Streptococcus pneumoniae (the pneumococcus) is the most common cause of community-acquired pneumonia in Europe and the United States and a leading cause of death in children worldwide. In addition to pneumonia, infection may be manifested as invasive pneumococcal disease (IPD), defined by the isolation of *Streptococcus pneumoniae* from a normally sterile site. Host genetic variation is widely believed to influence susceptibility to IPD, although only a limited number of common polymorphisms have been identified in association with IPD to date. Recent study of very rare human primary immunodeficiencies associated with selective predisposition to IPD has identified causative mutations within genes in the Toll-like receptor (TLR) pathway which result in impaired NF-κB activation. A key question is the relative contribution of multiple rare variants in these genes to IPD susceptibility at the population level. We therefore performed sequencing of the genes *MYD88*, *IKBKG*, *IRAK4*, and *TIRAP* in a population-based case-control association study of 164 adults with IPD and 164 controls. For both cases and controls, individuals were divided into 4 pools containing 41 genomic DNAs each. From these pools 20 amplicons (median length 4kb) were amplified using long range PCR and sequenced using next generation sequencing. We found several variants to be present in one or more case pools and absent from control pools, some of which are novel (defined by absence from dbSNP B135). Using syzygy software we estimated that case pools contained one copy of the missense variant S229L and a single copy of a novel splice variant in *MYD88*; one copy of a novel missense variant within *IRAK4* and 2 copies of a novel missense variant and one copy of the published loss of function variant rs8177400 which encodes D96N in *TIRAP*. Direct sequencing of these variants in each individual in the case and control pools will provide accurate genotypes for further analysis. These rare TLR pathway gene mutations in adults with IPD, suggest that at least a proportion of adults with this major infectious disease phenotype may have a previously unidentified, selective primary immunodeficiency state. This result provides an insight into the genetic architecture of infectious diseases as well as the nature of inherited immunodeficiency in humans.

Association of VPS26 variants with susceptibility to infection by Leishmania in Brazil, Iran and Sudan. *A. Romano[1,2], H. Dessein[1,2], A. Muller[1,2], F. Santoro[1,2], A. Salhi[1,2], S. Rafati[3], S. El Saafi[4], JP. Gorvel[5], L. Argiro[1,2], A. Dessein[1,2].* 1) INSERM, UMR906, Marseille, France; 2) Aix Marseille University, Faculty of Medicine, Marseille, France; 3) Pasteur Institute of Teheran, Teheran, Iran; 4) University of Karthoum, Karthoum, Sudan; 5) Aix Marseille University, CIML, Marseille, France.

Leishmaniasis are a group of parasitic diseases that affect millions of people in southern countries. Leishmania parasites multiply in macrophages and cause a wide spectrum of diseases including cutaneous lesions (CL) and lethal visceral disease (VL). The reasons why certain patients remain asymptomatic following infection whereas others develop severe lesions are unclear. We have performed a Genome Wide Linkage Study in affected siblings from a Brazilian sample living in an endemic region for L.braziliensis. This GWLS indicated a susceptibility locus for cutaneous lesions on chromosome 10, within the 10q21-q23 region. Fine mapping with additional families yield a maximum MLB lod-score of 2.39 for D10S522. Analysis of candidate genes in this region revealed a protein of the retromer complex VPS26 (Vacuolar Protein Sorting 26), involved in the maturation of endosome / lysosome. Thirty SNPs localised in VPS26 and surrounding genes were genotyped in 84 families corresponding to 141 trio (at least 1 affected child and his two parents). Most SNPs in VPS26 and in the flanking region were comprised in seven correlation (r2>0.8) bins. Transmission Disequilibrium Test analysis of the data indicated that SNPs of 3 correlation bins were significantly ($p<0.01$) associated with CL in the Brazilian sample. In addition, we found that several SNPs associated with CL in Brazil, were also associated with cutaneous lesions caused by L.tropica in an Iranian sample and with visceral leishmaniasis caused by L.donovani in a Sudanese sample. Immunostainning was done for LPG, Lamp1 and VPS26 on mouse macrophage cell line RAW infected by leishmania. We observed that VPS26 colocalised with LPG positive-leishmania very rapidly from the beginning of the phagocytosis. In addition, VPS26 staining persisted up to the late stage when leishmania containing vacuoles expressed LAMP-1. Another protein members of the retromer complex (VPS35) also gave a positive signal on the phagocyted leishmania. We hypothesize that polymorphisms in VSP26 gene modify expression of the retromer complex on the leishmania-phagocytic vacuoles resulting in an aggravation of the infection. Ongoing experiments are conducted to explore this hypothesis.

1950W

MTHFR 677 C>T polymorphism does not influence the risk of polycystic ovarian syndrome (PCOS). *S. Rajender[1], J. Carlus[2], K. Singh[3], K. Thangaraj[2].* 1) Endocrinology, Central Drug Research Institute, Lucknow, UP, India; 2) Centre for Cellular and Molecular Biology, Hyderabad, India; 3) Banaras Hindu University, Varanasi, India.

Statement of purpose: Polycystic ovarian syndrome (PCOS) is one of the most common forms of ovarian dysfunction accounting for a large proportion of infertile women. Sufficient folate intake and an optimum efficiency of folate pathway are considered essential for normal ovarian function. Elevated levels of homocysteine have been correlated with PCOS, and these patients respond to folic acid or vitamin B complex therapy. The homocysteine/methionine cycle runs efficiently only upon assistance from folate cycle. 677 C>T polymorphism in the 5, 10-methylene tertrahydrofolate reductase (MTHFR), an important enzyme of folate pathway, compromises the activity of this enzyme by about 50%. PCOS risk associated with this polymorphism has been analyzed in few small case-control studies. Studies from South Asian/Asian region are lacking and a meta-analysis on published data is urgently required to settle the discordance in results. Methods used: In the present study, we have undertaken analysis on a fairly large sample size (261cases and 256 controls) to address the level of association between this polymorphism and PCOS and to figure out the effect of ethnic variations on the possible association. For the latter, two ethnically divergent case-control groups (North Indian and South Indian) from the Indian sub-continent were recruited for analysis. MTHFR 677 C>T polymorphism was analyzed by direct DNA sequencing. Data were analyzed to find if rare allele (T) or the rare genotypes (CT and TT) conferred increased risk of PCOS. We also conducted a meta-analysis on the data published between 1999 and 2011. Results: Independent (group-wise) and combined analysis of allele/genotype data showed no association between this polymorphism and PCOS. No significant difference was seen when the patients were grouped according to the BMI. Similar results in the two ethnically divergent groups rules out the influence of ethnic variations on the level of association. The consensus emerged from the meta-analysis also suggest no significant association of this polymorphism with PCOS. Conclusions/significance: MTHFR 677 C>T polymorphism does not seem to affect the risk of PCOS. No influence of this polymorphism is seen even in the individuals with high BMI. This inference is not influenced by ethnic variations across study populations.

1951T

Mapping of a novel locus modifying glaucoma severity within the *GLC1K* region at 20p12. *P. Belleau[1], S. Dubois[1], K. Lebel[1], R. Arseneault[1], E. Shink[1], J.L. Anctil[2], G. Côté[2], M.A. Walter[3], M. Amyot[4], V. Raymond[1].* 1) Molecular Genetics of Sensory Systems, CHUL Research Centre, Quebec City, QC, Canada; 2) Ophthalmology, Universite Laval, Quebec City, QC, Canada; 3) Medical Genetics, University of Alberta, Edmonton, AB, Canada; 4) Ophthalmology, Universite de Montreal, Montreal, QC, Canada.

Chronic open-angle glaucoma (COAG, which refers to juvenile- and/or adult-onset open-angle glaucoma) is a major cause of blindness characterized by retinal ganglion cell death. Although COAG is primarily considered a complex genetic disorder, the disease may also segregate as a Mendelian trait in some families. Using such kindreds, 12 *GLC1* loci and 4 disease-genes have been identified. One of these genes is *myocilin* (*MYOC*) that causes autosomal dominant COAG. For the past 50 years, we have been investigating the huge French-Canadian CA pedigree (749 people) in which the $MYOC^{K423E}$ mutation expresses a very wide phenotypic variability. Recently, we identified a novel class of modifier elements that accounted for variable ages-at-onset of the glaucoma phenotype within the family. The modifiers might alter the outflow of aqueous humor thereby increasing intraocular pressures above normal. To decipher the molecular basis by which these modifiers caused variable ages-at-onset, we performed a genome-wide linkage analysis using a total of 184 CA family members. Out of the 133 individuals who were heterozygotes for the $MYOC^{K423E}$ mutation, 114 were affected while the 17 remaining persons were asymptomatic even if 9 of them were older then 35 years of age at their last exam. A total of 408 microsatellite markers were genotyped at an average interval of 10 cM. To prioritize *GLC1* loci previously linked to open-angle glaucoma (OAG), markers density was increased within these regions. Linkage values were then calculated using a Bayesian MCMC method implemented in Loki. This procedure calculates L-score values by estimating the posterior probability of linkage divided by the prior probability. Using this strategy, we detected a 5 cM region with an L-score value of 7.1 located between D20S189 and D20S898 at 20p12. Interestingly, both markers mapped within the *GLC1K* locus that contains a gene for early-onset OAG. Even if this L-score value was at the lower limit for such type of analysis, it clearly confirms that *GLC1K* encodes at least one gene (or non-coding DNA element) that is linked to early-onset glaucoma and/or modifies the severity of the glaucoma phenotype when the disorder is caused by the myocilin gene. Our data suggest that the modifier at *GLC1K* acts by altering the first episode when intraocular hypertension occurs in our $MYOC^{K423E}$ heterozygotes.

1952F

Fine-mapping of eight psoriasis susceptibility loci. *S. Das[1], P.E. Stuart[2], J. Ding[1], T. Tejasvi[2], Y. Li[1], L.C. Tsoi[1], V. Chandran[3], J. Fischer[4], C. Helms[5], K.C. Duffin[6], J.J. Psoriasis is a common immune-mediated disease with a genetic basis. Genome-wide association studies have identified more than 20 loci for this disease. In 2009 we designed a custom genotyping array and initialized a follow-up study to fine-map the eight genome-wide significant susceptibility loci known at that time (*IL23R*, *IL13*, *IL12B*, *TNIP1*, *MHC*, *TNFAIP3*, *IL23A* and *RNF114*). After quality control, the dataset consisted of genotypes of 1,962 SNPs from the 8 loci for 2,847 psoriasis cases and 2,208 unaffected controls of European Caucasian ancestry. To increase marker density, genotype data were imputed using the latest 1000 Genome reference haplotypes, which include both indels and SNPs, yielding 49,120 genetic variants in the 8 loci imputed with high quality. Stepwise conditional association analysis was used to identify independent signals from each of the 8 loci. We used a sequential forward selection method where, at each iteration, we identified the most significant variation in each locus conditional on signals from previous iterations. We identified 13 independent signals among the 8 loci and two of these were deletions. Among the 11 independently associated SNPs, rs848 and rs114175464 were found to be in strong LD with non-synonymous SNPs in *IL13* and *RNF114*, respectively. Three of the loci had more than one independent signal: *IL12B* (2), *MHC* (4), and *TNIP1* (2). These results add further definition to the genetic map of psoriasis.

1953W

Association of markers in DOCK6 with total cholesterol concentration in American Indians. *J.K. DiStefano[1], M. Khosroheidari[1], E. Eddy[1], S. Kobes[2], W.C. Knowler[2], R.L. Hanson[2].* 1) Diabetes, Cardiovascular Meta, TGen, Phoenix, AZ; 2) Diabetes Epidemiology and Clinical Research Section, NIDDK, NIH, Phoenix, AZ.

