards to their ELSI challenges: cumulative nature of the risks (risks accumulate during life), targeted populations (vulnerable), equity in access to health care, medical actions (diagnosis, prevention or treatment), environment (social inequalities in health) and protection of privacy. For each of these points various pieces of existing legislation (Research law, health law) should apply as well as ethical principles (Justice, Social inequalities), (Rothstein and al. Nat. Rev. Genet. 2009 April; 10(04):224) but for some of these challenges no rules have been adopted yet. Hence, less developed than for genetic information, we will push for the implementation of an ELSI watch of epigenetic information at the very beginning of the development of this scientific knowledge. In particular, we will suggest taking into account the existence of causal chains linking the social to the biological in public policy and we will propose some points to consider for the development of adequate policies.

1818F

Pervasive Sequence Patents Cover the Entire Human Genome. *J.A. Rosenfeld[1,2], P. Zumbo[3,4], C.E. Mason[3,4,5].* 1) IST/Division of High Performance and Research Computing at the University of Medicine & Dentistry of New Jersey, 185 South Orange Avenue NJMS/C630, Newark, New Jersey, 07103, USA; 2) American Museum of Natural History, Sackler Institute for Comparative Genomics, Central Park West at 79th Street, New York, NY, 10024, USA; 3) Department of Physiology and Biophysics, Weill Medical College, Cornell University, New York, NY, 10065, USA; 4) HRH Prince Alwaleed Bin Talal Bin Abdulaziz Alsaud Institute for Computational Biomedicine, Weill Medical College, Cornell University, New York, NY 10065, USA; 5) The Information Society Project, Yale Law School, New Haven, CT, 06520, USA.

There is substantial uncertainty about the scope and eligibility for patents on genetic sequences, as evidenced by the litigation concerning patents held by Myriad Genetics for testing for cancer associated genes (BRCA1/BRCA2). Claims from the BRCA patents provide intellectual property on sequences as small as 15 nucleotides (15mers). Here, we use an analysis of the human genome to show that the “15mer-rule” is too broad. We observe that 100% of human genes have 15mers that match at least one other gene, with segments of the average gene matching 364 other genes. Additionally, when we examine the patent landscape, we find that between 21% and 100% of the genes in the human genome have been claimed in patents, depending upon the alignment stringency. This indicates that existing genes sequences, surprisingly, are continually being patented even after the human genome has become “prior art.” These data also suggest that current legal rulings around short, non-unique nucleotide sequences create extensive problems for patent law. Thus, a re-examination of existing patent claims, specifically by the Supreme Court, is essential to clarifying the law and to bringing personalized medicine forward.

1819W

The revised points of ethical guidelines for human genome research in Japan. *Z. Yamagata[1], K. Muto[2].* 1) Health Sciences, University of Yamanashi, Yamanashi, Japan; 2) The Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Ethical guidelines for human genome and gene analysis research in Japan were formulated in 2001, by three government ministries: the Ministry of Education, Culture, Sports, Science and Technology; the Ministry of Health, Labour and Welfare; and the Ministry of Economy, Trade and Industry. The present review of the Personal Information Protection Law has taken into consideration advances in genome research such as the implementation of studies involving large amounts of genomic information, diversification of the study design such as genome cohort studies, and the recent ability of sequencing genomic information expeditiously, which is attributable to the advent of next-generation sequencers. The main aspects reviewed are the use of existing samples, method of collection and distribution of resources, the drafting of informed consent so that it will also be applicable to future genome research, and the disclosure of genetic information. With respect to the use of existing samples, institutions that do not possess a correspondence table can handle samples anonymized in a linkable fashion in the same way that they handle those anonymized in a non-linkable fashion. In terms of collection and sale of samples, requirements and administrative procedures have been revised to enable the more effective use of existing samples and other resources. Additional information can be attached to the description of these procedures by obliging organizations (biobank institutions) that collect samples from other research institutions and sell them to different research institutions. These organizations supply samples to user institutions in the linkable anonymized form. Regarding the disclosure of genetic information, the revisions adhere to the basic principle of disclosure with respect to the Personal Information Protection Law, but some disclosure-related issues remain unresolved. New regulations have also been established for safety management measures related to the handling of genetic information, compliance rules for the outsourcing of genetic research, and education and training for researchers and members of ethical review boards.

1820F

Does evidence justify the use of multigene sequencing panels for rare genetic disorders? *D. Allingham-Hawkins, A. Lea, L. Cushman-Spock, L. Wieselquist, S. Levine.* Hayes Inc, Lansdale, PA.

Objective: To assess the evidence behind the use of multigene panels for the diagnosis of rare genetic disorders. Context: Next generation sequencing technologies are advancing at a rapid rate, allowing the generation of a large amount of data in a relatively short period of time without expending significantly more precious laboratory resources. Many rare genetic disorders are genetically heterogeneous with more than one, and sometimes many, different genes contributing to the clinical presentation of the disease. From a laboratory perspective, inclusion of more genes in a testing panel does not present a technical challenge but is there evidence that testing more genes impacts patient outcomes? Methods: Proprietary methodology that combines the ACCE (Analytical validity, Clinical validity, Clinical utility, Ethical, legal and social implications) model for genetic test evaluations with internationally accepted health technology assessment methodology was used. Conclusions were based on published peer-reviewed scientific literature only. Results: The published evidence behind 8 multigene panels for rare genetic conditions including cardiomyopathy, neonatal jaundice and nonsyndromic hearing loss, among others was evaluated. The number of genes tested in these panels ranged from 5 to 66. In some cases (e.g. familial dilated cardiomyopathy), panels offered by different labs had little overlap with respect to the genes included, suggesting a lack of agreement between labs regarding the appropriate genes to test. For some cases, evidence suggested clinical benefit for testing one or a few genes in a panel. However, studies that evaluated the impact of the full panel on patient care were rare and, in most cases, nonexistent. Conclusions: There is currently little or no published scientific evidence of the clinical validity or clinical utility of most multigene panels. This suggests that the development of multigene panels is being driven by technology and laboratory considerations rather than clinical need or patient benefit. Studies are needed to evaluate the clinical impact of multigene panels before their use in patient care can be justified.

The student-athlete's knowledge, behaviors, concerns and perceptions in regards to mandatory sickle cell trait testing. *N.E. Thompson[1], B.W. Harrison[1], F. Ampy[2], R.F. Murray, Jr.[1].* 1) Howard University, Department of Pediatrics and Child Health, Division of Genetics, Washington, DC; 2) Howard University, Department of Biology, Washington, DC.

PURPOSE: Nearly 20 student-athlete deaths have been associated with sickle cell trait (SCT), a condition occurring among 1 in 12 African-Americans. The National Collegiate Athletic Association (NCAA) mandated that all Division I collegiate athletes participate in genetic testing for SCT, where 40.9% of the student-athletes are African-American. Traditionally, genetic counseling is recommended before/after genetic testing, and is imperative for increasing understanding, allowing for misconceptions to be addressed, and should be incorporated into the NCAA's mandate. We hypothesized that student-athlete's knowledge, behaviors, concerns and perceptions regarding SCT would be factors in determining the need for a standardized protocol for collegiate institutions; addressing stigmas, promoting education and offering genetic counseling. **METHODS**: A 57-item questionnaire was developed and administered to 91 student-athletes recruited before/after team practices, at a student-athlete dormitory, and during SCT testing. **RESULTS**: Significantly, 87.91% of the student-athletes expressed poor knowledge of SCT and 91.2% expressed a moderate or high interest in receiving genetic counseling/education before SCT testing. Overall, they expressed moderate concerns of discrimination and the majority of student-athletes chose not to discuss their SCT status. **CONCLUSION**: A standardized SCT testing protocol is needed due to the lack of SCT knowledge, the high interest in genetic counseling, the concerns of discrimination and lack of uniformity in regards to disclosure. This protocol will assist student-athletes in making informed decisions, while giving coaches/athletic staff the knowledge to protect their student-athletes' well-being. The field of genetic counseling has potential for growth and participation in the process of integrating genetic testing into collegiate sports.

Primary Care Patients' Experience of and Reactions to Direct-to-Consumer Genomic Testing: A longitudinal qualitative study. *K. Wasson[1], T.N. Sanders[1], N.S. Hogan[2], S. Cherny[4], K.J. Helzlsouer[3].* 1) Neiswanger Institute for Bioethics, Loyola University Chicago, Maywood, IL; 2) Niehoff School of Nursing, Loyola University Chicago, Maywood, IL; 3) The Prevention and Research Center, Mercy Medical Center, Baltimore, MD; 4) Loyola University Health System, Maywood, IL.

Introduction: Direct-to-consumer genomic testing (DTCGT) has generated debate due to the ethical, legal, and social implications of receiving genomic information of uncertain validity and clinical utility, and the ability to obtain it without a qualified health professional. Little data exists on primary care patients' experience of DTCGT. This qualitative study examined the views, attitudes and decision-making considerations of primary care patients. Methods: Twenty patients were recruited from a primary care clinic and offered DTCGT. Participants were interviewed at four points: pre-test, upon receiving results, and three and twelve months post-test. Results were explained by a genetic counselor. Topics included their decision to test, expectations, concerns, with whom they discussed testing, reaction to results, and the impact of testing. Interviews were audio taped and transcribed verbatim. The data were collected and analyzed simultaneously using grounded theory and constant comparison methods. Results: Participants had a mean age of 49.5 years (range 29–63) and were 60% female, 50% African American, all were high school graduates and 30% were college graduates. Five key categories emerged. 1) Motivations for testing included seeking knowledge about oneself, disease prevention or intervention measures, and altruism. 2)Concerns were limited to fear of misuse, privacy breaches, and test accuracy. 3)Expectations were few and many participants were unsure what to expect; others expected disease risk information and hoped for no “bad” results. 4)Responses to testing were mostly positive or neutral. 5)Many participants noted no impact of DCTGT over time. A few expressed increased awareness or reassurance about their health status and a few made positive health behavior changes. More participants predicted they would talk to their physicians than did after receiving results. The majority of participants were pleased to have undergone DTCGT and would recommend it to others. Conclusions: Results are mixed and suggest that DTCGT may not have the predicted burdensome impact on consumers or physicians as many participants reported no impact of results and did not talk to their doctor post-results. A few made positive health behavior changes post-results in light of “good” results. False reassurance remains a concern for those who were relieved by their “low risk” results due to the developing nature and accuracy of DTCGT.

1823W

Whole genome sequencing: will it destroy newborn screening? *C. Allen, D. Avard, B.M. Knoppers.* Center of Genomics and Policy, McGill Univ & Génome Québec Innovation Ctr, Montreal, Canada.

Introduction: As Francis Collins recently predicted, whole genome sequencing (WGS) will almost certainly become part of newborn screening (NBS) in the near future. A 2008 report by the President's Council on Bioethics describes the use of WGS in NBS as an appropriate and inevitable end point in the development of personalized medicine, while the NHGRI and the NICHD are preparing to provide $25 million to fund studies examining this practice. However, in March the ACMG published a report stating that WGS “should not be used as a first-tier approach for newborn screening”. To reconcile these two divergent perspectives, an analytical review of the legal and ethical issues associated with the use of WGS in NBS is needed. Methods: We performed a comprehensive, international review of the literature, guidelines and policies on the use of WGS in NBS. Content analysis identified arguments for and against this prospect, based for example on normative principles, psychological harms and benefits, and the appropriate roles of parents, professionals, and the state. Results: Those who promote the use WGS as a part of NBS programs do so because it will provide physicians with a powerful tool for delivering early individualized disease prevention initiatives, and researchers with an extended opportunity to study the prevalence and etiology of many diseases. It can also help families both with caring for their current children, and in reproductive decision-making. However, the use of WGS in NBS will exacerbate existing legal and ethical issues, and pose several novel ones as well. As WGS vastly increases the complexity and sheer amount of data arising from NBS, the difficulties associated with financing, consent and the notification process, the availability of counseling, educating parents, and providing follow-up care will increase significantly. Challenges unique to genetic screening, such as whether parents should be informed of a child's carrier status for late-onset genetic disease, will also arise. While parents often push for the expansion of screening to maximize information available, many argue that this violates children's future autonomy, limiting their choices as adults and depriving them of an `open future'. Conclusion: WGS will be implemented in NBS within the next decade. Before this occurs, it is imperative to develop guidelines based on empirical evidence to ensure that the advantages of this practice outweigh the risks.

1824F

Patient and provider perspectives on personalized genomic medicine: Qualitative sub-study of a multicenter feasibility study of genomic sequencing in advanced cancer patients. *J.P. Bytautas[1], F.A. Miller[1,2], R.Z. Hayeems[1], S. Ernst[3], H. Hirte[4], S. Hotte[4], A. Oza[5], A. Razak[5], S. Welch[3], E. Winquist[3], P.L. Bedard[5], J. Dancey[6], L.L. Siu[5].* 1) Health Policy, Management and Evaluation, University of Toronto, Toronto, Ontario, Canada; 2) Joint Centre for Bioethics, University of Toronto, Toronto, Ontario, Canada; 3) London Health Sciences Centre, London, Ontario, Canada; 4) Juravinski Cancer Centre, Hamilton, Ontario, Canada; 5) Princess Margaret Hospital, Toronto, Ontario, Canada; 6) Ontario Institute for Cancer Research, Toronto, Ontario, Canada.

Background: In oncology, personalized genome medicine (PGM) can identify somatic mutations in tumours predictive of therapeutic response and variants of uncertain significance, as well as germline mutations. Expectations for PGM are high but evidence for benefit is limited and clinical trials are complicated by end of life hopes and vulnerabilities. Patient expectations and the perspectives of physicians offering PGM should be assessed. **Methods:** We explored expectations and perspectives of patients and physicians involved in a multicenter pilot study evaluating the feasibility and value of high throughput sequencing of metastatic tumor biopsies compared to traditional genotyping in patients with advanced solid malignancies. Eligible patients were over 18, conversant in English, accessible for in-person interviews with exclusions for poor performance status. Eligible physicians were oncologist investigators who recruited patients to the pilot study. With informed consent, we conducted open-ended, semi-structured interviews. Transcripts were analyzed for thematic patterns with techniques of constant comparison. **Results:** 25 of 55 eligible patients completed interviews; most exclusions were for poor health (13). 13 of 17 physicians completed interviews. Patients were hopeful regarding new and targeted treatments; for some, an identified mutation led to trial access but others were disappointed by non-findings or limited access. Patients were willing to receive incidental inherited risk information; it was perceived as either burdensome given disease stage or inconsequential given faced-challenges. Physicians endorsed these technologies as cutting edge but were mindful of elevated patient expectations and the shortage of targeted agents in trials. Physicians felt consent and counselling processes could sufficiently mitigate challenges related to incidental findings. **Conclusions:** Our results suggest that patient and physician perspectives were conditioned by the late stage cancer context. Both groups were enthusiastic about PGM but acknowledged challenges. The potential to generate inherited risk information may pose more psychosocial challenges than physicians anticipate. Information and decision tools are needed to support patients in making decisions about participating in PGM research and receiving inherited risk information.

Consumer Genomics: Motivations and Intentions. *R.C. Green[1, 2], J. Mountain[3], A. Kiefer[3], T. Moreno[4], E. MacBean[4], S.S. Kalia[1], J.S. Roberts[5], the PGen Study group.* 1) Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) 23andMe, Inc., Mountain View, CA; 4) Pathway Genomics Corporation, San Diego, CA; 5) University of Michigan School of Public Health, Ann Arbor, MI.

Consumer genomics is increasingly being used to provide individuals with personal health-related information. Few data exist, however, regarding the characteristics of such consumers; their motivations for seeking genomic information; and factors involved in their decision-making. We report here on baseline data from the Impact of Personal Genomics (PGen) Study, a longitudinal survey of consumers of two leading personal genomics companies, Pathway Genomics and 23andMe. 1288 participants completed an online survey before receiving their personal genome results. Survey items assessed sociodemographic characteristics, motivations for and attitudes toward testing, and plans for use of personal genome information. The average age of respondents was 47.7 years (range: 19–94). A majority was female (60.5%), Caucasian (83.4%), had at least a college degree (77.0%), and had biological children (52.7%). 54.9% reported being in very good or excellent health. Nearly half were very motivated to pursue testing by a desire to improve their health (45.6%) and/or to create a plan for the future (45.0%). 36.1% indicated limited information about their family health history as a very important factor. 71.7% of participants reported being very interested in their risk of diseases, compared to 74.2% who were very interested in ancestry results. Respondents were most interested in learning their genetic risks for heart disease (67.8%), breast cancer (67.2% among females), and Alzheimer's disease (66.0%). 37.3% reported that they did not consider the possibility of unwanted results before ordering the testing, and 18.4% reportedly did not consider the predictive value of the results. 60.5% of respondents indicated that they strongly trusted the testing company to use their genetic information only for purposes to which they consented. Over half (57.6%) of participants plan to discuss their test results with their primary care provider, while only 6.1% plan to share their results with a genetics specialist. These data suggest that certain sociodemographic groups are more likely to purchase consumer genomics services and that ancestry information may be of equal interest as health-related information. Subsequent PGen surveys will track consumers' psychological and behavioral responses to their personal genome results.

1826F

The Ethical, Legal and Social Implications Program: Impact on Federal Policy. *D. Mathews, B. Drehman.* Berman Institute of Bioethics, Johns Hopkins Univ, Baltimore, MD.

The Human Genome Project (HGP) was launched in 1990, with the goal of mapping the entire human genome. Beyond the scientific issues the project would face, it was recognized that the HGP would also raise many ethical, legal and social issues. In an effort to address this concern, the Ethical, Legal and Social Implications (ELSI) Research Program was created to facilitate research to address the broader societal issues raised by the emerging science. One of the ELSI Program's major goals from the start has been to inform genetics-related policy, be it federal, state, professional or beyond. However, there has never been a systematic, empirical attempt to evaluate the success of the ELSI Program on this goal: this project is a first attempt to do so. Given that different types or levels of policy have different pathways for identifying issues ripe for policymaking, gathering information and formulating policy, this pilot project has focused on the impact of the ELSI Program on federal policymaking. We analyze the products (e.g., manuscripts, reports) of ELSI funding from 1990 through 2011 and look for evidence of these products' influence in publically available federal policy documents. The products of ELSI-funded projects, as listed in multiple public resources, were collected and coded for basic characteristics (e.g., author, title) and content. Publicly available federal materials that may document impact of the ELSI program (e.g., materials from Congress and federal advisory committees) were likewise collected and coded. We then look for evidence of interactions between these two bodies of data. We also use these data to track the focus of ELSI-funded products over time, for example, from fairly broad surveys of the ELSI issues raised by the HGP, which are highly represented in the early years of the Program, to studies on specific aspects of genetic research, which make up a major part of the ELSI-funded products over the past five to seven years. A primary goal of the ELSI Program has been to fund studies that will ultimately inform genetic-related policy. Further, the ELSI Program is used as a model for other areas of emerging science, and is federally funded. It is arguably in the interest of the public, scientists, the bioethics community and the ELSI Program itself, to understand the nature of the body of work the Program has funded and to establish the degree to which that body of work has been designed to and has in fact influenced policy.

1827W

Public perspectives regarding personalized medicine and genomic risk profiling within colorectal cancer screening. *S.G. Nicholls[1], B.J. Wilson[1], S. Craigie[1], H. Etchegary[2], D. Castle[3], J.C. Carroll[4], B.K. Potter[1], L. Lemyre[5], J. Little[1, 6] on behalf of the CIHR Emerging Team in Genomics in Screening.* 1) Epidemiology and Community Medicine, University of Ottawa, Ottawa, Ontario, Canada; 2) Clinical Epidemiology, Memorial University, Newfoundland, Canada; 3) ESRC Innogen Centre, University of Edinburgh, UK; 4) Department of Family Medicine, Mount Sinai Hospital, University of Toronto; 5) School of Psychology & Institute of Population Health, University of Ottawa, Canada; 6) Canada Research Chair in Human Genome Epidemiology.

Introduction: Colorectal cancer (CRC) is a leading cause of cancer death, yet is highly treatable if identified early. Screening programs now operate in a number of jurisdictions, principally using a fecal occult blood test (FOBT) as an initial (first-line) screening measure. Of the total number of CRC cases 15–20%; are thought to be due to multiple low penetrance variants. The inclusion of low penetrance variants in population-based genomic risk profiling ("genomic profiling") may provide more accurate risk information, potentially leading to better risk estimates. This strategy has been proposed as a way to more appropriately triage patients to more personalized types and intensities of screening and follow-up. However, the use of genomic profiling within standard screening depends on public attitudes and consequently it is important to engage publics and respond to concerns when considering these developments. Aims: To identify issues raised by the inclusion of genomic profiling into first-line screening tests for CRC in a population for whom CRC screening is routinely offered. Methods: Qualitative discussion workshops with Canadian residents of Ottawa, Ontario (n=46) and St John's, Newfoundland (n=74) aged 50 years or over. Results: Participants were largely supportive of the move to include genomic risk-profiling within existing CRC screening. Benefits were largely seen to be health related: the potential for early intervention, prevention, and closer monitoring. However, several important issues emerged relating to test validity, cost, and access to results. Discussion: Not only are these generic issues that one can ask about any new intervention, particularly when they are implemented in a publicly funded health system with finite resources, but they are consistent with the ACCE Framework for evaluation of genetic tests, with analytic and clinical validity together with clinical utility uppermost in participants minds. Moreover, access to results - particularly by insurance companies - was clearly articulated as an area of concern. These results indicate that whilst supporting the inclusion of genomic profiling into screening for colorectal cancer, the public see important issues and readily engage with concepts, if not terminology, employed by healthcare professionals when evaluating new health technologies.

1828F

Pursuing pharmacogenomic testing within a nonprofit healthcare system: a comparison of stakeholders' perspectives. *S.M. Fullerton[1], S.B. Trinidad[1], J.D. Ralston[2], J.T. Tufano[3], G.P. Jarvik[4], E.B. Larson[2].* 1) Bioethics & Humanities, University of Washington, Seattle, WA; 2) Group Health Research Institute, Group Health Cooperative, Seattle, WA; 3) Biomedical Informatics & Medical Education, University of Washington, Seattle, WA; 4) Medical Genetics, University of Washington, Seattle, WA.

The second phase of the Electronic Medical Records and Genomics (eMERGE) Network focuses on the incorporation of genomic research findings into clinical research and ongoing clinical care. The integration of genomic information into routine clinical delivery will require careful attention to health system management, the development and adoption of defined clinical decision support tools, and patient and physician education. We therefore conducted a comprehensive needs assessment within the setting of the Group Health Cooperative (GHC), a consumer-governed nonprofit health care system that coordinates care and coverage in the Pacific Northwest. Our qualitative research focused on three major classes of stakeholders: (1) select clinical leadership with responsibilities relevant to health system adoption (n=13); (2) patients, including those who do and do not regularly take prescription medications (n=50); and (3) physicians, including primary care doctors and specialists (n=20). Interviews and focus groups were designed to explore general attitudes toward the use of genomic information in clinical care, as well as the more specific possibility of using genomic information to inform drug prescribing (pharmacogenomics). While there was much interest, across all stakeholder categories, in the use of genomic information to identify better targeted treatments and minimize side-effects, numerous ethical and logistical considerations were also raised. Foremost among these were concerns that widespread genetic and/or genomic testing might have adverse effects on patient-physician interactions. The development of clinical decision support tools that facilitate shared decision-making were identified as a high priority for the next phase of the project's research.

Public preferences for the use of email and Internet communication in large-scale genetic and biobank research. *J. Murphy Bollinger, R. Dvoskin, K. Kreger, D. Kaufman.* Genetics and Public Policy Center, Berman Institute of Bioethics, Johns Hopkins University, Washington, DC.

The success of genetic biobank research depends on establishing and maintaining effective communication with participants that ensures transparency about study goals and procedures. The ability to efficiently contact participants can facilitate recruitment; consent; education; scheduling; data collection; delivery of study findings; and collecting feedback. The use of email and the Internet could effectively address many of these challenges. Few data are available, however, on public acceptance of Web-based tools for these purposes, and the recruitment biases that might result. We surveyed 3,061 U.S. adults about the use of online communication for seven research tasks. **Methods**: We surveyed a representative sample of U.S. residents (in English or Spanish) about the use of a password-protected website and email in a proposed national cohort study. We compared responses among various demographic groups, including social networkers (SNs)—defined as Facebook users who had posted to their account in the past week. **Results**: Among survey respondents, 56% were Facebook members and 30% were social networkers (SNs). A significantly higher percentage of younger participants, women, and people who took the survey in English were SNs. Overall, email was viewed as most acceptable for administrative tasks, including scheduling appointments (42% supported) and sending survey reminders (60%). Majorities supported the use of a password-protected website for receiving general (56%) and individual findings (52%), completing surveys (51%), updating health status (57%), and learning which researchers were using the data (51%). More respondents opposed the use of the Internet to relay individual results (29%) and update participants' health status (22%) than opposed uses for other tasks. More education, higher household income, and social networking were associated with higher support for the use of online communication for all tasks. Respondents who agreed that “I trust the study to protect my privacy” were more likely to accept use of the Web and email for all tasks. **Discussion**: While 7 in 10 participants supported email or Web use for the tasks tested, studies that exclusively use these tools may alienate older and lower-income participants. The higher acceptance among social networkers, coupled with the growth of social networking, suggests that acceptance of online research communications may increase, especially for tasks that do not involve personal health information.

1830F

Public attitudes towards consumer genetics in Japan, South Korea and Taiwan. *K. Muto[1,2], M. Sato[2], H. Hong[1,2], C. Chang[1].* 1) Dept Pub Policy, IMS, Univ Tokyo, Tokyo, Japan; 2) Graduate School of Frontier Sciences, Univ Tokyo, Tokyo, Japan.

Background: DTC (direct-to-consumer) genetic testing for health purposes have been featured in USA and Europe and stimulating discussions for regulation have been evolved. In contrast, several Shanghai-based companies stated to advertise in Japan to sell DTC genetic tests for non-health purposes, such as tests advertised to identify genes related to an individual's talent, character traits and aptitude. Purpose: We have explored sociocultural beliefs and eugenic thoughts behind these so-called `recreational testings` in East Asia. The same surveys in South Korea and Taiwan have been in progress. Methods: To address broad ethical, legal and social implications arising from such tests, we have conducted a web-based self-administered questionnaires among Japan, South Korea and Taiwan. Results: We have obtained 14,718 responses from Japanese citizens. Response rate was 37%. Results: Advertisement is commonly observed in East Asia though some of the tests have been banned in South Korea. Our survey shows that 3.1% of Japanese respondents has purchased DTC genetic tests, and 86.7% of them hasn't recognized such tests. They show higher interests towards tests for health purposes (23.8–47.2%) than non-health purposes (9.8–18.7%). Younger generation shows higher interests toward DTC genetic tests for their children and partners. Discussions: The trend of our survey shows the same trend from our postal survey conducted in 2007 and 2011. Many parents are deeply concerned about providing education for their children and it's difficult to intervention parental decision to purchase such tests.

1831W

Japanese Networkers ` attitudes toward Personal Genome Services. *T. Kido[1], M. Kawashima[2].* 1) Rikengenesis, Tokyo, Japan; 2) Tokyo University, Tokyo, Japan.

Purpose: This study explores potential early adapters of personal genome services in Japan, focusing on expectations related to the several kinds of future personal genome services. Methods: An online survey of 4,343 Japanese Internet users was conducted to assess 1) use and interest in personal genome services; 2) attitudes toward several kinds of personal genome services; 3) expectations for future personal genome services. Comparative analyses with past research on U.S social networkers and Japanese general populations were conducted to characterize Japanese networkers' attitudes on personal genome services. Results: In our research samples, 89.0% of respondents used Internet everyday, 87.5% registered the social network services (SNS), 16.6% used SNS every day. 1.5% used Personal Genome Testing (PGT) (six percent in U.S), 76.8% did not know PGT at all. 58.2% of responders would consider using PGT on life style related diseases or cancers, 50.8 % consider it on intelligence, and 48.7 % consider it on personality. Conclusions: Although the percentage of usage of PGT in Japan is lower than that of U.S, around 50 % of Japanese Networkers have interests to use it. The networkers seem to have more positive attitudes than general Japanese populations, especially on non-medical personal genome services such as applications on intelligence and personality. More detailed results and discussion will be reported in this poster presentation.

1832F

Genetic risk predictions - Attitude of the Estonian public. *L. Leitsalu-Moynihan[1,2], A. Allik[1], M.L. Tammesoo[1], A. Metspalu[1,2].* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia.

The Estonian Genome Center of the University of Tartu (EGCUT) is a research institute with a population-based biobank that includes biological samples and comprehensive health information on over 51,000 adults. The three main objectives of the center are to promote the development of genetic research, to collect information on the health of the Estonian population and genetic information concerning the Estonian population, and to use the results of genetic research to improve public health. In the coming years the EGCUT will start providing feedback to the participants on their personalized risks predictions, with the pilot project starting in the fall of 2012. Besides the necessary developments in genomics research and policy making, it is crucial to educate the physicians as well as the public in order to facilitate effective application of genomic information in clinical care. In order to investigate the public's standpoints the EGCUT conducted a survey via TNS Emor polling agency. The sample included 1000 Estonian residents between the ages of 15–74 and was composed to be proportional to the Estonian population structure with respect to age, gender, region, and nationality. In order to get an idea what the potential impact of such personalized risk predictions would be and how it might differ depending on the gender and age of the individual we used Chi-squared test and two-sample test to analyze the results of the survey. Overall, women and younger age groups were significantly more likely to change their health behavior according to the physicians' recommendations, and even more likely so if genetic information would be considered. The results also indicate that there is a disconnect between the perception of healthy behavior and the actual health behavior of the individuals. The results should be considered when educating the physicians on communicating risk predictions.

Attitude change for four years toward genetic testing of children for common disease risk in Japan. *I. Ishiyama[1,2], K. Muto[3], A. Tamakoshi[4], T. Maeda[5], A. Nagai[1], Z. Yamagata[1].* 1) Department of Health Sciences, School of Medicine, University of Yamanashi, Yamanashi, Japan; 2) Teikyo-Gakuen Junior College, Yamanashi, Japan; 3) The Institute of Medical Science, University of Tokyo, Tokyo, Japan; 4) Department of Public Health, Aichi Medical University School of Medicine, Aichi, Japan; 5) The Institute of Statistical Mathematics, Tokyo, Japan.

[Aim] The swift pace of the development of genetic testing for common disease risk raises expectations and concerns, in the case of minors in particular. The aim of this study was to assess the four-year attitude change of Japanese general public toward genetic testing of children for common diseases which will be able to be prevented or controlled, and to explore factors related to the change, by comparing two nationwide opinion surveys conducted in 2005 and 2009. [Methods] In each survey, 4,000 people (age, 20–69) were selected from the Japanese general population by a stratified two-phase sampling method. They were queried about the following topics in a mail survey: attitudes toward genetic testing for disease susceptibilities of children for common diseases, interest in medical genomic studies, belief in science, level of genomic literacy, images of the genomic studies related to medicine (using SD method), and awareness of the benefits and risks of medical genomic studies. The four-year attitude change and the factors related to the change were examined using logistic regression models. [Results] The response rate was 54.3% (2,171/4,000) in 2005; and 52.5% (2,009/4,000) in 2009. The genetic testing for disease susceptibilities of children for common diseases was favored by 55.5% people in 2005; and 58.8% people in 2009. A difference in the attitudes was observed. The interest in medical genomic studies was increased; belief of "scientific development has more advantage than disadvantage" was increased; the average score of genomic literacy became lower for four years. The positive images toward the medical genomic studies, such as "Good", "Certain", "Like", and "Not scary" were increased. Awareness of the risks such as medical genomic studies may "breed discrimination based on disease or disorder" and "have unexpected harmful effect" were decreased. Interest in medical genomic studies, belief in science, positive images and awareness of risks were significantly related to favorable attitudes in each survey. It was suggested that interest, belief, images (changed positively) and awareness of risks (changed negatively) were the factors related to the outcome of positive attitude change toward genetic testing for children. With the level of public acceptance of genetic testing increases, it will become crucial for peoples to make sense of children's right to autonomy and possible risks associated with genetic testing.

African-Americans in South Florida's Perceptions about Genetic Research Participation: Opportunities and Barriers. *J.M. Lee[1], M. Gavier[1], S.E. Hahn[1], L. Adams[1], D.A. Caldwell[1], K.G. Murphy[1], C. Jean[1], M.A. Pericak-Vance[1,2].* 1) University of Miami, Miller School of Medicine, John P. Hussman Institute for Human Genomics, Miami, FL; 2) University of Miami, Miller School of Medicine, Dr. John T. Macdonald Foundation Department of Human Genetics, Miami, FL.

Diverse representation in genomics research is imperative to ensure that the translation of findings into genomic medicine leads to health equity. Unfortunately, African Americans (AA) remain underrepresented in genetic research. Although strides have been made to increase participation of diverse groups in genomic research, the factors that motivate and inhibit participation still merit continued exploration. Previous qualitative research has identified that community partnership and the utilization of culture specific recruitment strategies is paramount to increasing participation in genomic research (e.g., Johnson, 2011; Corbie-Smith, 1999). South Florida's AA community is diverse and includes individuals of Caribbean ancestry with potentially unique cultural and community needs. The goal of this research was to identify attitudes and beliefs that influence participation in genomic research among AA in South Florida using a focus group methodology. Focus group participants were recruited from South Florida (Miami-Dade/Broward Counties). The following areas were explored through a structured question guide: 1) Access to health information and knowledge about genetic research, 2) Perceptions and attitudes regarding genetic research, 3) Cultural motivators and barriers to participation in genetic research, 4) Effective communication and outreach strategies. Six focus groups were completed by racially-matched facilitators. One group was dropped due to ascertainment bias, leaving five groups for analysis. A total of 45 participants (16 male, 29 female) participated in the groups. Preliminary analysis revealed several barriers to genetics research participation including: limited knowledge about genetics, fears of being incidentally diagnosed with a disease, mistrust of the intent of research, and economic barriers to participation (e.g., taking off work to participate is prohibitive). A number of strategies were identified including: matching the appropriate advertising to the individual, holding community meetings about health related topics, and using doctors and family elders as messengers regarding research studies. Content from the groups will be analyzed in detail to identify overlapping and unique themes related to this community in comparison with extant research on this topic. However, preliminary analysis supports the need to vary and tailor research recruitment strategies not only to the culture and community of interest, but to the individual.

1835W

Unexpected results in biobank research: Experiences of information delivery and direction to health care after detection of mutations leading to long QT syndrome. *H. Kaariainen[1], E. Kujala[2], P. Alha[1], V. Salomaa[1], S. Koskinen[1], H. Swan[3], A. Haukkala[2].* 1) National Institute for Health and Welfare, Helsinki, Finland; 2) Dpt of Social Research, University of Helsinki, Helsinki, Finland; 3) Dpt of Cardiology, Helsinki University Hospital, Helsinki, Finland.

During 2000–2001 a large Finnish population based cohort Terveys 2000 (Health 2000) including 6334 subjects (aged ≥ 30) was collected for public health studies, including relationships between genes, environment and disease. As some of the subjects were found to have mutations for heritable long QT syndrome, it was decided to inform them about these results. The experiences of the process of information delivery and directing the subjects to health care services were examined by sending a questionnaire to all 27 subjects who were found to have one of four mutations for long QT syndrome and interviewing 5 of them. Of the 17 respondents, 16 had experienced the process of returning the results as mainly positive and useful for them, while one had experienced this unexpected result negatively due to concerns related to informing children. All participants felt that genetic results should be reported back to subjects. The participants had received information on long QT syndrome and its inheritance by a nurse of the cardiology unit. Even though genetic counseling had not been offered, 15 of them reported that they had been sufficiently informed about the disease and its inheritance. The 17 respondents had 35 children altogether. They reported that they had informed all the children, except one, still a minor, about the genetic condition. Detailed results from the questionnaire study and the interview will be presented. Biobank studies raise several ethical concerns including the question of delivering genetic results to study subjects. This was one of the first occasions where participants in a large-scale population-based study were informed about a genetic finding and their experiences were studied. Despite of the long interval between giving the sample and receiving the result, subjects thought positively about the procedure. Subjects' main wish for future studies was that there should be a contact person for later questions and concerns relating to the genetic finding.

1836F

The Gene Partnership: A model for pediatric genetic repositories in the age of the Incidentalome. *I.A. Holm[1,2], C.M. Clinton[1], S.K. Savage[1], P.L. Taylor[2,4], K.D. Mandl[2,3,4], J.P. Bickel[2,3,4], D.J. Nigrin[2,3,4], I.S. Kohane[2,3,4], D.M. Margulies[1,2,3,4], L.M. Kunkel[1,2].* 1) Program in Genomics, Boston Children's Hospital, Boston, MA; 2) Department of Pediatrics, Harvard Medical School, Boston, MA; 3) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 4) Children's Hospital Informatics Program at the Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA.