We have previously identified a locus linked to fasting serum total cholesterol concentration (TC) in Pima Indians on chromosome 19p (LOD=3.89). This locus has been linked to both total and LDL cholesterol in at least 15 independent studies across four different ethnic groups, and is one of the most consistently observed regions of linkage for lipid traits. Subsequent fine-mapping of this region using 346 single nucleotide polymorphisms (SNPs) genotyped in Pima Indians reduced the linkage interval from 90 cM to 15.7 cM, which spans 19p13.1-p13.3 and contains 229 genes. To identify trait-associated SNP alleles, we genotyped 1536 markers within the region of interest in in two study samples derived from the Pima Indian population, including 1) a family-based sample comprised of individuals who participated in the original genome scan for total cholesterol (N= 958) and 2) a population-based sample representing individuals in whom TC levels have been measured (N=926). We analyzed log values of TC using measurements from the last examination at which diabetes status was known and age was at least 20 years. Adjustment was performed for age, sex, diabetes status, and examination date. The strongest evidence for association with TC concentration was found with markers located in the DOCK6 (dedicator of cytokinesis 6) gene, including rs4804576 (increase of 4.2% per copy of the C allele; $P=2.0 \times 10^{-7}$), rs2116876 (4.0% per copy of the G allele; $P=1.1 \times 10^{-6}$), rs2278436 (4% per copy of the G allele; $P=5.0 \times 10^{-6}$), and five additional SNPs (all $P<0.0005$). Conditional analyses among the four most strongly associated markers showed that rs4804576 provided most of the evidence for association; however, rs12608933 also provided independent evidence for association (P=0.02), suggesting the potential presence of multiple functional variants with effects on TC levels or a single functional variant that crosses the haplotype of these four SNPs. DOCK6 is guanine nucleotide exchange factor belonging to group C of the DOCK family, and is involved with actin cytoskeletal reorganization via activation of RAC1 and CDC42; however, its role in cholesterol metabolism is not known. However, it is worth noting that rs4804576 is highly concordant with rs737337, which was previously found to be associated with HDL-C ($P=3 \times 10^{-9}$) in >100,000 individuals of European ancestry. These findings suggest that genetic variation in DOCK6 influences TC levels in Pima Indians.

1954T

Fine-scale genetic mapping reveals multiple signals of association in waist-hip ratio loci and shows evidence of sexually dimorphic genetic effects. *T. Ferreira[1], D. Shungin[2,3,4], D.C. Waist-hip ratio (WHR) is a heritable measure of body fat distribution and a significant predictor of metabolic and cardiovascular risk independent of overall obesity, as measured by body mass index (BMI). To further our understanding of the genetic architecture of WHR adjusted for BMI (WHRadjBMI), we performed fixed-effects meta-analysis of 67,325 individuals from 28 studies genotyped with Metabochip and 142,762 individuals from 57 studies with genome-wide association imputed data, all of European ancestry. Given our previous reports of sexually dimorphic genetic effects on WHRadjBMI, we also performed sex-stratified meta-analyses. To search for multiple signals of association within WHRadjBMI loci, we performed approximate conditional analyses using GCTA, estimating the linkage disequilibrium between SNPs using genotype data from 949 Swedish individuals from PIVUS. We identified multiple independent signals of association at genome-wide significance ($p<5\times10^{-8}$) at 9 WHRadjBMI loci, many of which showed a complex pattern of sexual dimorphism in genetic effects. For example, at the *COBLL1* locus, all 4 association signals were female-specific (male-specific $p>0.4$ for all 4 signals), and at the *VEGFA* locus, both association signals were stronger in women than men (1-degree of freedom test of heterogeneity between sex-specific allelic effects $p=2.7\times10^{-10}$ and 2.2×10^{-2}). However, at the *WARS2/SPAG17* locus, we observed one male-specific, one female-specific, and two sex-combined association signals.

We also assessed fine-mapping resolution across 14 WHRadjBMI loci that are densely covered by Metabochip. Using the sex-combined meta-analysis results, we constructed credible sets of SNPs that account for 99% of the probability of being causal (or tagging an unobserved causal variant). For 6 of the loci, the interval covered by the credible set was <20kb, and at *VEGFA* contained just one SNP. We also observed that the addition of 14,340 individuals of non-European ancestry did not noticeably improve fine-mapping resolution, despite expected differences in LD structure between such diverse populations. Our results highlight the importance of fine-mapping to fully elucidate the complex underlying genetic architecture of body fat distribution, and show promise for extending our knowledge of the biological mechanisms contributing to the trait.

1955F

The FTO gene polymorphisms are associated with obesity in the Chinese Population: the SAPPHIRe follow-up study. *C.-M. Hwu[1, 2], M.-W. Lin[3, 4], P.-T. Tsai[3], C.-A. Hsiung[5], L.-M. Chuang[6], W.H-H. Sheu[7], Y.-R. Hung[8], L.-T. Ho[2, 4].* 1) Section of Endocrinology and Metabolism,, Taipei Veterans General Hospital, Taipei, Taiwan; 2) Faculty of Medicine, National Yang-Ming University School of Medicine, Taipei, Taiwan; 3) Institute of Public Health, National Yang-Ming University, Taipei, Taiwan; 4) Department of Medical Research and Education, Taipei Veterans General Hospital, Taipei, Taiwan; 5) Department of Bioinformatics and Biostatistics, National Health Research Institutes, Zhunan, Taiwan; 6) Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 7) Department of Internal Medicine, Taichung Veterans General Hospital, Taichung, Taiwan; 8) Division of Endocrinology and Metabolism, Tri-Service General Hospital, Taipei, Taiwan.

Obesity is an important risk factor for type 2 diabetes and cardiovascular diseases. The fat mass and obesity-associated gene (FTO) was recently identified as a susceptibility locus for both obesity and type 2 diabetes by genome-wide association studies in several European populations. To investigate the association between FTO gene polymorphisms and obesity and metabolic syndrome in the Chinese population, we genotyped three single nucleotide polymorphisms (SNP) of the FTO gene (rs1421085, rs9939609, and rs9930506) in 847 subjects of Chinese origin from the Stanford Asia-Pacific Program for Hypertension and Insulin Resistance (SAPPHIRe) family study. The rs1421085 and rs9939609 were found to be associated with risk of increased waist circumference in the SAPPHIRe cohort (p= 0.017 for rs1421085, p=0.031 for rs9939609). Moreover, The rs1421085 and rs9939609 were also revealed to be associated with the increase of body mass index (OR=1.71, 95%C.I. 1.07-2.73 for rs1421085 and OR=1.68, 95%C.I. 1.05-2.71, for rs9939609) after five-year follow-up of the study subjects. In conclusion, our results suggest the polymorphisms of the FTO gene are significantly associated with obesity as well as the progression of obesity. Our study validated the association between FTO gene polymorphisms and obesity in the Chinese population.

1956W

Consanguinity in Pakistani families reveals new loci in a complex genetic trait: stuttering. *M.H. Raza[1], R. Amjad[2], S. Riazuddin[2], D. Drayna[1].* 1) LCD, SSBCD, NIDCD, National Institute of Health; 2) Allama Iqbal Medical College, Lahore, Pakistan.

Stuttering is a complex genetic disorder which is characterized by involuntary disruption of the flow of speech. Although the twin and adoption studies have demonstrated high heritability of stuttering, incomplete penetrance and the absence of complete Mendelian segregation contribute to the limited success of linkage studies and next generation sequencing for this disorder. Linkage and gene finding studies of consanguineous stuttering families previously led to the identification of mutations in the GNPTAB gene associated with stuttering in Pakistani families. We have performed additional SNP linkage scans in 32 medium-to-large size consanguineous stuttering families ascertained from Pakistan, using the Human Linkage-12 and Human Linkage-24 chips (Infinium Assay) from Illumina that carries 5913-6090 SNPs occurring at an average density of 0.58 cM. Two-point linkage analysis was performed under different modes of inheritance using SuperLink in the EasyLinkage package. Pakistani stuttering family PKST77 generated a LOD score of 3.23 at SNP rs7631540 on chromosome 3q13.31 under a recessive mode of inheritance. Another family designated PKST58 produced suggestive linkage scores at loci on chromosomes 16, 6, 11, 9 and 21. Based on these results, targeted microsatellite genotyping was performed in families PKST77 and PKST58. Two point analysis using MLINK generated a maximum LOD score of 4.23 in PKST77 at marker D3S1310, and a score of 4.35 in PKST58 at marker D16S3025. Additional evidence of linkage was obtained through multipoint analyses, which produced LOD scores of 4.92 in PKST77 and 4.42 in PKST58 under recessive modes of inheritance. After including microsatellite genotype information on chromosomes 6, 11, 9 and 21, LOD scores fell under all modes of inheritance in PKST58. Our results demonstrate significant evidence of linkage to chromosome 3q and chromosome 16q in consanguineous stuttering families PKST77 and PKST58 respectively that harbor new stuttering genes. These studies indicate the power of consanguineous families for identifying rare variants of large effect that underlie common complex genetic disorders.

1957T

Genome-wide linkage scan of male sexual orientation. *A.R. Sanders[1,2], K. Dawood[3], G. Rieger[4], J.A. Badner[2], E.S. Gershon[2], R.S. Krishnappa[5], A.B. Kolundzija[6], S. Guo[7], G.W. Beecham[7], E.R. Martin[7], J.M. Bailey[8].* 1) NorthShore University HealthSystem, Evanston, IL; 2) University of Chicago, Chicago, IL; 3) Pennsylvania State University, University Park, PA; 4) Cornell University, Ithaca, NY; 5) East Tennessee State University, Johnson City, TN; 6) Columbia University, New York, NY; 7) University of Miami, Miami, FL; 8) Northwestern University, Evanston, IL.

As with many other psychological traits, sexual orientation appears genetically complex, with important genetic and environmental factors. Family and twin studies have consistently demonstrated that genetic contributions are important for the development of sexual orientation in men. Previous research has found evidence for linkage to chromosome Xq28 in some studies focusing on pairs of homosexual brothers, but not in other such studies. To map loci for sexual orientation, and to appraise for potential replication of previous findings, we have conducted a genome-wide linkage scan using genotypes from the Affymetrix 5.0 SNP array on 410 independent pairs of homosexual brothers in 385 families, a sample set independent from previous studies. We classified subjects as homosexual based on both their self-reported sexual identity ("homosexual") and sexual feelings (Kinsey score of 5-6, indicating predominant or exclusive attraction to men). After rigorous quality control steps, we performed non-parametric linkage analysis using MERLIN. The strongest linkage peak, with multiple two-point LOD scores over 3.5 (maximum 4.0) and multipoint support, was in the pericentromeric region of chromosome 8, overlapping with the second strongest linkage peak in the next largest reported linkage scan of 155 independent pairs of homosexual brothers in 146 families. Our second strongest linkage region was on chromosome X with a maximum two-point LOD score of 2.65 at Xq28, the previously reported linkage region. Our findings, taken in context with previous work, suggest that genetic variation in each of these regions contributes to development of the important psychological trait of male sexual orientation.

1958F

Linkage studies in a large stuttering family indicate multiple novel loci and possible assortative mating. *A.A. Schaffer[1], M.H. Raza[2], E.M. Gertz[1], J. Mundorff[2], J. Lukong[2], J. Kuster[3], D. Drayna[2].* 1) National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, Bethesda, MD USA; 2) National Institute on Deafness and Other Communication Disorders, National Institutes of Health, Bethesda, MD USA; 3) Department of Speech, Hearing, and Rehabilitative Services, Minnesota State University, Mankato, MN.

Stuttering is a common speech disorder that is a complex trait with high heritability. While linkage studies in consanguineous populations have produced highly significant evidence for linkage at a number of loci, such studies in outbred populations have been less successful. We have ascertained a large family with many cases of persistent stuttering from Cameroon, West Africa in which consanguinity is denied. An initial genome-wide linkage scan using microsatellites that tested the complete pedigree for linkage produced a suggestive score on chromosome 1. However subsequent linkage scans with SNPs that analyzed the complete family failed to confirm this linkage, and no significant linkage scores were observed genome-wide. In contrast, dividing the pedigree into five branches and analyzing individual branches and combinations of branches produced strong evidence for linkage with both SNP and microsatellite markers. In this family, we found evidence for linkage to previously reported loci on 3q and 15q, and to novel loci on 2p, 3p, 14q, and a different position on 15q. While the mechanism by which these multiple alleles came together in the same family is unknown, we found little evidence for consanguinity, and we suggest assortative mating as a likely explanation. Such assortative mating has been shown to be important in the epidemiology of hereditary deafness, and may play a role in the epidemiology of stuttering.

1959W

Fine mapping of 6q27 for association with blood pressure. *B. Tayo[1], B. Salako[2], A. Luke[1], X. Zhu[3], A. Adeyemo[4], C. Rotimi[4], A. Ogunniyi[2], R. Cooper[1].* 1) Prev Med & Epidemiology, Loyola Univ Chicago, Maywood, IL; 2) University of Ibadan, Ibadan, Nigeria; 3) Case Western Reserve University, Cleveland, OH; 4) NIH Intramural Center for Research on Genomics and Global Health, National Human Genome Research Institute, Bethesda, MD.

Hypertension is the most common cardiovascular condition in the world and accounts for a substantial proportion of adult mortality. Although elevated blood pressure (BP) has similar heritability to many other traits related to cardiovascular risk, genetic susceptibility loci have been difficult to localize. In a follow-up family-based association analysis of regions on chromosomes 6 and 7 linked to BP among Nigerians we observed strong preliminary evidence that the regions may influence susceptibility to elevations in BP. To refine identified association in 6q27, we conducted fine mapping analysis in a sample of 1614 unrelated adult Nigerians genotyped on Affymetrix 6.0 chip. The study sample comprised of 940 females and 674 males of which 797 were hypertensives. To increase single nucleotide polymorphisms (SNPs) density for the fine mapping, we performed genotype imputation using combined data from the HapMap and 1000 Genomes projects. A total of 3330 typed or imputed SNPs passed quality control in 6q27 and these were subsequently tested for association with BP and hypertension with covariates adjustment for sex, age and body mass index. After correction for multiple testing through Bonferroni adjustment, 7 intergenic SNPs within 70 kilobase pairs in 6q27 retained statistical significance (P<0.005) for association with hypertension. These data reinforce previous findings that variants in chromosome 6 influence susceptibility to elevated BP.

1960T

Efficient Pooled Sequencing of 1,077 Candidate Genes in Individuals With Short Stature. *S.R. Wang[1,2,3], D.B. Mirel[2], A. Dauber[2,3], J.N. Hirschhorn[1,2,3].* 1) Department of Genetics, Harvard Medical School, Boston, MA, USA; 2) Broad Institute, Cambridge, MA, USA; 3) Division of Endocrinology, Boston Children's Hospital, Boston, MA, USA.

Genome-wide association (GWA) studies have identified many common variants associated with height and other polygenic traits. These common variants typically account for well under half of the heritable variation. Many explanations have been proposed to account for this “missing heritability”, including the contribution of rare variants. In this study, we employ a candidate gene approach to search for rare variants associated with human height, focusing on genes within loci identified by previous GWA studies of height, and supplemented with genes known to underlie syndromic growth disorders or skeletal dysplasias, as well as genes involved in growth plate biology. In total, a list of 1077 genes were compiled and the exons (~2Mb in total) were targeted for resequencing. As an initial experiment, we resequenced 192 patients with short stature (>2 SD below the mean for age and gender). To increase sequencing efficiency, we applied a matrix pooling design. The short stature samples were arranged into a 14x14 matrix of 28 pools, with 13-14 patients in each pool (4 empty “holes” were included into the matrix for assessing false positive rate). After hybrid selection of each pooled sample against the baits representing the 1077 genes, barcoded libraries were created. The matrix design allows us to obtain allele frequency estimates for each pool and to ascertain variant carriers for singleton variants appearing once in the matrix. To call variants within pools, we used Syzygy software (Rivas et al. 2011) and then applied a new likelihood-based secondary calling strategy that integrated the extra information from our matrix design. We estimated the false negative and false positive rates of this strategy by comparison with exome sequencing performed in a subset of these samples and by looking for singleton variants that map to one of the holes in the matrix. The overall false negative rate was ~0.2%, while the false positive rate of singletons was ~0.8%. We identified a list of very rare variants (not observed in any currently available sequencing dataset) that appear in short stature samples. Of note, one individual who did not have a known genetic diagnosis previously, was a compound heterozygote for mutations in a gene known to cause a rare inborn error of metabolism (SLC35C1, congenital glycosylation disorder type IIC) that has short stature as a feature. Biochemical analysis of the individual and functional assessment of these mutations are now in progress.

1961F

Molecular analysis of common tag polymorphisms in Hemochromatosis (HFE) genes in Iranian patients affected with PCOS. *S. Matoo, A. Yasari Mazandarani, N. Hatamnejadian, B. Sedaghati Khayat, M. Moghaddam, A. Ebrahimi.* PARSEH GENETIC CENTER, TEHRAN, Iran.

Abstract: Polycystic ovary syndrome (PCOS) is a heterogeny disease digit between 4-7% of women of childbearing age will be involved. The most original Endocrine disorders is in women . One of the main mechanisms involve in pcos insulin resistance or mechanisms that cause diabetes. On the other hand, several epidemiological studies have shown a positive association between increased body iron stores and the risk of type 2 diabetes and of other insulin resistant states such as the metabolic syndrome, pregnancy diabetes and polycystic ovarian syndrome. Here is evaluated two different types of hemochromatosis, including: the classic hemochromatosis, caused by a mutation in a gene designated HFE and type 2A Hemochromatosis, caused by mutations in the HJV gene. Thus, using molecular techniques the relationship between HFE and HJV genes involve in insulin resistance and PCOS are reviewed Methods: To identify the molecular changes common HFE and HJV genes 100 affected patients clinically diagnosed as PCOS were selected. The blood samples were collected and DNA was extracted. And then using molecular techniques ARMS-PCR and PCR-RFLP variations were common, were investigated. Also, 10 percent of the samples were analyzed by direct sequencing method. Results: Our study showed that mutations in HFE and HJV are polymorphic and significant in Iranian population of affected with PCOS. Which polymorphic site could be gene biomarker for prediction of PCOS early signs and genotype-phenotype correlationS studies.

1962W

Molecular analysis of Hepcidin common polymorphisms in Iranian patients affected with PCOS. *A. Yasari Mazandarani, S. Matoo, N. Hatamnejadian, B. Sedaghati Khayat, M. Moghaddam, A. Ebrahimi.* PARSEH GENETIC CENTER, TEHRAN, Iran.

Introduction: The polycystic ovary syndrome (PCOS) is possibly the most common endocrine disorder, affecting several million women worldwide with approximately 6-7% prevalence. Several studies have reported that high body iron stores have a positive association with risk of diabetes and polycystic ovarian syndrome (PCOS).Since hereditary hemochromatosis (HH) is a common autosomal recessive disorder of iron overload, it can lead to insulin resistant disorders such as PCOS. On the other hand, one of the forms of HH is caused by mutations in the hepcidin antimicrobial peptide (HAMP) gene on chromosome 19, which makes iron overload by decreasing in hepcidin synthesis and thus reduced levels of hepcidin. Consequently, by considering the significant role of hepcidin in regulation of iron metabolism, we studied hepcidin common polymorphisms in order to find the association between the HAMP and PCOS in Iranian patients. Material: To identify the molecular common changes of HAMP genes, 100 patients affected with PCOS (100 PCOS patients and 100 control diagnosis samples) were selected. The blood samples were collected and DNA of samples were extracted. Then HAMP gene was amplified using primers and the PCR products were analyzed by direct sequencing. Results: Our study showed that mutations in HAMP are polymorphic and significant in Iranian population of affected with PCOS. Which polymorphic site could be gene biomarker for prediction of pcos early signs and genotype-phenotype correlations studies.

Mitochondrial haplogroups and age-related maculopathy. *Y.P. Conley[1,2], Y. Jiang[3], M.C. Kenney[4], N. Udar[4], R.E. Ferrell[2], D.E. Weeks[2,3], M.B. Gorin[5].* 1) Hlth Promotion & Development, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh PA; 3) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 4) Gavin Herbert Eye Institute, University of California, Irvine, CA; 5) Jules Stein Eye Institute, UCLA, Los Angeles, CA.

Age-related maculopathy (ARM) is a complex multifactorial condition where nuclear genomic variation plays a role in susceptibility; however the potential role for mitochondrial variation in susceptibility has been less frequently studied. The purpose of this study was to investigate whether mitochondrial haplogroups H and T play a role in susceptibility to ARM in our familial ARM cohort. TaqMan allele discrimination assays were conducted to classify haplogroup H (C702T) and haplogroup T (A4917G) and ad hoc tests for association conducted. For haplogroup H, we determined the status for 1,009 Caucasian individuals in 587 families, including 860 affecteds and 126 unaffected controls. Haplogroup H was associated with ARM in the total sample (p=0.019) but only in females in the sex-specific subgroup analyses (p=0.019). Haplogroup T indicated no significant association in our analyses. Haplogroup H has been previously associated with ARM; however this is the first study conducted within a cohort of ARM families and the first to find a sex-specific association. Additionally, our findings indicate that the presence of haplogroup H increases risk for ARM, particularly in females, which is counter to previous findings that haplogroup H is associated with reduced risk. This may be an artifact due to our sampling scheme. In order to investigate the functional consequences of the mitochondrial DNA variants that define the ancestral haplogroups, we also developed cybrids (cytoplasmic hybrids) using human retinal pigment epithelial cells. Our findings show that the different cybrids, including the haplogroup H containing cybrid, have different modes of energy production, rates of cell growth, and altered expression of nuclear genes involved in critical molecular pathways and cellular functions. These data support that different haplogroups have unique features which may relate to disease development.

1964F

Candidate genes as a modifier of age at Huntington disease motor onset. *E.M. Ramos[1,2], J. Latourelle[3], J.-H. Lee[1], T. Gillis[1], J.S. Mysore[1], J.F. Gusella[4, 1], J.-M. Lee[1], I. Alonso[2,5], J. Sequeiros[2,5], R.H. Myers[6,3], M.E. MacDonald[1].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) UnIGENe, IBMC - Institute for Molecular and Cellular Biology, University of Porto, Porto, Portugal; 3) Department of Neurology, Boston University School of Medicine, Boston, MA, USA; 4) on behalf of the COHORT study of the HSG; 5) CGPP, IBMC - Institute for Molecular and Cellular Biology, University of Porto, Porto, Portugal; 6) on behalf of the HD-MAPS Investigators.

Huntington's disease (HD) is a dominantly inherited neurodegenerative disorder characterized by motor, cognitive, and behavioral disturbances, caused by the expansion of the *HTT* CAG trinucleotide repeat. The expanded CAG repeat is the major determinant of age-at-onset of motor symptoms (AO), such that the longer the repeat the earlier the onset. CAG size accounts for 70% of the variability in onset age. The remaining variance in AO (residual AO) is highly heritable but remains unexplained. In the search for modifiers, polymorphisms in about 20 loci have been implicated in AO or progression of HD, though with different results in different studies. We have now critically evaluated some of these polymorphisms located either in the mitochondrial regulator *PPARGC1A*, N-methyl D-aspartate receptor subtype genes (*GRIN2A* and *GRIN2B*) or in genes in the dopamine pathway (*DAT1*, *DRD4*, *DRD2* and *COMT*). We genotyped genomic DNA from a total of 1,727 HD patients with 40 to 53 CAGs and known genetic/self-reported ancestry and familial relationship. Multivariate analyses using GEE assessed the effect on HD residual motor onset, adjusting for familial component and ancestry. For the *PPARGC1A* gene, in the entire cohort, rs7665116 genotype had a significant effect on AO, both in additive (p=0.009) and dominant models (p=0.008). However, when examined by origin, the Southern European and the Northern European and North American HD samples, differed for rs7665116 MAF, consistent with a SNP tagging-ancestry, as, despite similar mean CAG sizes, Southern European samples had an older mean AO, revealing phenotype stratification. Population-specific regression analysis did not show a significant association of rs7665116 genotype with AO, in either additive or dominant models. Using this same approach, our analysis of the implicated polymorphisms in *GRIN2A*, *GRIN2B*, *DRD2*, *DRD4*, *DAT1* and *COMT* were also found not to significantly modify motor AO, either in a dominant or additive model, after adjusting for ancestry. Our results, therefore, do not support any of the previously implicated genes as modifiers of AO of motor symptoms. We found evidence for a dramatic effect of phenotypic (AO) and genotypic (MAF) stratification among European cohorts that was not considered in previously reported association studies. A significantly older AO in Southern Europe may reflect population differences in genetic or environmental factors that warrant further investigation.