In 2007 Kohane et al. defined a new "collaborative clinical research regime" called the Informed Cohort. The Informed Cohort is defined mainly by "the dynamic quality of the subjects' changing involvement over time," which translates into the ability for researchers to contact participants on an ongoing basis, both as necessary and as based on participant-expressed preferences. This paradigm allows participants to be mutual partners in research rather than passive donors of material. We have established the Informed Cohort at Boston Children's Hospital by creating a project called the Gene Partnership. The Gene Partnership consists of a large de-identified repository of genetic and health information and an established communication tool called a personally-controlled health record, which encourages communication and collaboration between researchers and participants, including the dissemination of individualized research results. Participants are offered the opportunity to opt-in to results return. 94% of our participants have requested to receive research results, 5% declining results return, and 1% have not confirmed their choice. The Gene Partnership allows parents to grant adolescent access to their child who is 13 years of age or older so they may also engage in the result return process. Even with the wide adoption of the feedback process, parents of adolescent participants were most likely to deny access to their adolescent children, with 70% of them declining access. Many factors influence this decision from developmental ability to family dynamics. We note that establishing this type of structure in a pediatric setting yields a number of challenges, mainly from an ethical perspective of informed consent and return of research results. Despite these complexities, we argue that this is the future of repository design, as it engages the participant community and enables research staff to manage the intricacy of incidental and research results that will certainly arise from genome-wide association studies.

1837W

The Medical College of Wisconsin Program in Genomics and Ethics: An empirical bioethics venture. *K.A. Strong, T. May, K.L. Zusevics, A.R. Derse.* Center for Bioethics and Medical Humanities, Medical College of Wisconsin, Milwaukee, WI.

In 2010 the Medical College of Wisconsin utilized genome sequencing to diagnose a six-year-old boy's mysterious digestive disease, enabling a life-saving bone marrow transplant and representing the first documented clinical application of whole genome sequencing (WGS). The clinical application of WGS will continue to grow as the technology becomes more efficient, the cost of testing decreases and the potential for WGS to guide treatment becomes more established. In preparation for this increase in clinical use of WGS, the Program of Genomics and Ethics has been established at the Center for Bioethics and Medical Humanities at the Medical College of Wisconsin (MCW). An aim of this program is to bridge the gap between the clinical application of WGS and its ethical implications. Ethical discourse in relation to genetic testing in general tends toward psychological harm/benefit arguments, impacts on family relationships, social discrimination potentiality, and influences on autonomy (particularly in the case of testing minors). Concerns about WGS encompass all of the above, but given the inherent uncertainties regarding potential results, also relate to difficulties around traditional concepts of informed consent, the meaning and disclosure of incidental findings and the impact those results may have on patients and their families. Whilst traditional normative philosophical analysis is important in identifying and addressing the ethical questions, this Program will also utilize empirical methods (eg. interviews, surveys, focus groups) to explore the attitudes, experiences, values and processes involved in decision-making that may differ from normative expectations and provide additional guidance regarding clinical practice. The employment of `empirical bioethics' in this manner can be particularly helpful when exploring ethically contentious technologies where concerns regarding those technologies involve empirically testable claims.

1838F

Evaluation of a scalable method for returning results and genetic findings from genomic research to research participants. *J.Y. Tung, S. Wu, B.T. Naughton, J.L. Mountain.* 23andMe, Inc, Mountain View, CA.

Discussions around the return of research results and incidental findings to research participants have come to the forefront recently, in particular as genome-wide sequencing becomes more common. Studies have shown that most research participants who have donated DNA samples to research would like to receive individual results from studies performed using their samples. While multiple groups have published recommendations on how best to return results, very few research groups have actually returned such data. 23andMe, a personal genomics company, not only provides a service that interprets genetic information for non-scientists but also conducts its own research and shares those results with participating customers. These activities put 23andMe in a unique position to assess methods of returning results and findings to research participants. We describe our approach for returning different types of information and compare it to recommendations made by independent working groups. For example, as recommended by many, our genotyping is performed in a CLIA-certified lab, and we have already developed and implemented a system for evaluating whether a finding should be shared with our participants. In addition, we have an established method for recontacting our participants when new findings become available. We also evaluate differences in information-seeking behavior between individuals who came to our service based on their interest in genetic testing and individuals who joined as part of a research project, and show that these differences vary according to the nature of the information presented and the way the individuals were introduced to the service. Though 23andMe's research participants may not be representative of all research participants, these data still suggest that individuals whose primary motivation for joining 23andMe is to participate in research are interested in learning about the "incidental findings" uncovered in the sample they contributed.

The problem of how to return results and incidental findings to research participants in a responsible, scalable, cost-effective, and updatable way is a daunting one. One possible solution is for researchers to partner with entities like 23andMe that specialize in communicating this type of information. Whatever the channel of communication of results, many lessons can be learned from the work already in progress at personal genomics companies.

1839W

Perceptions of genetic counseling services in direct-to-consumer personal genomic testing. *B.F. Darst[1], N.J. Schork[1, 2], E.J. Topol[1, 2, 3], C.S. Bloss[1].* 1) Scripps Translational Science Institute and Scripps Health, La Jolla, CA; 2) Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA; 3) Scripps Clinic Mecial Group, La Jolla, CA.

Aim of Investigation: To describe consumers' perceptions of genetic counseling services in the context of direct-to-consumer (DTC) personal genomic testing. Methods: We performed a secondary analysis of data from the Scripps Genomic Health Initiative, a longitudinal cohort study originally designed to assess the psychological and behavioral impacts of DTC genomic testing for common disease in a large sample of adults. Analyses presented are based on web-based assessments performed at baseline and long-term follow-up, which was completed an average of 14 months (SD= 1.3) after receiving genomic test results. At long-term follow-up, participants were asked to respond to several items gauging their interactions, if any, with a Navigenics genetic counselor, and their perceptions of those interactions. Participants purchased the Navigenics Health Compass at a discounted rate and genetic counseling was provided at no additional charge. Results: Out of 1325 individuals who completed long-term follow-up, 187 (14.1%) indicated that they had spoken with a genetic counselor. Primary reasons given for not utilizing the counseling service included the perception of already understanding one's results (55.6%), being too busy (20.3%), and unawareness that the service was available (10.5%). Of those who did have contact with a genetic counselor, the most common reasons given for utilizing the service included wanting to take advantage of a free service (43.9%), wanting more information on risk calculations (42.2%), and being contacted by a counselor who therefore prompted the interaction to occur (39.0%). Among those who utilized the service, a large fraction reported that counseling helped them to feel more educated about genetics in general (43.9%) and that it improved their understanding of their results (54.5%). A total of 17.6% reported that genetic counseling made them likely to discuss their results with their physician. Conclusions: Only a small proportion of participants utilized genetic counseling after receipt of DTC genomic testing for common disease. Those who did, however, appeared to find it beneficial with many indicating that it improved their understanding of genetics in general, as well as understanding of their own test results more specifically. Our results suggest that genetic counseling may not be a necessary component of genomic testing for most consumers, but that for some, it may have notable beneficial effects.

1840F

Shared decision-making: Seeking a change in the genetics consult. *S. Adam[1], P.H. Birch[1], A. Townsend[2], F. Rousseau[3,4], J.M. Friedman[1,4].* 1) Dept of Medical Genetics, Children & Women's Hospital, University of British Columbia, Vancouver, BC, Canada; 2) Dept of Occupational Science and Occupational Therapy, W. M. Young Centre for Applied Ethics, University of British Columbia, Vancouver, BC, Canada; 3) Medical Biology, Université Laval, Montreal, PQ, Canada; 4) The APOGÉE-Net/CanGèneTest research and knowledge network in genetic health services and policy.

The physician-patient encounter is increasingly regarded as `a meeting between experts' reflecting a change from a former emphasis on paternalism to recognition of patients' unique understanding of their health. It is a shift in philosophy of health care from beneficence to autonomy and from physician-directed care to shared decision-making. More recently, an explosion of health Internet use has accelerated this transition and the `e-patient' (e.g. educated and empowered) has emerged. This trend is an important dynamic for the genetics community to consider especially in complex ethical and medical situations such as clinical whole genome sequencing (WGS). We conducted two focus groups, one with 8 parents of children with intellectual disability (ID) of unknown etiology; the other with 10 members of the lay public (from diverse educational backgrounds and little knowledge of WGS). Qualitative analysis of the transcripts revealed that both groups expressed support for this construction of expert and engaged patients in the context of receiving clinical WGS results. Perhaps surprisingly, both lay and parent groups held very similar views. They gave various explanations for the need to be “expert” patients: 1) Patient choice was emphasized, especially around the ability to choose the types of WGS results to receive; 2) Personal responsibility was conveyed by many as central to the need to keep informed of medical and technological advances; 3) Advocacy was conveyed by both groups as key to receiving full information and optimal care for themselves and their children. For some, this was associated with a lack of trust in the health care system; and 4) An over-burdened health care system was identified by some as a reason to be pro-active. Problems with complex data and understanding results were identified as obstacles to being an expert patient. However, both groups offered novel educational solutions including websites, discussion groups and other formats to suit a range of learning styles. Our findings indicate that the public wishes to engage in shared responsibility for the enormous amount of data that will be generated by clinical WGS by taking control of their own results. In turn the genetics community needs to recognize and facilitate the learning needs of e-patients, providing a variety of effective multi-media tools as options to support the inevitable, and potentially enormously beneficial, evolution of the medical encounter.

1841W

Personal genomics: A study assessing the safety and health outcomes of receiving whole exome sequencing results. *Y. Bombard[*, 1, 2], K. Schrader[*, 2], E. Glogowski[2], R. Rau-Murthy[2], S. Patil[1], A. Eaton[1], E. Elkin[1], M.J. Massie[3], J. Hay[3], S. Shah[2], J. Vijai[2], N. Kauff[2], Z. Stadler[2], M. Robson[2], K. Offit[2], (* Equal contributions).* 1) Department of Epidemiology and Biostatistics, Memorial Sloan-Kettering Cancer Center; 2) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center; 3) Department of Psychiatry and Behavioral Sciences, Memorial Sloan-Kettering Cancer Center.

In the wake of whole genome and exome sequencing (WG/ES), return of individuals' research results involves numerous challenges mainly due to the large volume of incidental data. Research infrastructures need to include counseling and provision of incidentally-identified disease risk (IIDR). Using a prospective, observational cohort design, we are conducting a feasibility study offering the return of IIDR results identified using WGS/WES to 100 participants from existing research protocols involving cancer survivors and their unaffected relatives. Participants are offered communication of categories of incidental results, using a decision aid based on the binning scheme proposed by Berg et al. This offers return of presumed pathogenic variants within genes represented in http://www.genetests.org, a clinical resource providing, expert-authored, peer-reviewed, genetic disease descriptions informing diagnosis, management and genetic counselling. SNPs associated with pharmacogenomic and common disease risk are also included. Genes and SNPs have been categorized according to their levels of clinical actionability and potential distress. Category 1 of the decision aid includes medically actionable genes and SNPs with established disease prevention or treatment guidelines; Category 2 includes clinically valid genes and SNPs without actionable interventions; Category 3 includes genes associated with reproductive implications; Category 4 refers to variants of unknown significance. Participants select categories for receipt during the pre-disclosure counselling. Participants are strongly encouraged to learn Category 1, and must opt-out of receiving this category, but can opt-in to receive results of Categories 2 and 3. Category 4 is not available for receipt. Variants will be validated and approved for return by N.Y. State Department of Health. The counseling team reviews their IIDR and offers medical recommendations. Participants are followed for 1-week, 3-, 6- and 12- month intervals to determine the safety (self-reported psychological distress), perceived utility, adherence to recommendations, health behaviors and healthcare utilization associated with receiving IIDR from WG/ES. Preliminary analysis to estimate returnable results from our sequenced dataset demonstrates a low number of presumed pathogenic variants occurring within each category (zero to three), which suggests that the return of IIDR results will be feasible in a single session.

1842F

Integrating Exome/Genome Sequencing into Clinical Genetics Practice. *S.M. Jamal[1], H.K. Tabor[1,2], J. Conta[3], J. Yu[1], M.J. Bamshad[1,4].* 1) Department of Pediatrics, University of Washington, Seattle, WA; 2) Seattle Children's Research Institute, Seattle, WA; 3) Seattle Children's Hospital, Seattle, WA; 4) Department of Genome Sciences, University of Washington, Seattle, WA.

Exome sequencing (ES) and whole genome sequencing (WGS) have emerged as powerful tools for identifying novel disease genes, and are quickly being developed in service labs as an alternative to targeted genetic testing. Several widely publicized examples in which ES has been used to facilitate a clinical diagnosis have further stoked enthusiasm for adopting ES/WGS into clinical practice. We are similarly enthused but caution that translation of ES/WGS into clinical settings raises important questions about the circumstances in which ES/WGS is likely to be of greatest benefit, how to effectively obtain consent for clinical testing, how to control expectations and by what means results return should be managed for providers and families. While these questions frame the discussion, there is little empirical data about how to best answer them. This is a major obstacle to integrating ES/WGS into clinical care. To provide the clinical genetics community with guidance on these issues, we systematically reviewed the consenting process and the approach to ES/WGS results return used in a variety of research settings. Based on this review, we developed “core” content and procedures that we think begins to address the challenges of using ES/WGS in a clinical setting and sets the cornerstone for development of “best practices.” Furthermore, we reviewed the suggested indications for use of ES/WGS, informed consent documents and return of results reports from each lab in the U.S. offering diagnostic clinical ES/WGS. The presence of core content varied widely among the consent documents and results reports, and none contained all of the elements that we identified as the minimal required. For example, descriptions of what results would be returned (information from parental samples, incidental findings, adult-onset conditions for pediatric samples, and non-actionable results) and whether participants could opt out of certain kinds of results (e.g., “relationship confirmation” or “cancer”) were highly varied. The disparity of core content suggests a critical need for standardization, transparency and clarity in the information provided for clinicians and patients. This would improve the translation of ES/WGS to a range of clinical settings, improve outcomes and maximize clinical benefits while avoiding confusion, unnecessary expense, and miscommunication about the presence or absence of primary and unanticipated results.

1843W

A proposed approach to the integration of sequence data at a pediatric academic institution. *S.K. Savage[1], C.M. Clinton[1], I.A. Holm[1,2,3], I.S. Kohane[2,5,6], D.M. Margulies[1,2,4,5].* 1) Division of Genetics and Program in Genomics, Boston Children's Hospital, Boston, MA; 2) Department of Pediatrics, Harvard Medical School, Boston, MA; 3) The Manton Center for Orphan Disease Research, Boston Children's Hospital, Boston, MA; 4) Department of Developmental Medicine, Boston Children's Hospital, Boston, MA; 5) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 6) Children's Hospital Informatics Program, Boston Children's Hospital, Boston, MA.

The Gene Partnership at Boston Children's Hospital is a research effort focused on the disclosure of individual research results from a large genomic repository to promote personal and clinical benefit to participants. The return of results derived from whole exome/genome sequencing (WES) performed for research presents many challenges, in part due to the anticipated diversity of result types. In addition to research results, there are likely to be findings that have high clinical validity and are available in a clinical setting. Some findings may be directly relevant to the participant's clinical phenotypes, whereas others may be related to unanticipated phenotypes. As we are dealing with these issues in the research setting, clinical providers at our own institution are implementing WES as a diagnostic tool, and the same diversity of result types will likely be produced. To maximize the benefits to patients and research participants, it is important to develop consistent criteria for differentiating result types and a collaborative approach for the use and disclosure of data and results derived from WES. To this end we propose an approach for the integration of research results and data derived from WES into clinical care in a way that promotes participants' autonomy. The central element of our proposed approach is a rules-based decision-making model that manages physicians' access to data and results produced from WES for research and addresses our ethical obligation to protect participant privacy, promote autonomy, and facilitate quality care. Under this model, we propose that research results derived from WES that meet a designated threshold of analytic validity and clinical validity (determined through a scientific review process) be approved for return to the medical record. We also propose that participants in the research be given the opportunity to designate their preferences for results return to themselves, as well as their preferences for placing research results in the medical record. To facilitate appropriate clinical diagnostic testing, we also propose that physicians be granted access to the research-derived WES data for targeted reinterpretation, if coverage of the genes or regions that are directly pertinent to the patient's clinical presentation is of high-quality. This approach will allow researchers and clinicians to realize the full potential of DNA sequencing in a manner that is ethical, scalable, and clinically-beneficial.

1844F

Assessing Participant Preferences for the Return of Genomic Research Results. *L. Shahmirzadi[1], M.K. Cho[2, 3], S. Soo-Jin Lee[3], K.E. Ormond[1, 3].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Pediatrics: Division of Medical Genetics, Stanford University, Stanford, CA; 3) Stanford Center for Biomedical Ethics, Stanford University, Stanford, CA.

Purpose: Advances in whole genome (WGS) and whole exome sequencing (WES) have provided vast amounts of information on a wide range of genomic results, posing practical challenges in determining what information to return to patients and/or research participants. Although several groups have proposed categories for returning genomic research results, there are no consensus guidelines in this area. The purpose of this exploratory study was to assess underlying preferences of participants of genomic research with regards to return of genome data. **Methods:** We performed an exploratory study on individuals enrolled in two WGS or WES studies at Stanford University in 2011–2012. Semi-structured telephone interviews were conducted to assess participants' views for the return of WGS/WES research results. Data were analyzed using grounded theory. **Results:** Four participants, all with a personal or family history of cardiovascular disease, completed interviews to date. Regarding motivations for participation in WGS/WES studies, participants expected that their enrollment would lead to: 1) information that may guide medical management for themselves or family members 2) answers to complex presentations. Participants also enrolled out of a sense of altruism. Overall, participants wanted to learn more about their condition and participate in research even without immediate benefit and believed that benefits outweighed the risks. Three preferred to receive comprehensive results of WES/WES, including all variants that have known medical risks, with and without current treatment, and with uncertain significance. One participant preferred not to receive results of uncertain significance or without current intervention because of the worry it may cause. One participant specifically voiced interest in learning about protective variants in addition to those associated with disease. Participants were also interested in learning other incidental findings that may arise, such as mistaken relationships, pharmacogenomic risks and protective genes. **Conclusion:** Our results suggest that while people with a personal or family history of disease report altruistic motives for participation in genome research, they are interested in receiving their own results and view benefits as outweighing risks. As this is a small study drawing from only one genomic research pool, it is unclear whether these results generalize to those without a history of disease.

1845W

The NHGRI/NIH Clinical Sequencing Exploratory Research Program. *B.A. Ozenberger[1], L.A. Hindorff[1], S.D. Schully[2], J. Boyer[1], N. Lockhart[1,2], L. Lund[1], C. Mahomva[1], A. Felsenfeld[1], J.E. McEwen[1].* 1) National Human Genome Research Institute, NIH, Bethesda, MD; 2) National Cancer Institute, NIH, Bethesda, MD.

In 2010, the National Human Genome Research Institute (NHGRI) undertook an extensive expert consultation to formulate a strategic forecast for genomic research and the emerging application of genomic approaches in medicine, culminating in publication of a vision for genomics research (Charting a Course for Genomic Medicine, NATURE Feb 11, 2011). This strategic plan recognized the potential benefits to patients of comprehensive genomic data that soon will be available to clinicians with the rapid deployment of new DNA sequencing instruments and methods. NHGRI subsequently crafted the Clinical Sequencing Exploratory Research initiative to: 1) leverage the Institute's long-standing experience in genomic sequencing and analysis to ease the adoption of these methods into clinical care, 2) guide the development and dissemination of best practices for the integration of clinical sequencing into clinical care, and 3) research the ethical, legal, and psychosocial implications of bringing broad genomic data into clinical decision-making including, for example, evaluation of the risks and potential benefits associated with the return of incidental findings or information on variants of weak effect. Six grants were awarded in late 2011 [to Baylor College of Medicine, Brigham and Women's Hospital, Children's Hospital of Philadelphia, Dana Farber Cancer Institute, U of North Carolina, and U of Washington], with the National Cancer Institute cofunding two of the awards. The consortium of grantees will expand to additional sites with new awards expected to be issued in 2013. Over the next four years, these groups will generate and incorporate sequence data in the clinical care of patients and examine the relevant ethical, legal, and psychosocial issues. Several Working Groups are collaboratively defining the state of the art and exploring opportunities to coordinate efforts within and outside the consortium in the areas of: Sequencing Standards, Electronic Medical Records, Phenotype and Analysis Measures, Actionable Variants/Return of Results, Informed Consent, Outcomes and Measures for the psychosocial component of this research, and special issues relating to pediatric populations. The anticipated products and results from the Clinical Sequencing Exploratory Research consortium, and its role in NHGRI's broader efforts relating to genomic medicine, will be described.

1846W

Genomic Incidental Findings: Perspectives of Geneticists and Genetic Counselors in the Context of Clinical Sequencing. *Z. Lohn[1], S. Adam[1], P.H. Birch[1], A. Townsend[2], J.M. Friedman[1].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, Canada; 2) Department of Occupational Science and Occupational Therapy, University of British Columbia, Vancouver, Canada.

Clinical whole genome and whole exome sequencing are powerful tools for genetic diagnosis; however, incidental findings (IF) will also be discovered, which may have important medical and social implications. There is consensus in the literature that analytically valid and medically actionable IF should be returned to patients if practically possible, but whether additional findings warrant return is debated. Therefore, we aimed to determine whether geneticists and genetic counselors support the disclosure of various types of IF, and whether there is a difference in professionals' opinions towards the management of IF for pediatric versus adult patients. To explore this, an online cross-sectional questionnaire was distributed to members of the Canadian College of Medical Geneticists and the Canadian Association of Genetic Counsellors in November and December 2011. In total, 210 genetics professionals completed the questionnaire (response rate=42%), which used clinical scenarios to elicited opinions regarding degree of support for IF disclosure. The proportion of professionals who supported the disclosure of IF ranged from 95% for information pertaining to a serious and treatable condition to 12% for information with only social implications. There was discordance surrounding the disclosure of other types of IF including information of unknown significance, a serious and untreatable condition, and a multifactorial condition. Three factors were identified as being important to impacting disclosure decisions: condition-specific factors (e.g., treatment availability), test accuracy, and the evidence for pathogenicity. In regards to differences between pediatric and adult patients, there was significantly less support for disclosure of carrier status or information pertaining to an adult-onset condition for pediatric patients compared to adult patients. Some professionals expressed concern for pediatric autonomy when disclosing IF that are not directly relevant during childhood. These data suggest that genetics professionals might support development of independent IF policies for pediatric and adult patients. In conclusion, the disclosure of IF from clinical genomic sequencing is a complex and controversial issue among genetics professionals. Future research could incorporate more detailed clinical scenarios to fully explore the disclosure of IF from clinical sequencing investigations among genetics professionals.

Accounting for racial disparities in mortality among children with Down syndrome. *S. Santoro[1], A. Esbensen[2], L. Hendershot[2], F. Hickey[2], B. Patterson[2].* 1) Human Genetics, CCHMC, Cincinnati, OH; 2) Developmental and Behavioral Pediatrics, CCHMC, Cincinnati, OH.

Abstract: Aim: Life expectancies observed among individuals with Down syndrome (DS) are substantially shorter for African-Americans than Caucasians. There is a need to understand how racial disparities in comorbid health conditions contribute to these disparate life expectancies. Methods: Data were obtained from a DS specialty clinic at a Midwestern children's hospital. Medical history, pre- and post-natal history, current medical conditions, and referral patterns were obtained from 831 children with DS in a clinic sample (10.2% African-American). Results: Minimal racial group differences in comorbid medical conditions were observed. Group differences were observed in the frequency of nystagmus and PE tubes. Group differences were observed in the need for ongoing support from ophthalmology and cardiology. No differences were observed in the frequency of congenital heart disease (CHD), possibly suggesting that severity and not frequency of CHD warranted the ongoing cardiology support. Conclusions: The hypothesized racial disparity in comorbid conditions contributing to mortality was only minimally supported. Racial disparities in life expectancy are likely related to other factors warranting investigation, such as differential use of or access to health care services, or severity of comorbid health conditions. How use of health care services is related to severity of health conditions warrants future investigation.

ELSI 2.0: A new initiative to create an international infrastructure for the ethical, legal and social implications of genomic research. *K. Kato[1], J. Kaye[2], E.M. Meslin[3], B.M. Knoppers[4], E.T. Juengst[5], M. Deschenes[6], A. Cambon-Thomsen[7], D. Chalmers[8], J. De Vries[9], K. Edwards[10], N. Hoppe[11], A. Kent[12], C. Adebamowo[13], P. Marshall[14].* 1) Graduate School of Medicine, Osaka University, Suita, Osaka, Japan; 2) HeLEX, Department of Public Health, University of Oxford, Oxford UK; 3) Center for Bioethics, Indiana University, Bloomington, IN; 4) Centre for Genomics and Policy, McGill University, Montreal, Canada; 5) UNC Center for Bioethics, University of North Carolina, Chapel Hill, NC; 6) P3G, Montreal, Canada; 7) UMR 1027, INSERM, Epidemiology and analyses in public health, Toulouse, France; 8) Faculty of Law, University of Tasmania, Hobart, Tasmania, Australia; 9) Faculty of Health Sciences, University of Cape Town, South Africa; 10) Department of Bioethics and Humanities, University of Washington, Seattle, WA; 11) CELLS, Leibniz Universitaet, Hannover, Germany; 12) Genetic Alliance UK, London, UK; 13) Institute of Human Virology, Garki, Abuja, Nigeria; University of Maryland School of Medicine, Baltimore, MD; 14) Department of Bioethics, Case Western Reserve University, Cleveland, OH.

Genomic science is advancing rapidly and is increasingly international, proactive and coordinated, but so far ELSI research remains national, reactive and fragmented. However, given the exceptional scholarship, policy information and public engagement that have emerged from ELSI's conventional research methodology so far, important achievements are to be expected if ELSI research adopts the same strategic, large-scale and collaborative approaches that have characterized genomic science. This international initiative will develop an infrastructure to make large-scale ELSI research more efficient, effective and economical. The aim of this initiative is facilitate new collaborations, increase output, provide tools to help coordinate endeavours, and to avoid research redundancy. This will facilitate networking, critical reflection and the development of proactive strategies for international ELSI research in genomics. In doing so, it will provide maps of the international ELSI landscape to inform and coordinate future research, but also will also foster a new way of thinking and doing international ELSI research (Kaye, J. et al. *Science*, 336, 673–674, 2012). This paper will outline the pathway taken by ELSI programmes up to this point, identify shortcomings in conventional research approaches and build a new model on the basis of the lessons learnt from globalised genomics research. We will then present a concrete proposal for a research infrastructure and methodology, which will match the scale and output of ELSI research in genomics with that of other research in genomics, before concluding with an invitation to the genomics community to contribute to and build this ELSI initiative.

The challenges of defining a phenotype for addiction: In the words of addiction scientists. *J.B. McCormick[1, 2], J.E. Ostergren[2], R.R. Hammer[3], H.S. Harvey[2], M. Dingel[4], B.A. Koenig[5].* 1) Divisions of General Internal Medicine and Health Care Policy Research, Mayo Clinic, Rochester, MN; 2) Clinical Translational Science Activities, Biomedical Ethics Research Unit, Mayo Clinic, Rochester, MN; 3) Biomedical Ethics Research Unit, Mayo Clinic College of Medicine, Rochester, MN; 4) University of Minnesota Rochester, Rochester, MN; 5) Department of Social and Behavioral Sciences Institute for Health and Aging, University of California San Francisco.

The possibility of discovering a biological basis for addiction has prompted optimism, an influx of research funding, and a sense that the future of addiction research is fundamentally in neurogenetics research. However, like other frontiers of research, the development of novel treatments and preventive measures has lagged far behind the rate of discovery. In particular, there is disconnect between the complex phenotype of addiction and what we know about genes for susceptibility and drug targets. The utility of genetic research relies on an accurate account of the addiction phenotype. Yet the addiction phenotype remains a fuzzy concept because of its pleiotropic nature and the vast social and environmental factors that can influence the manifestation of the condition. Refining the phenotype of addiction and creating mechanisms for measuring it that can be shared broadly have been a priority for the National Institute on Drug Abuse (NIDA). To explore views on the state of addiction phenotype science, we interviewed 20 scientists conducting research on addiction in 2004–2005. Researchers expressed concern about the seemingly slow translation of findings. They discussed the need to better define addiction phenotype(s) and to develop tools that would enable them to find and measure existing and new phenotypes. In 2011 we interviewed 20 additional scientists conducting addiction research to explore this further. All interviews were analyzed using standard qualitative methods. Some said the Diagnostic and Statistical Manual (DSM) criteria were somewhat useful, but have “weaknesses.” They talked about molecular “pathway alteration” leading “to some phenotypic behaviors.” We heard that phenotype is “an outward expression,” but that it doesn't have to be. When asked whether genotype defines phenotype or vice versa, interviewees said that it is complicated: “these are interdependent entities.” Yet, some talked about how identifying genetic components to addiction would help “parse a lot of these fine differences” of phenotype. Several noted how useful epigenetics would be. Our findings show that addiction scientists acknowledge the fundamental tension between the socio-environmental elements of addiction and the neurogenetic basis, demonstrating a need for more careful evaluation of the relationship between the development of models of addiction, the phenotypes used, and the broader social environment in which addiction occurs.

Discriminating faces: Visual cues of ancestry. *J. Wagner[1], P. Claes[2], M. Shriver[3].* 1) University of Pennsylvania, Center for the Integration of Genetic Healthcare Technologies, Philadelphia, PA USA; 2) Katholic University of Leuven, KU Leuven, Belgium; 3) Pennsylvania State University, Department of Anthropology, University Park, PA, USA.

Racial disparities exist in health and justice. While there are no biological human races, cultural constructs of race (which have relied upon *perceived* biological differences) are real, many, and variable. Much variation (biological and cultural) is masked by such classifications. Racial discrimination, a known contributor to psychological and physiological health problems, is not an equal opportunity offender but is related to one's appearance and racial identity. How individuals self-identify and are identified by others is shaped to an unknown degree by our expectations of how an individual of a particular ancestry “should” look (e.g., laypersons note familial resemblances; cosmetic surgeons note patients wish to preserve racial identity; researchers report own race bias, other race effect, and cognitive adaptation). The level of discordance between one's appearance, perceived ancestry, and genomic ancestry may affect the formation and stability of one's racial identity; the form, frequency, and severity of discrimination one experiences; and even one's own prejudices. Yet relationships between identity, appearance, and genealogical, genomic, apparent, and perceived ancestry remain poorly understood. Using data from participants recruited in USA and Brazil (race; ancestry; 3D facial photos; skin and hair color; face shape; and genomic ancestry estimates), we investigated perceived ancestry from faces. Using 3D facial photos from 100 participants with mainly European and West African genomic ancestry, false color GIFs were prepared and incorporated into perception instruments. Observers were asked to provide their own information (e.g., race, ancestry, skin color, residence before age 18) before viewing 10 facial images with corresponding questions. In addition to exploring relationships between racial identity, appearance, and genealogical, genomic, and perceived ancestry of 100 research participants, data were analyzed to compare observers' ratings and explore how observers' characteristics influenced perceptions. N=822 observers participated. Perceived ancestry is correlated with face shape and genomic ancestry. Sigmoidal curves show both categorical and biased perception. By better understanding perceived ancestry, we may develop effective interventions to mitigate racial disparities in justice attributable to racism, colorism, and beautyism and may get one step closer to isolating factors contributing to racial disparities in health.

Integrating medical genetics into primary health care: report of a pilot program in Brazil. *T. Vieira[1, 2, 3, 4], C. Giugliani[5], L. Silva[1,2], L. Faccini[1,2,3,4], J. Leite[1,2], O. Artigalás[1,2,6], M. Lenz[7], M. Rojas[8], R. Giugliani[1,2,3,4].* 1) Medical Genetics Service, Hosp Clinicas Porto Alegre, Porto Alegre RS, Brazil; 2) WHO Collaborating Centre for the Development of Medical Genetics Services in Latin America, Porto Alegre RS, Brazil; 3) Postgraduate Program in Medical Sciences, Universidade Federal do Rio Grande do Sul, Porto Alegre RS, Brazil; 4) INaGeMP - Instituto Nacional de Genética Médica Populacional, Porto Alegre RS, Brazil; 5) Department of Social Medicine, Universidade Federal do Rio Grande do Sul School of Medicine, Porto Alegre RS, Brazil; 6) Children's Hospital, Grupo Hospitalar Conceição, Porto Alegre RS, Brazil; 7) Community Health Service, Grupo Hospitalar Conceição, Porto Alegre RS, Brazil; 8) Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Porto Alegre RS, Brazil - Current affiliation: Medical Department, Genzyme do Brasil, São Paulo, Brazil.

Introduction: The integration of Medical Genetics (MG) and Primary Health Care (PHC) seems to be an alternative to develop actions of prevention and control of genetic conditions, and to facilitate community access to health care based on knowledge about genetics. Therefore, it is necessary that primary care professionals have a basic knowledge about genetics, the main conditions, management measures and prevention of genetics conditions. Aim: To evaluate if the application of an educational program in MG directed to PHC teams can help to integrate concepts and attitudes related to the identification, management and prevention of congenital malformations and genetic diseases. Method: The program was designed by health professional of the Medical Genetics Service/Hospital de Clínicas de Porto Alegre and applied to three Basic Health Unitis (BHU) of Grupo Hospitalar Conceição. The program consisted of meetings that took place at the BHU, which emphasis on the following topics: basic concepts; evaluation of families; teratogenic agents and prevention of birth defects; mental disability; inborn errors of metabolism and neonatal screening; cancer genetics; genetics of common chronic diseases; and genetic and preconception counseling. It was developed support materials for participants and educational material for the community. The program was evaluated through pre and post-test, as well through self-assessment questionnaire applied to the PHC professionals. Results: Forty three professionals participated in the program. In two of the three BHU it was found a statistically significant increase in the number of hits in post-test. Most professionals reported increased knowledge and confidence after the program, said that the program influenced their clinical practice and informed that the information resources and educational material presented during the program were useful. Conclusions: The program provided an approximation between GM and PHC, so that professionals pay attention to the genetic determinants of disease in the community. However it was realized the need for strategies for continuing education and ongoing support to the APS, with the aim of strengthening the integration of the two specialties, bringing to practice the community genetics. Support: March of Dimes.

1852F

The Gene Messenger impact project: a genetics e-learning program for family physicians. *J.C. Carroll[1], R. Grad[2], P. Pluye[2], J. Allanson[3], J. Permaul[1], N. Pimlott[4], B.J. Wilson[5].* 1) Department of Family Medicine, Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada; 2) Department of Family Medicine, McGill University, Montreal, QC, Canada; 3) Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 4) Department of Family Medicine, Women's College Hospital, University of Toronto, Toronto, ON, Canada; 5) University of Ottawa, Ottawa, ON, Canada.

Context: Patients look to their family physicians (FPs) for guidance making informed choices about genetic testing. FPs express willingness to deliver some genetics services, but are challenged by lack of knowledge, and the rapid pace of genetic discovery. Our recent trial, GenetiKit, demonstrated effectiveness of a multi-component knowledge translation strategy on FPs' genetics referral decisions and confidence in core genetics competencies. We designed an additional project to disseminate and further evaluate one component, a knowledge support service called Gene Messenger (GM). GMs are 2-page reviews of genetic tests/disorders featured in the media. Objective: To determine the value of GMs as a genetics e-learning program for FPs. Design: FPs received 3 email invitations. After completing an online demographic questionnaire, participants received 12 GMs by email, one every 2 weeks for 6 months. Setting: Electronic participation. Participants: All English-speaking, active members of the College of Family Physicians of Canada were invited. Intervention: After reading each GM, participants completed an Information Assessment Method (IAM) questionnaire, a validated and useable evaluation tool for linking delivery of emailed information with continuing professional development. The IAM assesses participants' perceptions of the value of clinical information: cognitive impact, relevance, use, and expected health benefits. Demographic data and IAM ratings of GMs were analyzed and compared. Results: 1402 of 19,060 (7.4%) FPs participated. Most rated GMs as valuable: GMs will “improve practice” (mean=73%); are “relevant for a patient” (mean=79%); if relevant FPs will “apply GM information to patients” (mean=88%); and “expect health benefits” (mean=58%). How each GM would impact practice varied by topic. Overall 93% would like to continue to receive GMs. Findings are limited by participation rate, possibly affected by recruitment method. Conclusions: This appears to be an effective approach for supporting FPs' educational needs for practical up-to-date genetics information. FP feedback will be used to improve GMs, and explore sustainability of this e-learning genetics program.