1965W

Variations in Potassium Channel Genes are Associated with Persistent Breast Pain after Breast Cancer Surgery. *D.J. Langford[1], B. McCann[1], T. Koetters[1], C. Baggott[1], C. West[1], J.D. Levine[2], C. Elboim[3], G. Abrams[2], D. Hamolsky[2], L. Dunn[2], H. Rugo[2], M. Dodd[1], S.M. Paul[1], J. Neuhaus[2], B.A. Cooper[1], B. Schmidt[4], J. Cataldo[1], A. Dhruva[2], B.E. Aouizerat[1,5].* 1) Physiological Nursing, University of California, San Francisco, San Francisco, CA; 2) School of Medicine, University of California, San Francisco, San Francisco, CA; 3) Redwood Regional Oncology Group, Santa Rosa, CA; 4) School of Dentistry, New York University, New York, NY; 5) Institute for Human Genetics, University of California, San Francisco, CA.

Background/Purpose: Persistent pain after breast cancer surgery is common and prevalence estimates vary widely. Evidence suggests a role for common genetic variation in nociception (i.e., perception of noxious stimuli). Given their putative role in nociceptive transmission, we hypothesized that variation in potassium (K+) channel genes may be associated with persistent breast pain after surgery. Therefore, the purpose of this study was to test for associations of single nucleotide polymorphisms (SNPs) and inferred haplotypes among 10 K+ channel genes with persistent breast pain after breast cancer surgery.**Methods:** We recently used growth mixture modeling in an effort to identify latent classes (i.e., subgroups) of patients with distinct trajectories of worst pain scores using a 0-10 numeric rating scale (NRS). Pain was rated prior to and monthly for 6 months after breast cancer surgery. The comparisons were made solely between the two largest classes (i.e., No Pain and Mild Pain). Using a tag-SNP and literature-driven approach to SNP selection, genotyping was conducted using a custom genotyping array and blinded to clinical status. Only common SNPs (minor allele frequencies>.05) that passed quality control filters were analyzed. Haplotypes were constructed using a Bayesian approach. Contingency table tests identified significant differences in genotype or haplotype frequency between the pain groups. **Results:** Four subgroups were identified: 126 patients (31.7%) with "No Pain", 173 (43.4%) with "Mild Pain" (NRS of ~3 that remained constant for 6 months), 53 (13.3%) with "Moderate Pain" (NRS of ~2 that increased over 6 months), and 46 (11.6%) with "Severe Pain" (NRS of ~8 that persisted for 6 months). Compared to the No Pain group, patients in the Mild Pain group were younger (p<.01), had lower functioning (p<.05), had more lymph nodes removed (p=.02), more frequently had reconstruction at the time of surgery (p<.01), were pre-menopausal (p<.05), and had strange sensations in the breast prior to surgery (p<.001). We found significant associations between variations in 6 genes [KCNA1 (n=1, p<.01), KCND2 (n=1, p<.05), KCNJ3 (n=6, all p<.05), KCNJ6 (n=10, all p<.05), KCNK9 (n=3, all p<.05) and KCNS1 (n=2, both p<.05)] and pain group membership.**Conclusion:** K+ channel gene variation and important clinical and demographic characteristics are associated with novel phenotypic characterization of persistent breast pain after breast cancer surgery.

1966T

HLA Haplotypes Influence Hearing in Old Age. *T. Solomon[1], D.L. Newman[2].* 1) College of Health Science and Technology, Rochester Institute of Technology, Rochester, NY; 2) Thomas H. Gosnell School of Life Sciences, Rochester Institute of Technology, Rochester, NY.

Age-related hearing impairment (ARHI), or presbycusis, is characterized by reduced hearing sensitivity and speech understanding in noisy environments, slowed central processing of acoustic information, and impaired localization of sound sources. While both environment and genetic factors affect hearing loss, evidence has been shown that up to 50% of the variance in presbycusis is genetic. Thus far, only a few genes have been implicated in ARHI, including *GRM7*, *GRHL2*, and *NAT2*. There have been several studies correlating the human leukocyte antigen locus (HLA) with other inner ear and neurological diseases, specifically an extended HLA haplotype that contains the A1/B8 haplotype. We are investigating the A1/B8 haplotype for over 600 subjects with varying degrees of hearing capabilities. We are genotyping the patients for four SNPs that represent this abbreviated haplotype by using restriction fragment length polymorphism (RFLP) analysis and real-time PCR. Preliminary results suggest that the HLA-B8 haplotype is associated with worse pure tone detection and worse hearing in a noisy background (p = 0.024 and p = 0.017, respectively). In contrast, the HLA-A1 haplotype is associated with an improved ability to detect small temporal gaps in sound (p = 0.007). In the future, we would like to further investigate this extended HLA haplotype, particularly the DR3 haplotype.

A Y chromosome association study in inflammatory bowel disease. *L. Jostins, C.A. Anderson, J.C. Barrett, The International IBD Genetics Consortium.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Studies have suggested a link between sex chromosomes and immunity. Autoimmune diseases are more prevalent in females than in males, and are more common in individuals with Turner syndrome (absence of one sex chromosome). There is also evidence that Y haplogroups affect progression of HIV infection in males. However, there are few additional large studies of the effect of Y chromosome variation on human immune-mediated diseases.

We performed an association analysis of Y chromosome haplogroups in inflammatory bowel disease (IBD) using data from the International IBD Genetics Consortium's Immunochip project. This dataset contains 12,318 male IBD cases and 9,811 male controls from 15 European countries typed on a custom genotyping chip that includes 1735 Y chromosome variants. Using a novel method to assign Y haplogroups, we showed that these samples represent 11 major haplogroups, including 6 with a frequency above 1%. The frequency spectrum of these 6 haplogroups shows evidence of differing between IBD cases and controls after controlling for country-of-origin, genotyping batch and principal components (logistic likelihood-ratio $\chi 2 = 14.2$, d.f. = 5, p = 0.014), driven by an enrichment of haplogroup N in IBD cases (OR = 1.53, p = 0.006). Restricting the analysis to a homogeneous subset of 674 cases and 343 controls from populations with a high frequency of haplogroup N did not reduce the strength of the association (OR = 1.90, p = 0.003), suggesting that the association is not due to population stratification. We used sequence data from the 1000 Genomes Project to identify haplogroup N specific mutations that may account for this association. Mutations in or near 15 genes, including a variant 3kb upstream of CD24 (a cell adhesion gene upregulated in IBD) and a missense mutation in KDM5D (a MHC antigen involved in graft rejection) are among possible causal variants.

To extend our analysis, we generalized our haplogrouping method to include probabilistic sequence data, and will use cases and controls sequenced at low depth to further clarify Y chromosome associations in IBD. Additionally, we will analyze other immune-related diseases with varying sex ratios, such as primary sclerosing cholangitis (male-biased) and primary biliary sclerosis (female-biased), to investigate broader relationships between Y chromosome variation and immunity.

1968W

Prevalence of alpha-1 antitrypsin deficiency and hereditary hemochromatosis gene mutations in Algarve, Portugal. *V. Gaio[1], A. Fernandes[2], F. Mendonça[3], F. Orta Correia[3], A. Beleza[2], A. Gil[1], M. Bourbon[1], A.M. Vicente[1], C.M. Dias[1], M. Barreto da Silva[1].* 1) Instituto Nacional de Saúde Doutor Ricardo Jorge, Lisboa, Portugal; 2) Laboratório de Saúde Pública Dra. Laura Ayres, Faro, Portugal; 3) Administração Regional de Saúde do Algarve, Faro, Portugal.

Alpha-1 antitrypsin (AAT) deficiency and hereditary hemochromatosis (HH) are two of the most fatal genetic disorders in adult life, affecting million individuals worldwide. They are often under-diagnosed conditions and diagnosis is only made when the patient is already in the advanced stages of damage. AAT deficiency results from mutations in one highly pleiomorphic gene located on chromosome 14, *SERPINA 1*, being Z and S mutations the most relevant clinically. These mutations will lead to an AAT deficit that compromises the lungs protection, originating emphysema, chronic bronchitis, asthma or even chronic obstructive pulmonary disease (COPD) and it is also strongly associated with various liver diseases. On the other hand, C282Y and H63D mutations in the *HFE* gene, located on chromosome 6, are reported to be mostly responsible for the iron accumulation in HH disorder, leading to severe damage in different organs. Disease manifestations include cirrhosis, hepatic fibrosis, diabetes mellitus, arthropathy and hepatocarcinoma. Given the insufficient population-based information about the prevalence of these gene variants in the Portuguese population, the aim of this study was to assess their frequency in a representative sample from São Brás de Alportel, in the South of Portugal. To achieve our goal, we have genotyped a total of 208 adult subjects, including 118 females and 90 males (mean age: 58 years, range: 26-91). Regarding AAT deficiency, we found 4,3% MZ, 0,5% SS and 15,4% MS genotypes. The calculated frequency for the Z allele was 2,2% (95% CI: 0-11,7%) and for the S allele was 8,2% (95% CI: 0-17,4%). About HH, we found 1,4% C282Y/H63D, 2,4% H63D/H63D, 5,8% C282Y/N and 23,6% H63D/N genotypes. Frequencies of C282Y and H63D alleles were 3,6% (95% CI: 0-13%) and 14,9% (95% CI: 6-23,8%), respectively. The observed allele frequencies were in Hardy-Weinberg Equilibrium and no association was found with related diseases likely due to the smaller sample available. Our findings show the highest prevalence of Z allele from *SERPINA1* gene found, when compared to other populations. The remaining findings are in agreement with previously published studies. Future studies involving a larger sample size will be necessary to evaluate the penetrance of the studied gene mutations and to assess gene-environment interactions that influence disease risk, contributing to reduce the burden of these diseases which can have a great public health impact.

1969T

Menarche timing-related variants identified by recent GWAS are associated with growth outcomes in male and female children. *C. He[1], E. Wagner[1], G. Eckert[2], Z. Yu[2], H. Pratt[3], W. Tu[2].* 1) Dept. of Public Health, Indiana Univ Sch Med, Indianapolis, IN; 2) Dept. of Biostatistics, Indiana Univ Sch Med, Indianapolis, IN; 3) Dept. of Medicine, Indiana Univ Sch Med, Indianapolis, IN.

Weight and height increase in an accelerated fashion during puberty. Previous studies identified novel genetic variants that were associated with age at menarche, a marker for female puberty timing. However, the effects of these variants on growth related outcomes have not been investigated. We examined the growth effects of 31 menarche-related SNPs newly identified by genome-wide association studies (GWAS) in white women of European ancestry. We analyzed longitudinal data collected from 601 adolescents (263 African Americans and 338 Whites) using mixed effect models. Subjects between ages 4 and 17 were enrolled and followed for an average of 6 years. After adjusting for age and multiple testing, we found 2 menarche-related SNPs, rs1398217 in *SKOR2* and rs17268785 in *CCDC85A*, were respectively associated with more rapid weight gain and greater weight in African American males and females (all P< 0.0022); and two other SNPs, rs7642134 near *VGLL3* and rs9635759 near *CA10*, were respectively associated with increased weight and faster weight gain in White males and females (all P<0.0022); and rs7642134 and rs7821178 near *PEX2* were associated with greater body mass index (BMI) and greater BMI gain in Whites (all P<0.0032). None of the 16 menarche-related SNPs were associated with changes in height. Of the 8 menarche and weight-related SNPs, none was associated with changes in height; but 3 SNPs, rs2815752 near *NEGR1*, rs7647305 near *ETV5* and rs6548238 near *TMEM18*, were associated with increased weight and BMI in Whites and African Americans (all P<0.0034); and rs7138803 near *FAIM2* and rs9939609 in *FTO* were respectively associated with increased weight and BMI in Whites (all P<0.0059). Among the 7 menarche and height-related SNPs, we found rs1042725 near *HMGA2* and rs4549631 near *LOC728666* were associated with increased height and more rapid height gain in African Americans, and rs4800148 in *CABLES1* was associated with height increase in Whites (P=0.0018), whereas rs757608 near *TBX2* was associated with faster height gain in both Whites and African Americans (all P<0.0007); In addition, rs757608 and rs6440003 in *ZBTB38* were also associated with a faster gain in weight in African Americans (all P=0.00003). In conclusion, novel genetic variants associated with age at menarche were found to correlate with various growth measures in male and female children, although the genetic effects appear to be sex and race- specific.

1970F

Haplotypes of the inducible nitric oxide synthase gene are strongly associated with levels of exhaled nitric oxide in adults: a population-based study. *S. Dahgam[1], L. Modig[2], AT. Naluai[3], AC. Olin[1], F. Nyberg[1,4].* 1) Occupational and Environmental Medicine, University of Gothenburg, Gothenburg, Sweden; 2) Department of Public Health and Clinical Medicine Occupational and Environmental Medicine, University of Umeå, Sweden; 3) Department of Medical and Clinical Genetics, Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden; 4) AstraZeneca R&D, Mölndal, Sweden.

Introduction: Inducible nitric oxide synthase (iNOS; NOS2) is one of three distinct isoforms of NOS enzymes and it is encoded by the *NOS2* gene. NOS2 appears to be the primary source of nitric oxide in exhaled breath. Haplotypes and several genetic variants in the *NOS2* gene have been associated with levels of fractional exhaled nitric oxide (FENO), a biomarker of airway inflammation, in American and European subjects [1,2]. Aim: To fine map previous findings by us and others using an extended study population and enlarged SNP set, to further understand the contribution of genetic variation within the *NOS2* gene for levels of FENO. Method: In total 11 SNPs in the *NOS2* gene located between 26.07 and 26.12 Mb on chromosome 17 were genotyped by a Sequenom MassArray platform or a competitive allele specific PCR. Seven were from our previous study (rs4795051, rs9901734, rs2297514, rs2248814, rs12944039, rs3729508 and rs2779248)[2] and four from the Southern California Children's study (rs4796017, rs2297520, rs9895453 and rs10459953)[1]. We measured FENO at an exhalation flow-rate of 50 m/s for each subject. Haplotype association of the *NOS2* gene with levels of FENO was investigated in 5912 Swedish adults aged 25-75 years, assuming an additive genetic model. Results: The analyses show that haplotypes of the two SNPs rs9901734 (C/G) and rs2779248 (T/C) are significantly associated with FENO. Compared with the baseline CT haplotype (frequency 45%), haplotypes CC (31%), GC (7%) and GT (16%) were associated with an increase in FENO levels of approximately 6.2% (95CI 4.1-9.4%; p=4.1E-07), 11.6% (95CI 7.2-17.3%; p=7.8E-07) and 10.5%. (95CI 7.2-15%; p=8.7E-10), respectively. Conclusion: The fine-mapping analyses have enabled us to narrow down the relevant genetic region of the *NOS2* gene and provide a strong foundation for further work to identify causative polymorphisms which may affect FENO in the region by e.g. sequencing. 1971W

Identification of genetic factors for chronic otitis media with effusion using a targeted resequencing approach. *E. Allen[1,2], J. Mychaleckyj[1,3], X. Hou[1], W. Chen[1,3], A. Quinlan[1,2,3], K. Keene[1,3], S. Rich[1,3], K. Daly[5], M. Sale[1,2,4].* 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) Dept Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA; 3) Dept Public Health Sciences, University of Virginia, Charlottesville, VA; 4) Dept Medicine, University of Virginia, Charlottesville, VA; 5) Dept Otolaryngology, University of Minnesota, Minneapolis, MN.

Objectives: We previously conducted the first Genome Wide Association Study (GWAS) of chronic otitis media with effusion and/or recurrent otitis media (COME/ROM), identifying associations at chromosomes 2 and 15. Additionally, our prior linkage analysis identified a region of chromosome 19q as harboring a susceptibility locus for COME/ROM. The aim of this study is to identify the causal variant(s) at these loci using a targeted massively parallel resequencing approach. Methods: Agilent's SureSelect Target Enrichment assay was utilized to create a custom RNA bait library to capture the regions chr 2: 174286992-174307309, chr 15: 90098150-90200735, and chr 19: 55434878-59128983 in 100 affected COME/ROM individuals (10 pools of 10 individuals per pool). The captured regions were sequenced using 100 base pair (bp) paired end reads on Illumina's HiSeq 2000 platform. Sequence data was aligned to the human reference (Build 37) using Novoalign, and genetic variants were identified using SAMtools mpileup, GATK Unified Genotyper, and Freebayes. Results: Sequencing on the HiSeq 2000 yielded 36.9 Gb of sequence data at an average coverage of 175x per individual. After alignment with Novoalign, quality control measures were performed, excluding duplicates to remove potential PCR bias. Three complimentary variant detection methods, mpileup, Unified Genotyper, and Freebayes, were used to analyze the targeted resequencing data. The use of three variant detection methods allows for confirmation of variants identified by more than one program, along with detection of rare variants by Freebayes which incorporates ploidy of each pool into the analysis. Collectivley, the total number of unique variants detected by the three methods is 12,866. Conclusion: We have successfully performed targeted sequencing of three regions (chromosome 2, 15, and 19) that contain genetic variants influencing COME/ROM. The sequence data generated in this study is of high quality with coverage that will allow for discovery of rare variants. Subsequent analyses will include the prioritization of SNPs with the most relevant functional role in disease pathogenesis. Individual level genotyping and replication is required to determine the causal variant(s). These data will facilitate the discovery of rare and novel variants contributing to the susceptibility of chronic otitis media with effusion.

1972T

Genetic polymorphisms of long pentraxin-3 are associated with polypoidal choroidal vasculopathy and exudative age-related macular degeneration. *J.H. Chen[1,2], Y. Yang[1], Y. Zheng[1], C. Xu[1], W. Chen[1], M. Zhang[1], H. Chen[1,2], C.P. Pang[1,2].* 1) 1. Joint Shantou International Eye Center, Shantou University & the Chinese University of Hong Kong, Shantou, China; 2) 2. Department of Ophthalmology and Visual Sciences, the Chinese University of Hong Kong, Hong Kong, China.

Purpose: To evaluate the association of polymorphisms in the vascular inflammation marker gene long pentraxin-3 (*PTX3*) with polypoidal choroidal vasculopathy (PCV) and exudative age-related macular degeneration (AMD). **Methods**: The study subjects were unrelated and included 68 PCV, 78 AMD patients, and 346 controls recruited at Joint Shantou International Eye Center, Shantou, China. Five single nucleotide polymorphisms (SNP) of *PTX3*, including a SNP rs9289983 at the 5′ upstream, three intronic SNPs rs2305619, rs3845978, rs1840680, and a SNP rs4680367 at the 3′ downstream were selected as tag SNPs based on the linkage disequilibrium (LD) data in HapMap Han Chinese. Genotyping was conducted using Taqman assays, and genotype data were analyzed by Haploview version 4.2 and logistic regression. 10000 Permutation tests were used to correct multiple comparisons. **Results**: The homozygous minor genotype of rs1840680 conferred risk to PCV (OR = 2.84, P = 0.009), but no single SNP association with AMD was detected. A LD decay between rs9289983 and rs3845978 was observed in PCV and AMD. There was significant association of the rs9289983-rs3845978 haplotypes with PCV and combined AMD+PCV (P = 0.001 and 0.025 respectively). The A-T haplotype of rs9289983-rs3845978 conferred the highest risk to PCV (OR = 19.44, P = 0.017), and also high risk to AMD (OR = 10.22, P = 0.002). **Conclusions**: The current study for the first time provided evidence that *PTX3* was associated with PCV and AMD, suggesting a common role played by *PTX3* in the two choroidal neovascularization diseases.

1973F

Contribution of the reading disability risk locus DYX2 and dopamine signaling factors ANKK1/DRD2 to language impairment and brain imaging phenotypes. *J. D. Eicher[1], N. R. Powers[1], L. L. Miller[2], K. L. Mueller[3], J. B. Tomblin[3], S. M. Ring[2], J. R. Gruen[1,4], Pediatric Imaging Neurocognition Genetics Study*. 1) Department of Genetics, Yale University, New Haven, CT; 2) School of Social and Community Medicine, University of Bristol, Bristol, Bristol, United Kingdom; 3) Department of Speech Pathology and Audiology, University of Iowa, Iowa City, IA; 4) Departments of Pediatrics and Investigative Medicine, Yale University, New Haven, CT.

Children with Language Impairment (LI) have deficits in verbal language despite otherwise normal development. LI is a common impairment in children (prevalence: 5-8%) and is frequently comorbid with reading disability (RD)=munexpected difficulty in reading despite adequate opportunity and instruction=mwith 50% of children with LI also developing RD. Past studies have identified genes on the DYX2 locus, including KIAA0319 and DCDC2, as conferring risk to RD. Our lab also recently identified prenatal nicotine exposure as a potential risk factor for both RD and LI, suggesting that nicotine-related pathways may contribute to language development. The overall aims of this study are to determine whether DYX2 and nicotine dependence (ND) genes contribute to language deficits and how these genes may impact structural brain imaging phenotypes. We genotyped 209 SNPs designed to capture common variation in the DYX2 locus, and 31 variants in ND genes (e.g. ANKK1, CHRNA4) in subjects from the Avon Longitudinal Study of Parents and Children (ALSPAC) (n=5579). We tested single marker and haplotype associations of DYX2/ND variants, and then replicated significant SNPs in an independent cohort (Iowa LI) (n=428). Replicated variants were then interrogated using genetic and MRI data from the Pediatric Imaging, Neurocognitive, Genetics (PING) study (n=839). We observed associations of DYX2 genes, including KIAA0319, DCDC2, THEM2, and C6orf62, in ALSPAC (p<0.0004). Associations were also seen in ND genes ANKK1/DRD2 (p<0.0004). These associations with DYX2 and ANKK1 were replicated in the Iowa LI cohort (p<0.006). Variation in ANKK1 was associated with differences in occipital lobe volume (p=0.025). KIAA0319 variants were found to show differences in volumetric asymmetry in inferior temporoparietal and postcentral cortexes (p=0.0007), while DCDC2 variants associated with differences in cortical thickness in various brain regions of interest (p=0.0007). We found associations of DYX2 and ANKK1/DRD2 with LI and language performance with these variants also associating with structural imaging phenotypes. Our investigation demonstrates the influence of DYX2 and nicotine pathways on core language processes and suggests that they contribute to language deficits seen in distinct neurobehavioral disorders.

1974W

The Maternal Folate Hydrolase Gene Polymorphism Is Associated with Neural Tube Defects in a High-risk Chinese Population. *J. Guo, JH. Wang, H. Xie, HZ. Zhao, F. Wang, C. Liu, L. Wang, XL. Lu, YH. Bao, JZ. Zou, GL. Wang, B. Niu, T. Zhang.* Capital Institute of Pediatrics, Beijing, China.