1853F

Examining the Research Training of Recent Genetic Counseling Graduates. *S. Hahn[1], A. Rupchock[1], E. Bendik[1], E. Burkett[2], E. Heise[3].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Legacy Health System, Portland, OR; 3) Duke University Medical Center, Durham, NC.

The American Board of Genetic Counseling requires accredited programs incorporate research training in the curriculum, but programs are granted latitude regarding what and how this is incorporated. Previous research shows that among GCs specializing in research, the majority of skills and knowledge necessary for this role were learned on the job, rather than in their training program. In this study, we sought to determine how key skills and knowledge necessary for conducting research are currently included in GC program curriculum using a web-based survey of GCs who graduated within the last five years. Participants were recruited via the NSGC discussion forum, their program directors via the Association of Genetic Counseling Program Directors, and through an email to ABGC diplomats. The survey included questions regarding research training experiences, perceived competency with research skills at graduation, perceived importance of research training, and opinions about GC involvement in research. The survey was taken by 260 participants, representing at least 29 different GC training programs. Since graduating, 37% of respondents have held a position where they ascertained research subjects at least 10% of the time. Eighty-three percent of respondents conducted a research project that involved human research subjects as part of their genetic counseling training. Over 35% indicated research rotations were available as an option as part of their training, and, of those, 66% elected to complete this rotation. Research rotations and thesis requirements were rated as important or extremely important by 67% and 83%, respectively, and 40% of respondents would have liked more experience with human subjects research in graduate school. 96% feel genetic counselors should conduct their own research, and 91% feel counselors should obtain training in their programs so they can conduct their own research. These preliminary data illustrate the varying methods and degrees to which research is incorporated in training programs and may be used to guide the development of core competencies or GC program curriculum.

Increasing the number of URMs in Genomice Science. *D. Murray[1], D. Whittington[2], R. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Strategic Evaluations, Inc., Durham, NC.

The Human Genome Sequencing Center (HGSC) at Baylor College of Medicine provides training opportunities for under-represent minorities to interest them in a career in the genomic sciences. The HGSC provides exposure to genetic/genomic research and educational enhancement activities through a summer research program (HGSC-G/GREAT) and a post-baccalaureate program (HGSC-PGET). Since the program's inception in 2003, we have collected data on our program participants at the end of their respective program and through follow up evaluations. A Cross-Sectional Survey was used to generate background data and narrative data from the participants. Once collected the data was analyzed using description, analysis, and thematic development methods. Based on our analysis, we have improved our program through developing activities and recruitment strategies that will ensure the success of our participants. Our HGSC-PGET data indicates that over the last three years, our graduate school acceptance rate has increased with 60% of our research post-baccalaureate fellows and 70% of our laboratory technicians being accepted in doctorate programs. We have seen a 40% increase in the number of our summer interns enter Ph.D. programs in the last three years. The changes we have made to our undergraduate and post-baccalaureate opportunities has a positive impact on our ability to achieve our program goals.

1855F

Pharmacotherapy of Inherited Metabolic Diseases PharmD Fellowship Training Program. *J. Utz, W. Whitley.* Adv Therapies, Pediatrics, Univ Minnesota, Minneapolis, MN.

Background: Clinical pharmacy services (CPS), including Pharmaceutical Care (PC) or Medication Therapy Management (MTM), are provided in an increasing number of primary care settings, and have been shown to improve clinical outcomes and reduced overall healthcare costs in managing common chronic diseases. Although raining in provision of CPS for common chronic disease states is required curriculum in colleges of pharmacy in the United States, training in providing CPS in rare diseases has not been available. The orphan diseases known as inherited metabolic disorders (IMD) include conditions that require care from multiple specialty providers and treatment with numerous, costly medications, including orphan drugs. Objectives/ Methods: We instituted a 2-year post-doctoral PharmD training program that provided advanced clinical practice training for IMD, and explored the usefulness of CPS towards improving clinical outcomes for patients with IMDs. Results: During the 2-year training program, CPS were provided for patients with lysosomal storage diseases and PKU in the Advanced Therapies Clinic at the University of Minnesota. Clinical advancements for IMD patients that were realized during this training program included: 1) identifying 3 major types of infusion reactions to enzyme replacement therapies (ERT) through PC/MTM; 2) establishing methods for managing all 3 types of infusion reactions through PC/MTM; 3) instituting medication treatments for gangliosidoses; 4) improving neuropathic pain management in Fabry patients; 5) instituting a formal process for evaluating Fabry disease pain; 6) implementing systematic pharmacogenetic evaluations of medications for IMDs. Clinical research advances and educational experiences included: 1) initiating a clinical trial to study treatment of Fabry disease neuropathic pain; 2) submission of FDA IND for Fabry pain trial; 3) manuscript writing; 4) grant writing; 5) on-site industry training; 6) presenting abstracts at 4 international scientific meetings. Conclusions: The addition of a Doctor of Pharmacy (PharmD) to the clinical team in specialty clinics for rare diseases and institution of formal PharmD training programs for rare diseases enhances clinical program offerings and clinical research progress for rare diseases. Continued growth and expansion of rigorous professional PharmD training programs in rare diseases is warranted for the improvement of clinical outcomes in rare disease states.

1856F

Promoting student engagement and critical thinking in genetics: An evaluation of "Luck of the Draw" game. *M. Godfrey[1], A. Bower[2], K. L. Tracy[2], R. Anderson[1], A. Jameton[1], B. Arobba[3], C. Ryan[2].* 1) University of Nebraska Medical Center, Omaha, NE; 2) University of Nebraska, Omaha, NE; 3) Inter Tribal Buffalo Council, Rapid City, SD.

Students in the United States have fallen behind in international comparisons of math and science proficiency. Some educators have called for greater use of teaching methods that promote student engagement in science and math and that provide opportunities to develop critical thinking skills. One such method involves the use of classroom games. The current study represents initial efforts to evaluate "Luck of the Draw," a game designed to engage students in genetics and encourage critical thinking about issues, such as genetic engineering. Science teachers (N=24) attending a summer workshop responded to open-ended questions concerning their initial impressions of the game; middle and high school students (N= 134) completed questionnaires concerning their experiences playing the game. Results indicated that teachers and students enjoyed the game and identified positive outcomes, including greater engagement and critical thinking. Further, students' responses suggested that the potential problems that teachers thought might be encountered occurred infrequently.

1857F

Genetic Numeracy in College Students: A quantitative analysis. *M. Bergman[1], H. Honore Goltz[2].* 1) University of Washington, Seattle, WA. 9418 24th AV SW, Seattle, WA 98106; 2) University of Houston - Downtown Department of Social Sciences One Main Street, Houston, TX 77002.

Determining the genetic numeracy levels of populations is necessary for determining if, and where, interventions to improve genetic numeracy are needed. To date, very few quantitative studies of genetic numeracy have been performed (Lea et al., 2011). In this paper we assess quantitative levels of numeracy; identify differences in subgroups, if present; and determine if these differing levels impact behavior. This study is based on secondary analysis on data from the Perception of Genetic Risk in Sexual and Reproductive Decision-Making (PGRID) by College Students dataset (Honoré, 2008), a 138-item web-based survey instrument. The results of the study (N=2,568) imply that people believe that risk relationships with their parents follow inheritance patterns of autosomal dominant genes. Overestimating risk was another finding in this area of investigation. For example, many respondents believed that their inherited risk of disease from their parents was 70%. This was also the third most common response for inherited risk of disease from siblings. These estimated risk relationships implies that these people have poor understanding of genetic risk at it relates to their own family. Another implication is that many respondents do not believe that parents and children have reciprocal risk relationships. Education, especially didactic genetic information, seems to be a predictor for genetic understanding (Biological science degree OR = .73; Taken a genetics course OR = .76; Taken a course with genetic information OR = .70). Religiosity also seems to play a role in determining genetic numeracy (Services attended per week OR = 1.16) so respecting these differences in risk perception is important for public health genomics practitioners. Respondents in this study reported that they were increasingly unwilling to marry or have children perceived as having a genetic disorder (70% - Date; 58% - Marry; 45% - Have Children), but these trends do not seem to relate to their numeracy level. Study findings provide support for creating educational interventions that improve understanding of the mathematics of inheritance and the recognition of all the factors that can affect disease. Finally, improving patient/ provider communication relating to the patient's perception of risk is an important step in ensuring that the information received can impact patient behavior.

The Growing Stronger Organization and the Acondroplasia - Achondroplasia Blog: a parents' initiative to share knowledge and foster alliances towards potential therapeutic approaches for achondroplasia. *M. Kaisermann.* Consultant Physician, Rio de Janeiro, Rio de Janeiro, Brazil.

Background: Achondroplasia (ACH) is the most common cause of dwarfism. Despite the fast progress in the understanding of the mechanisms of this disorder, there is little research in potential therapies for ACH, either due to lack of official focus on this kind of disorder or because of its low prevalence. On the other hand, there are many web based sources available where interested people can find data about ACH. A single search in Google for *achondroplasia* retrieved 737K entries (Jun 2). However, with a number of few relevant exceptions, information is frequently outdated, misleading, fragmented, not referenced or is written in technical language, which can be difficult for non-specialists to understand. **Objective**: To describe the *Growing Stronger Initiative* (www.growingstronger.org, GS) and the blog **Acondroplasia-Achondroplasia** (www.tratando-acondroplasia.blogspot.-com). Discussion: **GS** is a non-for-profit organization founded by parents with the mission of improving the medical care of little people through supporting research. **GS** is establishing alliances to fund research towards therapeutic approaches for the several kinds of dwarfism and specially ACH, with the main goal of preventing or reducing the medical complications associated with this condition. The blog **Acondroplasia-Achondroplasia** is an independent, trilingual web based source of information about ACH directed to non-specialists, parents and affected individuals. It is linked to **GS** and offers articles in Portuguese, English and Spanish comprising reviews of genetics, molecular biology and potential pharmacological approaches to treat ACH. Articles are referenced and illustrated preferentially with web based accessible and validated scientific data, including direct links to peer reviewed articles, abstracts in Pubmed and animations provided by reliable sources (e.g.: Nature). It offers links to the main ACH Investigators' webpages; searches in Pubmed and ClinicalTrials.gov; links to relevant papers and to non-for-profit organizations devoted to support achondroplasia and / or other causes of dwarfism. **Conclusion**: By integrating the current information about ACH into a dynamic web based source containing adapted wording for the non-specialists, **GS** and the **Acondroplasia-Achondroplasia** blog can help interested individuals to improve their knowledge about the condition. Finally, they also aim to increase the research in new therapeutic approaches for ACH by directly funding research.

1859F

Genetics Home Reference, Ten Years In: Where We Are Now. *S.M. Morrison, M.L. Cheh, S. Calvo, H. Collins, J. Fun, K. Greenberg, L. Forman-Neall.* Lister Hill National Center for Biomedical Communications, U.S. National Library of Medicine, National Institutes of Health.

Genetics Home Reference (GHR) is an online resource from the U.S. National Library of Medicine (http://ghr.nlm.nih.gov/). This website provides an overview of genetic conditions and associated genes and is intended as a resource for patients, families, and the general public needing information about genomic medicine. GHR also provides background information including a primer (Help Me Understand Genetics), a glossary of genetic and medical terms, and links to numerous other quality resources. The “Spotlight” feature highlights important observances and discoveries in the field of human genetics and draws attention to useful learning tools and clinical resources. The GHR website was launched in 2003 with 19 condition summaries and 16 gene descriptions. Today, GHR offers easy-to-read summaries of more than 720 genetic conditions, more than 960 genes, around 65 gene families, all human chromosomes, and mitochondrial DNA. New summaries are added regularly. During the last ten years of development, GHR has grown in scope and content in order to better serve our audience. This presentation describes the improvements to the website, including new features, changes in focus, and new procedures for development and management, along with the rationale for their inclusion. We provide a discussion of future goals for the project and ways we plan to meet those goals. This work was supported by the Intramural Research Program of the National Institutes of Health, National Library of Medicine.

1860F

Investigating a conceptual change strategy to improve student understanding of basic genetics concepts in undergraduate non-science major and nursing student populations. *B. Bowling[1], M. Glassford[1], S. Barnes[1], S. Borgman[1], E. Reilly[2], T. Beery[3], C. Huether[4].* 1) Dept Biological Sci, Northern Kentucky University, Highland Height, KY; 2) University of Kentucky Markey Cancer Center, Lexington, KY; 3) College of Nursing, University of Cincinnati, Cincinnati, OH; 4) Dept Biological Sci, University of Cincinnati, Cincinnati, OH.

Replacing student misconceptions in genetics with the correct scientific conceptions can be difficult and may not be possible via conventional teaching strategies. Conceptual change texts (CCTs), brief passages that introduce a misconception, refute it, and explain the correct conception, are a possible intervention for correcting such student misconceptions. This study involved testing of CCTs to address the following misconceptions in undergraduate level courses: 1) DNA is different in different types of cells within one individual, 2) the terms gene, DNA, and chromosome can be used interchangeably, and 3) all mutations have a negative effect. Students enrolled at two Midwestern universities in both a non-science majors' general biology course and genetics for nursing course were randomly assigned to the control or experimental groups. Students in the experimental group received a CCT on the identified misconception, while students in the control group received information that discussed a topic from the course, but was not associated with the misconceptions. One hundred twenty students responded to three open-ended questions regarding the basic genetics concepts at the beginning of the course, at the time of reading the CCTs, and during the final week of class. The responses were scored using rubrics previously determined to be valid and reliable. While the post-course responses were on average higher for students completing the CCTs, statistically significant increases from pre- to post-course were observed in both the control and experimental groups. For all three questions, the post-course responses remained deficient with the average response including less than 50% of the key components of a comprehensive answer. Two additional aspects of the study will allow further investigation of the impact (or lack of impact) of the CCTs. A portion of the students are participating in a one-year post-course assessment to test the durability of their learning. In addition, content analysis will include identifying common themes in the responses and misconceptions held by the students throughout the different time points.

Alignment and assessment problems in the undergraduate genetics curriculum. *M. Dougherty[1,6], T. McElhinny[2,3], B. Bowling[5], J. Libarkin[2,4].* 1) Education, ASHG, Bethesda, MD; 2) Department of Geological Sciences, Michigan State University, MI; 3) Department of Zoology, Michigan State University, MI; 4) Center for Integrative Studies in General Science, Michigan State University, MI; 5) Department of Biological Sciences, Northern Kentucky University, Highland Heights, KY; 6) Department of Pediatrics, University of Colorado School of Medicine, CO.

`Backward design' is a model of curriculum development that relies on identifying learning outcomes and defining what constitutes evidence of learning before planning the teaching. Although backward design is widely considered best practice, it is often overlooked by university faculty and may help explain the inconsistency between faculty teaching behavior and the genetics concepts they claim are most important. This paper will review the state of genetics instruction in the United States from the perspective of backward design, with particular attention to the goals and assessments that inform curricular practice. An analysis of syllabi and leading textbooks indicates that genetics instruction focuses most strongly on the structure and function of DNA and Mendelian genetics. At the same time, a survey of faculty indicates that other concepts, such as the application of genetics to society or the environment, are viewed as equally or even more important than certain foundational concepts. This disconnect suggests a need for more explicit goal setting prior to curriculum development. Preliminary analysis of existing assessments, specifically concept inventories developed for higher education, indicates that assessments are poorly aligned with faculty goals for instruction and need to be modified into more valid and reliable measures of student conceptions.

YouTube as an educational resource for visual and kinesthetic learners: A study of DNA replication animations. *J.M. Lind.* University of Western Sydney, School of Medicine, NSW, Australia.

Background: Learning styles can be broadly classified into visual (diagrams), aural (listening), read-write (information displayed as words), and kinaesthetic (real/simulated events). Lecturing is a common mode of content delivery within undergraduate genetics teaching, which traditionally caters for aural and read-write learners. Students and educators can now easily access resources that assist visual and kinesthetic learning via websites such as YouTube, a video sharing website. This study aimed to determine how the medium of YouTube has been utilised in the demonstration of genetics fundamentals by way of content upload and content viewing, with a focus on DNA replication animations. **Methods:** A search of www.youtube.-com using the criterion “DNA replication animation” was performed. Videos uploaded between the inception of YouTube (February, 2005) and December 31, 2010, with primary content about DNA replication were included. Only short videos (less than 20 mins) were included. Date of video upload, number of times viewed, and length of video were collected. Data for videos uploaded multiple times were combined to get a total number of views per video, using the first upload occurrence as the date uploaded. A general linear model was used to test for associations, with a significance level of p=0.05. **Results:** A total of 127 unique videos, viewed a total of 21,264,244 times, were included in the analysis. The first video was uploaded on May 3, 2006. As of June 4, 2012, the number of views per video ranged from 15 to 2,891,443, with an average of 41,787 views per video, per year. The number of new videos uploaded each year ranged from 17 in 2006 to 33 in 2009, with a mean of 25.4. There was a significant association between the time since upload and the number of views, with an additional 360.8 views for each additional day the video had been online (95%CI 220.6–501.1, p<0.001). There was no association between length of video and number of views. **Conclusions:** YouTube has been extensively utilised to demonstrate the fundamentals of human genetics. It has enabled students and educators to easily access resources for visual and kinesthetic learners to study processes occurring at the molecular level. YouTube content can enhance student learning by appealing to a broad range of learning styles.

1863F

Genetic Counseling in India: Current certification courses and a need for the development of a Master's training program. *K. Shah.* SEATTLE CHILDREN'S HOSPITAL, SEATTLE, WA.

Non-communicable diseases such as diabetes, cardiovascular disease, chronic respiratory disease and cancer are becoming significant in India since their incidence is increasing. While infectious diseases remain the leading causes of death in the earlier years of life, injury and non-communicable chronic disease predominate in older age groups. With the hope of the potential decline in communicable diseases, the emerging importance of genetic disease is inevitable. The access to clinical genetic services in India is mostly confined to the urban areas. Genetic counseling has been traditionally conducted by physicians in India. While some genetic testing centers or institutions based in a university setting have implemented genetic counseling workshops or courses for their clinicians; an official certification/diploma course in genetic counseling has only been recently initiated (as of January 2012) in India as a full time 1 year course. The two new genetic counseling certification programs in India could aid in generating an educated genetic counseling work force that can meet patient demands for genetic services. We will attempt to compare the curriculum offered by the 2 institutions, including their target student admission criteria and hope that these programs can serve as a potential model for developing a comprehensive 2 year Masters' program in genetic counseling in India, similar to the ones offered in the United States.

1864F

A strategy of applying comprehensive therapeutic approaches for training autism children. *H. Xu[1], N. Zhong[2].* 1) Dept. Children Health Care, Hubei Provincial Maternal and Children's Hospital, Wuhan, China; 2) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Objective: To explore a comprehensive training strategy for autism. Methods: 185 Children with core autism aged from 2.5 to 6.2 years were given comprehensive training between October 2009 and December 2010 in Hubei maternal and children's hospital. The training time was 40 hours per week, and lasted 6 months. Before and after treatment, autistic children were evaluated with both Autism Treatment Evaluation Checklist (ATEC) and Revision of Chinese Version of Psycho-Educational Profile (C-PEP). Results: The average ATEC total score of all children with autism was significantly decreased from (99. 12±15. 95) to (53. 91 ±11. 24) (P <0. 001). The subscale scores including language, social interaction, sensory and behavior were all decreased (P < 0. 05, P < 0. 001) as well. The average C-PEP score was increased from (30. 17 ±9. 58) to (49. 84 ±10. 17). The equivalent of age increased (9. 67±0. 59) months. When 6 months physiological development subtracted, it actually increased (3. 67 ±5. 32) months. Conclusions: Our results support the fact that for children with autism, the comprehensive training is a rather effective approach.

1865F

Genetics and Public Health: The Experience of a Referral Center for Diagnosis of 22q11.2 Deletion in Brazil and Suggestions for Implementing Genetic testing. *T. Vieira, I. Sgardioli, V. Gil-da-Silva-Lopes.* Medical Genetics, University of Campinas, Campinas, São Paulo, Brazil.

The introduction of new technologies of molecular diagnosis for health care has been a challenge in the last years, especially in Brazil, where the majority of the population is served by the public health system. The 22q11.1 deletion syndrome is the most common syndrome that has palatal anomalies as a major feature, with a prevalence of 1/4000 births. Considering this prevalence, the Brazilian health system characteristics and the current situation of medical and clinical genetic services in the country, the main aim of this study was to conduct a multicenter study for 22q11.2 deletion diagnosis as a model for the optimization of diagnostic strategies in medical genetics. We investigated the access to laboratorial diagnosis of 22q11.2 deletion at 11 genetic services and centralized this diagnosis for 100 patients with palatal abnormalities and suspicion of 22q11.2 deletion syndrome, referred from these centers during 30 months, at the Cytogenetics and Molecular Biology laboratories of the FCM/UNICAMP. To detect 22q11 deletions FISH (Fluorescence in situ Hibridization) and MLPA (Multiplex Ligation-dependent Probe Amplification) techniques were used. Previous and temporary availability for the diagnosis of 22q11 deletion, associated with research projects, was mentioned by seven centers, with remarkable geographic disparities. We detected 22q11 deletion in 35% of the patients, and chromosome abnormalities not related to 22q11 region in three patients; thus we reached diagnostic conclusion in 38% of the cases. There was significant difference between some clinical signs found in patients with or without 22q11 deletion. There was 100% of sensibility and specificity for both MLPA and FISH techniques. Considering the required infrastructure and the modifications in the FISH (allowing to reduce probe quantity), this technique was efficient, more economical and faster than MLPA. Centralizing the laboratorial diagnosis was considered advantageous, pointing to this model as an important and feasible strategy for genetic diagnosis in Brazil. These results allowed to suggestions for the improvement of laboratorial diagnosis of this and other genetic conditions in our country. Financial support: FAPESP, CAPES and CNPq.

1866F

Outreach, genetic counseling and testing of patients at risk for hereditary breast and ovarian cancer (HBOC) ascertained through the use of the electronic medical record. *H. Kershberg[1], E. Parkhurst[1], M. Alvarado[1], H. Zhou[2], J. Natoli[3], G. Tiller[1].* 1) Regional Genetics, Kaiser Permanente Southern California, Pasadena, CA; 2) Dept. of Research and Evaluation, Kaiser Permanente Southern California, Pasadena, CA; 3) Dept. of Clinical Analysis, Kaiser Permanente Southern California, Pasadena, CA.

Knowledge of mutation status has health management implications for patients and their family members, and the National Comprehensive Cancer Network (NCCN) recommends that women diagnosed with breast cancer under age 46 years be referred for genetic counseling. The genetics department in Kaiser Permanente Southern California (KPSC) provides clinical services in an integrated health care system serving nearly 3.5 million members. Using data from multiple sources including: KPSC tumor registry, a departmental cancer test results database, and the KPSC electronic medical record system, we noted that less than half of women diagnosed with early breast cancer had received genetic counseling and the offer of genetic testing. Using the same data sources, we identified 455 early breast cancer patients who were diagnosed between September, 2005 and September, 2010 and had not received genetic counseling. We sent these women a letter and followed up with a phone call offering a genetics consultation, and we offered BRCA testing to all those who came for counseling. **Results**: 32% (n=145) of women came for a genetic counseling appointment and were offered genetic testing. 83% (n=120) of those offered genetic testing underwent BRCA mutation analysis. 5 % (n=6) were positive for a deleterious mutation and 5% (n=6) had a variant of uncertain significance. The rate of acceptance of the genetic consultation and subsequent testing showed some significant differences. Hispanics were almost twice as likely to respond to the outreach and schedule an appointment compared to Caucasians (OR =1.87, 95% CI, 1.02, 3.43). Women diagnosed with cancer within a year of contact were 4 times as likely to schedule the genetic consultation than those diagnosed more than 5 years before (OR= 4.06, 95%CI, 1.03, 16.02). Of those who came in for counseling, African Americans were significantly less likely to accept genetic testing than Caucasians (OR = 0.25, 95%CI, (0.09, 0.73). **Conclusions:** This project demonstrates how an integrated care approach and electronic medical record system provide a unique opportunity to identify and contact women who are at increased risk. In view of the varied response rates among different racial/ethnic groups, multiple approaches may be required to reach diverse populations. Similar methods could be used to ascertain patients at risk for other hereditary cancers and genetic disorders.

1867F

Prevalence of Down syndrome in the United States. *A.P. Presson[1, 2], G. Partyka[3], K.M. Jensen[3, 4], S.A. Rasmussen[5], O.J. Devine[5], L. McCabe[3], E.R.B. McCabe[3].* 1) Division of Epidemiology, University of Utah, School of Medicine, Salt Lake City, UT; 2) Department of Biostatistics, UCLA, Los Angeles, CA; 3) Department of Pediatrics, University of Colorado School of Medicine, Aurora, CO; 4) Department of Internal Medicine, University of Colorado School of Medicine, Aurora, CO; 5) Centers for Disease Control and Prevention, Atlanta, GA.

Background: Life expectancy of people with Down syndrome (DS) in the United States (US) has increased remarkably over the past four decades. While births and deaths among people with DS have been studied in detail, we currently lack a reliable estimate of the population prevalence of DS. Using data available from the past century and projections of US population size, we estimated the prevalence of individuals with DS in 2008 and project these estimates to 2100. Objective: To estimate prevalence of DS in the US on January 1, 2008 and to project the prevalence of DS in 2100. Methods: Utilizing CDC data for annual US total births (1909–1939), births by maternal age (1940–2008) and published rates of DS by maternal age, we estimated annual births with DS (1909–2008). We estimated annual deaths by age for people with DS for 1900–1967 through extrapolation from available death certificate data (1968–2007). Using a time-specific life table approach, we estimated the US prevalence for DS on January 1, 2008 and applied Monte Carlo sampling methods to form 90% uncertainty intervals (UI) for our estimates. We then estimated the prevalence of DS in 2100 using the January 1, 2008 prevalence estimate and the middle and high projections of the US population size from the US Census Bureau, with the assumptions that DS prevalence would increase uniformly with the US population and there would be no change in the current rate of pregnancy terminations. Results: The estimated US prevalence of people with DS on January 1, 2008 was 240,500 (90% UI: 177,700 - 308,800) based on proportions of deaths by age from the most recent two years (2006–2007) of death certificate data. This estimate corresponded to a prevalence of 7.94 (90% UI: 5.86–10.19) people with DS per 10,000 in the US population. We projected an estimated 465,700–936,300 people with DS in 2100. Conclusion: Our estimate of DS prevalence is 30–40% lower than estimates based solely on current birth prevalence, but is similar to estimates in European countries. Survival among people with DS has increased dramatically since 1970, which suggests continued growth in DS prevalence over the next century. Thus, our projection of 465,700–936,300 people with DS in 2100 could be an underestimation. A more realistic projection based on expert opinion is warranted and planned. More accurate prevalence estimates are critical to facilitate planning for services for people with DS.

1868F

Rare Disease Initiatives in Europe: Centres of Expertise in Germany. *C. Huebner[1], M. Stuhrmann-Spangenberg[1], C. Zeidler[2], J. Schmidtke[1].* 1) Institue of Human Genetics, Hannover Medical School, Hannover, Niedersachsen, Germany; 2) Molecular Hematopoiesis and Pediatric Hematology and Oncology, Hannover Medical School, Hannover, Germany.

A disease which affects not more than 5 in 10,000 people is considered to be rare. Therefore 7,000–8,000 of 30,000 known diseases are categorized as rare diseases, with a great majority being of genetic origin. According to WHO estimates some 30 million people suffer from a rare disease in the European Union. After the European Council recommended an action in the field of rare diseases in 2009, national strategies were set up in many European countries, including the formation of centres of expertise. The Rare Disease Center at Hannover Medical School was initiated by the Department of Human Genetics and opened in November 2011. An interdisciplinary facility where research and care for patients with known diagnosis and patients with chronic conditions not yet having received a definite diagnosis was set up. All patient referrals including self-referrals have been documented in detail. A patient registry is being developed. Between 30 and 50 paediatric and adult patients were referred per month with a rising tendency over time. Preliminary data suggest that the majority of requests are self referrals (88% after 6 month) and only about 10% are referrals from primary care physicians. More than half of the patients did not have a reliable diagnosis at referral. As expected most of the undiagnosed patients were asking for a diagnosis and patients with known diagnosis were asking for experts. Interestingly more than 30% of patients were seeking for information, indicating a lack of information available on rare diseases. As a unique feature the German Orphanet team is part of the Hannover Rare Disease Centre. Orphanet is the reference portal for information on rare diseases and orphan drugs particularly in Europe. Here, we will report our experience of the first year, the organizational structure and financing of the Rare Disease Centre at Hannover Medical School including its 11 subcentres and specialized clinics, describe internal patient paths, diagnostic successes and failures, enrolment of patients in research projects, and compare our structure and experience with the few other centres in Germany and elsewhere, from which data are available. We will present an outlook into future regional, national and international networking of rare disease centres.

1869F

Implementation of Universal Lynch Syndrome Screening in an Integrated Health-Care Delivery System. *K.A.B. Goddard, T. Kauffman, M. Morse, J. Davis, C. Young, E. Esterberg, C. McGinley, J. Reiss.* Kaiser Permanente Northwest, Portland, OR.

Screening tests for Lynch syndrome (LS) have been recommended as an evidence-based practice which decreases disease burden and save lives. Nationally, more than half of patients meeting criteria do not receive LS screening. In a recent study of seven integrated health-care delivery systems, fewer than 5% of patients diagnosed with colorectal cancer (CRC) received screening for LS. How do we effectively improve access to LS screening? We hypothesize that universal LS laboratory-based screening will improve appropriate referrals for subsequent genetic counseling and consideration for additional testing, compared with the current practice of self-referral or provider-based referrals to medical genetics. Through a randomized-controlled trial, this project evaluates a strategy to maximize screening of CRC patients for LS. We will invite all CRC patients undergoing colon surgery to join the trial and compare universal LS screening in the intervention arm to usual care. We report on the development of processes and resources for the implementation of this screening program. We developed an algorithm to identify eligible patients undergoing bowel surgery daily from the electronic medical record. We implemented a procedure to order LS screening for patients randomized to the intervention arm, and to integrate a procedure to prepare tissue for microsatellite instability (MSI) testing within the pathology department procedures for managing the surgical specimens for the case. MSI test results are returned from an outside laboratory directly to medical genetics, and the laboratory report is integrated within the electronic medical record. We created genetic counseling educational talking points and result disclosure processes. Program implementation is being measured through a variety of mechanisms including interviews with clinical staff, patient surveys, and monitoring of downstream utilization through the electronic medical record. Evaluation of the steps required for implementation will aide in the determination of best strategies for successful universal LS screening, and will inform future implementation efforts at new sites considering this approach for LS screening.

1870F

Beyond NGS technology - overcoming key challenges for nation-wide implementation of next-generation sequencing into routine diagnostics. *T. Vrijenhoek on behalf of the Centre for Genome Diagnostics.* Centre for Genome Diagnostics, Utrecht, Netherlands.

We present an approach to implement next-generation sequencing (NGS) in routine diagnostics across clinical genetic centers. As diagnostic application of NGS has become **technically feasible**, many institutes have individually set up experimental and data analysis procedures accordingly. However, if we want to develop NGS into a **high-quality clinical decision tool** in national healthcare, we need to think beyond individual centers. At that point, issues like **standards** for diagnostic procedures, (legal) **agreement** on the use of personal genomic data, and **harmonization** of consent procedures are to be solved. The clinical genetics community in the Netherlands - a frontier country in self-regulation of technology-driven diagnostics - has overcome such cross-center challenges. All of the nation's clinical genomic research groups and diagnostic centers, as well as technology and service providers participate in the Centre for Genome Diagnostics, aiming to **identify and tackle** multi-center bottlenecks and challenges. Collectively we have developed an implementation approach based on e.g. experimental guidelines from the Board of Dutch DNA diagnostics laboratories (LOD), and circulating consent procedures within the Netherlands' Association of Clinical Geneticsts (VKGN). We piloted the approach in a joint project (CARDIO), thereby generating concrete data on how NGS-based diagnostics works in practice. CARDIO comprised 10 patients with cardiomyopathy, of whom DNA samples and medical records were sent to all clinical genetic centers. These performed comprehensive NGS-based diagnostics on all patients, from clinical assessment to diagnostic counseling. The centers were free in using their preferred approach of enrichment, sequencing, data analysis, and diagnostic interpretation. They all carefully reported on their internal diagnostic process. Based on 32 reports and detailed follow-up we were able (1) to assess bottlenecks, challenges and best practices based on concrete and concordant results, not on hypothetical situations; (2) to identify the key people in the diagnostic process and especially their position in the organization; and (3) to develop a framework for optimal coordination and communication among research groups and diagnostics centers. With the results of project CARDIO at hand, we present a **model for optimal transition** of NGS technology from research to diagnostics, regardless of technology.

Inherited Neuropathies Consortium: A Collaborative Approach to Genetic Research in Charcot-Marie-Tooth (CMT) disease. *F. Speziani[1], S.M.E. Feely[2], C. Siskind[3], S.H. Blanton[1], G. Beecham[1], J.M. Vance[1], M. Shy[2], S. Zuchner[1], Inherited Neuropathies Consortium.* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) University of Iowa, Iowa City, IA; 3) Stanford University, Palo Alto, CA.

Charcot-Marie-Tooth (CMT) disease encompasses a group of clinically and genetically heterogeneous hereditary peripheral neuropathies. Despite the identification of >50 CMT genes, only 30% of axonal CMT2 patients have mutations in known genes. Further, variable phenotypic expressions have long been noted within and across CMT families and patients, suggesting unknown genetic modifying factors. To efficiently approach these questions in a rare disease such as CMT, large-scale collaborations are necessary. With the support of NINDS we have formed the Inherited Neuropathies Consortium (INC), which is a member of the Rare Disease Clinical Research Network (RDCRN). The INC has currently 13 national and international sites led by prominent CMT investigators. The clinical aims of the INC include the development of standardized clinical measures for adult and pediatric CMT and natural history studies. Genetic studies are focused on the goal of exome sequencing 1,000 CMT2 samples and a genome wide association study of genomic modifiers of clinical outcome in CMT1A. INC members have organized a working structure that includes standardized IRB protocols, centralized DNA isolation/banking, and web-based data management portals. During the first three years of the INC, 2,120 patients have been registered; with 985 patients recruited in the past year. For genetic modifiers in CMT1A we have completed genotyping for the first GWAS analysis in CMT, which is currently under analysis. To date, 49 axonal CMT families from ten INC sites have had whole exome sequencing. Several novel candidate CMT genes are currently being followed up. We will present the unique and growing structure of the INC as a promising model for research of rare diseases.

1872F

Genomic Technologies: Effective Integration into Pediatric Clinical Care. *R. Hayeems[1,3], N. Hoang[1], S. Chenier[1], J. Stavropoulos[1], S. Pu[1], S. Wodak[1], R. Babul-Hirji[1], J. Davies[2], L. Velsher[2], J. Aw[2], R. Weksberg[1], C. Shuman[1].* 1) Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Genetics, Medcan Clinic, Toronto, Ontario, Canada; 3) Institute of Health Policy Management and Evaluation, University of Toronto, Ontario, Canada.

Clinical interpretation, genetic counseling, and medical management for pediatric chromosome microarray (CMA) present ongoing challenges. To guide current practice and to inform future strategies for genome-wide analyses, the impact of CMA technology on clinical care warrants evaluation. Our study aims to understand the impact of CMA on pediatric medical management. A retrospective chart review of children who underwent CMA in 2010–2011 is underway. 900 charts were selected for review, 300 from each CMA result type: pathogenic, uncertain, benign. Data elements include: age, gender, ethnicity, phenotype, family history, microarray results, and medical investigations immediately prior to and following microarray testing. Descriptive and multivariate analyses are being used to understand the association between microarray results and post-test medical investigations. We hypothesize that an increase in medical investigations will be observed in children with pathogenic copy number variants (CNVs) compared to those with uncertain or benign CNVs. 129 charts have been reviewed to date (146 CMA results: 30.1% pathogenic, 37.7% uncertain, 32.2% benign). Preliminary results show that 44.9% of post-array investigations occurred in the pathogenic variant group, 34.1% occurred in the uncertain variant group, and 21.0% occurred in the benign variant group. For pathogenic CNVs, 53.4% of investigations were prompted by the CNV itself and 46.6% were prompted by phenotype. For non-pathogenic CNVs, 25.4% of investigations were prompted by the CNV and 74.6% of investigations were prompted by phenotype and diagnostic quest (p=0.0001). Our findings suggest that for pathogenic CNVs, medical investigations are prompted equally by the CNV finding itself and phenotype. For non-pathogenic CNVs, the majority of medical investigations are prompted by phenotype and diagnostic quest. These findings will be instructive in anticipating the impact of next generation genomic analyses on medical management and downstream use of health services.

1873F

Genomic Technologies: Effective Integration into Adult Preventive Medicine. *N. Hoang[1], R. Hayeems[1,3], J. Davies[2], L. Velsher[2], J. Aw[2], S. Chenier[1], J. Stavropoulos[1], S. Pu[1], S. Wodak[1], R. Babul-Hirji[1], R. Weksberg[1], C. Shuman[1].* 1) Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Genetics, Medcan Clinic, Toronto, Ontario, Canada; 3) Institute of Health Policy Management and Evaluation, University of Toronto, Toronto, Canada.

Genome-wide single nucleotide polymorphism (SNP) arrays that assess individual genetic risk for common polygenic diseases can be useful tools to guide proactive health screening and overall preventive health care. While evidence is emerging related to why consumers are motivated to purchase genome-wide testing and how they are integrating results into health-related decision-making, little is known about how array information impacts clinical recommendations and health services used. Navigenics Health Compass is one example of such tests; it is currently available at Medcan, an executive health clinic in Toronto. Our study aims to understand how Navigenics risk results relate to medical recommendations and subsequent health service utilization. We are conducting a retrospective medical record review for two groups of Medcan clients, dating back to 2009: those who have pursued Navigenics testing (cases) and those who have not (controls). Navigenics risk estimates for nine conditions will be examined, including: abdominal aneurysm, atrial fibrillation, celiac disease, colon cancer, type 2 diabetes, glaucoma, heart attack, melanoma, and prostate cancer. Client data are being collected on: age, gender, ethnicity, clinical phenotype, environmental modifiers (exercise level, alcohol intake, and smoking behaviours), family history, medical recommendations, and services used within one year of receiving Navigenics results. We will analyze the association between Navigenics risk estimates and (i) medical recommendations and (ii) services used for each condition, controlling for the other variables. We hypothesize that for each condition, medical recommendations and services used will be increased for patients with elevated Navigenics risk estimates compared to those with average/reduced risk estimates and compared to controls. Analyses to date will be presented. Understanding the impact of genome-wide SNP arrays (i.e. used for individual risk assessment of common polygenic conditions) on downstream clinical management and health service utilization will inform strategies for effective delivery of these new technologies.

Evaluating laboratories' interpretation of genetic test results through a EuroGentest Proficiency Testing survey. *E. Girodon[1,11], S. Berwouts[2,11], M. Rodriguez de Alba Freiria[3,12], AF. Roux[4,13], D. Barton[5,13], L. Hoefsloot[6,13], S. Gardner[7,14], O. Kamarainen[7,13], B. Fowler[8,14], M.A. Morris[9,11], E. Dequeker[2,11], R. Hastings[10,12].* 1) Genetics, GH Henri Mondor APHP and INSERM U955, Creteil, France; 2) University of Leuven, Department of Public Health, Biomedical Quality Assurance Research Unit, Leuven, Belgium; 3) Fundacion Jimenez Diaz, Genetics Department, Madrid, Spain; 4) CHU de Montpellier et IURC, Laboratory of Molecular genetics, Montpellier, France; 5) National Centre for Medical Genetics and School of Medicine & Medical Sciences, University College Dublin, Dublin, Ireland; 6) Radpoud University Nijmegen Medical Centre, Department of Human Genetics, Nijmegen, The Netherlands; 7) Genetic Medicine, St Mary's Hospital, Manchester, United Kingdom; 8) Paediatrics, University Children's Hospital, Basel, Switzerland; 9) Hôpitaux Universitaires de Genève, Département de Médecine Génétique et de Laboratoire, Genève, Switzerland; 10) John Radcliffe Hospital, Oxford University Hospitals NHS Trust, Women's Centre, Oxford, United Kingdom; 11) Cystic Fibrosis European Network (CF Network); 12) Cytogenetic European Quality Assessment (CEQA); 13) European Molecular Quality Network (EMQN); 14) European Research Network for evaluation and improvement of screening, Diagnosis and treatment of Inherited Disorders of Metabolism (ERNDIM).

Interpretation of test results is a key component of a genetic laboratory report, ensuring full understanding of the results by the referring physician, including potential implications for the patient and the family. Proficiency Testing (PT) or External Quality Assessment (EQA), in which many laboratories report on the same clinical scenario, provides an ideal tool to study reporting practices. In order to evaluate laboratory performance in this area, a EuroGentest survey among PT programs from four European providers (CF Network, CEQA, EMQN & ERNDIM) was set up, with the aim of determining the interpretation elements that were missing in laboratory reports, in regard to existing guidelines and recommendations (*e.g.* OECD). PT reports from 2011 representing 422 laboratory participants and relating to six different PT programs: cystic fibrosis, Friedreich ataxia, hereditary deafness at the DFNB1 locus, postnatal microarray (CEQA), prenatal diagnosis of chromosomal abnormalities on amniotic fluid and metabolic diseases, were evaluated using criteria derived from the OECD Guidelines for Quality Assurance in Molecular Genetic Testing. Mean interpretation scores varied between cases, ranging from 1.61/2 to 1.98/2. Despite heterogeneity in the scoring systems and in assessment for the different schemes, the data analysis revealed the following: 1) although the answer to the question was provided in the majority of reports, the survey emphasized the need to clearly restate the indication of testing in reports; 2) items related to follow-up testing were the most critical: search for a 2nd mutation was missing in 36% of DFNB1 reports, testing the parents to confirm compound heterozygosity was missing in 29% of CF reports and need for parental bloods was not mentioned in up to 27% of prenatal cytogenetics reports (where applicable). Moreover, confirmation of unexpected results was not recommended in 75% of CF reports. A notable proportion of molecular genetics (~36% in FRDA, 28% in DFNB1 and 26% in CF) and cytogenetics (~29%) reports did not mention the recurrence risk of disease and/or the possibility of prenatal diagnosis for future pregnancies. This first and preliminary horizontal survey among different PT programs providers emphasizes the need to find effective training and communication processes, including harmonization of assessment between PT programs, so that laboratories can improve the interpretation content of their reports.

Interstate Compatibility and Emergency Preparedness of Newborn Screening Laboratories at the Interface of Clinical Medicine and Public Health. *J. Mulvihill[1], P. Hopkins[2], S. Berberich[3].* 1) Dept Pediatrics, University of Oklahoma, Oklahoma City, OK; 2) Missouri Public Health Laboratory, Jefferson City, MO; 3) State Hygienic Laboratory, University of Iowa, Iowa City, IA.

Clinical decisions about laboratory results for newborn screening assays should be identical across the US. Emergency preparedness is essential to maintaining the integrity and capacity of state-run newborn screening programs and laboratories. We assessed results of parallel assays by different state laboratories on the same dried blood spot—thereby, truly validating the clinical equivalence of results. To do so, we executed drills between such laboratories to rehearse continuity in the event of an unanticipated collapse of one state's program. After numerous in-person and electronic meetings with all stakeholders to dissect all points of each state's policies, procedures, and protocols, 14 complete drills were held, of one and three days' duration, first between Missouri and Iowa, then seven other states, involving both the laboratory staff and supervisors, as well as professionals in information technology, state emergency preparedness, and short-term reporting and follow-up. A total of 5,864 dried bloodspot samples were involved and 351,840 laboratory results on identical specimen cards were compared. Detailed minutes of meetings were examined for issues anticipated and resolved, and logs of the actual drills revealed additional lessons learned. The quantitative laboratory results and clinical decisions between laboratories were compared with usual statistics. The 14 exchanges among nine states included 18 days of newborn screening. A 1996 Federal Law, the Emergency Management Assistance Compact (EMAC), successfully resolved legal, states' rights, and sovereignty issues and permitted the demonstration of emergency preparedness. Respective staffs achieved sufficient harmonization of computer and laboratory systems to assure comparability of results. Interstate laboratory results were highly correlated with only minimal differences in a few borderline abnormal results. No new positive cases were uncovered that would have required clinical intervention. The laboratories of nine participating states produced findings that led to exactly the same rate of positive results that would require diagnostic evaluation of the newborn, documenting the great reliability the laboratories have achieved. Emergency preparedness that includes fully functional drills should be a routine element of all states' newborn screening programs. They are feasible and economical. Our regional approach has been a successful model. HRSA Grant U22MC03962.

1876F

Evaluation of the Bogotá Congenital Malformations Surveillance Program. *I. Zarante[1,2], C. Mallarino[1], G. Gracia[2].* 1) Inst de Gen Humana, Pontificia Univ Javeriana, Bogota, Bogota, Colombia; 2) Secretaria de Salud de Bogota.

Introduction: The Bogotá Congenital Malformations Surveillance Program was designed in the year 2001, based on the Latin American collaborative study of congenital malformations (ECLAMC). The program is hospital-based and currently covers almost 90% of the total births of the city. CDC guidelines for evaluating public health surveillance systems clearly state that these programs should be evaluated. Methods: We evaluated the attributes of the Bogotá Congenital Malformations Surveillance System based on the CDC guidelines for evaluating public health surveillance systems. Results: 1. Simplicity: the general structure of the program is relatively simple, compared to the majority of surveillance systems functioning in Colombia. Additionally, only 14 people are needed for the program to work properly, and it functions with a single centralized system for capturing, managing and analyzing data, which also adds simplicity. 2. Flexibility: In retrospective, the program has been able to adapt to changes without great inconvenient. 3. Data quality: The mean percentage of blank responses to items on the surveillance forms was 5% for the case-control modality and 17% for the monitor modality in the year 2011. 4. Sensitivity: Compared to the Metropolitan Atlanta Congenital Defects Program, our program has a 48% sensitivity for the detection of all defects, the lowest being congenital cataract and interatrial communication, and the highest being Down syndrome. 5. Predictive value positive: in the year 2011 we followed a total of 513 patients with 510 having a confirmed diagnosis, which gives us a predictive value positive of 99.4%. 6. Representativeness: The program covers almost 90% of the births that occur in the city of Bogotá and the population is heterogeneous, which means that it is fairly representative of the general population of newborns in the city. 7. Timeliness: Information gathered during one month is entered into the central electronic server during the first ten days of the following month for the case-control modality and during the first 20 days for the monitor modality. Follow-up is initiated at two months of age. 8. Stability: Before the year 2010, the program had some periods of instability because resources were very limited making it very difficult to hire essential personnel, which resulted on inactivity of the surveillance in some hospitals.

Drivers, barriers and opportunities for genetic testing services in emerging economies: the GenTEE (Genetic Testing in Emerging Economies) project. *I. Nippert[1], A. Christianson[2], D.D.G. Horovitz[3], R. Raouf[4], C.D. Padilla[5], V. Penchaszadeh[6], A. Rajab[7], I.C. Verma[8], N. Zhong[9], L. Gribaldo[10], U. Kristoffersson[11], J. Schmidtke[12].* 1) Women's Health Research, Muenster Medical School, Westfaelische Wilhelms-Universitaet, Muenster, Germany; 2) Division of Human Genetics, National Health Laboratory Service & University of the Witwatersrand, South Africa; 3) Centro deGenética Médica - Instituto Nacional de Saúde da Mulher, da Criança e do Adolescente Fernandes Figueira (IFF/Fiocruz), Rio deJaneiro, Brazil; 4) Institute of Post Graduate Childhood Studies/Ain-Shams University, Cairo, Egypt; 5) Department of Pediatrics, College of Medicine and Philippine General Hospital; Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila, Philippines; 6) Centre of Genetics and Public Health. Department of Health Sciences, Universidad Nacional de La Matanza, Buenos Aires, Argentina; 7) Genetic Unit, Directorate General of Health Affairs, Ministry of Health, Muscat, Sultanate of Oman; 8) Centre of Medical Genetics, Sir Ganga Ram Hospital, Rajender Nagar, New Delhi, India; 9) Peking University Center of Medical Genetics, Beijing, People's Republic of China; 10) Institute for Health and Consumer Protection, European Commission Joint Research Centre, Ispra, Italy; 11) Department of Clinical Genetics, University Hospital Lund, Lund, Sweden; 12) Institute of Human Genetics, Hannover Medical School, Hannover, Germany.

Background: Due to the epidemiological transition in the emerging economies of China, East Asia, India, Latin America, the Middle East and South Africa, these economies are facing (i) an increasing proportion of morbidity and mortality due to congenital and genetic conditions, (ii) a rising need for genetic services to improve patient outcomes and overall population health. These economies are facing the challenge how: (i) to ensure the successful translation of genetic/genomics laboratory and academic research into quality assured pathways, (ii) to develop a service delivery infrastructure that leads to equitable and affordable access to high quality genetic/genomic testing services. *Objectives:* (i) to document and compare current practices and the state of genetic service provision in eight emerging economies: Argentina, Brazil, China, Egypt, India, Oman, Philippines and South Africa, (ii) to identify current knowledge gaps and unmet service needs. The GenTEE international project is intended to inform policy decisions for the challenges of delivering equitable high quality genetic services and to promote international collaboration for capacity building. *Methods:* (i) a standardized survey that is the first of its worldwide that allows comparison of services internationally across a number of key dimensions by using a core set of indicators, selected by the GenTEE consortium for their relevance and comparability, (ii) capacity building demonstration projects. To date, the GenTEE project has completed its survey that maps the current state of genetic services in the participating countries and identifies current drivers, barriers and opportunities for genetic services development. *Results:* There is no equitable access to genetic services in all countries mainly due to financial barriers (underfunded fragmented public services, out-of-pocket expenses tend to be the norm for genetic testing services), geographical barriers (concentration of services in main cities) and skill gaps, resulting in inequitable services or delayed access. The development of services in the private sector is opportunistic and mostly technology and market driven. There is a marked lack of standard operating procedures and agreed quality assessment processes for new technologies. *Discussion:* International collaborative networks can provide support for capacity building and help to strengthen the provision of quality genetic/genomic services in emerging economies.

Genetic variation in susceptibility to hypothyroidism induced hearing impairment. *Q. Fang[1], T.J. Jones[1], T.-W. Gong[1], A.H. Mortensen[1], M.T. Fleming[1], D.F. Dolan[1], M.I. Lomax[1], K.R. Johnson[2], M. Mustapha[3], S.A. Camper[1].* 1) University of Michigan, Ann Arbor, MI; 2) The Jackson Laboratory, Bar Harbor, ME; 3) Stanford University, Stanford, CA.

Hypothyroidism during pregnancy or in newborns can impair hearing and cognition, although individual children vary in their sensitivity. Our studies in genetically hypothyroid mice demonstrated that the genetic background of the fetus confers susceptibility or resistance to hypothyroidism-induced hearing impairment (1, 2). Thyroid hormone deficiency has pleiotropic effects on development of neurosensory and conductive aspects of hearing in susceptible mouse strains, including effects on innervation and potassium flux in the cochlea and maturation of the middle ear (2, 3). The DW/J-*Pou1f1*$^{dw/dw}$ mutants produce little or no thyroid hormone and have severe dwarfism and profound, congenital deafness. Mutant F2 progeny from a cross of this strain with CAST/Ei had equal growth insufficiency but exhibited a range of hearing abilities, from normal hearing to profound deafness. Initial microsatellite mapping studies suggested that a locus on chromosome 2 could explain about 20% of the variation in hearing, and we named it Modifier of *dw* hearing, *Mdwh* (4). Both AKR and C57BL/6 are susceptible, and C3H/HeJ and 129P2/Ola are resistant. The strain distribution pattern analysis of the DW/J stock revealed that it is similar to C57BL/6 in the *Mdwh* region. Here we report the results of genome-wide SNP typing for 1500 loci on DW/J × CAST/Ei F2 *Pou1f1*$^{dw/dw}$ mice and DW/J × 129P2/Ola F2 mutants whose hearing was quantified by auditory brain stem response testing. The data from both crosses implicate the same region of chromosome 2 and refine the *Mdwh* to 20 Mb with over 500 genes. We carried out gene expression profiling with cochlear RNA from DW/J-*Pou1f1*$^{dw/dw}$ and wild type mice and identified over 500 genes that are regulated by thyroid hormone in the cochlea, and 10 map to the *Mdwh* region. We are comparing expression of these genes in susceptible and resistant strains to evaluate them as candidates for *Mdwh*. Identification of a gene that can protect against the pleiotropic effects of thyroid hormone deficiency on the development of hearing could lay the foundation for designing therapeutics for children who are not responsive to thyroid hormone supplementation. Transethnic Mapping of Putative Diabetic Nephropathy Loci in African Americans. *N.D. Palmer[1,2,3], M.C.Y. Ng[2,3], J.N. Cooke[5], M. Petrulis[1], B.I. Freedman[4], D.W. Bowden[1,2,3].* 1) Biochemistry Department, Wake Forest School of Medicine, Winston-Salem, NC; 2) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Molecular Medicine and Translational Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 5) Internal Medicine, Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, NC.

Diabetes-associated nephropathy (DN) is the most common cause of end-stage renal disease (ESRD) in the United States, with disproportionately higher rates in African Americans. The purpose of this study was to perform fine mapping of 23 reported DN loci in the African American population. Our African American Genome-Wide Association Study (GWAS) dataset was composed of 965 DN cases and 1029 population-based controls. In total, 3,122,014 SNPs were evaluated including those from the Affymetrix 6.0 array with imputation to HapMap Phase II. All analyses were performed with adjustment for admixture using a principle components approach and adjusted for multiple comparisons by accounting for the effective number of independent SNPs (n_{eff}) at each locus. Examination of 23 reported DN genes revealed three loci statistically associated (P<0.05) with DN in African Americans after adjustment for multiple comparisons: myosin heavy chain 9 non muscle (*MYH9*; n_{eff}=56, rs5750250, OR=0.72, P=1.6E-05), carnosine dipeptidase 1 (*CNDP1*; n_{eff}=45, rs65666815, OR=1.31, P=7.6E-03 and chimerin 2 (*CHN2*; n_{eff}=194, rs3729621, OR=1.57, P=0.037). Given the high frequency and strong effect of variants in apolipoprotein L1 (*APOL1*) on DN-susceptibility, G1 and G2 haplotypes were included as covariates in the analysis. As a result, association was eliminated at *MYH9* while the significance at *CNDP1* (rs65666815, P=0.011) was attenuated and a new variant in *CHN2* rose to significance (rs17157914, OR=0.65, P=0.025). These results suggest that causal genes may be shared across populations. The reduced, differential linkage disequilibrium pattern observed in African Americans will facilitate fine mapping of causal variants associated with DN.

1880F

The Exon 3 deleted/full-lenght polymorphism of the Growth Hormone Receptor in the Brazilian Population: Association with idiopathic short stature and body composition measurements in osteoporosis. *F.A. Marques[1], T.C.L. Lins[2], C.T. Neves[3], M.T.O. Cardoso[3], R.M. Lima[4], R.J. Oliveira[4], R.W. Pereira[1,2], R. Pogue[1].* 1) Programa de Pós-Graduação em Ciências Genômicas e Biotecnologia, Universidade Católica de Brasília, Brasília, DF, Brazil; 2) Programa de Pós-Graduação em Patologia Molecular, Universidade de Brasília, Brasília, DF, Brazil; 3) Núcleo de Genética da Secretária de Saúde do Distrito Federal, DF, Brazil; 4) Faculdade de Educação Física, Universidade de Brasília, Brasília, DF, Brazil.

The influence of the growth hormone receptor (GHR) exon 3 full-length/deleted (fl/d3) polymorphism on the response to growth hormone is undetermined, but has been suggested to be associated with linear growth, and also with phenotypes such as obesity and diabetes. The work described here involves genotyping of this polymorphism in different Brazilian population groups. Instead of direct genotyping, the use of the single nucleotide polymorphism rs6873545 as anindirect/surrogate marker was validated. Genotyping by two methods (multiplex PCR/direct and TaqMan-SNP/indirect) of 105 admixed individuals from the general Brazilian population showed 100% concordance between the GHR polymorphism and the SNP alleles. The distribution of genotypes was in Hardy-Weinberg equilibrium (HWE) and no statistical difference was observed according to genetic ancestry among genotypes. Subsequent SNP genotyping of 32 patients with idiopathic short stature showed a significant association (p=0.013) between the full-length (fl) allele and short stature, and the polymorphism was not in HWE in this group. Furthermore, genotyping in 175 women between the ages of 56 and 82 with and without osteoporosis showed that while there was no association with the development of osteoporosis, there was an association between the fl/fl genotype and lower bone mineral density (p=0.0004), and between this genotype and lower lean mass (p=0.018) in women with the condition. These results suggest that: a) the SNP rs6873545 can be used as a surrogate for the GHR fl/d3 polymorphism due to linkage disequilibrium in the Brazilian population; b) the polymorphism may play a role in the multifactorial determination of normal and pathological height; and c) the interference of the fl allele on the response to growth hormone may affect the severity of osteoporosis in post-menopausal women.

1881W

Variants in PTPN22 and SMOC2 genes and the risk of thyroid disease in the Jordanian population. *A. Alkhateeb[1], N. Marzouka[1], R. Tashtosh[2].* 1) Biotechnology and Genetics Department, Jordan Univ Science & Tech, Irbid, Jordan; 2) Endocrinology Department, Ibn Alnafees hospital, Irbid, Jordan.

Autoimmune thyroid diseases (AITDs) are one of the most prevalent autoimmune diseases, especially among females. AITDs contain two main categories: Graves Disease (GD) and Hashimoto Thyroiditis (HT). The causes of AITDs are not clear, though twins and familial studies give many evidences on a genetic susceptibility. Our study focused on two polymorphisms: rs2476601 (C1858T) polymorphism in PTPN22 gene which is an autoimmune risk locus and rs13208776 polymorphism in intron 4 in SMOC2 gene which was found to be associated with generalized autoimmune vitiligo. In our case-control study, we collected blood samples from 216 normal Jordanians and 204 Jordanian patients with clinical symptoms of autoimmune thyroid diseases, these samples were used for DNA extraction. Genotyping of polymorphisms in PTPN22 and SMOC2 genes were done by Polymerase chain reaction (PCR) followed by Restriction Fragment Length Polymorphism (RFLP) technique. We statistically analyzed the genotyping data by Open-Epi software to calculate P-value, our results show that there is no difference between patients and controls genotypes and allele frequencies on C1858T locus (P=1), thus no association was found between this locus and AITDs as a whole or GD and HT separately. Rs13208776 variant in SMOC2 gene showed more variant distribution between controls and patients genotypes (P=0.17) and allele (P=0.12) frequencies, especially in case of females subgroup when the genotypes statistically tested on combined dominant model (P=0.052). Even though P-values were above 0.05 we suggest that SMOC2 gene may play role in AITD susceptibility as a dominant variant. Additional samples might be needed to confirm or exclude association of SMOC2 and AITD.

Genetic associations with neonatal thyroid stimulating hormone levels. *F. Alul[1], O. Shchelochkov[1], S. Berberich[2], J. Murray[1], K. Ryckman[1].* 1) Department of Pediatrics, University of Iowa, Iowa City, IA; 2) State Hygienic Laboratory, University of Iowa, Iowa City, IA.

Background: Thyroid hormones are critical regulators for protein synthesis, carbohydrate metabolism and cellular differentiation. Elevations or deficits in thyroid hormone levels are responsible for a wide range of neonatal and adult phenotypes. Even small differences in thyroid function are correlated with body mass index, blood pressure, lipid levels, atrial fibrillation and cardiovascular disease. Newborns are commonly screened for biochemical evidence associated with hypothyroidism which, if untreated, can result in severe cognitive disability. Several genome-wide, candidate gene and meta-analysis studies have been performed with thyroid hormones in adults; however, to our knowledge no studies have examined genetic associations with neonatal thyroid levels. Objective: To identify genetic factors contributing to thyroid stimulating hormone (TSH) variation in newborns. Design: A population of Iowa neonates; term (n=827) and preterm (n=815), were genotyped at 45 single nucleotide polymorphisms encompassing 24 candidate genes. TSH measurements were obtained from the Iowa Neonatal Metabolic Screening Program (INMSP). Analysis of variance (ANOVA) was performed to identify genetic associations with TSH concentrations. Results: The strongest association was rs4704397 in the *PDE8B* gene (p=1.3×10-4), followed by rs965513 (p=6.4×10-4) on chromosome 9 upstream of the *FOXE1* gene. Both of these SNPs met statistical significance after correction for multiple testing; Bonferonni correction significance threshold set at p<0.001 (0.05/45 markers). Six other SNPs show marginal significance (p<0.05) after correction for multiple testing. Conclusions: Several genetic polymorphisms previously associated with adult TSH levels are also associated with neonatal levels. This may be useful in the early prediction of risk for adult diseases and conditions associated with thyroid hormone levels. Furthermore, this provides a better understanding of the thyroid profile and potential risk for thyroid disorders in newborns.

1883F

TNF-β Nco1 polymorphism in relation to postoperative sepsis outcome in joint care surgery. *K. Baghel, R. Srivastava, S. Raj, D. Sanghi.* Orthopaedic Surgery, KG Medical College, CSM Medical University, Lucknow, UP, India.

Background: Tumor Necrosis Factor (TNF) is believed to be a cytokine central to pathogenesis of sepsis and the TNF-β Nco1 polymorphism has been found to be associated with increased mortality rate in severe sepsis following major surgeries. We postulated that Nco1 polymorphism may be associated with post operative infection in some patients but not in others Methods: The study group consisted of 153 patients undergoing major elective surgery (surgical time more than 1 hour and requiring general anesthesia and or respiratory assistance). Blood samples were obtained for genomic DNA isolation. Genotyping of each patient for TNF-β polymorphism was performed. All the patients were followed for 1 month following surgery for any evidence of sepsis as determined by guidelines from Bone et al. Subjects with and without post-operative infection were compared on presence or absence of polymorphism and of confounder status. Results: The overall allele frequency for TNF-β genotype was 0.32 for TNFB1 and 0.68 for TNFB2. In TNF-β genotype, homozygous recessive TNFB1 were 17 (11.1%), heterozygous TNFB1/ TNFB2 were 63 (41.2%) and homozygous dominant TNFB2 were 73 (47.7%). 125 patients showed an uncomplicated postoperative recovery, while 25 developed mild sepsis and 3 developed severe sepsis. Genotype distribution in patients with an uncomplicated clinical course was significantly different from that in patients with postoperative sepsis. Development of postoperative sepsis was significantly higher in patients homozygous for the allele TNFB2. When compared with patients carrying at least one TNFB1 allele (TNFB1 homozygous and heterozygous genotype), the TNFB2 homozygous genotype was associated with an OR of 3.39 (p=0.005) for the development of severe sepsis. Compared with the heterozygous genotype, the OR for the homozygous TNFB2 genotype was 5.5 (p=0.001) Conclusions: The Nco1 polymorphism within the TNF-β gene influences the development of postoperative sepsis suggesting a genetic determination in susceptibility to postoperative infection in surgerical interventions.

1884W

Preeclampsia is associated with variation in endoglin pathway genes. *M. J. Bell[1], J. M. Roberts[1, 2], S. A. Founds[1, 2], A. Jeyabalan[1,2], L. Terhorst[1], Y. P. Conley[1].* 1) University of Pittsburgh, Pittsburgh, PA; 2) Magee-Womens Research Institute and Foundation, Pittsburgh, PA.

Preeclampsia is a pregnancy disorder that greatly impacts maternal and fetal/neonatal health and wellbeing. Preeclampsia's pathophysiology remains unclear, but gene expression studies and the presence of increased circulating soluble endoglin before clinically evident disease have implicated endoglin as a potential factor involved in its development. The purpose of this case-control candidate gene association study was to investigate the association between endoglin pathway genetic variation and preeclampsia. Data collected from 355 white (181 cases/174 controls) and 60 black (30 cases/30 controls) women matched on ancestry, age, and parity were analyzed. Tagging single nucleotide polymorphisms (tSNPs) in ENG, TGFβ1, TGFβR1, ALK1, and TGFβR2 were evaluated with iPLEX® and TaqMan® technologies. Allele/genotype/haplotype tests were conducted separately in white/black subgroups with a $\chi 2$ or Fisher's exact test. Odds ratios were computed with binary logistic regression for tSNPs with significant genotype tests. In white women, variation in ENG (rs11792480, rs10121110) and TGFβR2 (rs6550005) was associated with preeclampsia. Allelic frequency distributions in rs11792480, rs10121110, and rs6550005 were significantly different among cases and controls while genotype distributions of rs10121110 and rs6550005 were further associated with preeclampsia (*p*-values < .05). For rs10121110, women with the AA genotype were 2.290 times more likely to develop preeclampsia compared to the GG genotype (99% CI [1.022, 5.133], p = .008). The ENG haplotype TACGA, which contains the risk alleles for rs11792480 and rs10121110, was also over-represented in cases (p = .022). In black women, variation in TGFβ1 (rs4803455, rs4803457), TGFβR1 (rs10739778), and TGFβR2 (rs6550005, rs1346907, rs877572) was associated with preeclampsia. Allelic frequency distributions in rs10739778, rs6550005, rs1346907, and rs877572 were significantly different among cases and controls while genotype distributions of rs10739778, rs4803455, and rs4803457 were further associated with preeclampsia (*p*-values < .05). For rs4803457, women with the CT genotype were 7.437 more times likely to develop preeclampsia compared to the CC genotype (99% CI [1.192, 46.408], p = .005). These results demonstrate that variation in ENG pathway genes is associated with preeclampsia in white and black women, with different genes from the same pathway being involved in white women compared to black women.

1885T

Genetic Polymorphisms in ESR1 and ESR2 Genes and Risk of Hypospadias in a Multi-ethnic Study Population. *S. Choudhry[1], E.J. Lammer[2], J.S. Witte[3], S. Dasgupta[1], C. Ma[4], G.M. Shaw[4], L.S. Baskin[1], S.L. Carmichael[4].* 1) Dept Urology, Univ California, San Francisco, CA; 2) Children's Hospital Oakland Research Institute, Oakland, CA; 3) Dept of Epidemiology & Biostatistics, Institute of Human Genetics, Univ California, San Francisco, CA; 4) Dept of Pediatrics, Division of Neonatology, Stanford University, Stanford, CA.

Hypospadias is a common congenital malformation of the male external genitalia with a multifactorial etiology. Little is known about the genes involved in hypospadias. Estrogenic endocrine disruptors acting via estrogen receptors α (ESR1) and β (ESR2) have been implicated in the etiology of hypospadias. Our objective was to examine genetic polymorphisms in ESR1 and ESR2 genes and their association with hypospadias in a racially-ethnically diverse study population of California births. We investigated the relationship between 108 ESR1 and 37 ESR2 SNPs and hypospadias in 647 cases and 877 population-based non-malformed controls among infants born in selected California counties from 1990–2003. For risk of hypospadias, odds ratios (OR) for 16 of the 108 ESR1 SNPs and 2 of the 37 ESR2 SNPs had p-values <0.05 (p-value range: 0.05–0.002). Due to high LD across the SNPs, haplotype analyses were conducted, and 18 and 5 two-SNP or larger haplotype blocks were examined for ESR1 and ESR2 respectively. These analyses identified two haplotype blocks in ESR1 that were associated with increased risk of hypospadias (OR 2.67, p<0.002 and OR 2.5, p<0.006). No significant haplotype association was observed for ESR2. These findings suggest that SNPs in ESR1 may influence the risk of hypospadias.

A missense mutation in Exon 2 of Adiponectin receptor 2 (ADIPOR2) is associated with serum insulin in overweight and obese African-American subjects. *A. Doumatey, G. Chen, J. Zhou, H. Huang, A. Adeyemo, C. Rotimi.* NHGRI/CRGGH, National Institutes of Health, Bethesda, MD.

Introduction: Obesity (Ob) and overweight (OW) are associated with a number of metabolic disorders including insulin resistance, type 2 diabetes, hypertension, and dyslipidemia. Insulin is one of the most perturbed biochemical markers in OW and Ob, and it has been shown that adiponectin has an insulin-sensitizing action. Thus, we hypothesized that variants in genes encoding adiponectin and/or adiponectin receptors may influence insulin levels and action in Ob and OW persons. Methods: The subjects comprised 490 Ob and OW (BMI≥ 25 kg/m2) African Americans from the Howard University Family study. Genotypes for SNPs in ADIPOQ, ADIPOR1 and ADIPOR2 were obtained from the Affymetrix genome- wide Human SNP array 6.0. Imputation was done using MACH with HapMap CEU and YRI as the reference population panels. A total of 169 genotyped and imputed SNPs ±50 kb around adiponectin (ADIPOQ) and adiponectin receptors (ADIPOR1, ADIPOR2) were tested for association with fasting serum insulin levels. Association models assumed an additive genetic model with adjustment for age, sex and the first two principal components of the genotypes. Results: Nine variants in AdipoR2 gene including a missense mutation (rs12298275) in exon 2 were associated with fasting insulin levels. In addition, one variant in CYB5R1 gene and four others in CACNA2D4 gene were associated with fasting insulin (p-values ranging from 4.1×10-2 to 5.4×10-3). CYB5R1 and CACNA2D4 are the closest genes to ADIPOR1 and ADIPOR2 respectively. Conclusion: These findings provide evidence for the role of adiponectin receptors in insulin metabolism in OW and Ob African Americans.

1887W

Common variants associated with normal tension glaucoma and optic nerve degeneration are also associated with glaucoma in exfoliation syndrome. *B. Fan[1], S. Loomis[1], J.H. Kang[2], D.Y. Wang[1], B. Yaspan[3], M.A. Hauser[4], L.R. Pasquale[1], J.L. Haines[3], J.L. Wiggs[1].* 1) Dept of Ophthalmology, Harvard Med Sch, Massachusetts Eye & Ear Infirmary, Boston, MA; 2) Dept of Medicine, Channing Lab, Brigham and Women's Hospital, Boston, MA; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 4) Dept of Ophthalmology & Medicine, Duke Univ Medical Center, Durham, NC.

The *CDKN2BAS* region at 9p21and the *SIX1/SIX6* region at 14q22 has been previously associated with primary open angle glaucoma (POAG), a genetically and phenotypically complex trait that is a leading cause of blindness worldwide. Recently we showed that the *CDKN2BAS* region and a novel regulatory region on 8q22 are associated with normal-tension glaucoma (NTG), suggesting that these SNPs primarily influence the development of optic nerve disease in glaucoma. In this study we evaluated the association of SNPs located in the 9p21, 14q22 and 8q22 genomic regions with another common form of glaucoma, exfoliation glaucoma (EG), to determine if these SNPs also contribute to optic nerve disease in other types of glaucoma. The lead SNP from each region was analyzed in 104 exfoliation glaucoma patients and 344 controls. Single-SNP associations were initially analyzed using the chi-square test and further evaluated using logistic regression models adjusted for age. The lead SNP in *CDKN2BAS* was significantly associated with EG (rs2157719, p=0.004, OR=0.59, 95%CI: 0.41-0.84), while the 8q22 SNP was nominally associated with EG (rs284489, p=0.02; OR=0.68, 95%CI: 0.48-0.95) and the *SIX1/SIX6* SNP did not show evidence of association (rs10483727, p=0.14, OR=1.28, 95%CI: 0.92–1.77). These results suggest that common SNPs at 9p21 and 8q22 contribute to optic nerve disease in exfoliation glaucoma, and thus may be risk factors for optic nerve disease in other common forms of glaucoma. **Grant support:** NEI Grants R01EY020928, R01EY015872 and P30EY014104-06, Research to Prevent Blindness and The Massachusetts Lions Eye Research Fund.

1888T

Genetic variants in Selenoprotein P plasma 1 gene (*SEPP1*) are associated with fasting insulin and first phase insulin response in Hispanics. *J.N. Hellwege[1,2,3], N.D. Palmer[2,3,4], J.T. Ziegler[5], C.D. Langefeld[5], C. Lorenzo[6], J.M. Norris[7], T. Takamura[8], D.W. Bowden[2,3,4,9].* 1) Molecular Genetics & Genomics, Wake Forest School of Medicine, Winston Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 5) Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 6) Department of Medicine, University of Texas Health Science Center, San Antonio, TX; 7) Department of Epidemiology, Colorado School of Public Health, University of Colorado Denver, Denver, CO; 8) Department of Disease Control and Homeostasis, Kanazawa University Graduate-School of Medical Science, Kanazawa, Ishikawa, Japan; 9) Internal Medicine-Endocrinology, Wake Forest School of Medicine, Winston-Salem, NC.