Folate hydrolase 1 (FOLH1) gene encodes intestinal folate hydrolase, which regulates intestinal absorption of dietary folate. Previous studies on the association between polymorphisms rs202676 and rs61886492 and the risk of neural tube defects (NTDs) were inconclusive. A case-control study of women with NTD-affected pregnancies (n=160) and controls (n=320) was conducted in the Chinese population of Lvliang, a high-risk area for NTDs. Prior to performing the experiments, this study was reviewed and approved by the ethic evaluation committee of Capital Institute of Pediatrics, Beijing, China. We genotyped the polymorphic sites rs202676 and rs61886492 and assessed maternal plasma folate and total homocysteine (tHcy). Our results showed that in case group, plasma folate concentrations was 18% lower compared with control group (8.32nmol/l vs 6.79nmol/l, p=0.033) and tHcy concentrations was 17% higher (10.47μmol/l vs 12.65μmol/l, p=0.047). Almost all samples had the rs61886492 GG genotype (99.78%). The result showed that the frequency of GG genotype in rs202676 was significantly higher in group with multiple NTDs than controls (p = 0.030, OR = 2.157, 95% CI, 1.06-4.38). The multiple NTD group showed significantly higher maternal plasma concentrations of tHcy(10.47μmol/l vs 13.96μmol/l, p= 0.024). The GG genotype of rs202676 had a lower maternal folate and higher tHcy concentrations than other genotypes with no significant differences. The result of structural prediction indicated this variation may change the spatial structure of the protein. These results suggest that the maternal polymorphism rs202676 was a potential risk factor for multiple NTDs in this Chinese population. The allele G may affect maternal plasma folate and tHcy concentration. Jin Guo and Jianhua Wang contributed equally to this manuscript. Correspondence: Ting Zhang and Bo Niu.

1975T

Association study of NPR3 polymorphisms with aspirin exacerbated respiratory disease. *J.H. Kim[1], B.L. Park[2], C.S. Park[3], H.D. Shin[1,2].* 1) Sogang Unoversity, Seoul, South Korea; 2) SNP Genetics, Inc., Seoul, South Korea; 3) Soonchunhyang University Bucheon Hospital, Bucheon, South Korea.

Aspirin exacerbated respiratory disease (AERD) is a clinical syndrome characterized by persistent and severe inflammation of the upper and lower respiratory tracts when taken with non-steroidal anti-inflammatory drugs (NSAIDs) including aspirin. Natriuretic peptides have been implicated in modulating asthma and inflammation. Among natriuretic peptide receptors (NPRs), NPR3 has recently been highlighted to have a role in blood pressure. To investigate the association between NPR3 polymorphisms and AERD, a total of 17 common single nucleotide polymorphisms (SNPs), with minor allele frequency (MAF) over 0.05, were genotyped in 163 AERD and 429 aspirin-tolerant asthma (ATA) subjects in a Korean population. Regression analysis showed no associations between NPR3 polymorphisms and FEV1 decline after aspirin provocation in asthmatics (P > 0.05). However, logistic analysis revealed that NPR3 polymorphisms and haplotypes might be potential risk factors for the development of AERD (P = 0.006-0.03). Despite the needs for replications in large cohorts and further functional evaluations, our preliminary findings suggest that NPR3 polymorphisms might be associated with aspirin hypersensitivity in asthma.

1976F

Identification of DNA variants in 11 candidate genes for developmental dyslexia by next generation sequencing. *H. Matsson[1], E. Tiraboschi[1], M. Huss[2], J. Noppola-Hemmi[3], H. Lyytinen[4], P.H.T. Leppanen[5], N. Neuhoff[6], A. Warnke[7], G. Schulte-Körne[8], M.M. Nöthen[9], J. Schumacher[10], M. Peyrard-Janvid[1], J. Kere[1,2,11].* 1) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 2) Science for Life Laboratory, Karolinska Institutet, Solna, Sweden; 3) Division of Child Neurology, Department of Gynecology and Pediatrics, Jorvi Hospital, University Central Hospital, Espoo, Finland; 4) Department of Psychology and Child Research Center, University of Jyväskylä, Jyväskylä, Finland; 5) Department of Psychology, University of Jyväskylä, Jyväskylä, Finland; 6) Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University of Munich, Munich, Germany; 7) Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University of Wuerzburg, Wuerzburg, Germany; 8) Department of Child and Adolescent Psychiatry and Psychotherapy, University of Marburg, Marburg, Germany; 9) Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 10) Institute of Human Genetics, University of Bonn, Bonn, Germany; 11) Department of Medical Genetics, Biomedicum, University of Helsinki, Helsinki, Finland.

Developmental dyslexia is present in 5-10% of the population. Dyslexia manifests with specific reading problems despite normal learning opportunities, intellectual ability and independently of socio-economical status. Previous studies have shown a large genetic burden for dyslexia and at least 10 genetic loci are described. A handful of genes, DCDC2, DYX1C1, KIAA0319, MRPL19, C2orf3 and ROBO1, show significant association replicated in several independent samples. Genome-wide association studies have not been fruitful, probably due to limited power and the exclusion of rare variants. An in-depth analysis of candidate genes in order to find causative variants has not yet been reported. Previously, we used genomic DNA from 100 selected Finnish dyslexics in 10 pools with the aim to identify and analyse all single nucleotide variants (SNVs) in exons of the dyslexia candidate genes C2orf3, CYP19A1, DCDC2, DIP2A, DYX1C1, KIAA0319, MRPL19, PCNT, PRMT2, ROBO1 and S100B. The enrichment was designed to capture 96% of all protein coding and UTR sequences. After next generation sequencing by SOLiD 4, we predicted 350 novel and known SNVs using the CRISP algorithm. Here, we re-sequenced 90% of all individuals using SOLiD 5500 resulting in 271 known SNPs of which 236 SNPs (of 259 totally) overlapped with our first run. For verification, we selected 111 SNVs for Sequenom genotyping in DNA from the same 100 dyslexics and in additional samples consisting of German and Finnish cases/controls and families with dyslexia. The family samples included at least one affected proband and both parents of 153 families (156 affected) and 252 families (419 affected) from Finland and Germany, respectively. Additionally, 92/67 cases/controls of Finnish origin were included. We excluded SNPs with success rate <95% and individuals with >25% missing genotypes. Analysis of single allele association is currently on-going. By using deep sequencing, we can overcome limitations of traditional DNA genotyping for the identification of rare and novel DNA variation. In this study we also screen, for the first time, the PCNT, DIP2A, S100B and PRMT2 genes contained in a 21q22.3 deletion and co-segregating with dyslexia in a father and three sons, and believe that we will identify the gene(s) for dyslexia on chromosome 21. We expect our set of verified SNVs to aid future genotyping efforts and to increase our understanding of the DNA variants contributing to an increased risk for dyslexia.

Sequencing of *IL10* in Behçet's disease patients. *I. Sousa[1,2], J.M. Xavier[1,2], N. Rei[1,2], F. Barcelos[3], P. Abrantes[1,2], J. Vedes[4], G. Jesus[5], M. Salgado[6], F. Fontes[7], J.V. Patto[3], J. Crespo[8], S.A. Oliveira[1,2].* 1) Instituto de Medicina Molecular/ Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Instituto Português de Reumatologia, Lisboa, Portugal; 4) Hospital de Sousa Martins, Guarda, Portugal; 5) Hospital Infante D. Pedro, Aveiro, Portugal; 6) Hospital Pediátrico de Coimbra, Coimbra, Portugal; 7) Hospital Curry Cabral, Lisboa, Portugal; 8) Hospitais da Universidade de Coimbra, Coimbra, Portugal.

Behçet's disease (BD) is a chronic inflammatory disorder classified as a vasculitis, and may involve several organs, such as skin, mucocutaneous membranes (oral and genital aphtae), eyes, joints, lungs, gastrointestinal and central nervous systems. Common variants in *IL10* have been recently associated with BD in two independent genome-wide association studies (GWAS) in the Turkish and Japanese populations and replicated by our group in an Iranian dataset. Despite the GWAS success in identifying single nucleotide polymorphisms (SNPs) that contribute to some complex diseases, the majority of genetic variants contributing to disease susceptibility are yet to be discovered. In fact, it has been argued that these variants are not likely to be captured in current GWAS that focuses on common SNPs. Sequencing enables the identification of new rare variants of small/moderate effect and/or mutations that can be related to the BD phenotype, which in turn promise to help explain the missing heritability after the GWAS era.

50 Portuguese cases with BD were sequenced using the traditional Sanger sequencing for the entire *IL10* open reading frame, including also 1Kb upstream and downstream of *IL10*. Additionally, two conserved regions located in the *IL10* promoter were also sequenced.

We identified so far 24 known single nucleotide variants (SNVs) in our sample with minor allele frequencies (MAF) ranging from 0.01 to 0.40, and three new SNVs in our BD cases. These new SNVs were present in a heterozygous state. One of these new variants is located at intron 3 and was detected in two individuals while the other two are located in the promoter region and were identified in one individual each. The absence of these three novel variants has been confirmed in 50 healthy Portuguese individuals and genotyping of 100 additional healthy Portuguese controls is ongoing to assess if these SNVs are specific of Behçet's disease patients or if they are rare variants not yet reported. Genotyping of these three new variants will also be performed in 300 Iranian BD patients and controls to investigate if they are specific to Portuguese BD patients.

1978T

Variants of XBP1 are associated with vitiligo in the presence of autoimmunity. *R.G. Tarlé[1,2], L.M. Nascimento[2], C.C.S. De Castro[1,2], R.I. Werneck[3], V.M. Fava[1], M.T. Mira[1,3].* 1) Group for Advanced Molecular Investigation, Medical School, Pontifical Catholic University of Paraná, Curitiba, Paraná, Brazil Rua Imaculada Conceição, 1155. Curitiba, Paraná, Brazil.80215-901; 2) Department of Dermatology, Santa Casa de Misericórdia Hospital, Pontifical Catholic University of Paraná, Curitiba, Brazil; 3) School of Health and Biosciences, Pontifical Catholic University of Paraná, Curitiba, Brazil.

Vitiligo is a chronic, multifactorial disease clinically characterized by depigmentation of segments of the skin. Genetic studies have shown familial aggregation of cases of vitiligo, following a non-Mendelian pattern, and different strategies of genetic analysis have resulted in the description of several genes associated with the disease. Interestingly, a number of these genes have also been associated with autoimmune diseases that often co-occur with vitiligo. Chromosome 22q12 has been described as a generalized vitiligo susceptibility locus in Chinese families. A follow-up study resulted in epidemiological and functional data implicating variant rs2269577 of the XBP1 gene located at 22q12 in the control of susceptibility to vitiligo. The observation has been replicated later in a Caucasian population sample. The goal of our study was to advance on the understanding of the nature of the association between vitiligo and XBP1 variants, by (i) replicating the association signal using an independent, family-based population sample, and (ii) investigating the impact of autoimmune co-morbidities over the observed association. Our study was performed using a Southern Brazilian population sample of 596 individuals distributed in 212 trios composed by an affected child and both parents. Unbiased selection of markers was performed in order to capture the entire information of the XBP1 locus. Family based association analysis resulted in positive evidence for association between marker rs2239815 and vitiligo (p=0.04), and a trend towards association with rs2269577 (p=0,09), with the two SNPs in strong linkage disequilibrium (r2=91). A second, stratified analysis revealed that the association signal between vitiligo with rs2269577 (p=0.007) and rs2239815 (p= 0.01) was concentrated in the sub-sample of 42 and 45 trios, respectively, presenting autoimmune co-morbidity. XBP1 encodes a transcription factor that regulates the expression of MHC class II genes. Variants of XBP1 have been associated with Chron's disease and ulcerative colitis. Our results support the hypothesis that at least certain forms of vitiligo are of autoimmune nature; it also suggests the existence of a common mechanism of genetic control shared by a group of autoimmune diseases.