Type 2 diabetes (T2D) is a major health problem worldwide, with over 25 million people in the US affected. T2D is characterized by insulin resistance, as well as the body's inability to produce sufficient amounts of insulin to maintain homeostasis. Insulin resistance is not yet fully explained on a molecular level, though several genes and proteins have been tied to this defect. Knockdowns of the *SEPP1* gene, which encodes the Selenoprotein P (SeP) protein, increase insulin sensitivity in mice. SeP is a liver-derived plasma protein and a major supplier of selenium. Selenium is a proposed insulin mimic and antidiabetic agent. Due to a suggestive role in insulin resistance, 21 *SEPP1* polymorphisms were selected for analysis with glucometabolic measures in 1424 Hispanics from families in the Insulin Resistance Atherosclerosis Family Study (IRAS-FS). A frequently sampled intravenous glucose tolerance test was used to obtain precise measures of first phase insulin release (acute insulin response, AIR) and insulin sensitivity (S_I). Tagging SNPs (12) from HapMap (including 2 SNPs previously associated with SeP levels), 4 coding variants from the ESP_GO database and 5 SNPs in the promoter region were genotyped and analyzed for association using SOLAR. Two highly correlated (r^2=0.88) coding SNPs showed significant association with AIR (rs28919926; Cys368Arg; p=0.0028 and rs146125471; Ile293Met; p=0.0026) while rs16872779 (intronic) was associated with fasting insulin levels (p=0.0096). Replication genotyping was performed in the multi-ethnic non-family based IRAS cohort, which included 480 Caucasian, 382 Hispanic and 288 African American samples. Meta-analysis of the IRAS cohorts identified two markers (rs6882786, promoter and rs7579, 3' UTR) associated with S_I (p=0.0079 and 0.010, respectively), while rs6882786 and rs16827262 (3' UTR) were found to be associated with AIR. In the IRAS Hispanic cohort, the associations seen in the IRAS-FS were not replicated (p≥0.05) but meta-analysis of IRAS-FS and all 3 IRAS cohorts (N= 2446) supported association of rs7579 with S_I (p=0.047) and rs28919926 with AIR (p=0.013). Overall, these results are consistent with the literature suggesting an important role for *SEPP1* in insulin resistance and the development of T2D.

Replication of GWAS meta-analysis associations in a large Amish pedigree support *VWF*, *ABO*, *STXBP5*, *STAB2*, and *SCARA5* as modifiers of VWF and FVIII levels. *J. Hinckley[1], K. Wang[2], T. Burns[2], L. Law[1], A. Shapiro[3], J. Di Paola[1].* 1) Univ Colorado, Denver, Aurora, CO; 2) Univ Iowa, Iowa City, IA; 3) Indiana Hemophilia and Thrombosis Center, Indianapolis, IN.

Closed populations have proven valuable in elucidating genes of Mendelian traits and are becoming more recognized in the study of complex and quantitative traits due in part to a more homogenous environmental component and a similar distribution of common variants compared to outbred populations. We characterized a 2171-member Amish family with von Willebrand disease caused by a single autosomal-dominant C4120T mutation and demonstrated the variability between individuals and the reproducibility within individuals of coagulation factor VIII (FVIII:C) and von Willebrand factor (VWF) levels. Analysis of VWF levels and FVIII:C in SOLAR (covariates: age, sex, C4120T) estimated a heritability (h^2) of 0.301 for VWF antigen levels (VWF:Ag; $p=2.7\times10^{-6}$), 0.386 for VWF ristocetin cofactor activity (VWF:RCo, functional assay; $p=1.16\times10^{-8}$), and 0.280 for FVIII:C ($p=1.52\times10^{-5}$). The recent CHARGE Consortium meta-analysis reported 8 chromosomal regions associated with VWF levels, 5 of which are also associated with FVIII levels, and the most significant intragenic SNP for each region. We genotyped 10 of 13 SNPs covering all 8 genes in 448 members of our Amish cohort and replicated significant associations for 6 SNPs (SOLAR, covariates: age, C4120T): rs1063857 (VWF; VWF:Ag, p= 0.01), rs1063857 (ABO; FVIII:C, $p=8.28\times10^{-6}$; VWF:Ag, $p=1.34\times10^{-5}$), rs9390459 (STXBP5; VWF:Ag, p=0.03), rs9644133 (SCARA5; FVIII:C, p= 0.01), and rs12229292 (STAB2; FVIII:C, p=0.021). Of 94 HapMap tagging SNPs genotyped through VWF, rs7964554 (intron 4), demonstrated the most significant association with VWF:Ag and VWF:RCo ($p=6.46\times10^{-4}$ and 4.17×10^{-7}, respectively; SOLAR, covariates: age, C4120T, ABO). SNPs near the functional domains of VWF were associated with VWF:RCo but not VWF:Ag. ABO, the best-characterized modifier of VWF levels, explained an additional 8, 12, and 7% of the variability of VWF:Ag, VWF:RCo, and FVIII:C, respectively, in the Amish cohort (covariates: age, sex, C4120T). Inclusion of VWF:Ag as a covariate of FVIII:C suggests the effect of ABO on FVIII:C is mediated through VWF. Exonic sequencing of STXBP5 and STAB2 in 48 samples identified only common variants in dbSNP. In summary, we report replication of 6 CHARGE study associations and evaluation of VWF, ABO, STXBP5, and STAB2 as candidate modifier genes of FVIII and VWF levels, demonstrating the usefulness of closed populations in the study of complex traits.

Mutation Analysis in Zinc Finger Protein Isoform 1 (*ZNF644*) in Cases with Moderate and High Myopia. *N. Kaur, S. Saini, V. Vanita.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: To perform mutation screening in *ZNF644* in patients with moderate and high myopia from North India. Materials and Methods: The present study included 58 families having patients with moderate and high myopia. All the cases were recruited from Dr. Daljit Singh Eye Hospital, Amritsar. All these patients went through complete ophthalmologic examination that included visual acuity, refractive error, corneal thickness and axial length. Of these 40 patients were high myopic (-6.00 D and above) and 18 were with moderate myopia (-2.00 D to -5.00 D). The mutation screening in *ZNF644* was performed by bi-directional sequence analysis of the amplified products. Results: We observed few previously unreported polymorphisms and substitutions in the coding and 3' UTR region of *ZNF644* in the analyzed patients. Also a polymorphism i.e. Arg455Arg was observed in one of the analyzed patient. Conclusions: We report identification of few previously unreported nucleotide substitutions in *ZNF644* in the analyzed moderate and high myopia cases in present study.

1891T

Title: To study the association of Peroxisome Proliferative Activated Receptor Gamma (*PPARG*) gene polymorphism (p.Pro12Ala) with diabetic retinopathy. *R. Kaur, S. Goyal, V. Vanita.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: To study the association of Peroxisome Proliferative Activated Receptor Gamma (*PPARG*) gene polymorphism (p.Pro12Ala) with diabetic retinopathy (DR) in type 2 diabetic patients from North India. Material and Methods: The present case control association study included 148 type 2 diabetic patients. All the subjects were unrelated and were recruited from Dr. Daljit Singh Eye Hospital, Amritsar. Out of these, 65 patients were suffering from different types of retinopathies. Of these 49 were having Proliferative Diabetic Retinopathy (PDR), eleven had Background Diabetic Retinopathy (BDR) and five were with Non Proliferative Diabetic Retinopathy (NPDR). The 83 diabetic patients without any sign of retinopathy were also collected as controls. The genotyping was carried out by bi-directional sequencing analysis of the amplified products. The statistical analysis was done using SPSS (version 16.0) and one way ANOVA test was performed to find any association with clinical parameters (age, age of onset, duration of disease, basal metabolic index (BMI), systolic and diastolic blood pressure). Genotypic and allelic frequencies were calculated using statistical calculator (StatPac V. 3.0). Odds Ratio (OR) and 95% confidence intervals (CI) were determined by MedCalc (V 9.3.9.0). Results: The present study showed statistically significant differences between age of onset (p=0.009), duration of diabetes (0.005), and systolic blood pressure (0.001), when DR patients were compared with controls. Significant difference was found in allelic frequencies (p=0.0033) when DR patients were compared with controls and on comparison of different types of diabetic retinopathy (NPDR, BDR, PDR) patients among themselves as well as in comparison to controls. OR analyses revealed a significant relationship of (CG) heterozygote of *PPARG* with 1.8 times increased risk of diabetic retinopathy. Conclusion: The present finding suggest positive association of *PPARG* polymorphism (p.Pro12Ala) with DR. Present data also showed an increased risk of DR with CG heterozygote genotype. We conclude that *PPARG* polymorphism (p.Pro12Ala) seem to be a useful marker for diabetic retinopathy in the analyzed cases in present study.

1892F

Association of the IL17 gene polymorphisms with Lumbar Disc Disease. *A. Kelempisioti[1], I. Daavittila[1], N. Noponen[1], S. Barral[2], J. Ott[3], J. Niinimaki[4], T. Koskelainen[5], L. Ala-Koko[1,6], J. Karppinen[7,8], M. Männikkö[1,9].* 1) Department of Medical Biochemistry and Molecular B, University Of Oulu, Oulu, Finland; 2) Gertrude H. Sergievsky Center, College for Physicians and Surgeons, Columbia University, New York, USA; 3) Institute of Psychology, Chinese Academy of Sciences, Beijing, China; 4) Department of Diagnostic and Interventional Radiology, Oulu University Hospital, Oulu, Finland; 5) Department of Neurosurgery, Oulu University Hospital, Oulu, Finland; 6) Connective Tissue Gene Tests, Allentown, Pennsylvania, USA; 7) Institute of Clinical Medicine, Department of Physical and Rehabilitation Medicine, University of Oulu, Oulu, Finland; 8) Finnish Institute of Occupational Health, Oulu, Finland; 9) Institute of Health Sciences, Public Health and General Practice, University of Oulu, Oulu, Finland.

Lumbar disc disease (LDD) is a common condition influenced by genetic and environmental factors. LDD causes symptoms such as sciatica and low back pain with negative effect on patient's quality of life. Although various risk factors have been reported, the etiology and pathogenesis remain unclear. Genome wide analysis in a total of 186 members of 14 Finnish families with sciatica identified potential loci in 10 chromosomal regions with suggestive logarithm of odds (LOD)greater than 1. Fine mapping confirmed the susceptibility locus on chromosome 6 with a maximum two point LOD score of 2.36 suggesting evidence for linkage around marker D6S294. This marker is located near IL17A and IL17F genes. The exons, as well as the intron-exon boundaries of these two genes were screened in 30 symptomatic individuals using direct sequencing. Out of 17 single nucleotide polymorphisms (SNPs) (nine in IL17A, and eight in IL17F), we proceeded with three SNPs that showed most variation (rs7747909 in IL17A, rs763780 and rs11465553 in IL17F). Association studies of the candidate SNPs were performed in a total of 635 individuals from a Finnish case control set characterized by sciatica symptoms. The SNPs were genotyped using the SNaPshot multiplex method and were in Hardy Weinberg Equilibrium. Association analysis under an additive model of inheritance showed association ofSNP rs763780 [OR 1.61 (95percent CI 1.01–2.57)] but not with the other 2 SNPs. G-C-G haplotype was shown to be the risk haplotype [OR 1.75 (95percent CI 1.12–2.74)]. Both IL17A and IL17F are proinflammatory cytokines that induce expression of other cytokines and chemokines. Inflammatory etiology has been suggested to contribute to the generation of back pain. Our findings indicate that IL17 is involved in LDD.

Association and interaction of Polymorphisms in Angiogenic genes with Endometriosis. *M.M. Latha[1,2], Q. Hasan[3], V.L Kodati[1].* 1) Dept of Genetics and Molecular Medicine, Vasavi Medical and Research Centre, Hyderabad, India; 2) Nizam Institute of Medical Sciences,Hyderabad India; 3) Kamineni Hospital,, India.

Endometriosis is a multifactorial disorder where angiogenesis (neo vascularisation) plays an important role in the etiopathogenesis of the disease associated infertility and pelvic pain with a prevalence rate of 10–15% in women of reproductive age. It is know that the endometrium of women with endometriosis has an increased capacity to proliferate, implant and grow in the peritoneal cavity. Polymorphisms in functionally relevant angiogenic candidate genes are considered to be important for identifying individuals at high risk especially in case of polygenic disorders like endometriosis. Hence three single nucleotide polymorphisms in MMP-2 (rs243865), MMP-9 (rs3918242) and ICAM-1 (rs1799969) genes were evaluated in individual with endometriosis. The present study indicates significant difference in allele distributions of three SNPs between endometriosis patients and control women (P>.05;). Compared with the C allele, T allele frequency of MMP-2 is showing risk for endometriosis (OR=1.5556 95%CI=1.046–2-3133, P<0.05). Results of MMP-9 indicate that `TT' genotype is present with a higher frequency in women with endometriosis in our population (OR OR= 1.7147 95%CI=1.1029–2.6659 P<0.05). Results of ICAM-1 indicate a strong association of G allele association with the disease (OR=1.7983,95%CI 1.3101–2.4685,P<0.05). Clinical features like dysmenorrhea and menstrual irregularities were associated with MMP2 and MMP9 but no association with ICAM-1 genotypes. According to MDR analysis MMP-2, MMP-9 and ICAM-1 genes were individually contributing their role in causing the disease but they are not interactive with each other. Hence these three SNPs can be used for risk assessment of endometriosis in South Indian population. Interaction among MMP-2 (rs243865), MMP-9 (rs3918242) and ICAM-11799969) SNPs with the Risk of Endometriosis As shown in radial graph (fig-1) there was an additive influence of MMP-2 and MMP-9 polymorphisms in the risk of developing endometriosis. Where has ICAM1 and MMP9 are showing synergistic action and more significantly modify the risk of developing endometriosis and MMP2, ICAM1 are counteracting in the development of the disease and showing a less significant risk and less interaction compared with the other two genes in causing the endometriosis.

1894T

The HLA-DPB1 and DRB1 genes are synergistically associated with Graves disease in Han Chinese children. *Y. Lee[1,2,3], C. Huang[1], W. Ting[1], F. Lo[4], T. Chang[1], C. Chu[1], Y. Wu[1], S. Chang[1], W. Lin[1], M. Lin[1].* 1) Dept Pediatrics & Med Res, Mackay Memorial Hosp, New Taipei City, Taiwan; 2) 8Institute of Biomedical Sciences and Department of Medicine, Mackay Medical College, New Taipei City, Taiwan; 3) Department of Pediatrics, Taipei Medical University, Taipei, Taiwan; 4) 2Department of Pediatrics, Chang Gung Memorial Hospital; College of Medicine, Chang Gung University, Taoyuan, Taiwan.

Associations of HLA with Graves disease (GD) vary between races. Our study showed DRB1*09:01 is associated with and linked to GD. Recently the DPB1 gene was found to be independently associated with GD. We investigated which was the strongest factor associated with GD. **Subjects and Methods** The patients were 181 unrelated children with GD. Their age at the diagnosis was 10.5 ± 3.4 years. The controls consisted of 377 subjects. **Statistical analysis** Agreement with Hardy-Weinberg equilibrium, linkage disequilibrium (LD), and estimation of HLA DPB1-DRB1 haplotypes were performed on both patients and controls using PyPop 0.7.0. Differences in the frequencies of alleles, carriers, and haplotypes between patients and controls were evaluated using the Chi-square test. To evaluate the influence of linkage disequilibrium (LD) between HLA-DPB1 and DRB1 loci and find which of them conferring the stronger risk, we tested association with one locus in the presence or absence of the associated allele at the second locus. ORs and 95% CIs were calculated. The Bonferroni correction was used for multiple comparisons. A value of Pc < 0.05 was considered statistically significant. **Results** The distribution of genotypes of the HLA-DPB1 and -DRB1 genes of controls were in Hardy-Weinberg equilibrium. The frequency of the DPB1*05:01 allele was significantly higher in patients than in controls, OR (95%CI) = 1.61 (1.25–2.07), Pc = 0.0024. The HLA-DPB1-DRB1 haplotype 05:01-09:01 was significantly more frequent in patients than in controls, 75 (20.7%) vs. 75 (9.9%), OR = 2.37, Pc = 1.49E-05. In DRB1*09:01 carriers, DPB1*05:01 was significantly more frequent in patients than in controls, 88 (93.6%) vs. 86 (76.8%), OR = 4.43, Pc = 0.0054. But in those carrying no DRB1*09:01, the frequency of DPB1*05:01 was not significantly different between patients and controls. In DPB1*05:01 carriers, DRB1*09:01 was significantly more frequent in patients than in controls, 88 (54.3%) vs. 86 (30.9%), OR = 2.65, Pc = 7.84E-06. But its frequency was not significantly different between patients and controls carrying no DPB1*05:01. The frequency of carriers of both DPB1*05:01 and DRB1*09:01 was greater in patients than in controls, 88 (87.1%) vs. 86 (54.1%), OR = 5.75 (2.97–11.12), Pc = 3.07E-07. **Conclusion** HLA-DPB1*05:01 and DRB1*09:01 were synergistically associated with GD in Han Chinese children. Both of them must be simultaneously present to confer a risk of GD.

1895F

Fine-Mapping within Regions of Admixture Linkage to Sarcoidosis Risk in African Americans. *A.M. Levin[1], P. McKeigue[2], I. Datta[1], C.G. Montgomery[3], I. Adrianto[3], M. Colombo[2], M.C. Iannuzzi[4], B.A. Rybicki[1].* 1) Public Health Sciences, Henry Ford HIth System, Detroit, MI; 2) Public Health Sciences Section, University of Edinburgh Medical School, Edinburgh, Scotland; 3) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 4) Department of Medicine, Upstate Medical University, Syracuse, NY.

Sarcoidosis is a multi-organ granulomatous disease of unknown etiology. Populations of primarily West African descent have higher sarcoidosis incidence than European populations, which compelled us to search for sarcoidosis genes using admixture mapping. In previously identified admixture linkage regions, we conducted fine mapping using genome-wide single nucleotide polymorphism (SNP) data genotyped on a sample of 2,727 self-identified African Americans and additional SNP imputation using the 1000 Genomes project data. Local ancestry was estimated genome-wide using the Local Ancestry in Admixed Populations method[1]. Employing a case-only technique we more finely mapped admixture linked regions using two approaches: 1) association testing adjusting for local ancestry and 2) the MIX score method[2], which tests the likelihood of whether a particular SNP association explains an admixture signal. We confirmed and more finely mapped sarcoidosis admixture linkage regions, two where increasing West African (6p24.3-p12.1 and 17p13.3-13) and two where increasing European (2p13.3-q12.1 and 6q23.3-25.2) ancestry were associated with susceptibility to sarcoidosis. The most significant admixture linkage locus was 6p24.3-p12.1 ($p=9*10^{-8}$), which encompasses the HLA class II region known to include sarcoidosis risk loci. Within this region, the most significant SNP after adjustment for local ancestry was rs74318745 (OR=0.69, 95%CI=0.62-0.78, $p=4.5*10^{-11}$), which resides within the HLA-DRA gene and explains the majority of the admixture signal at this locus (MIX $p=7.9*10^{-12}$). The 17p13.3-13.1 region ($p=2.0*10^{-4}$) was the most significant novel region of admixture linkage, and the association at SNP rs6502976 (OR=0.74 95%CI= 0.65–0.84, $p=1.2*10^{-4}$) within the X-linked inhibitor of apoptosis associated factor (XAF1) gene accounted for the majority of the admixture linkage (MIX $p=7.9*10^{-5}$). The SNP rs6502976 is in high linkage disequilibrium ($r^2=0.80$) with rs9891567, which has been identified as an expression quantitative trait locus for XAF1. As a negative inhibitor of apoptosis, XAF1 may play a role in granuloma formation and maintenance. In summary, our findings suggest that XAF1 is a novel sarcoidosis susceptibility locus in African Americans and demonstrate how admixture mapping can be used to prioritize regions of the genome for fine mapping susceptibility loci for sarcoidosis. **References:** [1]Baran et al. Bioinformatics (2012). [2]Pasaniuc et al. PLoS Genet (2011).

1896W

Fine-mapping of Central Adiposity Loci Using Association Results from Multi- ethnic Populations. *C. Liu, the CHARGE—GIANT—CARe—African American Adiposity Consortium.* Biostatistics, Boston University SPH, Boston, MA.

Background: Genome-wide association studies in European Ancestry (EA) samples have identified many loci associated with central obesity, measured by waist-to-hip ratio (WHR). Yet, the causal variants at these loci remain unknown. We used an integrated approach combining results from European and African American (AA) ancestry samples to aid in localizing causal variants at these loci identified in EA samples. **Methods:** Population-specific meta-analysis of association results were obtained from ~77,000 participants of European Ancestry and ~ 23,500 participants of African Ancestry. We interrogated SNPs within the ±250kb flanking region of 14 previously reported waist-related loci in European ancestry populations by performing trans-ethnic meta-analysis of association studies from these samples. We used a Bayesian approach (Morris 2011 - MANTRA) that leverages allele frequency variability across populations and allows heterogeneity in effect size. We applied this approach to meta analytic results from GIANT EA and separately from AA samples. **Results:** All fourteen loci identified in GIANT EA samples were confirmed to be associated with WHR-adjusting for BMI in this joint analysis of EA and AA samples. All fourteen but one (at *CPEB4*) index SNPs retain evidence of association with log-transformed bayes factor > 5. In interrogation of the genomic regions around these 14 loci with trans-ethnic meta-analysis, four index SNPs (rs984222 at *TBX15-WARS2*; rs6784615 at *NISCH-STAB1*; rs1443512 at *HOXC13*; rs4823006 at *ZNRF3-KREMEN1*) still serve as the most significant SNP within the region. Among the other ten loci, the surrogates for the functional variants, with stronger signals than the original index SNPs, were identified from trans-ethnic meta-analysis: rs9286854 at *DNM3-PIGC*, rs2820443 at *LYPLAL1*, rs1128249 at *GRB14*, rs4132228 at *ADAMTS9*, rs10516107 at *CPEB4*, rs1294410 at *LY86*, rs7766106 at *RSPO3*, rs1358980 at *VEGFA*, rs4141278 at *NFE2L3*, rs7302344 at *ITPR2-SSPN*. **Conclusion:** In leveraging varying linkage disequilibrium structures across different populations, the SNPs with strongest signals from our trans-ethnic meta-analysis provide a more precise localization of functional variants for future functional analysis.

1897T

Investigation of genetic variation in scavenger receptor class B, member 1 (*SCARB1*) and association with serum carotenoids. *G.J. McKay[1], E. Loane[2], J.M. Nolan[2], S. Beatty[2], G. Silvestri[3].* 1) Centre for Public Health, Queen's University Belfast, Belfast, Northern Ireland, United Kingdom; 2) Macular Pigment Research Group, Waterford Institute of Technology, Waterford, Ireland; 3) Centre for Vision and Vascular Science, Queen's University Belfast, Belfast, Northern Ireland, United Kingdom.

Objective: To investigate association of scavenger receptor class B, member 1 (*SCARB1*) genetic variants with serum carotenoid levels of lutein (L) and zeaxanthin (Z) and macular pigment optical density (MPOD). **Introduction:** Age-related macular degeneration (AMD) is the most common cause of blindness in older people in developed countries. Previous studies suggest carotenoids confer protective measures against oxidative stress ongoing in the macular region of the retina and variation in *SCARB1* has been implicated in this process. SCARB1 is a key lipoprotein receptor which participates in the transfer of neutral lipids. Common variants within the gene have been reported in association with serum lipid levels. **Methods:** This was a cross-sectional study of 302 healthy adult subjects. MPOD was measured by customised heterochromatic flicker photometry. Fasting blood samples were taken for serum L and Z measurement by HPLC and lipoprotein analysis by spectrophotometric assay. Forty-seven single nucleotide polymorphisms (SNPs) across *SCARB1* were genotyped using Sequenom technology. Association analyses were performed using PLINK to compare allele and haplotype frequencies, with adjustment for multiple testing by permutation. **Results:** Following logistic regression analysis adjusted for age, body mass index, gender, high-density lipoprotein (HDL), low-density lipoprotein (LDL), triglycerides and smoking status, five SNPs (rs11057841, P=3.4×10-4; rs10773109, P=0.002; rs11057830, P=0.003; rs12581963, P=0.004 and rs838873; P=0.005) were significantly associated with serum L levels, although only rs11057841 survived after correction for multiple testing by permutation (P<0.01). Haplotype analysis supported single SNP analysis but failed to identify additional novel association. **Discussion:** Our study has examined common variants in *SCARB1* and identified association between rs11057841 and serum L in healthy subjects. We have adjusted for potential confounding through levels of HDL and LDL cholesterol, triglycerides, BMI, age and gender with the association observed independent of these factors. The high level of linkage disequilibrium between rs11057841 and rs11057830 (r^2=0.93) further supports the significant association observed with serum L. Replication in independent cohorts is necessary to evaluate the role of SCARB1 in the transportation of macular pigments and possible modulation of AMD risk in combating the effects of oxidative stress within the retina.

1898F

Genetic Analysis of FUS/TLS gene in Essential Tremor. *K. Mirzozoda[1], N. Parmalee[1], S. Kisselev[2], N. Merner[4], P. Dion[4,5], G. Rouleau[4,6,7], E.D. Louis[1,8,9,10], L. Clark[1,2,3].* 1) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY; 2) Department of Pathology and Cell Biology, Columbia University, New York, NY; 3) Center for Human Genetics, Columbia University, New York, NY; 4) Centre of Excellence in Neurosciences, CHUM Research Center, and Department of Medicine, Université de Montréal, Montréal, Québec, Canada; 5) Department of Pathology and Cellular Biology, Université de Montréal, Montréal, Québec, Canada; 6) Research Center, CHU Sainte-Justine, Montreal, Quebec, Canada; 7) CHUM and the Department of Medicine, Université de Montréal, Montreal, Québec, Canada; 8) Gertrude H. Sergievsky Center, Columbia University, New York, NY; 9) Department of Neurology, Columbia University, New York, NY; 10) Department of Epidemiology, Mailman School of Public Health, Columbia University, New York, NY.

Background: Although essential tremor (ET) has a genetic basis, specific genes have not been identified. Recently, in a large ET family (FET1) from Quebec, a nonsense mutation (p.Q290X) in the amyotrophic lateral sclerosis (ALS) gene fused in sarcoma/translated in liposarcoma (FUS/TLS) was identified by exome sequencing. No confirmatory studies have been published. Methods: 259 ET cases and 262 controls were enrolled in a study at Columbia University. We performed a comprehensive analysis of the FUS/TLS gene by sequencing all exons in a subsample of 116 ET cases with early onset (≤40 years) ET. We evaluated an association between ET and SNPs in the FUS/TLS gene by genotyping 4 haplotype tagging SNPs in all 259 ET cases and 262 controls. Additionally, 7 clinically associated variants, 2 variants of unknown pathogenicity detected in ALS cases, 8 missense variants predicted to be damaging, and 6 rare variants were genotyped in these 259 ET cases and 262 controls. Results: FUS/TLS mutations previously reported in ALS, the FET1 family, or novel mutations were not found in any of the 116 early onset ET cases. In the case-control analyses, no significant association between tagging SNPs in FUS/TLS and ET was observed, and none of the analyzed SNPs showed evidence of association with ET. Conclusion: Our study suggests that pathogenic mutations in FUS/TLS are rare in a sample of early onset ET cases in the U.S. Also, we did not find evidence that the FUS/TLS gene is a risk factor for ET. Funding for this study was provided by: NIH, NINDS #R01 NS073872 (Louis, Clark), the Parkinson's Disease Foundation (Louis, Clark), the Arlene Bronstein Essential Tremor Research Fund, and the Claire O'Neil Essential Tremor Research Fund.

Genetic and functional data implicates BCHE as a novel vitiligo candidate gene. *L. Nascimento[1], C. Castro[1, 2], V. Fava[1], R. Werneck[3], M. Mira[1, 3].* 1) Group for Advanced Molecular Investigation, Graduate Program in Health Sciences, School of Medicine, Pontifical Catholic University of Paraná, Curitiba, Brazil; 2) Department of Dermatology, Santa Casa de Misericórdia Hospital, Curitiba, Brazil; 3) School of Health and Biosciences, Pontifical Catholic University of Paraná, Curitiba, Brazil.

Vitiligo is an acquired, systemic, chronic disease of unpredictable evolution, characterized by achromic macules on skin resulting from the absence of functioning melanocytes in the affected areas. The disease affects 1% of the population, both genders equally, with onset at any age. The pathogenesis of vitiligo is still poorly understood; however, experimental data suggests that melanocyte damage may be mediated by impaired clearance of cytotoxic metabolites. In this context, oxidative stress and the accumulation of free oxygen radicals in the epidermal layer of skin may play a role in the pathophysiology of vitiligo. An immunohistochemistry study has shown that epidermal butyrylcholinesterase (BChE) enzyme expression and activity are altered in vitiligo skin, suggesting the BCHE gene as a candidate for genetic analysis. Here we present the results of a family-based association analysis between vitiligo and ten tag SNPs capturing the entire information of the BCHE locus. SEQUENOM MassARRAY and fluorescence-based TaqMan technology were used to genotype 189 family trios recruited from Southern Brazil. Two independent association signals were observed between the disease and BCHE: allele “C” of SNP rs1355538 was associated with an increased risk of vitiligo (P= 0.006; OR 1.90; 95% CI 1.20–3.02) and allele “A” of SNP rs1803274 was associated with protection (P = 0.03; OR 0.70; 95% 0.49–0.98); the latter signal was concentrated among trios presenting non-segmental vitiligo, in the presence of autoimmune co-morbidities. Both association signals were then tested for replication in an independent case-control population sample consisting of 134 non-related affected individuals and 134 controls matched according to age and gender. Again, statistically significant association was observed between allele “A” of SNP rs1803274 and non-segmental vitiligo, in the presence of autoimmune co-morbidities (P = 0.02; OR 0.56; 95% CI 0.32–0.97). Finally, we confirmed previous data showing an impact of rs1803274 alleles over BChE enzymatic activity: a genotype-phenotype correlation experiment in 49 vitiligo-affected subjects resulted in positive evidence for association between rs1803274 allele “A” and lower BChE plasma activity (P = 0.01). In conclusion, our study provides strong experimental evidence supporting BCHE as a novel vitiligo susceptibility gene, and implicates the oxidative stress pathway in vitiligo pathogenesis.

1900T

Targeted deep-resequencing of the CLDN1 gene in African Americans for asthma. *N.M. Rafaels[1], L. Huang[1], C. Vergara[1], R. Lewis[1], L. Gao[1], I. Ruczinski[2], T.H. Beaty[3], A. De Benedetto[4], L.A. Beck[4], R.A. Mathias[1], K.C. Barnes[1].* 1) Division of Allergy and Clinical Immunology, Johns Hopkins, Baltimore, MD; 2) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins, Baltimore, MD; 3) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins, Baltimore, MD; 4) Department of Dermatology, University of Rochester Medical Center, Rochester, NY.

Rationale: Asthma is a common complex disease with higher prevalence among African Americans which cannot be entirely explained by environmental, social, cultural, or economic risk factors. Increased airway smooth muscle (ASM) mass is essential to airway remodeling and asthma development. Tight junction proteins, specifically claudin-1 (*CLDN1*), expressed in endothelial and epithelial cells, were found to have increased expression in ASM of asthmatics. **Methods:** We sequenced the entire *CLDN1* gene and 2kb up and downstream using Agilent's targeted deep-resequencing platform on 200 asthmatics and 200 non-asthmatic controls of African ancestry from the Baltimore/Washington area from the *Genomic Research on Asthma in the African Diaspora Study* (GRAAD) previously genotyped on the Illumina HumanHap650Y BeadChip. Genetic associations for risk of asthma were determined by Fisher's exact test under a dominant model for rare variants (minor allele frequency or MAF< 0.05) and logistic regression using PLINK for common variants under the additive model (MAF>0.05) in a final dataset of 183 cases and 192 controls. **Results:** We identified 121 novel variants not previously documented in dbSNP or the Thousand Genomes Project: TGP). Tests of association revealed 13 variants associated with asthma at the α=0.05 level, the most significant being rs9825088 in the 3'-UTR region, and intronic SNPs rs9847792 and rs9834611 (*P*= 0.002). In addition, these 3 variants are common among TGP Yoruban (MAF=0.155), but rare or absent among Europeans and Asians (MAF= 0.003; MAF=0, respectively). None of the 13 variants were included in the GWAS marker panel previously genotyped in GRAAD. **Conclusions:** Our findings suggest variants in *CLDN1* may be associated with asthma in populations of African descent. Validation and replication genotyping in the full GRAAD population is underway.

1901F

TARGETED RESEQUENCING OF SLE SUSCEPTIBLE LOCI. *E. Rai[1], B. Wakeland[1], C. Liang[1], P. Raj[1], K. Viswanathan[1], D. Karp[1], N. Olsen[1], I. Dozmorov[1], L. Davis[1], P. Doshi[1], QZ. Li[1], G. Wiley[2], K. Kaufman[2], JA. Kelly[2], J. Harley[2], P. Gaffney[2], EK. Wakeland[1].* 1) Dept Immunology, UTSouthwestern Med Ctr, Dallas, TX,USA; 2) Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma, USA.

Susceptibility to SLE is impacted by both genetic and environmental factors. More that 30 SLE susceptible loci have been identified, however, the causal variants responsible for these associations are largely unknown. We have developed a high throughput sequencing technology to perform targeted resequencing of 30 SLE susceptible LD segments (~4.3 Mb genomic sequence). 192 Caucasian ((107 SLE cases and 85 controls) were sequenced using combined method of SureSelect array capture (Agilent) and Paired End sequencing protocol from Illumina. High quality non redundant reads were assembled and variations were called using GATK and VCFtools. Of the targeted bases, an average of ~99% bases was captured by at least one non-redundant read and ~93.4% bases by at least 15 non-redundant reads, yielding average fold coverage of ~107X. The high quality sequencing calls were confirmed by having >99% concordance with the Immunochip array data. A total of ~21,000 variations (SNPs and Indels) were identified, of which ~38% were novel. Of the total variations, ~32% potentially impacted function, categorized as ~5% non-synonymous; ~4% synonymous; ~13% UTR; ~2% deleterious; ~1% splice; and 37% cis-eQTL. Most of the non-synonymous and deleterious variations were rare, suggesting that either they are newly evolved or have been subjected to purifying selection. Most of the non-synonymous and deleterious variations were rare, suggesting that either they are newly evolved or have been subjected to purifying selection. Interestingly, a high accumulation of rare deleterious variations restricted to cases were observed in the loci reported to have major effect on SLE susceptibility in humans or animal models (C1Q; TREX1; C2-CFB; MSH5; PTPN22 etc). To explore the allelic architecture of functional variations in tight LD with SLE tagging SNPs, phylogenic networks were drawn using the Median joining networks. Phylogenic networks were drawn using haplotypes formed by potentially functional SNPs in LD with SLE associated SNPs. This analysis identified a specific CLADE of alleles containing multiple SLE associated SNPs in several regions (IRF5, BLK, TNFAIP3, ITGAM etc.) that have strong cis-eQTL impact and identified extensive variations in functional SNPs among families of alleles that carried disease associated SNPs for many other genes. These results suggest that many disease-associated SNPs actually identify a cluster of functional variants, rather than a single disease allele.

Study of BMP4 gene in a Brazilian sample with Congenital Anomalies of Kidney and Urinary Tract. *G.S. Reis[1], A.C.S. Silva[1,2], T.R. Heilbuth[1], I.S. Freitas[1], L.A. de Marco[1,3], D.M. Miranda[1,2].* 1) Universidade Federal de Minas Gerais - Faculdade de Medicina - INCT MM. Avenida Alfredo Balena, 190, SL114. Bairro Santa Efigenia. Belo Horizonte - MG. CEP.: 30130-100 Brazil; 2) Universidade Federal de Minas Gerais - Faculdade de Medicina - Departamento de Pediatria. Avenida Alfredo Balena, 190. Bairro Santa Efigenia. Belo Horizonte - MG. CEP.: 30130-100 Brazil; 3) Universidade Federal de Minas Gerais - Faculdade de Medicina - Departamento de Cirurgia. Avenida Alfredo Balena, 190. Bairro Santa Efigenia. Belo Horizonte - MG. CEP.: 30130-100 Brazil.

Congenital anomalies of the kidney and urinary tract (CAKUT) occur in 0,5–6% of all births and include a wide spectrum of malformations such as dysplasia, vesicoureteral reflux, polycystic kidney, horseshoe kidney and others. CAKUT are an important cause of renal failure in children and renal end stage disease in adults. CAKUT conditions are polygenic and multifactorial. Genes modulating nephrogenesis are good candidate genes for CAKUT. BMP4, a TGF-β family member, regulates various processes during human development, especially in those organs in which epithelial-mesenchymal interactions are essential for development, as kidney. The BMP4 determine the right insertion position of the ureteric bud. For this reason, we established a case-control study composed by 457 individuals from several areas of Brazil to identify association between BMP4 gene and the CAKUT diagnosis. Samples were classified in two groups: control (n=246) and case (n=211). We investigate three tagSNPs (rs762642, rs207147 and rs17563) allelic and genotype frequencies and determinated its association with CAKUT. The study followed the guidelines of the Declaration of Helsinki and was approved by the Ethics Local Board. Statistical analysis were performed from the UNPHASED 3.1.4©. Differences between non-contiguous variables, genotype distribution and allele frequency were tested by calculating chi-square (X 2) and P <0.05 was considered statistically significant. As expected, the prevalence of CAKUT was higher in male population than in female population. By haplotype analysis we found two statistically significant results for P-value post 1000 permutations: between SNPs rs17563 and rs2071047 (A-G) P-value was 0.01856. Between the three markers, rs17563, rs2071047and rs762642, (A-G-A) we found P-value equal to 0.02117. We also found the following allelic frequency: rs17563, P value = 0.002552. Genotype frequencies were higher when rs17563 was present. Our data suggests a higher risk to develop CAKUT in individuals with polymorphisms in the BMP4 gene. The growing knowledge about the molecular origins of CAKUT might improve the early diagnoses and new targets for the pharmacological treatment of those disorders.

Detection of 4 new mutations related to Oral Clefts by direct sequencing. *M. Simioni, T.K. de Araujo, R.G Faria, C.V. Maurer-Morelli, V.L. Gilda-Silva-Lopes.* Medical Genetics, FCM/UNICAMP, Campinas, Brazil.

Oral clefts (OC) are the most common craniofacial defects with a worldwide prevalence ranging from 1:500 to 1:2500 newborns. This group includes cleft lip (CL), cleft palate (CP) and cleft lip and (or) palate (CLP). OC can occur as an isolated feature (non-syndromic) or with additional findings (syndromic). Among different etiologies, mutations in several genes have been documented. Considering this, a total of 23 patients with OC (15 syndromic and 8 non-syndromic) were simultaneously investigated by direct sequence for mutation at following genes: IRF6, FOXE1, GLI2, MSX2, SKI, SATB2, SPRY, MSX1, FGF8 and FGFR1. All individuals were previously evaluated by clinical geneticists from Crânio-Face Brazil Project. It was identified in unrelated individuals 4 novel sequence alterations. In syndromic cases, it was detected one mutation at FOXE1 gene (748C ->T; Ala28Ala) in a CLP individual and one mutation at MSX1 gene (329C->T; Ala32Val) in a patient with CL. In non-syndromic, a mutation at GLI2 gene (2341C->T; Leu761Fenil) was found in one case of CL and a mutation in FGF8 gene (765C->A; Glu236Lis) in a CLP child. Except by the MSX1 mutation, which is still under investigation, none of them were detected in a group of 100 controls individuals. Results of in silico analysis to nonsynonymous alterations based in four different algorithms were not concordant about the effect at protein level. Functional studies would be necessary to elucidate the effect of each one. These genes are expressed during embryonic development of lip or palate and had mutations previously described in patients with OC. The results herein described reflect the diversity of genetic factors involved in the etiology of OC and provide new insights for future analyses of FOXE1, MSX1, GLI2 and FGF8 genes. Financial support: Fapesp and CNPq.

1904F

Meta-analysis Demonstrates that an Interleukin-6 Polymorphism is Protective Against Preterm Birth in Women of European Descent. *W. Wu[1], E. Clark[2], G. Stoddard[3], S. Esplin[2], T. Manuck[2], J. Xing[1,4], M. Varner[2], L. Jorde[1].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Dept of Obstetrics and Gynecology, University of Utah, Salt Lake City, UT; 3) Study Design and Biostatistics Center, University of Utah, Salt Lake City, UT; 4) Department of Genetics, Rutgers, the State University of New Jersey, Piscataway, NJ.

Preterm birth (PTB), defined as birth before 37 weeks gestation age, is the leading cause of neonatal mortality and long-term morbidity. The PTB rate is increasing worldwide despite available intervention and prevention strategies. Genetics is a known contributor to PTB and and the heritability of PTB is approximately 30%. PTB is associated with increased concentration of interleukin-6 (IL-6) in maternal serum, as well as cervical and amniotic fluid. Many IL6 polymorphisms have been studied, including -174 G/C, a single nucleotide polymorphism (SNP) located in the IL6 promoter region. Functional studies have shown that the derived C-allele is associated with decreased IL6 expression. Homozygous C/C individuals have lower plasma IL-6 concentration, while individuals with one or more G alleles have higher IL-6 production. However, previous reports associating the IL6–174 polymorphism with PTB have yielded conflicting results. In addition, HapMap data show this SNP has very different frequencies in different populations. Therefore, in addition to small sample size issue, we hypothesize that this conflicting result can in part be explained by differences in population structure and admixture. To address this issue, we conducted a meta-analysis with subgroup analysis by population. We searched PubMed for studies testing associations between the IL6 -174 polymorphism genotype, and the PTB phenotype. We identified eligible studies, extracted and pooled the data, and stratified them by their underlying population structure. Authors were contacted to supply missing information. Maternal and fetal genotypes were analyzed separately. Nine studies were included for maternal genotype analysis. The overall odds ratio (OR) is 0.71 for genotype CC versus CG+GG, with a 95% confidence interval (CI) 0.54 - 0.92, showing a significant protective effect of the CC genotype. For women of European descent, the OR is 0.68 (95% CI:0.51-0.91), but the association is not significant in other populations. For fetal genotypes, only three studies could be included, and the overall OR is 0.92 (95% CI 0.66 - 1.28). In conclusion, the IL6 -174 CC genotype is protective against PTB in women of European ancestry. No significant association was observed for fetal genotypes, or for non-European maternal genotypes.

1905W

Gender-Specific Association of the Interleukin 18 Gene with Gallstone Disease. *H. Yang[1], S. Shih[2, 3], T. Chang[1], H. Wang[2, 3], K. Hu[2, 3], C. Chang[2, 3], C. Chang[2, 3], C. Hung[2, 3], H. Chan[1], M. Lin[1], Y. Lee[1, 4, 5, 6].* 1) Medical Research, Mackay Memorial Hospital, Taipei, Taiwan; 2) Division of Gastroenterology, Department of Internal Medicine, Mackay Memorial Hospital, Taipei, Taiwan; 3) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 4) Department of Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 5) Department of Pediatrics, Taipei Medical University, Taipei, Taiwan; 6) Department of medicine, Mackay Medical College, New Taipei City, Taiwan.

Gallstone disease (GSD) induced strong inflammatory responses and affected extrahepatic bile ducts. Although the pathology and environmental risk factors of GSD are well documented, immune or inflammatory responses in GSD development are still inconclusive. Interleukin 18 (IL18) is a proinflammatory cytokine that plays an important role in immune, infectious, and inflammatory diseases due to induction of interferon-γ. In this study, we investigated whether polymorphisms of the IL18 gene were associated with GSD susceptibility. Genomic DNA was isolated from whole blood samples of 445 patients with GSD and 1121 gallstone-free controls. The IL18 rs549908T>G, rs5744247C>G, rs187238G>C, rs1946518T>G, and rs360719A>G polymorphisms were genotyped using pre-developed TaqMan allelic discrimination assay. No statistical differences of genotype, allele, carrier, and haplotype frequencies of these IL18 gene variants were found between patients with GSD and controls. Interestingly, we found IL18 rs5744247C allele conferred susceptibility to GSD in female patients (OR = 1.33, Pc = 0.015). Haplotype analysis revealed that TGGTA protected against GSD development in females (OR = 0.75, Pc = 0.014). Based on our findings, IL18 rs5744247C>G polymorphism could be a potential genetic marker to predict GSD susceptibility in Han Chinese women.

1906T

Search for new modifiers of disease severity in Jamaican sickle cell disease patients using whole-exome DNA sequencing. *G. Lettre[1,2], G. Galarneau[1,2], M. Beaudoin[1,2], K.S. Lo[1,2], M. Reid[3], G. Serjeant[4], I.R. Hambleton[5], J.N. Hirschhorn[6,7], C.A. McKenzie[3].* 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Universite de Montreal, Montreal, Quebec, Canada; 3) Sickle Cell Unit, University of West Indies, Mona, Kingston, Jamaica; 4) Sickle Cell Trust, Kingston, Jamaica; 5) University of the West Indies, Cave Hill, Barbados; 6) Children's Hospital Boston, Boston, MA, USA; 7) Broad Institute, Cambridge, MA, USA.

INTRODUCTION: The β-hemoglobinopathy sickle cell disease (SCD) is characterized by extreme clinical heterogeneity: from asymptomatic presentation to life-threatening complications. To better understand this variable clinical course and identify genetic modifiers of disease, we studied Jamaican SCD patients with >20 years of follow-up. METHODS & RESULTS: Using the Agilent SureSelect All-Exon 50 Mb capture library and the Illumina GAIIx next-generation DNA sequencer, we sequenced the whole-exome of 19 Jamaican SCD patients with a low burden of SCD-related complications. For each patient, we generated ~11 Gb of sequence, providing a mean coverage of 129X, or 84% of the targeted genomic regions re-sequenced at ≥20X. We identified 41,829 high-quality non-synonymous (nonsense, missense) or splice site variants, 25% of which are not reported in public databases. The transition-to-transversion (Ti/Tv) ratio, a metric used to assess the quality of the DNA sequence variants identified, is 3.14. These numbers are consistent with other large-scale next-generation DNA re-sequencing projects, suggesting that the quality of our data is high. To prioritize genes for follow-up in large SCD patient collections, we developed a gene score based on the number and type of mutations found while taking into account important confounders such as gene length. This preliminary analysis yielded several genes involved in lipid metabolism and free radical scavenging, two pathways previously linked to SCD severity. CONCLUSION: We used whole-exome DNA sequencing to identify new genetic modifiers of SCD severity in a unique SCD birth cohort. Combining these sequence results with other available genome-wide association study datasets will provide new opportunities to understand clinical variability in SCD.

1907F

Complex trait alleles are enriched for cell-specific chromatin marks. *S. Raychaudhuri[1,2,3,4], G. Trynka[1,2,3,4], H. Xu[5], B.E. Stranger[1,4], X.S. Liu[5].* 1) Division of Genetics, Brigham and Women's Hospital, Boston, MA; 2) Division of Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 3) Partners Center for Personalized Genetic Medicine, Boston, MA, USA; 4) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 5) Department of Biostatistics and Computational Biology, Dana-Farber Cancer Institute and Harvard School of Public Health, Boston, Boston, MA, USA.

Complex trait alleles might act by altering regulatory regions. In this case, chromatin marks highlighting active regulatory regions should overlap alleles in the specific cell-types most relevant to the trait. However, those marks that are most useful in defining cell-types and fine-mapping common variants have not been defined. We hypothesized that marks that have greatest utility must be “phenotypically cell-specific”, that is the overlap of alleles with marks is restricted by the phenotype to specific cell-types.

To identify these marks, we examined 15 chromatin marks across multiple cell-types (ENCODE) and 510 independent variants associated with 31 phenotypes. H3K4me3 showed the highest phenotypic cell-specificity ($p<10^{-6}$). We observed only those marks highlighting active gene regulation, such as DNase HS I and H3K9ac, were phenotypically cell-specific. Conditional analysis demonstrated that the phenotypic cell specificity of these marks were largely redundant.

We assessed whether the phenotypic cell-specificity of H3K4me3 was related to the specific location of the peaks or the simple presence of peaks related to cell-specific gene expression. We observed repeatedly that repositioning peaks locally within disease loci reduces phenotypic cell-specificity ($p<0.001$). This suggests that the phenotypic cell-specificity of H3K4me3 is driven by the specific location of cell-specific peaks.

Finally, we examined H3K4me3 marks (NIH epigenome project) to identify key cell-types for four phenotypes. We found that H3K4me3 peaks most significantly overlapped 37 plasma low-density lipoprotein concentration alleles in the liver ($p<10^{-6}$), 40 rheumatoid arthritis alleles in CD4+ memory T-cells ($p=1x10^{-4}$), 32 body mass index alleles in pancreatic islet cells ($p=1x10^{-4}$) and 11 neuropsychiatric disease alleles in the mid frontal lobe ($p=0.015$). We illustrate how these results can be used to fine-map trait-associated variants to causal variants. This study suggests that common, complex trait-associated variants implicate regions involved in cell-specific gene regulation, and that selected high quality chromatin marks can be comprehensively applied to many cell-types to identify critical cell-types and specific regulatory elements in an unbiased fashion.

1908W

A regulatory variant in FZD6 gene contributes to Nonsyndromic Cleft Lip and Palate (NSCLP). *J. Hecht[1], N. Cvjetkovic[1], L. Maili[1], A.M. Letra[2], M. Raia[1], E.C. Swindell[1], J.F. Teichgraeber[3].* 1) Pediatrics, Univ Texas Med Sch, Houston, TX; 2) University of Texas Dental Branch at Houston; 3) Department of Pediatric Surgery, University of Texas Medical School at Houston.

Nonsyndromic cleft lip with or without cleft palate (NSCLP) is a common birth defect with a multifactorial etiology. Despite decades of research, the genetic underpinnings of NSCLP still remain largely unexplained. A genome wide association study (GWAS) of a large NSCLP African American family with seven affected individuals across three generations found evidence for linkage at 8q21.3-24.12 (LOD = 2.98). This region contained three biologically relevant candidate genes: Frizzled-6 (FZD6) (LOD = 2.8), Matrilin-2 (MATN2) (LOD = 2.3), and Solute Carrier Family 25, Member 32 (SLC26A32) (LOD = 1.6). Sequencing of the coding regions and the 5′ and 3′ UTRs of these genes in two affected family members identified a rare intronic variant, rs138557689 (c.-153+432A>C), in FZD6. The rs138557689/C allele segregated with the NSCLP phenotype; in silico analysis predicted and EMSA analysis showed that the 138557689/C allele creates new DNA binding sites. FZD6 is part of the WNT pathway, which is involved in craniofacial development, including midface development and upper lip fusion. Our novel findings suggest that an alteration in FZD6 gene regulation may perturb this tightly controlled biological pathway and in turn contribute to the development of NSCLP in this family. Studies are underway to further define how the rs138557689/C variant affects expression of FZD6.

1909T

Next-Generation sequencing of unresolved Meckel Syndrome pedigrees reveals a complex genetic makeup. *K. Hopp[1], C.M. Heyer[2], J.L. Sundsbak[2], S.J. Koon[1], V.J. Kubly[2], V.E. Torres[2], P.C. Harris[1,2].* 1) Biochem. and Molec. Biology, Mayo Clinic, Rochester, MN; 2) Nephrology and Hypertension Research, Mayo Clinic, Rochester, MN.

Meckel Syndrome (MKS) is an embryonic lethal disorder characterized by polycystic kidney disease (PKD), central nervous system (CNS) defects, polydactyly and liver fibrosis; phenotypic parameters that classify it as a ciliopathy. Genetically, MKS has been linked to autosomal recessive inheritance of variants in 13 ciliogenes, however only five of these are mutated in multiple families, highlighting a high level of genetic heterogeneity driven by privately mutated genes. In concordance, Sanger sequencing of the five commonly associated genes (*MKS1*, *TMEM67*, *CEP290*, *CC2D2A*, *RPGRIP1L*) revealed two mutated alleles in only 51% of our MKS cohort (49 families). Interestingly, in 20% of the cases (10 families) we identified only one pathogenic variant, suggesting a more complex, multi-loci inheritance. To investigate the genetic complexity and to resequence all implicated MKS genes, we performed a targeted *Agilent SureSelect* exon-capture of 707 cilia genes on our genetically unresolved pedigrees. We identified a *CC2D2A* frame-shift mutation (c.3534delG) that was missed by Sanger sequencing in a pedigree that had already one *CC2D2A* change (W1182R). Interestingly, the same patient carried private frame-shifting mutations in three additional ciliogenes and a likely pathogenic missense change in *CEP290* (D433G); highlighting a high level of genetic complexity. In other patients we identified multiple (range 1-5), private and potentially pathogenic variants not present in dbSNP135, the 1000 Genomes or the HapMap project. A number of these are frame-shifting variants in ciliogenes with known homology domains to already identified ciliopathy targets; we are currently evaluating them for their disease association using *in silico* tools (particularly for missense variants), patient cell lines, and over-expression systems. Together, these findings suggest that simple, recessive and more complex, oligogenic inheritance may associate with MKS. In addition, we have developed an *Agilent HaloPlex* gene panel including all known identified ciliopathy genes plus ~200 strong candidates to sequence 96 single indexed samples; mimicking diagnostic settings. In suitable families we are also performing whole exome analysis to identify the full mutation load beyond the ciliary complex.

Role of the PRICKLE genes in neural tube defects in humans. *R. Allache[1,2], V. Capra[3], M.Q. Wang[2], C.M. Bosoi[2], P. Drapeau[1], A.G. Bassuk[4], Z. Kibar[2].* 1) Pathology and Cell Biology, University of Montreal, Montreal, Quebec, Canada; 2) Department of Obstetrics and Gynecology, CHU Sainte Justine Research Center and University of Montréal; 3) Laboratorio del Servizio di Neurochirurgia, Instituto G. Gaslini, Genova, Italy; 4) Department of Pediatrics, University of Iowa, Iowa City, Iowa, USA.

PK1 and PK2 are core members of the planar cell polarity (PCP) pathway that controls the process of convergent extension (CE) during gastrulation and neural tube closure in vertebrates. This pathway has been implicated in the pathogenesis of neural tube defects (NTDs) in animal models and human cohorts. In this study, we analyzed the role of PK1 and PK2 in these malformations by re-sequencing analysis of their open reading frames and exon-intron junctions in a cohort of 810 unrelated NTD patients. We identified 9 and 7 rare missense heterozygous mutations in each of PK1 and PK2 respectively that were absent in all controls analyzed. Polyphen and SIFT analyses predicted 10 of these mutations to be functionally deleterious. In a yeast-two-hybrid (Y2H) assay, 4 mutations identified in PK1 were found to affect the interaction of PK1 with its binding partners, VANGL2, DVL3 and DIV. In overexpression studies in Zebrafish, 4 zPk2 variants were found to produce a significantly less severe phenotype compared to the wild-type Pk2 suggesting a loss of function mutations. Functional validation of PK2 variants with Y2H assay is currently underway. Our study demonstrates that PK1 and PK2 could act as predisposing genetic factors to NTDs in a subset of patients and further expands our knowledge on the role of PCP genes in the pathogenesis of these malformations.

Investigation of Complex Copy Number Polymorphisms and Age-related Macular Degeneration. *S. Cantsilieris[1,2], S. White[2], R. Guymer[1], P. Baird[1].* 1) Centre for Eye Research Australia, University of Melbourne, The Royal Victorian Eye and Ear Hospital, Melbourne, Victoria, Australia; 2) Centre for Reproduction and Development, Monash Institute of Medical Research, Melbourne, Victoria, Australia.

Age-related Macular Degeneration (AMD) is a leading cause of vision loss in the developed world. There is compelling evidence that AMD is associated with several gene regions involved in immunity, lipid metabolism and angiogenesis. The role of inflammation, particularly complement regulation, appears to be involved in the disease process. We have undertaken a study to investigate the role of three complex copy number polymorphisms (CNPs) containing, CCL3L1, FCGR3B and C4 involved in encoding chemokines and chemotatic cytokines, chemotaxis and complement regulation. The aim was to determine the potential role of these CNPs in AMD. We employed Multiplex Ligation-dependent Probe Amplification (MLPA) to measure CNV at these three loci. We analysed 346 AMD cases and 377 controls using MLPA, then genotyped a further 230 AMD cases and 44 controls for the C4A and C4B genes using agarose gel electrophoresis, for a total of 576 AMD cases and 421 control samples. We achieved clear separation of copy number integers, ranging between 0-6 for CCL3L1, 1-4 for FCGR3B, 0-4 for C4A and 0-3 for C4B. The frequency distributions for both low and high copy number for CCL3L1 and FCGR3B were not significantly different between cases and controls. In the case of C4A, we observed a 2-fold difference in the number of homozygous deletions between cases and controls (3.1% vs 1.4%) which was nominally significant (p=0.06), t-test. For homozygous deletions of C4B, we observed an almost 4-fold difference between cases and controls (3.5% vs 0.9%) which was statistically significant (p=0.005), t-test. These results suggest that CNPs encompassing C4A and C4B are associated with risk of AMD, and support the role of complement dysregulation in AMD pathogenesis.

1912T

Identification of a pleiotropic effect locus associated with a composite CVD risk trait in the genetic isolate of Norfolk Island. *L.R. Griffiths[1], M. Benton[1], H. Cox[1], C. Bellis[2], M. Carless[2], M. Hanna[1], D. Eccles[1], J. Blangero[2], R.A. Lea[1].* 1) Genomics Research Centre, Griffith Health Institute, Griffith University, Southport, Australia; 2) Department of Genetics, Texas Biomedical Research Institute, San Antonio, Texas, USA.

Many heritable cardiovascular disease (CVD) risk traits tend to be correlated suggesting the underlying presence of pleiotropic effect genes. Genome-wide association studies (GWAS) aimed at composite CVD traits may reveal such genes, which would remain latent using single phenotype analyses. Analysis of large pedigrees offers the added advantage of assessing the heritability of composite traits, which can help prioritise genetically influenced phenotypes for GWAS analysis. In this study we have utilized the Norfolk Island genetic isolate to investigate composite CVD risk traits. This population originates from a small number of British and Polynesian founders who are descendents of the Bounty mutiny with the majority of the population forming a very large multigenerational pedigree. In this study we performed a principal components analysis (PCA) and subsequent heritability (H2) estimation of n=37 CVD-related phenotypes in 330 related individuals from the Norfolk Island genetic isolate. We then performed a pedigree-based GWAS using Illumina 610K quad chips to search for pleiotropic effect loci. PCA revealed 13 components explaining >75% of the total variance within the sample space. Nine components yielded statistically significant H2 values ranging from 0.22 to 0.54 (P<0.05). The most heritable component was comprised of 7 phenotypic measures including; % body fat, waist-to-hip ratio, systolic and diastolic blood pressure, creatine, urea, uric acid. A GWAS of this composite phenotype revealed statistically significant associations for 3 adjacent SNPs on chromosome 1p22 (P<1x10-8). These SNPs form a 42kb haplotype block and explain 11% of the genetic variance indicating a major susceptibility locus for this phenotype. No associations were observed for the phenotypes assessed individually, nor were any significant associations observed for the other 6 heritable component traits. Our results support the `phenome scanning' approach to search for pleiotropic effect loci associated with correlated CVD phenotypes. Further research is now underway to elucidate the causative gene variant(s) within the identified susceptibility region and explain the functional impact on this composite CVD phenotype.

1913F

Association of BMI and waist-related genetic variants with visceral adipose tissue volume in the Family Heart Study. *A. Justice[1], M. Graff[1,2], N. Franceschini[1], A.P. Reiner[3], M.F. Feitosa[4], J.J. Carr[5], J.G. Terry[5], P. Gordon-Larsen[2], M.K. Wojczynski[4], I.B. Borecki[4], K.E. North[1,2].* 1) Epidemiology, University of North Carolina, Chapel Hill, NC, USA; 2) Carolina Population Center, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Department of Epidemiology, University of Washington, Seattle, WA; 4) Department of Genetics, Washington University School of Medicine, St Louis, MO; 5) Department of Radiology, Wake Forest University School of Medicine, Winston Salem, NC.

Genome-wide association (GWA) studies have identified multiple single nucleotide polymorphism (SNP) associations with body mass index (BMI) and anthropometric waist measures (waist circumference [WC] and waist to hip ratio [WHR]). Computed tomography (CT) assessed visceral adipose volume (VAT) is a more sensitive and specific measure of central adiposity, which is correlated to both BMI and anthropometric waist measures, and their shared disease risk. However, VAT measurements are generally unavailable in large population-based studies. The extent to which BMI and central adiposity SNPs reflect visceral, general central adiposity or body mass is unknown. We evaluated the association of 38 established BMI and 14 WC/WHR SNPs with VAT and VAT corrected for BMI (VAT/BMI) using GWAS data from the Family Heart Study (FamHS), which was comprised of 2,658 European-American individuals measured by CT scans. Within the FamHS cohort, high correlations exist between VAT and BMI (r^2=0.70), WC (r^2=0.73), and WHR (r^2=0.58). From the 38 BMI SNPs, we found three SNPs for VAT and three for VAT/BMI that had nominally significant ($p \leq 0.05$) associations. Of these, five were non-overlapping between phenotypes, but none of these remained significant after correction for multiple testing. One SNP, rs2241423 was nominally associated with both VAT and VAT/BMI but the BMI increasing allele was negatively associated with VAT and VAT/BMI (β=-8.78±2.80 and -4.92±1.99 respectively). Of 14 WC/WHR SNPs, one was nominally associated with VAT (rs1294421, β= 5.51±2.43) and two with VAT/BMI (rs6795735, β= 3.316±1.66; rs6861681, β= 4.908±1.86), with the waist increasing alleles displaying directionally consistent association with VAT and VAT/BMI. While our findings support the hypothesis that BMI, WC/WHR, and VAT share common genetic influences the inconsistent effect estimates demonstrate that the previous established SNP-BMI associations are expectedly crude and may represent various markers of adiposity, such as overall body size, general adiposity, and more specific measures of central adiposity. These genes deserve further investigation to elucidate the relationship among these BMI genes and actual central adiposity. In contrast, the WC/WHR loci nominally associated with VAT and VAT/BMI display effect estimates that are directionally consistent with previous WC/WHR studies, suggesting that these loci are capturing central adiposity and not overall adiposity.

1914W

Follow up analyses of the APOL1/MYH9 locus and non-diabetic end stage renal disease (non-DM ESRD) in African Americans: the FIND Consortium. *M. Li, FIND consortium.* Epidemiology, Johns Hopkins Univ, Baltimore, MD.

Previous studies identified an admixture-generated signal on chromosome 22 with non-DM ESRD in African Americans (AA). Subsequent work showed that the signal was due to strong associations between the APOL1 G1 and G2 alleles and the MYH9 E-1 haplotype. To further understand the genetic architecture of this locus, we conducted follow-up analyses in the FIND AA non-DM samples: 1) sequencing of exons and the 3′- and 5′-flanking regions of MYH9 in 186 individuals, followed by sequence-enhanced genotyping in 529 non-DM ESRD cases and 727 controls; 2) a haplotype-based association analysis of both MYH9 and APOL1 variants to differentiate the effects of APOL1-only at-risk haplotypes from MYH9-only at-risk haplotypes; and 3) an admixture mapping analysis in 1058 AA individuals who did not have 2 copies of the at-risk APOL1 alleles. In the sequenced samples, 377 SNPs were identified (242 with frequencies<5%). Five exonic SNPs were associated with non-DM ESRD (p<0.05), but the Madsen Browning test was not significant (p=0.68). In the samples with the follow-up genotyping, only one exonic SNP (rs2269529) remained associated with non-DM ESRD (OR= 1.71, p=0.002); however, the association signal shrank to insignificance after adjustment for APOL1-MYH9 haplotypes (OR=1.06, p=0.80). Meanwhile, individuals with 2 copies of the APOL1-only haplotype were about 8 times more likely to have non-DM ESRD compared to those with the low-risk haplotype at APOL1 and MYH9 (OR=8.34;p=4.94 x 10-12). In contrast, those with 2 copies of the MYH9-only at-risk haplotypes were not significantly more likely to have non-DM ESRD (OR=1.03, p=0.92). Finally, in a genome-wide admixture scan of AA individuals without 2 copies of APOL1 at-risk alleles, the genome-wide LOD score on chromosome 22 was -0.07. Sequence analyses suggest that common exonic variants in MYH9 are not associated with non-DM ESRD in AA, and that the APOL1 G1 and G2 risk alleles are significantly associated with non-DM ESRD in a recessive manner and account for the admixture-generated signal on chromosome 22.

HLA typing of a large type 1 diabetes cohort using SNP genotyping of the extended MHC. *J. Bradfield[1], D.S. Monos[2], H.Q. Qu[3], C. Kim[1], M. Rossman[4], K.D. Rosenman[5], S.F.A. Grant[1,6], C. Polychronakos[7], H. Hakonarson[1,6].* 1) Center for Applied Genomics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania and The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Division of Epidemiology, Human Genetics and Environmental Sciences, University of Texas School of Public Health, Brownsville Regional Campus, Brownsville, TX; 4) Department of Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA; 5) Department of Medicine, Michigan State University, East Lansing, MI; 6) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 7) Endocrine Genetics Laboratory, McGill University Health Center (Montreal Children's Hospital), Research Institute, Montreal, Quebec, Canada.

Type 1 diabetes is strongly associated with specific HLA polymorphisms and with the MHC region in general. The HLA genes contribute over 50% of the genetic risk for the disease. Due to the highly polymorphic nature of the region and its long-range linkage disequilibrium, identifying additional variants with independent effects, besides those that have already been described, is very challenging. Towards this objective, knowing the HLA type is essential, as any type of analysis needs to both account and stratify the population for this HLA information. For this purpose, and in the absence of HLA typing information, we imputed the classical HLA alleles (HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1, and HLA-DPB1) in a cohort that was recently used in a meta-analysis of T1D with approximately 10,000 cases and 17,000 controls. The imputation was performed using Beagle with a reference set of approximately 1,500 individuals who were HLA genotyped and were genotyped on SNP platforms from Illumina and Affymetrix used in the analysis. The exception to this is the HLA-DPB1 reference set, which was only genotyped on the Illumina platform for ~430 individuals. We also imputed all variation (~133,000 SNPs and indels) in the extended MHC from the 1000 genomes project to fill in gaps between the classical HLA alleles. The 1000 genomes imputation was performed with Imputev2. We have identified association with a high degree of resolution of each of the classical HLA alleles, as well as all common diallelic SNPs and indels contained within the extended MHC. While imputing classical HLA alleles may have its shortcomings, we believe that it is a meaningful way to economically analyze large numbers of individuals and to properly control for prior discoveries in the extended MHC.

1916F

Systematic evaluation of validated type 2 diabetes and glycemic trait loci for association with insulin clearance. *M.O. Goodarzi[1], X. Guo[1], J. Cui[1], M.R. Jones[1], T. Haritunians[1], A.H. Xiang[2], Y.I. Chen[1], K.D. Taylor[1], T.A. Buchanan[3], W.A. Hsueh[4], L.J. Raffel[1], J.I. Rotter[1].* 1) Cedars Sinai Medical Center, Los Angeles, CA; 2) Kaiser Permanente Southern California Medical Group, Pasadena, CA; 3) University of Southern California Keck School of Medicine, Los Angeles, CA; 4) Methodist Hospital Research Institute, Houston, TX.

GWAS and GWAS meta-analyses have identified over 50 loci for type 2 diabetes (T2D), as well as a several loci for fasting (FG) and 2-hour glucose (2hrG), fasting insulin (FI), and hemoglobin A1c (HbA1c). Follow-up studies, mainly utilizing fasting or oral glucose tolerance measurements, suggest the great majority of these loci affect insulin secretion, with only a minority appearing to influence insulin sensitivity. Whether validated T2D and glycemic trait loci affect insulin clearance has not been systematically evaluated. We analyzed the Cardio-Metabochip finemapping content for T2D (34 finemapped loci), FG (19 loci), 2hrG (3 loci), FI (2 loci), and HbA1c (5 loci) in two family-based Hispanic-American cohorts, the Mexican-American Coronary Artery Disease (MACAD) cohort, n=676, and the Hypertension-Insulin Resistance (HTN-IR) cohort, n=638. Insulin clearance was measured via the steady state plasma insulin (SSPI) level during euglycemic hyperinsulinemic clamps in both cohorts. ~15,200 SNPs were sufficiently polymorphic and passed quality control for analysis. Association between SNPs and SSPI was evaluated using general estimating equations (GEE1) implemented in the GWAF program, using an additive model (adjusted for age, sex, BMI, diabetes status, and principal components). 23 variants had a $p<0.05$ for association with SSPI in both cohorts, with consistent beta values. We generated meta-analysis p values on these 23 SNPs, which represent 6 loci. The top meta-analysis signals for each locus were rs10241087, $p=1.5\times10^{-5}$ (*DGKB/TMEM195*); rs849334, $p=2.0\times10^{-4}$ (*JAZF1*); rs2380949, $p=3.6\times10^{-4}$ (*GLIS3*); rs55903902, $p=1.3\times10^{-3}$ (*FADS1*); rs35749, $p=4.0\times10^{-4}$ (*IGF1*); and rs9204, $p=4.7\times10^{-3}$ (*HNF1A*). To account for multiple testing, we conducted LD pruning of the 15,200 SNPs, using a LD cutoff of 0.5, yielding 3827 independent SNPs and thus a correction factor of $0.05/3827=1.3\times10^{-5}$. This cutoff was nearly met by the SNP at rs10241087, which lies in an intron of DGKB (diacylglycerol kinase beta, which regulates intracellular levels of the second messenger diacylglycerol, DAG, which may affect hepatic insulin sensitivity). It is possible that additional T2D and glycemia loci discovered subsequent to design of the MetaboChip may also influence insulin clearance. While apparently not the case for the majority of loci, these data raise the possibility that some validated loci for T2D, FG, 2hrG, FI, and HbA1c might exert their effects via insulin clearance in Hispanics.

1917W

Whole Genome Sequencing to Identify Functional Variants that Contribute to Type 2 Diabetes and Obesity in Pima Indians. *K. Huang, C. Bogardus, L. Baier.* Phoenix Epidemiology and Clinical Research Branch, NIDDK, NIH, Phoenix, AZ.

To identify functional variants that affect risk for type 2 diabetes (T2D) or obesity in Native Americans, we are analyzing whole genome sequence data on Pima Indians. Sequencing is being performed by Complete Genomics, Inc., and to date, 30 genomes have been completed. Among these initial genomes, 9,235,137 variants were found (7,283,045 SNPs, 800,901 insertions, 795,389 deletions and 255,802 substitutions) of which 32,596 variants were nonsynonymous (28,041 were SNPs). Multiple prediction programs were used to predict that 12,795 nonsynonymous variants were "functional" (damaging or damaging). These "functional" variants underwent data cleaning: variants located within segmental duplication or non-conserved regions were removed, variants with genotypes called in <80% of the samples were removed, and variation observed in fewer than 3 alleles (MAF<5% in the 30 samples) were removed. The 30 subjects who were sequenced had also been part of a prior genome-wide association study (GWAS) and had been genotyped using the Affymetrix 1 million SNP chip. Therefore, many of the remaining 1,528 "functional" variants could be tagged ($r2 \geq 0.8$) by SNPs previously genotyped in 954 Pima Indians as part of our GWAS. Several of the GWAS tag SNPs (e.g. SNPs near ACTRT2, VNN3 and POC5) had been modestly associated with T2D in the GWAS (tag SNPs' P value $\approx$ 10E-3 - 10E-4). Other GWAS tag SNPs (e.g. SNPs near CCDC67, PKD1L3 and C17orf103) had been modestly associated with BMI in the GWAS (tag SNPs' P value $\approx$ 10E-4). The predicted "functional" variants within these genes, as well as untagged "functional" variants located within physiologic candidate genes for type 2 diabetes and obesity, are currently being genotyped in a population-based sample of 3500 Pima Indians to determine whether they are associated with type 2 diabetes or obesity.

1918T

Tracking elusive modifier loci using identity-by-descent and influential alleles. *E. Marchani[1], E. Wisjman[1,2,3]*. 1) Div Med Gen, University of Washington, Seattle, WA; 2) Dept Biostat, University of Washington, Seattle, WA; 3) Dept Genome Sci, University of Washington, Seattle, WA.

It is not simple to identify genetic loci influencing complex traits, which are often genetically heterogeneous. As modifier and risk alleles are neither necessary nor sufficient to cause disease, they may not be shared by all cases and can hide among unaffected individuals. This is especially true for late-onset traits with censored phenotype data. A rigorous approach is required.

We previously identified three regions linked to modifiers of age-at-onset among Volga German families sharing a *PSEN2* variant causing early-onset Alzheimer's disease. Our goal is to find the biologically relevant variant(s) driving these linkage signals. Sequencing-based analyses at this early stage are prohibitive: the regions are too broad (27.9 - 72.8 Mb) for cost-effective candidate gene screening, and we hesitate to assume the type (copy number variant, missense) or frequency (common, rare) of the underlying variants necessary for exclusion mapping using next-generation sequence data. Instead, our strategy is to find the smallest chromosomal segment with the strongest evidence of linkage, then focus on validating variants co-segregating with that segment in a large pedigree.