1979F

Genetic association of SLE with CD247 (CD3ζ). *M. Martins[1,2], A.H. Williams[3], M. Alarcon-Riquelme[4], J.M. Anaya[5], S.C. Bae[6], S.A. Boackle[7], L.A. Criswell[8], G.S. Gilkeson[9], D.L. Kamen[9], C.O. Jacob[10], J.A. James[4], J.A. Kelly[4], K.L. Moser[4], R.H. Scofield[4], R.P. Kimberly[11], J.C. Edberg[11], L.M. Vila[12], M. Petri[13], R. Ramsey-Goldman[14], M.E. Comeau[3], J. Ziegler[3], M.C. Marion[3], J.T. Merrill[4], T.B. Niewold[15], B.P. Tsao[16], B.I. Freedman[3], S.B. Glenn[4], J.B. Harley[4], C.D. Langefeld[3], C. Fesel[2].* 1) Neurologic Unit of Clinical Investigation (UNIC), Instituto de Medicina Molecular (IMM), Lisbon, Lisbon, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Wake Forest University School of Medicine, Winston-Salem, NC, USA; 4) Oklahoma Medical Research Foundation, Oklahoma City, OK, USA; 5) Universidad del Rosario, Bogota, Colombia; 6) Hanyang University Hospital for Rheumatic Diseases, Seoul, Korea; 7) University of Colorado Denver School of Medicine, Aurora, CO, USA; 8) Department of Medicine, University of California, San Francisco, CA, USA; 9) Department of Medicine, Medical University of South Carolina, USA; 10) University of Southern California School of Medicine, Los Angeles, CA, USA; 11) Department of Medicine, University of Alabama, Birmingham, USA; 12) University of Puerto Rico Medical Sciences Campus, San Juan, Puerto Rico; 13) Johns Hopkins University School of Medicine, Baltimore, MD, USA; 14) Northwestern University, Feinberg School of Medicine, Chicago, IL, USA; 15) University of Chicago, Section of Rheumatology, Chicago, IL, USA; 16) Department of Medicine, University of California, Los Angeles, USA.

Downregulation and replacement of the CD3z chain, leading to altered TCR signaling, is a known characteristic of T-cells in SLE patients. However, genetic variation in the CD247 locus that encodes CD3ζ is so far not well documented for association with SLE. Independent replication of association findings is clearly necessary to validate the most significant results in independent and large datasets. Our aim was to test the association of the gene encoding the CD247 (CD3ζ) molecule previously identified as a Systemic Lupus Erythematosus (SLE) risk factor in functional and association studies. 44 contiguous SNPs in CD247 were typed in 8,922 SLE patients and 8,077 controls from four ethnically distinct populations. Population stratification was assessed using a panel of 347 ancestral-informative markers. The strongest associations of CD247 with SLE were found in the Asian samples (11 SNPs in intron 1, $4.99x10\text{-}4<p<4.15x10\text{-}2$). Imputation analysis showed evidence of association ($p<0.005$) at additional 5 SNPs. Examination of haplotypes within the Asian samples identified a five-marker haplotype (rs12141731-rs2949655-rs16859085-rs12144621-rs858554; G-G-A-G-A) that exceeded single SNPs in significance. Cross-ethnic meta-analysis assuming an additive genetic model and adjusted for population proportions showed a significant association after Bonferroni correction for multiple testing, with rs704848 being the most associated single SNP. Our study independently confirmed and extended the association between SLE and CD247. These associations give new directions to understand the molecular mechanisms of disease and to pursue new therapeutic targets.

1980W

Estrogen receptor beta genetic variants are associated with intraocular pressure elevation in women. *F. Mabuchi[1], Y. Sakurada[1], K. Kashiwagi[1], Z. Yamagata[2], H. Iijima[1], S. Tsukahara[1].* 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Yamanashi, Japan.

Purpose: We previously reported that the estrogen receptor beta (*ESR2*) genetic variant was associated with an intraocular pressure (IOP) elevation in female patients with primary open-angle glaucoma (POAG). However, the association between the *ESR2* genetic variant and the maximum IOP was identified for only 1 genetic variant (rs1256031). The aim of this study was to confirm the association between the *ESR2* genetic variants and the IOP in women.

Methods: Eight single nucleotide polymorphisms (SNPs) covering the *ESR2* whole region (rs1256031, rs4986938, rs1256049, rs1273916, rs1256120, rs928554, rs1256059, and rs944461) were genotyped in 326 Japanese female patients, including 205 patients with POAG and 121 patients without glaucoma. The participants were divided to the normal (IOP < 20mmHg, n = 190) and high (IOP ≥ 20mmHg, n = 136) IOP groups. The allele frequency differences between normal and high IOP groups were estimated using the Fisher's exact test. In addition, a logistic regression model was used to study the effects of the 8 genotyped SNPs alleles to compare the normal IOP group with the high IOP group adjusted for age and refractive error. Linkage disequilibrium among 8 genotyped SNPs to compare the normal IOP group with the high IOP group was evaluated using the Haploview program.

Results: There were significant differences in the allele frequencies of 4 SNPs (rs928554, rs944461, rs1256059, and rs1256031) between the normal and high IOP groups. (P = 0.012, P = 0.023, P = 0.012, and P = 0.0006 respectively, Fisher's exact test) An increased risks of high IOP were confirmed with the risk alleles of these 4 SNPs (P = 0.0019 to 0.031, odds ratio 1.43 to 1.67) by logistic regression analysis adjusted for age and refractive error. These 4 SNPs showed significant association were in high linkage disequilibrium, based on the findings obtained using the Haploview program.

Conclusions: This study confirmed that the *ESR2* genetic variants were associated with IOP elevation in women.

1981T

Expression of Alternatively Spliced Transcripts of MAP2K4 Gene in Rheumatoid Arthritis. *K. Shchetynsky, M. Ronninger, L. Padyukov.* Rheumatology Unit, Department of Medicine Solna, Karolinska Institutet./ Karolinska University Hospital, Stockholm, Sweden.

BACKGROUND: MAP2K4 gene encodes a mitogen activated protein kinase kinase 4 (MKK4), important for optimal activation of JNK1-3 and p38 - the two members of the MAP kinase family previously implicated in several rheumatic diseases, including rheumatoid arthritis (RA). Recently, MAP2K4 locus has been identified as being in statistical interaction with the major risk factor for RA - HLA-DRB1 shared epitope (SE) - in patients with anti-citrullinated protein antibody (ACPA). In this study we explore the variety of alternatively-spliced transcripts for MAP2K4 gene and investigate differential expression profile and phenotype associations of MAP2K4 splice variants in RA patients and healthy individuals. **METHODS:** We performed an exploratory study to detect novel splice variants of MAP2K4 in total RNA from human peripheral blood cells (PBCs). Variants of interest were amplified by conventional PCR and cloned using bacterial expression systems; sequence data were obtained for selected variants. The relative expression of MAP2K4 transcripts was accessed by TaqMan real-time PCR in PBCs from 44 RA patients and 44 controls of Caucasian ancestry and analyzed against available genotypic and phenotypic data. **RESULTS:** We detected a novel splice variant of human MAP2K4, lacking one of the exons, which form the catalytic domain of MKK4. The MAP2K4 splice forms were differentially expressed in PBCs from 88 RA cases and controls. Additionally, within the group of RA patients, a correlation was observed between MAP2K4 variants expression and phenotypical data for ACPA, rheumatoid factor, and SE. **CONCLUSIONS:** We described a novel splice variant of human MAP2K4, which may be potentially translated as a MKK4 isoform, prompting further functional studies. Our results show differential expression of the canonical and alternatively spliced MAP2K4 mRNAs in peripheral blood of RA patients compared to healthy controls. The expression ratio of two studied MAP2K4 transcripts may also reflect other genetic and phenotypic features of RA. These data imply that MAP2K4 splicing and expression profile may be associated with RA pathogenesis and should be assessed as a potential biomarker.

1982F

RNA-SEQ survey of human lymphoid and myeloid cells - a resource for identifying causal genes in validated immune-mediated disease loci. *S. Foisy[1], C. Beauchamp[1], A. Alikashani[1], F. Latour[1], M. Ladouceur[1], S. Lessage[2,3], J.D Rioux[1,2].* 1) Montreal Heart Institute, Montreal, Canada; 2) Faculte de Medecine, Universite de Montreal; 3) Centre de recherche, Hopital Maisonneuve-Rosemont.

In the last few years we have witnessed an explosion in the number of validated loci for complex diseases, in large part due to the success of genome-wide association studies (GWAS). This success has been most notable for immune mediated diseases where >200 genetic risk factors have been discovered, some that are phenotype-specific and others that are common to more than one disease. The unbiased nature of GWAS has led to the discovery of biological pathways not suspected to play a role in disease pathogenesis, such as the ATG16L1 and IRGM loci and autophagy in Crohn's disease (CD). Although this progress has been significant, for many of these loci we do not have identified the causal gene. While targeted sequencing of genes within validated loci has begun to help identify the causal gene(s), complementary approaches are clearly necessary. As importantly, for most risk loci we only have very rudimentary functional information (or none at all) on the genes within associated regions. In order to unravel the role played by the different genes from each region in disease pathogenesis (disease mechanism) it is critical to place the newly discovered genes in their proper biological context; more specifically, classify them within functional pathways in a cell-specific and environmental context. We hypothesize that disease-causing genes within risk loci are involved in a limited number of biological pathways that are key to the development of disease and will likely play a role in different immune cell subpopulations. Importantly, cells of the immune system are highly specialized and thus knowing the patterns of expression can provide significant insights into their potential functional role. We therefore are building a survey of global gene expression in circulating immune cells (of lymphoid and myeloid origin), isolated by fluorescence-activated cell sorting (FACS) from healthy and diseased individuals. The resulting RNA-SEQ sequence data allow us to: (1) identify all genes expressed in a given cell type; (2) identify putative new exons, isoforms and new genes; and (3) observe if any of the genes in the associated loci are differentially expressed in normal and/or diseased cells. We will present the approach and results from nine different cell types purified from eight different healthy individuals.

1983W

Preliminary data suggest an upstream IRX1 sequence variant identified in a family with kyphoscoliosis disrupts the wild-type expression pattern in zebrafish. *C.M. Justice[1], K. Bishop[2], B. Carrington[2], P. Cruz[3], K. Swindle[4], R. Sood[2], N.H. Miller[4], A.F. Wilson[1], NISC Comparative Sequencing Program.* 1) Genometrics Section, IDRB, NHGRI, NIH, Baltimore, MD; 2) Zebrafish Core, GMBB, NHGRI, NIH, Bethesda, MD; 3) NISC, NHGRI, NIH, Rockville, MD; 4) University of Colorado, The Children's Hospital, Denver, CO.

When idiopathic scoliosis, a structural lateral curvature of the spine ≥ 10;dg in individuals who are otherwise phenotypically normal, is associated with an increase in the normal thoracic kyphosis in the sagittal plane (≥ 40;dg), the condition is referred to as kyphoscoliosis. A previous model-independent linkage analysis of 7 families (53 individuals) with ≥ 2 family members with kyphoscoliosis identified candidate regions on 2q22, 5p15, 13q and 17q11, and analyses of single nucleotide polymorphism (SNP) markers narrowed the region on 5p15 to 3.5 Mb. This region contains only 3 genes, IRX1, IRX2 and IRX4, all members the Iroquois (IRX) gene family that codes for homeoproteins. The most significant linkage peak was in IRX1. The exons from IRX1, IRX2 and IRX4 were sequenced in all 53 individuals, but no functional sequence changes were identified. In this study, the highly conserved non-coding regions (HCNRs) 500 kb upstream and downstream from IRX1, IRX2 and IRX4 were sequenced in these 53 individuals in search of cis-regulatory elements. Quantitative association analysis revealed several SNPs with p-values < 0.01. The allele of 9 sequence variants (SVs; 2 of them novel) differed from the reference allele in a heterozygous state in 6 of 7 affected individuals in one family, and did not differ from the reference allele in all other individuals genotyped. One of these SVs is in a HCNR that functions as an enhancer in mice (enhancer.lbl.gov) and is 413 kb upstream from IRX1. We observed this SV in a heterozygous state (C/T) in 1 out of 90 controls. In order to determine if variation at this SV causes functional changes in vivo, an HCNR surrounding this SV (198 bp in size) was identified, amplified and cloned into a zebrafish enhancer detector (ZED) vector for Danio rerio transgenesis with the wild-type allele (C), the T allele, and the A allele reported by 1000 Genomes (MAF = 0.008). Preliminary data using transient transgenesis showed that the wild-type (C) allele drove strong expression in the midbrain and along the neural tube, while the fragments with the T and A alleles did not show a consistent definite expression pattern. We are in the process of generating stable transgenic lines for each allele. Our preliminary data suggest that sequence variation in a 198 bp HCNR disrupts the wild-type expression pattern in zebrafish and may be involved in the expression of kyphoscoliosis in humans.