For each linkage region, we have tested thousands (6,512 - 11,574) of markers to find those that tag the chromosomal segment driving the linkage signal. We prioritized markers with large effect sizes that eliminate the linkage signal when included as a covariate (4 - 11 markers). We deduced the tagging haplotype with Markov chain Monte Carlo segregation and linkage analyses performed by Loki 2.4.7. Each haplotype has estimated effect sizes comparable to *APOE*. We determined which relatives carry that haplotype using the MORGAN package's computationally savvy identity-by-descent estimation.

This process has allowed us to narrow our focus to chromosomal regions 10 to 30 times smaller than the original linkage signals: 0.9 - 7.6 Mb. We are sequencing carriers of these modifier haplotypes, and will soon identify co-segregating variants. We will also estimate the frequency of these haplotypes among related populations, such as CEPH Europeans and other Volga German families affected by Alzheimer's disease.

1919F

Genetic dissection of Chiari Type I Malformation using stratified whole genome linkage approaches. *C. Markunas[1], K. Soldano[1], K. Dunlap[1], H. Cope[1], E. Asiimwe[1], J. Stajich[1], D. Enterline[2], G. Grant[3], H. Fuchs[3], S. Gregory[1], A. Ashley-Koch[1]*. 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Division of Neuroradiology, Department of Radiology, Duke University Medical Center, Durham, NC; 3) Division of Neurosurgery, Department of Surgery, Duke University Medical Center, Durham, NC.

Chiari Type I Malformation (CMI) is a developmental disorder characterized by displacement of the cerebellar tonsils below the base of the skull, resulting in significant neurologic morbidity. Although cerebellar tonsillar herniation (CTH) is hypothesized to result from a small posterior fossa (PF), patients are frequently diagnosed by the extent of CTH without cranial morphometric assessment. The resultant clinically heterogeneous CMI population has subsequently hampered gene identification efforts. We performed a whole genome qualitative linkage screen using 66 non-syndromic CMI multiplex families (367 individuals). Both two-point and multipoint parametric and nonparametric linkage analyses were conducted. Initial results showed minimal evidence for linkage. Thus, additional analytic approaches were applied to reduce potential genetic heterogeneity.

First, due to the frequent co-occurrence of CMI with connective tissue disorders (CTD), families were stratified based on a family history of CTD related conditions. Stratified linkage analyses resulted in a marked increase in evidence of linkage to multiple genomic regions. Of particular interest were two regions (Chr8, LOD=3.0; Chr12, LOD=2.1), both of which harbor genes (GDF6, GDF3) implicated in the development of Klippel-Feil syndrome, which co-occurs with CMI in roughly 5% of patients. Sequencing efforts for both genes are underway and currently two putative causal variants have been identified.

Second, using twenty four cranial morphology measurements derived from the PF we estimated heritability for individual PF traits, performed principal components (PC) analysis to identify the most heritable PCs, and performed ordered subset analysis (OSA) using PF traits that were both heritable and associated with CMI. Several interesting regions were implicated from OSA, including chromosome 22. The region harbors EP300, a histone acetyltransferase associated with Rubenstein-Taybi syndrome (RSTS) which can co-occur with CMI. Interestingly, within a morphometrically similar subset of families we observed a slight increase in evidence for linkage to a region containing a related gene, CREBBP, which is also associated with RSTS. These analyses demonstrate the utility of reducing genetic heterogeneity by implicating credible candidate genes in CMI susceptibility.

1920W

Heritability and Linkage Analysis of the Scale of Aging Vigor in Epidemiology (SAVE) in the Long Life Family Study. *J.L. Sanders[1], J. Singh[2], R.L. Minster[2], C.M. Kammerer[2], M.M. Barmada[2], E.W. Daw[3], M. Feitosa[3], R. Costa[4], N. Schupf[4], J. Walston[5], A.B. Newman[1]*. 1) Departments of Epidemiology, GSPH, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, GSPH, University of Pittsburgh, Pittsburgh, PA; 3) Division of Statistical Genomics, Department of Genetics, Washington University School of Medicine, St. Louis, MO; 4) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY; 5) Center on Aging and Health, Johns Hopkins Medical Institutions, Baltimore, MD.

Frailty, a complex phenotype of older age, is characterized by weakness, slowness, weight loss, low energy, and fatigue. Frailty is strongly associated with increased morbidity, hospitalization, and mortality - thus, frailty is a heavy burden to individuals and communities. Preventing frailty is a prime concern, but its etiology is unknown. There is evidence that unfavorable levels of serum inflammatory markers and hormones, metabolic factors, and short telomeres, all of which are heritable, may spur frailty. However, there are few studies of the possible genetic components of frailty. We used a new trait, Scale of Aging Vigor in Epidemiology (SAVE), a measure of vigor (similar to frailty) that is informative across age groups and comprises measures of strength, speed, and liveliness, to assess possible genetic components of vigor in the Long Life Family Study (LLFS). LLFS is a two-generation, family-based cohort designed to study sibships of exceptionally healthy older individuals and their adult offspring and spouse controls. LLFS consists of 4451 individuals in 480 families; 1512 in the older generation (mean age = 89.4 yr), 2199 in the offspring generation (mean age = 60.5 yr), and 740 spouses (mean age = 61.0 yr). The SAVE trait comprises grip strength, gait speed, physical activity, fatigue, and weight loss; each scored 0, 1, or 2 using approximate tertiles; and summed from 0-10 to create a continuous, normal vigor distribution in both generations, thus vigor decreases with an increasing score. Using maximum likelihood methods, heritability of this trait was estimated overall (age-adjusted $h2=0.33\pm0.04$, $p<10^{-21}$). We next performed variance components linkage analyses using multipoint IBD probabilities estimated using SNPs with approximately 1.0cM spacing. Although we did not detect any significant signals (i.e., LOD > 3.0), we obtained suggestive evidence that a quantitative trait locus for SAVE was located near the end of chromosome 18q (maximum LOD = 2.9 and the chromosomal region of interest encompassed 118 - 131 cM). These findings support further evaluation of the genetic and environmental factors contributing to this phenotype of vigor in the elderly.

1921T

Genomewide linkage analyses of hematological phenotypes in Long Life Family Study. *J. Singh[1], R.L. Minster[1], M.M. Barmada[1], E.W. Daw[2], B. Thyagarajan[3], K. Christensen[4], A.B. Newman[5], C.M. Kammerer[1].* 1) Department of Human Genetics, GSPH, University of Pittsburgh, Pittsburgh, PA; 2) Division of Statistical Genomics, Department of Genetics, Washington University School of Medicine, St. Louis, MO; 3) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 4) Institute of Public Health at the University of Southern Denmark, Odense, Denmark; 5) Department of Epidemiology, GSPH, University of Pittsburgh, Pittsburgh, PA.

Hematological phenotypes such as white blood cells (WBC), red blood cells (RBC) and platelets play important roles in immune response, oxygen carrying and blood clotting. These traits are heritable and tightly regulated within narrow physiological limits. Abnormalities in these traits are associated with a number of diseases such as anemia. To detect possible quantitative trait loci (QTL) involved in regulation of these traits, we performed genomewide linkage analyses using data from the Long Life Family Study (LLFS) - a two-generation family-based cohort study designed to elucidate the genes and environmental factors that influence exceptional aging. Data on hematological phenotypes (including hematocrit, hemoglobin, lymphocytes, neutrophils, RBC, and WBC counts) were available on 4520 individuals belonging to 480 families of European ancestry. Based on the literature, we used maximum likelihood variance components methods to assess traits for effects of the following covariates (field center, age, sex, age-squared, BMI, smoking status, drinking habits, and menopausal status); residuals of each trait were obtained for significant ($p \leq 0.05$) covariates and used in subsequent analyses. Similar to previous reports, residual additive genetic heritability ranged from 0.20±0.03 (for hemoglobin) to 0.42±0.04 (for platelet count); all p-values $<10^{-21}$. Variance component linkage analyses were performed using multipoint identical by descent probabilities (IBD) estimated from SNPs with approximately1cM spacing. We obtained evidence for a QTL influencing RBC count on chromosome 11p15.1 to 11p15.2 (maximum LOD score = 3.2 at 37 cM, genomic p-value <0.05). Interestingly, the Framingham Heart Study previously reported linkage of RBC count to a QTL at 11p15.2. The hemoglobin beta-cluster located at 11p15.5 (>10 Mbp away) is outside our region of interest. We also obtained evidence for a QTL for platelet count on chromosome 8p22 (maximum LOD = 3.4 at 31cM, genomic p-value<0.05). Reports from large consortium genomewide association studies have not implicated either chromosomal region, indicating that we may have identified additional genes influencing RBC count and platelets. Our findings illustrate the utility of long-lived families to enhance our understanding of biology involved in genetic control of hematological traits.

1922F

Effect of DNA polymorphisms of apolipoprotein B gene on lipid homeostasis in obese Egyptians. *G. El-Kannishy[1], R. Elbaz[2], A. Wafa[1], H. AbdElHafez[1], A. Settin[3].* 1) Internal Medicine Dept., Mansoura Faculty of Medicine, Mansoura University, Mansoura, Egypt; 2) Genetic Unit, Faculty of Medicine, Mansoura University; 3) Peadiatric Dept., Faculty of Medicine, Mansoura University.

Background: Numerous polymorphisms of Apoliporotein B (ApoB) gene may predispose to obesity, particularly a variable number of tandem repeats (VNTR) polymorphism. association between the 3′APOB-VNTR polymorphism and serum lipid levels was observed in many ethinic groups. Objective: The aim of this study is to investigate the association of the 3′VNTR polymorphisms of the ApoB gene in obese Egyptians with normal and abnormal lipid profile. Methods: The 3′APOB-VNTR alleles were determined and classified according to the number of repeats in 180 subjects with simple obesity as well as 100 age and sex matched healthy controls. Obese group was further subdivided according to lipid profile into normolipidemic and dyslipidemic groups. Results: Different numbers of alleles were identified in the studied groups. The most frequent allele in all the studied groups was VNTR 31, followed by VNTR 38. VNTR 38 repeats were significantly higher in control group than total obese and dyslipidemic groups. Dyslipidemia was associated with significantly higher frequency of the homozygous VNTR-SS genotype; on the otherhand, normolipidemic group had a significantly lower frequency of the heterozygous VNTR-LS genotype compared to healthy controls. Conclusions: VNTR 38 repeats seems to be protective from lipid abnormality in normal weight and obese. High VNTR-SS genotype among subjects with dyslipidemia possibly indicate that VNTR-SS genotype could be considered as a genetic risk factor for lipid abnormality among obese Egyptians.

1923W

Identification of genes influencing serum levels of brain-derived neurotrophic factor in large Mexican American pedigrees. *M.A. Almeida[1], J.M. Peralta[1], J.W. Kent[1], J.E. Curran[1], T.D. Dyer[1], G. Juan[2], T.M. Teslovich[2], C. Fuchsberger[2], A.R. Wood[3], T.M. Frayling[3], P. Cingolani[4], T.W. Blackwell[2], R. Sladek[4], G. Atzmon[5], J. Laramie[6], S. Lincoln[6], D.M. Lehman[7], G. Abecasis[2], L.A. Almasy[1], R. Duggirala[1], D.C. Glahn[8], J. Blangero[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI 481092; 3) Peninsula Medical School, University of Exeter, Exeter UK; 4) McGill University, Montreal, Quebec, Canada; 5) Departments of Medicine and Genetics, Albert Einstein college of medicine, Bronx NY, 10463; 6) Complete Genomics; 7) University of Texas Health Science Center at San Antonio; 8) Yale University, New Haven, CT.

Brain-derived neurotrophic factor (BDNF), a member of the neurotrophin family, is a 14 kDa polypeptide involved in regulating neuronal survival, differentiation, and outgrowth. Serum levels of the BDNP protein have previously been associated with a number of psychiatric diseases such as depression and also with neurodegenerative diseases. We measured serum BDNF levels in a sample of 860 San Antonio Family Heart Study (SAFHS) individuals who are members of extended Mexican American pedigrees. To localize genomic regions influencing BDNF, we performed quantitative trait linkage analysis utilizing high density SNPs to calculate identity-by-descent probabilities. Genome-wide linkage analysis localized four genomic regions harboring quantitative trait loci (QTLs). The observed LOD scores were 4.45 (chromosome 22), 3.29 (chromosome 1), 2.41 (chromosome 19) and 2.39 (chromosome 5). We then examined existing whole genome sequence (WGS) data for a subset of 491 individuals to search for causal variants/genes in these genomic regions. WGS data (either directly sequenced commercially by Complete Genomics or accurately imputed using familial data as part of the T2D-GENES Consortium) were available for 491 total individuals. Each variant within a QTL-specific 1-LOD support interval was tested for association with BDNF levels using a measured genotype model in a variance component framework. Variants were also prioritized for testing by their functional potential. Three of the QTL regions yielded substantial evidence for causal gene identification. For the chromosome 22 QTL, we identified a non-synonymous variant (N759D) in the PLXNB2 gene that was significantly associated with BDNF. This variant is predicted to be strongly deleterious. The PLXNB2 gene is involved in axon growth and guidance. For the chromosome 5 QTL, we identified multiple significant associations ($p = 1 \times 10\text{-}6$) including a private novel variant in an extremely evolutionarily conserved region in the IRX1 gene. This gene represents an excellent causal candidate with a known major role in neurodevelopment. For the chromosome 19 QTL, our top hits ($p < 5 \times 10\text{-}7$) occurred in rare variants in/near GNG7 that has been previously associated with epilepsy. These results empirically demonstrate the potential of deep sequence data to follow up QTL localization studies to identify novel likely causal variants/genes.

1924T

First genome-wide analysis in pediatric multiple sclerosis (MS) confirms a role for adult MS risk variants and reveals new candidates. *L.F. Barcellos[1], J.R. Oksenberg[2], E. Elboudwarej[1], H. Quach[1], F. Briggs[1], A. Belman[3], A. Chokkalingham[1], P.A. Buffler[1], L. Krupp[3], E. Waubant[2].* 1) Div Epidemiology-SPH, UC Berkeley; 2) Dept Neurology, UC San Francisco; 3) Dept Neurology, Stony Brook University, NY.

Multiple sclerosis (MS), a complex autoimmune disorder, is the leading cause of non-traumatic neurological disability in young adults. Disease onset typically occurs between the ages of 20 and 40; however, up to 10% of all MS patients have symptoms before 18 years. Pediatric MS (onset before age 18) affects between 10,000 and 20,000 patients in the United States. Disease course in children is similar to adults with some exceptions. Compared to adults, young children with MS are more likely to develop seizures and ataxia during the course of the disease; males are equally affected compared to females within the youngest pediatric MS cases. In addition, cases almost exclusively have a relapsing-remitting course, and are less likely to be of European ancestry. Exact mechanisms involved in pediatric MS pathogenesis remain unclear; however, similar to adult MS, both genetic and environmental factors have been implicated in disease susceptibility. A role for DRB1;k415:01 within the MHC has been established for MS, regardless of onset age. The largest GWAS ever performed in adult MS recently identified 52 non-MHC MS variants (WTCCC and IMSGC; Nature 2011). Here, we describe the first GWAS study in pediatric MS using the Illumina platform. Whole genome profiles for 200 pediatric MS cases and 400 race/ethnicity, gender and age matched pediatric control individuals were studied. Genetic imputation was performed using IMPUTE2, using the 1000 Genomes Phase 3 integrated variant set (March, 2012). The C-alpha method was used for rare variant analysis. Genes identified through GWAS results for both pediatric and adult MS were subjected to pathway bioinformatics analyses and compared for similarities and differences using DAVID (v 6.7). Variants within calcium signaling and axon guidance pathway genes were significantly over-represented among associated hits in pediatric MS ($p<10-4$; based on KEGG). Top established non-MHC adult MS risk variants associated with pediatric MS included rs949143 within MPHOSPH9 (OR= 1.82, 95% CI 1.38-2.40, p=2.3 x 10-5), rs229370 within TMEM39A (OR= 0.55, 95% CI 0.39-0.80, p=0.001) and rs3118470 within IL2RA (OR=0.67, 95% CI 0.51-0.90, p=0.007). Results suggest variants within genes involved in adult-onset MS are also risk factors in children and suggest that similar biological processes are present in both groups. Thus, disease-modifying therapies approved for adults with MS may similarly benefit children.

1925F

Metabochip analysis in over 12,000 African Americans identifies several variants associated with Metabolic Syndrome: results from the Population Architecture using Genomics and Epidemiology (PAGE) Study. *C.L. Carty[1], J. Haessler[1], I. Cheng[2], V. Aroda[3], T. Thornton-Wells[4], C.N. Hsu[5], S. Liu[6], R. Jackson[7], C. Carlson[1], L.A. Hindorff[8], L. LeMarchand[2], J.S. Pankow[9], U. Peters[1], K.E. North[10], C. Kooperberg[1].* 1) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Epidemiology Program, University of Hawaii Cancer Center, Honolulu, HI; 3) MedStar Health Research Institute, Hyattsville, MD; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 5) Information Sciences Institute, University of Southern California, Marina del Rey, CA; 6) Department of Epidemiology, School of Public Health, University of California, Los Angeles, CA; 7) Department of Internal Medicine, Ohio State University, Columbus, OH; 8) Office of Population Genomics, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 9) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 10) Department of Epidemiology and Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC.

Metabolic syndrome (MetS) is characterized by a clustering of cardiometabolic risk factors including dyslipidemia, central obesity, high blood pressure and high glucose. We sought to identify MetS susceptibility loci and investigate whether genetic variants with pleiotropic effects account for some of the correlated architecture of the MetS traits. Using the Metabochip genotyping array (n=161,098 SNPs passing quality control), we investigated SNP associations with MetS and its component traits in African Americans from the PAGE Study. Based on NCEP ATP III guidelines requiring ≥3 of 5 criteria to define MetS, we had 4989 cases and 7576 controls. We contrast findings from a subset-based meta-analysis method, ASsociation analysis based on subSETs (ASSET), (Bhattacharjee *et al.* 2012) with those from 1)logistic regression modeling MetS as a binary outcome, and 2)traditional meta-analysis of the 5 individual components of MetS coded as binary variables. Unlike the traditional meta-analysis which may lack power when associations for each of the components are null or have effects in opposite directions, ASSET uses two one-sided tests to detect positive and negative results for the components separately and combines the tests taking into account correlations among the components. Using ASSET, we identified 28 SNPs in 5 loci (chromosomes 8, 10, 11, 16 and 19) significantly associated with MetS, all $p< 2.5e-7$, the Bonferroni adjusted p-value. The chromosome 10 and 16 SNPs were associated with multiple MetS criteria: glucose and waist circumference, and HDL and waist circumference, respectively. SNPs on chromosomes 8,11 and 19 were associated with both lipid criteria. In contrast, using standard logistic regression or meta-analysis of all components we detected only one low density lipoprotein cholesterol SNP in the 19q13.32 locus, both $p< 2.5e-7$.

We identified several variants associated with MetS components in the ASSET analysis. While we found evidence of pleiotropy for some of these significant SNPs, none were significantly associated with ≥3 traits, as required for MetS. This study highlights the value of using novel methods to increase power and efficiency in large scale genomic association analyses. Importantly, it also brings into question the MetS construct, which is inherently heterogeneous by definition, and its utility in genetic studies in which SNPs may be associated with one MetS trait and not with another.

Power of population diversity and positive selection in probing the biology of asthma disparities. *G. Dunston[1,2,4], T. Mason[2], L. Ricks-Santi[2,3,4].* 1) Dept MicroBiol, Howard Univ, Washington, DC; 2) National Human Genome Center; 3) Dept Pediatrics Child Health; 4) Howard University Cancer Center.

Purpose: Asthma, a common chronic inflammatory disease caused by gene(s) and environmental interactions, has a worldwide distribution and is associated with alterations in airway smooth muscle reactivity and remodeling. GWAS have revealed several SNPs associated with asthma. However, the role of many of these SNPs in the etiology of asthma is unknown. We investigated asthma associated SNPs in genes with signatures of positive selection to evaluate population diversity in genetic susceptibility to asthma. Methods: The NHGRI GWAS Catalog was queried for signals associated with asthma and atopy. SNPs in genes were interrogated for strong signatures of recent positive selection via SNP;caEvolution, a database using a sliding window method that measures heterozygosity and the fixation statistic to locate genomic regions under selection. Regional results reflect geographical adaptation, founder effects and fixed or unfixed selections. The selection profile of genes surrounding those with signatures of positive selection was also examined. For genes with strong signatures of recent positive selection, the literature was mined and queried for information on their disease association, function, pathway analyses, and molecular processes relevant to the biology of asthma. Results: Forty-four SNPs were significantly associated with asthma and atopy. Twenty-one of these SNPS were in genes and 2 of these genes (i.e., RAD50 and CDK2) showed strong signatures of recent positive selection. While RAD50 was positively selected in the Gujarati Indians from Houston, TX, CDK2 showed strong signatures of recent positive selection in all the African descent populations in the International Haplotype Map Project. Four additional genes with a similar positive selection profile as CDK2 were discovered in the scanned region surrounding CDK2. Commonalities were noted between asthma associated genes with signatures of positive selection and schistosomiasis. Conclusion: Positive selection can be used as a tool to interrogate population diversity in GWAS signals associated with the biology of common complex diseases of public health interest (i.e., health disparities), like asthma. Additionally, this study highlights the possible effect of adaptation to infectious disease in GWAS signals associated with asthma and atopy in African descent populations. Conditional Analysis Identifies Three Novel Major Histocompatibility Complex Loci Associated With Psoriasis. *J. Knight[1], S.L. Spain[2], F. Capon[2], J.N. Barker[3], M.E. Weale[2], R.C. Trembath[4], WTCCC2, Genetic Analysis of Psoriasis Consortium, I-chip for Psoriasis Consortium.* 1) Neuroscience Research, Centre of Addiction and Mental Health, Toronto, ON, Canada; 2) Division of Genetics and Molecular Medicine, King's College London School of Medicine, London, United Kingdom; 3) St John's Institute of Dermatology, King's College London, London, United Kingdom; 4) Barts and the London School of Medicine and Dentistry, Queen Mary University of London, London, United Kingdom.

Many genetic loci have now been shown to influence psoriasis and these implicate a number of genes providing evidence for an integrated model for the pathogenesis of psoriasis that combines skin barrier function, innate immune pathogen sensing, adaptive immunity and Th17 cell responses. There is one major disease susceptibility locus located within the major histocompatibility complex (MHC), in which the signal is thought to be driven by *HLA-C*. Other independent association loci have been identified within the MHC, but determining the number and location of these has been hampered by extensive linkage disequilibrium across the region. We leveraged the power of large discovery and replication datasets of European ancestry to look for further association signals in the MHC region. In addition to the major loci at *HLA-C* ($p=2.20 \times 10^{-236}$), we found and replicated four additional hits, three of which are novel. The results from the discovery sample are as follows; rs2507971 $p= 6.73 \times 10^{-14}$, rs9260313 $p=7.93 \times 10^{-09}$, rs66609536 $p=3.54 \times 10^{-07}$ and rs380924 $p=6.24 \times 10^{-06}$), all replicate in an independent sample ($p<=0.01$). All lie within the MHC Class I region. The previously identified loci lies near *MICA*, the other three lie near *MICB*, *HLA-A* and *HCG9* (a non-coding RNA). The identification of disease associations with both *MICA* and *MICB* is particularly intriguing, since each encodes an MHC Class I-related protein with potent immunological function.

1928F

Prevalence of MYH9 common variants associated with non-diabetic end-stage renal disease and chronic kidney disease in the diverse National Health and Nutrition Examination Surveys as part of the Epidemiologic Architecture for Genes Linked to Environment (EAGLE). *S. Wilson, K. Brown-Gentry, N. Gillani, H. Jin, B. McClellan, J. Boston, C. Sutcliffe, H. Dilks, D. Crawford.* Vanderbilt University Medical Center, Nashville, TN.

Common genetic variants in the myosin, heavy chain 9, non-muscle (MYH9) gene were initially identified as associated with non-diabetic end-stage renal disease in African Americans. ESRD MYH9-associated variants rs4821480, rs4821481, and rs2032487 were demonstrated to be very frequent in African Americans compared with European-descent populations. Subsequent studies have suggested that MYH9 common variants also associated with chronic kidney disease and other measures of kidney function in various populations. To further characterize the prevalence of MYH9 variants and their association with kidney related traits, we have genotyped intronic rs4821480, intronic rs4821481, and intronic rs2032487 in 7,389 participants from the National Health and Nutrition Examination Surveys (NHANES) 1999-2002 as part of the Epidemiologic Architecture for Genes Linked to Environment (EAGLE). NHANES is a cross-sectional population-based survey of the United States conducted by the National Center for Health Statistics at the Centers for Disease Control and Prevention and consists of three major groups: non-Hispanic whites (NHW; n=4,003), non-Hispanic blacks (NHB; n=1,350), and Mexican Americans (MA; n=1,877). In this general adult (18 years old or greater) population ascertained regardless of health status excluding pregnant participants, rs4821480-G, rs4821481-C, and rs2032487-C alleles were most frequent among non-Hispanic blacks (0.63, 0.63, and 0.64) compared with either NHW (0.05 each) or MA (0.07 each). In linear regressions assuming an additive genetic model adjusted for age and sex, none of the MYH9 variants tested was associated with serum creatinine, serum albumin levels, or urinary albumin levels in this general population sample stratified by race/ethnicity ($p>0.05$). The lack of associations is most likely due to power highlighting the importance of the availability of large, diverse populations for genetic associations studies of complex diseases and traits.

1929W

Both classical and non-classical human leukocyte antigen (HLA) loci in the HLA region contribute to Graves disease (GD) susceptibility. *P. Chen[1,2,3], W. Yang[2,4,5], T. Chang[2,5].* 1) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan, Taiwan; 2) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan, Taiwan; 3) Graduate Institute of Clinical Genomics and Proteomics, National Taiwan University, Taipei, Taiwan, Taiwan; 4) Graduate Institute of Clinical Medicine, National Taiwan University, Taipei, Taiwan, Taiwan; 5) Department of Internal Medicine, National Taiwan University, Taipei, Taiwan, Taiwan.

GD (MIM 27500), the worldwide leading cause of hyperthyroidism and thyroid eye disease, is a common organ-specific autoimmune disorder with genetic predisposition. Our team previously published a GD-HLA association study using the direct genotypes of the 6 classical HLA alleles in 1704 individuals of ethnic Han Chinese (Chen *et al*. *PLoS One* 6, e16635 (2011)). Later Chu *et al*. (*Nat Genet* 43, 897-901 (2011)) reported a SNP genome-wide association study of GD, in which HLA demonstrated the highest association signals. It would be important to clarify whether the association signals in the HLA region from these two studies represented the same signals or not. In order to make comparison between our results and the report from Chu *et al*., we further genotyped those 5 SNPs (rs4947296, rs1521, rs6903608, rs6457617 and rs2281388) in the HLA region reported by Chu et al. in 499 unrelated GD cases and 504 unrelated controls in our collection from whom we have comprehensive genotypes of 6 classical HLA loci (*HLA-A*, *-B*, *-C*, *-DPB1*, *-DQB1* and *-DRB1*). We demonstrated that rs2281388 is in high linkage disequilibrium (LD) with the *HLA-DPB1;k405:01* allele (D' = 0.98, r-square = 0.86) in the ethnic Chinese Han population. This SNP was the SNP showing the strongest signal (odds ratio [OR] = 1.64, $P = 1.50 \times 10^{-65}$) in the GD association study by Chu *et al*., and it is also the SNP repeatedly being shown association with chronic hepatitis B infection in Japanese and in Chinese. This result implicates that *DPB1;k405:01* is the genuine susceptibility allele in the DPB1 region. Three out of 4 other SNPs also showed statistically significant associations in our cohort (rs1521: OR = 3.04, $P = 3.10 \times 10^{-3}$; rs6903608: OR = 1.83, $P = 5.02 \times 10^{-11}$; rs6457617: OR = 1.48, $P = 3.09 \times 10^{-5}$). However, there were no classical HLA alleles corresponding to the SNP associations. The LD between these 3 SNPs and any of our significant classical HLA alleles was quite low (all r-square < 0.09). This study illustrates that direct classical HLA genotype-based and indirect SNP-based association studies are complementary approaches. It also implicates that both classical and non-classical HLA loci in the HLA region contribute to GD susceptibility.

Fine mapping on chromosome 10q24.2 implicates *ADD3* in biliary atresia. *M.-M. Garcia-Barcelo[1], G. Cheng[1], C. S. M. Tang[2], X. L. Liu[1], R.Z. Zhang[1], M. T. So[1], E. H. M. Wong[2], P. H. Y. Chung[1], I. H. Y. Chan[1], J. Liu[3], W. Zhong[4], H. Xia[4], J. Yu[4], K. K. Y. Wong[1], S. S. Cherny[2], P. C. Sham[2], P. K. H. Tam[1].* 1) Dept Surgery, Univ Hong Kong, Hong Kong, Hong Kong; 2) Dept Psychiatry, Univ Hong Kong, Hong Kong; 3) Department of Pediatric Surgery, First Affiliated Hospital of Sun-Yatsen University, Guangzhou, China; 4) Department of Surgery, Guangzhou Women and Children's Hospital, Guangzhou, China.

Biliary Atresia (BA [OMIM 210500]) is a major cause of neonatal cholestasis (arrest of the normal flow bile) and is characterized by progressive fibrosclerosing and inflammatory obliteration of the extrahepatic biliary system during the first few weeks of life. The only current treatment is surgical (portoenterostomy -Kasai operation). The condition presents mainly sporadically, with only a few familial cases reported. BA is a rare congenital disorder whose incidence varies widely among populations (from 1 in 5,000 in Asians to 1 in 18,000 in Caucasians), being most common in East Asia and Polynesia. Through a genome-wide association study (GWAS) on Chinese individuals we identified the association of a 129Kb BA-associated region on chromosome 10q24.2 encompassing two biologically plausible genes, *ADD3* and *XPNPEP1*. The strongest association was for a Single Nucleotide Polymorphism (SNP; rs17095355; p=6.94x10-9), intergenic between ADD3 and XPNPEP1. To determine the genetic architecture within this region we increased the genotype density by genotyping 117 tag-SNPs in 339 Chinese BA patients and 389 Chinese controls and also used imputation. rs17095355 remained the most associated marker within the region (p=6.06 x10-9). To elucidate the risk-contribution model of regional variation, we performed stepwise regression and sequential conditional test of the genotyped SNPs with BA phenotype. The disease risk model included 6 SNPs (i.e. rs975442, rs17095355, rs10509906, rs11194975, rs2501577 and rs11194997), in which rs975442, rs10509906, rs11194975, rs11194997 were variants newly included in the fine mapping study but not in GWAS. In this model, rs10509906 was independently associated with BA (p=0.018 conditioned on rs17095355). This model explains 8.9% of the phenotypic variation (R2= 0.031 in GWAS) and indicates that multiple variants may contribute to BA susceptibility. The risk alleles of rs17095355 and rs10509906 were ancestral, suggesting an ancestral-susceptibility model of BA pathogenesis. We found that the haplotype comprising the risk allele of rs17095355 was associated with reduced *ADD3* gene expression in liver of BA patients. Thus, our data suggests that *ADD3* expression level in BA liver may contribute to BA pathogenesis. *ADD3* is a component of the actin-adducin-spectin complex which is known to be associated with pathologic cholestasis.

1931F

Whole exome sequencing and subsequent association studies reveals novel candidate variants associated with severe types of alopecia areata. *S. Lee[1,2], C. Park[1], OS. Kwon[3], J-I. Kim[1,2], J-S. Seo[1,2].* 1) Biomedical Sci, Seoul National Univ, Seoul, South Korea; 2) Genomic Medicine Institute (GMI), Medical Research Center, Seoul National University, Seoul, South Korea; 3) Department of Dermatology, Seoul National University College of Medicine, Seoul, South Korea.

Alopecia areata (AA) is a common autoimmune disorder mostly presented as round patches of hair loss and subclassified into alopecia totalis/alopecia universalis (AT/AU) based on the area of alopecia. Although AA is relatively common, AT/AU is exceptionally rare and only 5% of AA patients progress to AT/AU. To determine genetic determinants of this orphan disease, we undertook an exome-wide association study using 6 samples from AU patients, which were compared with 155 Asian controls. Using Fisher's exact test, our study revealed 27 immune-related candidates; 8 candidates were replicated in 14 independent AU samples (P < 0.05). Linkage disequilibrium was observed between some of the most significant SNPs, including rs41559420 of HLA-DRB5 (P < 0.001, OR 44.57) and rs28362679 of BTNL2 (P < 0.001, OR 30.21). While BTNL2 was reported as a general susceptibility gene of AA, HLA-DRB5 has not been implicated in AA. In addition, we have found several genetic variants on novel genes (HLA-DMB, TLR1, PMS2, LTF, and DMBT1), and replicated an additional 2 loci (HLA-A, C5). This study provides further evidence for association of previously reported immune-related genes with AA and novel findings such as HLA-DRB5, which might represent a hidden culprit gene of the disease.

1932W

Next-generation sequencing of 11 targeted genes show serum urate levels and gout age of onset are influenced by both rare and common variants. *A. Tin[1], L. C. Shimmin[2], A. Kottgen[1,3], E. Boerwinkle[2], J. Coresh[1], J. E. Hixson[2], W. H. Kao[1].* 1) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, U.S.A; 2) Department of Epidemiology, Human Genetics and Environmental Sciences, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX, U.S.A; 3) Department of Internal Medicine, Renal Division, University Medical Center Freiburg, Freiburg, Germany.

Background. Elevated serum urate level is an important risk factor for gout, which affects 3 million Americans. Genome-wide association studies (GWAS) have identified multiple loci associated with serum urate, but functional mutations in most, except for ABCG2, remain to be found. Method. We sequenced the exons, promoter regions, and 3′ flanking regions of 11 genes identified from serum urate GWAS (PDZK1, GCKR, SLC2A9, ABCG2, RREB1, SLC17A1, SLC16A9, SLC22A11, SLC22A12, R3HDM2, INHBC) in 819 European Americans (EA) and 287 African Americans (AA) from the Atherosclerosis Risk in Communities (ARIC) study. Within each population, we selected cases with self-reported gout (n=446 for EA and n=188 for AA) and controls without gout and serum urate levels <5th population-specific percentile (n=372 for EA and n=99 for AA). Variants with minor allele frequency (MAF) >5% were tested in single-SNP analysis using linear regression for associations with serum urate levels and self-reported age of onset of gout. For SNPs with MAF <5%, we conducted gene-based association analysis using the SKAT package. Results. We identified a total of 1009 SNPs with read depth >20 and mean quality score >=30. Of these, 73% have MAF <5%, and 43% were singletons within EA or AA. We confirmed previously reported associations of serum urate levels with nonsynonymous substitutions in ABCG2 (rs2231142, Gln142Lys, p=3.9x10-2) and SLC2A9 (rs16890979, Val253Ile, p=1.8x10-4) in EA. We did not identify associations of novel coding SNPs in either EA or AA. However, two novel missense variants were nominally associated with later age of onset of gout in EA (beta~2 year per copy of allele, p<=3.7x10-2). In addition, a novel promoter SNP (p=4.6x10-2) and a novel 3′ UTR SNP (p=4.3x10-2) were associated with serum urate in AA. Using gene-based analyses, we found rare variants in three of the genes showing suggestive associations (p<0.05) with serum urate levels. Conclusion. Next generation sequencing of 11 targeted genes associated with serum urate levels in a selected subsample of the ARIC cohort identified both common and rare novel variants potentially associated with serum urate levels or age of onset of gout; however, no novel SNPs appeared to account for the original GWAS signals. Further studies in the entire ARIC cohort are needed to clarify the associations of these novel variants.

1933T

Genetic variation in vitamin D pathway genes impacts serum vitamin D deficiency and cardio-metabolic traits in individuals with and without type 2 diabetes. *T.R. Braun, L.F. Been, P.R. Blackett, D.K. Sanghera.* Pediatrics, Section of Genetics, Univ Oklahoma Health Sci Center, Oklahoma City, OK.

Recent studies have examined the physiological functions of vitamin D beyond its well- established role in musculo-skeletal health. In addition to reports of oncologic and immunologic associations, vitamin D deficiency is associated with cardiovascular risk factors including obesity and type 2 diabetes (T2D). The purpose of this investigation was 1) to examine the distribution of vitamin D (25(OH)D) in a Punjabi diabetic cohort from Northern India; and 2) to replicate and validate the role of genetic variation in vitamin D pathway genes associated with serum 25(OH)D levels and cardio-metabolic risk. We measured serum 25(OH)D in 1,765 Punjabi participants (887 T2D cases, 878 NG controls) who were part of the Sikh Diabetes Study and were genotyped using Illumina's 660 Quad BeadChip arrays (Illumina, San Diego, USA).

A total of 76% of individuals were deficient (<50 nmol/L) in vitamin D. A higher percentage of diabetic patients (83%) were vitamin D deficient compared to controls (68%) (p<0.0001). A significantly increased prevalence of vitamin D deficiency was associated with increases in obesity (body mass index (BMI)<23kg/m2, 65%; BMI 23-27.5kg/m2, 75%; and BMI>27.5kg/m2, 81%). Low serum 25(OH)D was significantly associated with T2D (β= -0.41, p=2.8x10-20), elevated fasting glucose (β= -0.021, p=0.019), BMI (β= -0.71, p=1.4x10-7), and systolic blood pressure (β= -1.69, p=0.006). A positive association of 25(OH)D was observed with HOMA-B (β=0.16, p=8.0x10-6), and serum C-peptide (β=0.09, 0.017). Five SNPs in the vitamin D pathway genes IVL, VDR, CYP2R1, GC, and NADSYN1 showed significant associations with 25(OH)D levels. The strongest association with low serum 25(OH)D was observed in the IVL (rs11586313, p=6.1x10-8) gene. Risk alleles on VDR (rs11574143, p=0.03), CYP2R1 (rs12794714, p=0.02), GC (rs2282679, p=0.0019) and NADSYN1 (rs1792226, p=0.03) genes showed moderately significant association with decreased 25(OH)D levels.

This study confirms that low serum 25(OH)D may be a significantly predictor of cardio-metabolic risk. Our findings also suggest that the genetic variation in the vitamin D pathway genes may have a significant contribution in the observed deficiency of vitamin D, which could be synergistically contributing to increased T2D and cardiovascular risk in this population.

Coding variants at a single multiallelic amino acid position of a HLA class II gene influence follicular lymphoma risk in Europeans and Asians. *J.N. Foo[1], K.E. Smedby[2], P.I.W. de Bakker[3], I.D. Irwan[1], H. Darabi[4], X. Jia[3], L. Padyukov[5], D.E.K. Tan[1], H. Hjalgrim[6], A. Seow[7], K. Humphreys[4], J.J. Liu[1].* 1) Human Genetics, Genome Institute of Singapore, Singapore, Singapore; 2) Department of Medicine, Clinical Epidemiology Unit, Karolinska Institutet, Stockholm, Sweden; 3) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 4) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 5) Rheumatology Unit, Department of Medicine, Karolinska Institutet and Karolinska University Hospital Solna, Stockholm, Sweden; 6) Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 7) Saw Swee Hock School of Public Health, National University of Singapore, Singapore, Singapore.

Non-Hodgkin lymphoma represents a diverse group of blood cancers, of which follicular lymphoma (FL) is a common subtype. In a genome-wide association study of 379 FL cases and 791 controls, we identified two independent SNPs (rs10484561 and rs2647012) in the HLA class II region significantly associated with FL risk. Both associations were firmly validated across European datasets and each remained genome-wide significant when we adjusted for the effects of the other; rs10484561:C is a risk allele while rs2647012:T is a protective allele. To fine-map these signals and determine if coding variants in HLA genes are responsible for the associations, we imputed classical HLA alleles and coding variants in our discovery samples using SNP array genotypes. We used a phased reference panel consisting of 2767 unrelated founders of European descent, with genotypes for 2537 SNPs in the HLA region, classical HLA types determined to 4-digit resolution and all variable amino acid positions in the coding regions of the HLA genes encoded for each founder. A total of 263 classical HLA alleles were imputed to 2- and 4-digit resolution and 372 amino acid positions were imputed, out of which 86 were multiallelic. We conducted biallelic trend tests on all the imputed variants, testing every possible combination of 1, 2 or 3 amino acids against the rest at multiallelic sites. From this analysis, the top signal came from a single multiallelic amino acid position within the peptide binding groove of a HLA class II gene. This variant showed stronger association ($P=7.8x10^{-9}$, omnibus $P=9.8x10^{-8}$) than any other HLA variant or SNP and could fully account for both association signals in this region, with rs10484561:C partially tagging the high risk alleles (OR=1.37-1.63) and rs2647012:T partially tagging the low risk alleles (OR=0.61-0.80). There was a 3.8-fold difference in risk between subjects carrying two high risk alleles and those carrying two low risk alleles. We experimentally validated the imputed genotypes and found a 97.3% concordance, demonstrating high accuracy of the imputation. In a similar GWAS and imputation analysis on FL in 363 Singaporean Chinese samples, we observed a similar pattern of association at the same amino acid position. Our current findings suggest that coding variants at a single multiallelic amino acid position of a HLA class II gene may influence FL risk in both Europeans and Asians, and may explain the complex associations revealed by SNP analyses.

1935W

Common polymorphisms of dopamine D2 receptor (DRD2) gene are not associated with adolescent obesity, but with hyperinsulinemia. *N. Col Araz[1], M. Nacak[2], S. Oguzkan Balci[3], N. Benlier[2], S. Pehlivan[3], A. Balat[4], M. Araz[5].* 1) University of Gaziantep, Faculty of Medicine, Pediatrics, Gaziantep, Turkey; 2) University of Gaziantep, Faculty of Medicine, Pharmacology, Gaziantep, Turkey; 3) University of Gaziantep, Faculty of Medicine, Medical Biology and Genetics, Gaziantep, Turkey; 4) University of Gaziantep, Faculty of Medicine, Pediatric Nephrology, Gaziantep, Turkey; 5) University of Gaziantep, Faculty of Medicine, Endocrinology and Metabolism, Gaziantep, Turkey.

Objectives: Obesity is a multifactorial, complex disease of appetite regulation and energy metabolism which is influenced by genetic and environmental factors. Among the genetic factors, there are neuromodulators and multiple neurotransmitter systems which play an important role of feeding behavior. The dorsal striatum plays a n important role on consummatory food reward, and striatal DRD2 receptors has been found to be related to obesity and increased body mass index (BMI). Adolescent obesity may contribute increased prevalence of adult obesity, type 2 diabetes and metabolic syndrome. The aim of this study was to examine the possible relation between common polymorphisms of the DRD2 gene with adolescent obesity and hyperinsulinemia. Methods: Sixty-seven obese adolescents and 100 age- and sex-matched healthy controls were included. Hyperinsulinemia was determined as a basal insulin level ≥15 µIU/mL. Two polymorphisms (Taq1A and Taq1B) in DRD2 gene were genotyped by PCR-RFLP. Results: For DRD2 Taq1A polymorphism, the distribution of A1/A1, A1/A2, and A2/A2 genotypes was 7.5%, 23.9% and 68.6% in obese adolescents compared with 4.0%, 31.0% and 65.0% in controls. The distribution of B1/B1, B1/B2 and B2/B2 genotypes for Taq1B polymorphism was 7.5%, 20.9% and 71.6% for cases and 3.0%, 27.0% and 70.0% for the controls. There were no statistically significant differences in DRD2 Taq1A and DRD2 Taq1B genotypes or allelic frequencies between the obese adolescents and controls ($p>0.05$). Taq1A1/A1 genotype was associated with hyperinsulinemia in adolescent obese subjects ($p<0.05$). Conclusion: No association was found between the Taq1A and Taq1B polymorphisms in the DRD2 gene and adolescent obesity. But hyperinsulinemia was associated with A1/A1 genotype. Preliminary results of the ongoing study are presented here and these findings should be supported in larger obese adolescents groups.

Association analysis of chromosome 3q markers in nonsyndromic cleft lip/palate. *A. Letra[1], M. Cooper[2], T. McHenry[2], E. Czeizel[3], F.W.B. Deleyiannis[4], L. Ma[5], E.E. Castilla[6], F. Poletta[7], L.L. Field[8], A.R. Vieira[2], R.M. Silva[1], M.L. Marazita[2].* 1) Dept Endodontics and Pediatric Research Center, Univ Texas Health Science Center at Houston, Houston, TX; 2) University of Pittsburgh School of Dental Medicine and Center for Craniofacial and Dental Genetics, Pittsburgh, PA; 3) Center for the Control of Hereditary Diseases, Budapest, Hungary; 4) Departments fo Pediatric Plastric Surgery, Surgery and Otolaryngology, The Children's Hospital and University of Colorado School of Medicine; 5) School of Stomatology, Beijing University, Beijing, China; 6) ECLAMC at INAGEMP-CNPq (National Institute of Population Medical Genetics) in the Department of Genetics, Oswaldo Cruz Foundation, Rio de Janeiro, RJ, Brazil; 7) ECLAMC (Latin American Collaborative Study of Congenital Malformations) at CEMIC (Center for Medical Education and Clinical Research), Buenos Aires, Argentina; 8) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

Nonsyndromic cleft lip/palate (CL/P) is a common birth defect of complex etiology involving the interplay of genetic predisposition and environmental exposures. Several genes, including but not limited to MSX1, IRF6, CRISPLD2, FOXE1, and members of the WNT and FGF gene families, and additional loci on chromosomes 1p22, 8q24, 10q25.3, 17q22, and 20q12 have been implicated in the etiology of oral clefts. A previous genome wide linkage scan also identified a region on chromosome 3q27-28 with a significant multipoint HLOD peak of ~4.13.0 (α=0.34), warranting further studies in additional populations. Here, we performed a family-based association study of markers in chromosome 3q and CL/P in multiple populations. Data and samples from 885 families ascertained through a proband with CL/P families (1,498 affecteds, 3,468 unaffecteds) were ascertained through the University of Pittsburgh Oral-Facial Cleft study (POFC), including sites in the United States, Argentina, Guatemala, Spain, Hungary, Turkey, Philippines, China, and India. We investigated the association of 996 SNPs comprising 12 genes intertwined with 10 regions of no known genes in chromosome 3q for association with CL/P in our families. Alleles at each SNP were tested for association with CL/P using the Family-based Association Test (FBAT). We performed analyses for each population individually, all populations combined, and in the following groups: Caucasians, Latin Americans, and Asians. Haplotype analysis was also performed. Overall, the most significant association results in all populations and Caucasians combined were seen with markers in LPP, TPRG1, TP63 and FGF12 (P≤0.009) although none reached genome-wide significance. Analysis of individual populations showed association of SNPs in TP63 (rs10155037, P=0.000004; rs16864812, P=0.00001) and in CCDC50 (rs293813, P=0.0001) with CL/P in India, whereas a SNP in TMEM207 (rs10513852, P=0.0000003) was associated in South Americans. Under an additive model, an intergenic marker (rs11706540) between TP63 and LEPREL1 showed nominal association with CL/P in Caucasians (P=0.009). Marker haplotypes in the IL1RAP gene showed association with CL/P in all populations (P=0.005). Under a recessive model, marker haplotypes neighboring TPRGR1 and TP63 showed association in Caucasians (P=0.003). In summary, several markers in chromosome 3q had suggestive association with CL/P that warrant a more focused search for candidate loci in these regions.

1937F

Genotype-phenotype correlations of facial shape and asymmetry in unaffected relatives of children with non-syndromic cleft lip/palate and controls. *S. Miller[1], N. Nidey[4], S. Weinberg[3], M.L Marazita[3], J.C Murray[4], G.L. Wehby[2], L.M Moreno[1].* 1) Department of Orthodontics-Dows Institute, College of Dentistry, University of Iowa, IA; 2) Department of Health Management and Policy, School of Public Health, University of Iowa, IA; 3) Center for Craniofacial and Dental Genetics, Department of Oral Biology, University of Pittsburgh, PA; 4) Department of Pediatrics, University of Iowa, IA.

Individuals with Nonsyndromic cleft lip with or without cleft palate (NSCL/P) and their unaffected relatives often present with features of distinct facial morphology related to the phenotypic spectrum of orofacial clefting. The genetic etiology underlying this phenotypic variation is poorly understood. This study examines whether candidate genes associated with NSCL/P and left-right asymmetry are also correlated with the cleft risk related facial variation present in non-affected parents and siblings of children with NSCL/P. Relatives of individuals with NSCL/P (Cases, N= 188, unaffected parents (N=119), and siblings (n=69) and controls (N=194) with no family history of NSCL/P were genotyped for 20 SNPs across 13 candidate genes for NSCL/P (PAX7, ABCA4-ARHGAP29, IRF6, MSX1, PiTX2, 8q, FOXE1, TGFB3, MAFB) and left/right asymmetry (LEFTY1, LEFTY2, ISL1, and SNAI1). 3D facial shape plus asymmetry phenotypes including fluctuating asymmetry (FA), were derived from 32 3D coordinate landmarks digitized in 3D facial images. Patterns of facial shape and asymmetry were obtained separately for each gender, via relative warps analyses (RWA) and Procrustes ANOVA of the coordinate data. Phenotypes that differed between cases and controls (p<0.07) were subjected to multiple regression adjusting for age on the genotypes obtained. Results for the mother subsample (n=163), suggest that cases have larger faces, wider philtrums, more upper face retrusion, increased lower face height and prognathism and higher FA than controls (P<0.05). ABCA4-ARHGAP29, SNAI1 and LEFTY1 were correlated (p<0.05) with shape variation and FA respectively. FA was more significant (p=0.0063) in female relatives of children with unilateral clefts than controls. The father subsample (N=80) indicated that cases have increased lower face height and prognathism, and their philtrums deviate to the left side compared to controls (P=0.07), with significant correlations found for IRF6 and MAFB (p<0.05). Female siblings (N=68) also showed more upper face retrusion in the cases than in controls and suggestive correlations (p<0.07) with FOXE1, MSX1 and TGFB3. Lastly, male siblings (N=71) showed more retrusive upper faces, and a larger deviation of the philtrum to the left than controls, together with significant (p<0.05) correlations for IRF6 and LEFTY2. This study highlights the importance of genotype-phenotype correlations studies in discerning the genetic etiology of NSCL/P. DE016148, CDC5R01DD000295.

1938W

Cannabinoid Receptor-1 (CNR-1) gene 1359G/A polymorphism is related with childhood obesity, but not with insulin resistance. *M. Nacak[1], N. Col Araz[2], S. Oguzkan Balci[3], N. Benlier[1], S. Pehlivan[3], A. Balat[4], M. Araz[5].* 1) University of Gaziantep, Faculty of Medicine, Pharmacology, Gaziantep, Turkey; 2) University of Gaziantep, Faculty of Medicine, Pediatrics, Gaziantep, Turkey; 3) University of Gaziantep, Faculty of Medicine, Medical Biology and Genetics, Gaziantep, Turkey; 4) University of Gaziantep, Faculty of Medicine, Pediatric Nephrology, Gaziantep, Turkey; 5) University of Gaziantep, Faculty of Medicine, Endocrinology and Metabolism, Gaziantep, Turkey.

Objectives: Obesity is becoming global health problem in the world. The cannabinoid receptor (CNR) and its endogenous ligands, the endocannabinoids, are involved in regulation of feeding behavior and energy balance by stimulating appetite, increasing body weight, and implicated in human obesity. Furthermore, activation of the CNR1 may play a role in the development of insulin resistance. The aim of this study was to investigate the influence of the Cannabinoid reseptor-1 (1359G/A) gene polymorphisms on chilhood obesity and insulin resistance. Methods: A hundred obese subjects and 100 age-and sex-matched healthy controls were analyzed for CNR1 1359G/A polymorphisms. Genotyping were performed by PCR and/or RFLP. Homeostasis model assessment (HOMA) was used to consider insulin resistance. Results: The frequency of the A allele of the CNR1 1359G/A polymorphism was significantly higher in obese children than in control subjects (21.0 % versus 13.0 %, p=0.0166). The frequency of genotypes AG and GG of the CNR1 1359G/A SNP was statistically significant difference between the obese and control subjects (for AG: 34.0% versus 22.0%, p= 0.0294; for GG: 62.0% versus 76.0%, p=0.0162, respectively). However, there was no significant difference in the AA genotype distribution among patients and controls (4.0% versus 2.0%, p>0.05). The observed genotype counts were not deviated significantly from those expected according to the HWE. No relationship was found between CNR1 genotypes or alleles and insulin resistance in patients (p<0.05) Conclusion: 1359G/A polymorphism of the CNR1 gene may have a role in obesity. However, further studies will clarify the exact role of this gene on childhood obesity and insulin resistance.

Altered expression but no genetic association of the epidermal transglutaminases in atopic dermatitis. *M.CG. Winge[1;2], A. Lieden[1], A. Sääf[1], I. Kockum[3], E. Ekelund[1], E. Rodriguez[4], T. Hoppe[5], R. Fölster-Holst[4], A. Franke[6], M. Tengvall-Linder[7], H. Baurecht[4], S. Weidinger[4], CF. Wahlgren[2], M. Nordenskjöld[1], M. Bradley[1;2].* 1) Dept of Mol Med & Surgery, Karolinska Institutet, Stockholm, Stockholm, Sweden; 2) Dermatology Unit, Department of Medicine Solna, Karolinska University Hospital, Stockholm, Sweden; 3) Department of Clinical Neurosciences, Karolinska Institutet, Stockholm, Sweden; 4) Department of Dermatology, University of Kiel, Kiel, Germany; 5) Department of Medical Sciences, Dermatology and Venereology, Uppsala University, SE-75185 Uppsala, Sweden; 6) Institute of Clinical Molecular Biology, Christian- Albrechts-Universität zu Kiel, Kiel, Germany; 7) Clinical Immunology and Allergy, Department of Medicine Solna, Karolinska Institutet, Stockholm, Sweden.

Background: Atopic dermatitis (AD) is a common chronic inflammatory skin disorder where epidermal barrier dysfunction is a major factor and the identification of susceptibility genes in barrier dysfunction is therefore of importance. The epidermal transglutaminases (TGM1, TGM3 and TGM5) encodes essential cross-linking enzymes in the epidermis. Objective: In this study we investigated the expression in AD patients and healthy controls, and whether genetic variability at these loci contributes to AD susceptibility. Methods: Gene expression of the TGM1, TGM3 and TGM5 gene was determined by relative quantification with Real Time PCR (qRT-PCR) and in silico analysis of expression data compared to trans-epidermal water loss (TEWL), filaggrin mutations, pH and disease severity (SCORAD). Immunohistochemical (IHC) analysis was performed to detect TG1, TG3 and TG5 protein expression in the skin of patients and healthy controls. Forty-seven single nucleotide polymorphisms (SNPs) in the TGM1, TGM3 and TGM5 gene region were tested for genetic association with AD using a pedigree disequilibrium test (PDT) in a Swedish material consisting of 1753 individuals from 539 families and a candidate SNP (rs941505) was also tested in silico in a German case-control material consisting of 533 AD cases and 1996 controls. Results: increased TGM1 expression was detected in silico in non-lesional AD skin compared to healthy skin, and in skin from AD patients with a severe phenotype whereas no significant difference was detected for TGM3. Significantly increased TGM3 expression was however detected with qRT-PCR in lesional skin, together with a non-significant increase of TGM1 transcript levels in both non-lesional and lesional skin. Increased protein expression of both TG1 and TG3 was estimated in lesional skin. No differences in TGM1, TGM3 or TGM5 expression were found in relation to TEWL, pH or filaggrin genotype. Although the PDT analysis identified a significant association between the TGM1 SNP rs941505 and AD with allergen-specific IgE in the Swedish AD family material, the association was not replicated in a German case-control material. Conclusion: Expression analysis links the TGM1 and TGM3 gene to the manifestation of AD and may reflect ongoing inflammation and an altered barrier function. Furthermore, the results from the genetic analysis show that genetic variation in the epidermal transglutaminases is not an important modifier of AD susceptibility.

1940F

Genetic variation and epigenetic modification of *TACR1* gene are associated with postoperative nausea and vomiting in surgical patients. *T. Hayase, S. Sugino, M. Yamakage.* Department of Anesthesiology, Sapporo Medical University School of Medicine, Sapporo, Hokkaido, Japan.

Background: Postoperative nausea and vomiting (PONV) is a frequent and debilitating complication in surgical patients, but its occurrence and intensity vary individually. Although this interindividual difference could be influenced by genetic and/or environmental factors, the underlying mechanisms have not been fully elucidated. Neurokinin 1 receptor plays a major role in drug-induced emesis in the central nervous system, and recent studies have suggested an association with PONV. The aim of the present study was to determine whether genetic variations and epigenetic modifications of the *TACR1* gene, which codes neurokinin 1 receptor, are associated with the occurrence and intensity of PONV. **Methods:** Seventy-seven Japanese female patients undergoing gynecological surgery were enrolled in this study. The occurrence of PONV was recorded for 24 hrs after surgery and defined as ≥3 instances of retching and/or vomiting over a period of 24 hrs or nausea persisting for at least 12 hrs after surgery. The intensity of PONV was assessed using a 0 ~ 100 visual analogue scale (VAS). We selected seven tag SNPs of the *TACR1* gene for haplotype analysis (MAF>0.1, r^2<0.8). Genotyping for SNPs was carried out by a PCR-direct sequencing method. In a separate study, we investigated DNA methylation at 11 CpG sites in the -100/+6-bp upstream region of the *TACR1* gene using a methylation-sensitive high-resolution melting protocol as previously described by Wojdacz *et al*. The primer pair was designed using MethylPrimer Express software and amplicons were generated from bisulfite-converted DNA of the patients. Haplotype data were analyzed using a χ^2 test or Fisher exact test as appropriate. Methylation data were analyzed by Spearman's rank correlation coefficient. **Results:** The four most common haplotypes with a frequency of >5% were TAACATA (36%), TAATAGA (14%), TAATATA (7%), and TAATATC (6%). The frequency of PONV in patients with the TAACATA haplotype was significantly higher than that in patients with other haplotypes (P=0.04). Methylation level of the promoter region was inversely correlated with VAS scores of PONV (r = -0.17, P < 0.01). **Conclusions:** The TAACATA haplotype of the *TACR1* gene is associated with the occurrence and severity of PONV. *TACR1* promoter methylation is related to attenuation of the severity of PONV. The results of this study indicate that genetic polymorphisms and epigenetic regulations of the *TACR1* gene might be involved in PONV after surgery.

1941W

Identification of a novel 1p31 locus associated with the combined asthma plus allergic rhinitis phenotype through positional cloning in asthma-ascertained families. *M-H. Dizier[1], P. Margaritte-Jeannin[1], A-M. Madore[2], I. Annesi-Maesano[3], J. Just[4], F. Kauffmann[5], C. Laprise[2], M. Lathrop[6], E. Bouzigon[1], F. Demenais[1].* 1) INSERM U946, Paris, paris, France; 2) Université du Québec, Chicoutimi, Canada; 3) Inserm U707, Paris, France; 4) Centre de diagnostic et traitement de l'asthme, Hôpital Trousseau, Paris, France; 5) Inserm U1018, Paris, France; 6) CEA-CNG, Evry, France.

A genome-wide linkage scan conducted in the French Epidemiological study on the Genetics and Environment of Asthma (EGEA) showed strong evidence of linkage of 1p31 to asthma, allergic rhinitis (AR) and even more to the combined asthma plus AR phenotype (Dizier el al, 2005, 2007). Our purpose was to conduct fine-scale mapping of the 1p31 linkage region using a panel of 2062SNPs (spanning 10 Mb) in 388 EGEA families to identify the genetic variants associated with asthma plus AR. Association analyses were first carried out using the family-based association method (FBAT). We then applied logistic regression to the genetic variants showing significant association with asthma plus AR, to validate the FBAT results. To investigate whether the association was specific to the combined asthma plus AR phenotype, we tested for heterogeneity of association according disease status defined by the presence of the two diseases (asthma plus AR) versus the presence of only one disease ('asthma only' or `AR only') using FBAT. We found significant association of asthma plus AR to one 1p31 SNP using FBAT (P=2.10-5, which is below the multiple testing-corrected threshold of 5x10-5). This result was confirmed by logistic regression (P=2.10-4). That SNP showed significant heterogeneity of association with asthma plus AR vs. asthma alone or AR alone (P=0.02; moreover, there was no evidence for association with asthma alone or AR alone). We replicated our finding, in 253 French Canadian families from the Saguenay-Lac-Saint-Jean study, which, similarly to EGEA were ascertained through asthmatic subjects. Meta-analysis of EGEA and SLSJ results (P=0.03 for association of asthma plus AR to the 1p31 SNP using FBAT) showed strong improvement in both the evidence for association with asthma plus AR (P=4x10-6) and in the evidence for heterogeneity of association according to disease status (P=0.007 for association with asthma plus AR vs asthma alone or AR alone). Our study shows that the co-morbidity, asthma plus AR, is a phenotypic entity, that is influenced by genetic factors, including the 1p31 locus, which are distinct from those underlying asthma alone or AR alone. Although further confirmation of our results is needed, it is of note that the SNP associated with asthma plus AR belongs to a gene involved in the replication of adenovirus type 2, which makes it a promising candidate gene.

Atopic dermatitis (AD), or eczema, is one of the most common chronic inflammatory skin diseases, with a polygenic, multifactorial nature. To date, genome-wide association studies have established six susceptibility loci with genome-wide significance ($P < 5\times10^{-8}$). However, the causal variation at these loci remains unknown. To better define risk variants and identify additional susceptibility loci previously implicated in other autoimmune (AI) diseases, we performed a fine-mapping and association study using 2,425 German AD cases and 5,449 German population controls. All samples were genotyped on the ImmunoChip, a custom Illumina Infinium High-Density array containing 196,524 polymorphisms (195,806 SNPs and 718 small insertions/deletions) across 186 distinct AI risk loci, including the six known AD susceptibility loci and the HLA region. At these loci, the array contains all known SNPs in the dbSNP database, from the 1000 Genomes Project (release of February 2012), and from other AI disease resequencing efforts, therefore providing a powerful means of fine-mapping known AI loci. Following quality control, 128,830 polymorphic markers (SNPs with minor allele frequency > 1%) were available for association analysis, with an individual call rate > 99.9%. Genotypes were called using Illumina's GenomeStudio GenTrain 2.0 algorithm. Principal component analysis revealed no marked differences in ancestry between cases and controls. We observed that 132 SNPs within non-HLA risk loci reached genome-wide significance ($P < 5\times10^{-8}$) in the screening phase. For each locus, the possibility of the existence of multiple independent association signals will be investigated. In addition, we selected the most strongly associated SNPs (n=39) with $P < 10^{-4}$ from each associated locus for replication analysis in independent case-control collections. The final results will be presented at the conference.

Identification of functional variants in *FOXO3A*, a confirmed candidate gene influencing human longevity: Genetic investigation requires special attention to sequence homology with *FOXO3B*. *F. Flachsbart[1], L. Gentschew[1], C. Däumer[2], N. Badarinarayan[1], A. Caliebe[2], M. Krawczak[2,4], S. Schreiber[1,3,4], A. Nebel[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Schleswig-Holstein, Germany; 2) Institute of Medical Informatics and Statistics, Christian-Albrechts-University, Kiel, Germany; 3) Clinic for Internal Medicine I, University Hospital Schleswig-Holstein Kiel, Germany; 4) Popgen Biobank, Christian-Albrechts-University, Kiel, Germany.

Human longevity is influenced by multiple genetic and environmental factors. Approximately 30% of the overall variation in adult lifespan is because of genetic variation that becomes particularly important for survival at advanced age. Up to now, variation in only two genes has been identified, which has an effect on longevity in various populations: the apolipoprotein E gene (*APOE*) and the forkhead box O3A gene (*FOXO3A*). For *FOXO3A* the underlying molecular mechanisms still remain to be elucidated, because most of the longevity-associated single nucleotide polymorphisms (SNPs) analyzed are located in intronic regions and the “functionally relevant” SNP has yet to be identified. To explore potential unknown genetic variants both next generation and Sanger sequencing are being applied. Functional effects of all identified rare and common SNPs are evaluated by in silico analyses. Variants of interest are genotyped in our extensive German longevity sample (~1400 long-lived cases and 1100 younger controls). In our study we could recently demonstrate that the genetic investigation of *FOXO3A* is greatly hampered by the fact that the exonic regions have 99% sequence homology with the *FOXO3B* pseudogene. If unaccounted for, this high degree of homology can cause serious genotyping or sequencing errors. Here, we present an experimental set-up that allows reliable data generation for the highly homologous regions and that can be used for evaluation of assay specificity. Using this design, we could exemplarily show *FOXO3A*-specific results for two SNPs (rs4945816 and rs4946936) that are significantly associated with longevity in our German longevity sample (Peach = 0.0008). Because both SNPs are located in the 3′ untranslated region of *FOXO3A*, they could be of functional relevance for the longevity phenotype. Our experimental set-up can be used for reliable and reproducible data generation for further sequencing and genotyping studies of *FOXO3A* with the aim of discovering new SNPs of functional relevance. In the following, various in vitro and ex vivo assays will be applied for the functional characterization (gene expression profiles, mRNA stabilization, translational efficiency, splicing events) of associated variants. Subsequently, the functional assessment of the *FOXO3A* gene region could serve as the basis for future treatment strategies to achieve healthy ageing in the elderly.

***PDGFRa* Mutations in Humans with Isolated Cleft Palate.** *V. Shotelersuk[1,2], S. Rattanasopha[1,2], S. Tongkobpetch[1,2], C. Srichomthong[1,2], P. Siriwan[3], K. Suphapeetiporn[1,2].* 1) Center of Excellence for Medical Genetics, Department of Pediatrics, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; 2) Molecular Genetics Diagnostic Center, King Chulalongkorn Memorial Hospital, Thai Red Cross, Bangkok, Thailand; 3) Division of Plastic Surgery, Department of Surgery, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand.

Objective: *Pdfgra* knock-out zebrafish showed cleft palate (CP). We attempted to identify whether *PDGFRa* was responsible for isolated CP in humans. **Materials and Methods:** We recruited 102 patients with CP under the auspices of the Thai Red Cross, from 33 medical centers throughout Thailand. The entire coding regions and the 3′ UTR of the *PDGFRa* and *miRNA140* were PCR-amplified and sequenced. PCR-RFLP was used to confirm the variants identified in the patients and 500 unaffected ethic-matched controls. We then determined the pathogenicity of the mutations found in the *PDGFRa* 3′ UTR by luciferase reporter system. **Results:** PCR-sequencing identified seven novel single base-pair substitutions in the *PDGFRa* in 9/102 patients (8.8%) compared to 5/500 ethnic-matched unaffected controls (1%) (the two-tailed p value < 0.0001). Of these seven, four were missense mutations in the coding regions and three in the 3′UTR. Frequencies of four changes (three in coding, one in 3′UTR) were statistically different from those of controls (p value < 0.05). The c.;k434G>A was identified in 1/102 cases and 0/500 controls. This position is conserved in primates and located 10 bp away from a predicted binding site for the human microRNA, miR-140. Luciferase assay revealed that, in the presence of miR-140, the c.;k434G>A significantly repressed luciferase activity compared to that of the wild type. **Conclusion:** For the first time, we provided strong evidence supporting a role of *PDGFRa* in human palatal development.

Copy-number variation in chromosome 5q31-33 is associated with Graves' disease susceptibility. *X. Chu, M. Shen, Y. Bai, F. Xie, W. Huang.* Department of Genetics, Chinese Human Genome Ctr, Shanghai, China.

Graves' disease is a common multifactorial disease with familial aggregation. The common variants identified using single-nucleotide polymorphisms (SNPs) as markers only explained a modest proportion of the known heritability of Graves' disease, and could not give an explanation for familial aggregation in this disease. We and Japanese researchers have previously identified chromosomal region 5q31-33 for contribution to the genetic susceptibility to Graves' disease in East-Asian populations from linkage analysis. These results implicated high-penetrance variants associated with Graves' disease might be located in this region. Our further candidate gene analysis in 5q31-33 and recent genome-wide association analysis (GWAS) revealed SNPs associated with Graves' disease, but these low-penetrance variants could not account for the linkage signal in this region. Copy-number variation (CNV) is another type of variation widely existed in human genome and hereditary CNVs might be the genetic basis of familial aggregation in diseases. In our previously GWAS for Graves' disease, we genotyped 1,536 Graves' disease cases and 1,516 sex-matched controls using Illumina Human 660-Quad BeadChips, which included 657,314 SNP markers and 64,527 CNV markers. In this study, we aimed to identify Graves' disease associated CNVs with high-penetrance in the linkage region 5q31-33. CNVs were called by CNVPartition v1.2.1 and PennCNV on genotyping signal intensity data. CNVs were included for further association analysis only if they were detected by both software packages. We compared the frequency of CNVs between cases and controls using Plink. The potentially disease associated CNVs were further validated by quantitative PCR (qPCR), and TaqMan probes were custom-designed using Primer Express 3.0 (Applied Biosystems). We found a rare CNV at 5q31-33 were associated with Graves' disease susceptibility (P = 0.0034). The majortity cases with deletion were females with family history of Graves' disease. We would perform further validation in Graves' disease pedgrees in our further study and try to understand the genetic mechanisms underlying familial aggregation of Graves' disease.

Genetic analysis of HLA-G gene: association study in a Brazilian cohort relating the 14bp INDEL frequencies in a psoriasis case/control study. *G. Debortoli[1], B.S. Almeida[1], A. Firmino[1], D.H. Nunes[2], M.M. Sens[2], V.P.M. da Silva[2], A.R. Marrero[1], Y.C.N. Muniz[1], I.R. Souza[1].* 1) LAPOGE, Federal University of Santa Catarina, Florianopolis, Santa Catarina, Brazil; 2) HU, Federal University of Santa Catarina, Florianopolis, Santa Catarina, Brazil.

Psoriasis is an autoimmune disease which affects the skin and articulations. The HLA-G protein can influence the disease course, because your expression can act as an immune surveillance mechanism in tissue protection against autoimmune inflammatory responses. Researchers have reported in literature the InDel 14 bp polymorphism located in the 3′UTR of the HLA-G gene, where appears to influence the expression, generating an mRNA more stable. The main objective was the genotyping of 100 patients and 100 controls (matched for age and gender), analyzing the influence of the Indel 14pb in the psoriasis manifestation. We conducted a survey of risk factors for gender, age of manifestation onset, family history, smoking, and involvement of the joints. The DNA samples were extracted from whole blood, and the genotyping was carried out by PCR, whereas visualization by PAGE and stained with silver nitrate. The results showed that 57 of patients were women, 44 individuals had family history, 43 manifested the disease before the age of 30, 46 were smokers, and 16, expressed psoriatic arthritis. Allele frequencies were calculated resulting in a frequency of 0.25 InDel 14 bp in patients with psoriatic arthritis and 0.50 in patients without psoriatic arthritis. The results was not significant, but corroborates published studies, which show a protective trend of InDel 14 bp polymorphism (mRNA more stable), in this particular disease. For a better understanding of the gene influence and the role in the immune system in the development of psoriasis, the sample number will be raised as well as other markers of influence on the stability of mRNA (Financial support: PNPD CAPES, FAPESC and CNPq).

Lung eQTL in the major histocompatibility complex. *M. Lamontagne[1], C. Couture[1], M. Laviolette[1], Y. Bossé[1,2], The Merck-Laval-UBC-Groningen Lung eQTL consortium.* 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Québec, Canada; 2) Department of Molecular Medicine, Laval University, Quebec, Canada.

The major histocompatibility complex (MHC) is a key region in the human genome for the immune system. The extended MHC in humans (xMHC) covers 7.6 Mb on the short arm of chromosome 6. Variants in MHC genes are associated with hundreds of diseases, particularly autoimmune diseases. The genetic mechanisms regulating the MHC complex are still unclear. The lungs are extensively exposed to environmental pathogens and are the most common route of infections. The MHC is thus a critical genomic region to control infections in the lung such as pneumonia and tuberculosis. The MHC is also known to play a critical role in the development of chronic lung diseases (e.g. COPD and asthma). The goal of this study is to further our understanding of the mechanisms regulating this important region by using lung expression Quantitative Trait Loci (eQTL). Genome-wide gene expression profiles of 500 non-tumor lung specimens were obtained from patients undergoing lung surgery. Blood-DNA from the same patients were genotyped for 1,2 million SNPs. Following genotyping and gene expression quality control filters, 409 samples were analyzed. A total of 3948 cis-eQTLs and 507 trans-eQTLs were identified in the xMHC. This represents 13 fold more eQTLs than any other genomic region of the same size. The expression of a number of genes were regulated by multiple independent SNPs. Notably, the expression of HLA-DRB5 was regulated by more than 20 SNPs. rs35366052 was the most significant SNP regulating the expression of HLA-DRB5 (p = 2,488E-297). Regulatory genetic variants were also found to be pleiotropic. For example, rs2647012 located in the HLA-DQ loci was significantly associated with the expression of 6 genes. This study is important in increasing our understanding of the genetic mechanisms regulating the MHC region and its role in pulmonary infections and chronic respiratory diseases.