Phenotypic analysis of peptidylarginine deiminase type 4 knockout mice. *A. Suzuki[1], Y. Kochi[1], H. Shoda[2], K. Fujio[2], E. Kanno[1], T. Sawada[3], R. Yamada[1, 4], K. Yamamoto[1, 2].* 1) Ctr for Genomic Med., RIKEN, Yokohama City, Japan; 2) Department of Allergy and Rheumatology, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Department of Rheumatology, Tokyo Medical University, Tokyo, Japan; 4) Center for Genomic Medicine, Kyoto University, Kyoto, Japan.

Rheumatoid arthritis (RA) is well-known as an autoimmune disease and is a chronic inflammatory disorder characterized by the destruction of multiple joints. Many genome wide association studies were performed and multiple RA-susceptibility loci and autoimmune-susceptibility loci have been identified. These studies suggested that multiple genes and its functions were related with disease causing and development. Previouly, peptidylariginine deiminase type 4 (PADI4) was identified as a susceptibility gene for RA in a Japanese population by case-control association study (Ref 1). PADI4 is a member of the PADI gene family and converts arginine residue (peptidylarginine) to citrulline residue (peptidylcitrulline). PADI4 is highly expressed in bone marrow, macrophages, neutrophils and monocyte. Peptidylcitrulline is an interesting molecule in RA, because it is an antigen of ACPA and only PADs (translated protein from PADI genes) can provide peptidylcitrullines, via modification of protein substrates. To evaluate the importance of PADI4 gene in the progression of RA, we generated Padi4 -/- DBA1J mice by speed congenic method. We used Padi4-/- mice to show that PAD4 is affected to development and progression of collagen induced arthritis (CIA), well known as an RA model animal. Padi4-/- DBA1Jand WT mice were immunized with bovine type II collagen (CII) for CIA. Clinical disease score was significantly reduced. In Padi4-/- mice sera, the concentrations of serum anti-CII IgM, IgG, and TNF-alpha also decreased significantly rather than in WT mice. Resulting from these studies, we suggested that Padi4 enhanced collagen-initiated inflammatory responses. 1) Suzuki, A. et al Nat. Genet.34, 395-402 (2003).

1985F

Rs34424835 PGRN gene variation a possible modifier in Frontotemporal lobar degeneration (FTLD). *E. Vitale[1], A. Iuliano[1,2], A. Polverino[1], V. Agosti[2,5], C. Vitale[2,5], A. Postiglione[4], P. Sorrentino[3], S. Pappatà[6], G. Milan[3], G. Sorrentino[2,5].* 1) Cybernetics, CNR, Pozzuoli (NA), Italy; 2) Department of Institutional Studies Parthenope University Naples, Italy; 3) Geriatric Center "Frullone" ASL Napoli 1 - Naples, Italy; 4) Department of Clinical and Experimental Medicine, University of Naples "Federico II", Naples, Italy; 5) Neurological Institute for Diagnosis and Treatment Hermitage Capodimonte, Naples, Italy; 6) Institute of Bioimaging and Biostructures, CNR, Naples, italy.

Frontotemporal lobar degeneration (FTLD) is a degenerative disorder of the frontal and anterior temporal lobes and is a common form of dementia affecting individuals younger than 65 years. The syndrome is clinically characterized by initial behavioral disturbances, followed by cognitive decline, leading to dementia and death within a median of 7 years from symptom onset. FTLD usually segregates as an autosomal dominant trait. Linkage studies have identified several chromosomal loci and a number of genes, including microtubule-associated protein tau (MAPT), progranulin (PGRN) in about 50% of familial cases, valosin containing protein (VCP) and charged multivesicular body protein 2B (CHMP2B) to be associated with the disease. Recently a large hexanucleotide (GGGGCC) repeat expansion was identified in the first intron of C9ORF72 on chromosome 9p21 in amyotrophic lateral sclerosis-frontotemporal dementia (ALS-FTD). This locus contains one of the last major unidentified autosomal-dominant genes underlying these common neurodegenerative diseases. FTLD has three clinical subtypes: fontotemporal dementia (FTD), progressive nonfluent aphasia (PNFA), and semantic dementia (SD). We have identified a large pedigree from the Southern Italy region segregating FTLD in 11 patients over three generation with a dominant inheritance pattern. The family includes members with different clinical phenotypes manifesting neuropsychological and behavioral heterogeneity. These comprise a behavioral variant of frontotemporal dementia (bvFTD) with apathetic or disinhibited behavioral syndrome and executive, attentional and memory impairment. Parkinsonism and epilepsy are also common during the illness but rarely at onset. We screened the 5 remaining patients who were still alive from the 11 identified members of the pedigree for MAPT and PGRN genes. Specifically, we sequenced all exons, exon-intron boundaries and 5′ and 3′ regulatory regions in search for mutations in the exon areas. We determined that three out of the five patients revealed the RS34424835 variation on PGRN exon 5, which could be associated with disease severity and early onset expression. This suggests that PGRN may be a possible modifier of the course of the disease in FTLD patients.

1986W

Proteomic analysis of Shank3 over-expression in mouse neuroblastoma cultures showed differentially expressed proteins involved in glycolysis, cytoskeleton,biosynthetic and cell cycle processes,and ubiquitin-proteasome. *N. Zhong[1,2,3,4], W. Ju[1], W. Yan[2,3], X-L. Zhao[2,3], E.C. Jenkins[1], W.T. Brown[1], Y. Wang[4], J.H. Zhou[2,3].* 1) Dept. Human Genetics, New York State Institute for Basic Research in DD, Staten Island, NY; 2) Peking University Center of Medical Genetics, Beijing, China; 3) Dept. Medical Genetics, Peking University Health Science Center, Beijing, China; 4) Shanghai Municipal Children's Hospital Affiliated to Shanghai Jiaotong University, Shanghai, China.

Shank proteins assemble glutamate receptors with their intracellular signaling apparatus and cytoskeleton at the postsynaptic density. Shank expression is sufficient to induce functional dendritic spine synapses in aspiny neurons. In our study, overexpression of Shank3 in neuroblastoma cell cultures (Neuro-2A) followed by two-dimensional difference gel electrophoresis (2D-DIGE) analysis provided further understanding on the mechanism of Shank3 in forming spines and facilitating synaptogenesis. In the Shank3 overexpression cell model, proteins related to glycolysis that is a metabolic process to produce energy like ATP, such as Pkm2, Pgk1, Eno1, Pgam1 and Ldha were found to be up-regulated. Cytoskeleton protein γ-actin, tubulin alpha-1B and microtubule organizing center Cct5 were also found to be up-regulated, which further confirms that Shank3 can recruit cytoskeleton and microtubule protein to increase the number of spines. Another up-regulated protein was Phgdh that is involved in the L-serine biosynthetic and cell cycle processes. A down-regulated protein, Uchl1, was found, which is related to the ubiquitin-proteasome system. Our proteomic study of Shank3 over-expression in mouse Neuro-2A cells has shed new light on its function in spinogenesis and synaptogenesis.

1987T

Transcription Factor Profile of a Single Nucleotide Polymorphism located -224 A/G in Neuropeptide Receptor Y2 (NPY2R) Gene in Predisposition to Hypertension. *E. Albino[1], K. Sugimoto[2], T. Katsuya[2], A. Deng[3], J. Dutil[1].* 1) Department of Biochemistry, Ponce School of Medicine and Health Sciences, Ponce, PR; 2) Department of Geriatric Medicine, Osaka University Graduate School of Medicine, Suita, Osaka, Japan; 3) Molecular Genetics Laboratory, University of Montreal Research Center CHUM, Montreal, QC, Canada.

Essential hypertension (HTN) is a multifactorial disease under the complex regulation of genetic and environmental factors. Previous work in animal models and human populations identified Neuropeptide Y receptor 2 (NPY2R) as a candidate gene for HTN. In two independent Japanese populations, the GG genotype single nucleotide polymorphism (SNP) located 224 bp upstream of the transcription start site was associated with an increased risk of HTN. The aim of this study was to assess the effect of the A to G substitution in the promoter of NPY2R on the expression levels of this gene and to predict the transcription factors (TF) binding sites for each sequence using TESS and the ENCODE project. Human Embryonic Kidney (HEK) 293 cells were transfected with pGL4.10 DNA constructs containing the promoter of NPY2R with either an A or G nucleotide at the -224 position upstream of the luciferase reporter gene. Interestingly, the luciferase activity induced by the NPY2R promoter with the G allele in position -224 was reduced by 34% compared to the promoter containing an A in that position. Differences in the level of relative Luciferase activity between A and G constructs were statistically significant ($p < 0.01$). When sequences were analyzed using TESS, the two sequences containing either an A or a G were predicted to bind different transcription factors. The ENCODE project proposes CTCF as a functional element that binds to the -224 SNP in the NPY2R gene. The data provide strong evidence for a functional role of NPY2R in genetic predisposition to HTN.

1988F

Functional assessment of CRY2 Type II Diabetes variants using a targeted circadian Luciferase assay. *J. Lane[1, 2, 3], A. Tare[1,3], C. Cowan[4], R. Saxena[1,2,3].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Department of Anesthesia, Massachusetts General Hospital, Boston, MA, 02114, USA; 3) The Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 4) Department of Stem Cell and Regenerative Biology, Harvard University, Cambridge, Massachusetts 02138, USA.

Genome-wide association studies revealed a link between Type II Diabetes and variation in circadian genes. SNPs in CRY2, a core component of the circadian clock, are associated with increased fasting glucose levels and risk of Type II Diabetes. The means by which variation in CRY2 influences diabetes risk is currently unknown. In this study we utilize genome editing to create the first targeted human circadian Luciferase reporter. Mediated by the targeting specificity of TALENs, we introduce a Luciferase cassette into the cellular genome in the stop codon of PER2. We then utilized the circadian Luciferase cell lines to monitor changes to the cellular phase, amplitude, and period induced by CRY2 variants. We further utilized genome editing to assess the functional consequence of CRY2 variation in an isogenic cell line. Homologous recombination was used to create cell line homozygous for the major allele, minor allele, or heterozygous at causal CRY2 SNPs. Moving forward we will monitor the Luciferase output of CRY2 variant cell lines over 6 days to assess changes to circadian phase, period, or amplitude.

Modification of Endothelial Progenitor Cell Recruitment by Tyrosinase in Oxygen Induced Retinopathy. *B.E. O'Bryhim[1,2], R.S. White[1], R.C.A. Symons[1,2].* 1) Department of Ophthalmology, University of Kansas Medical Center, Kansas City, KS; 2) Molecular and Integrative Physiology, University of Kansas Medical Center, Kansas City, KS.

Retinopathy of prematurity (ROP) is a common cause of blindness in children. In addition to gestational age at delivery, birth weight, and overuse of oxygen in the nursery, genetic factors are thought to play a role in disease development. Similarly, inbred strains of mice revascularize at different rates after hyperoxic vascular damage in the murine oxygen-induced retinopathy (OIR) model of ROP. A mapping cross between albino BALB/cByJ mice, which revascularize more rapidly, and pigmented C57BL/6ByJ mice, which revascularize more slowly, identified a quantitative trait locus (QTL) on chromosome 7 (LOD = 8.9). This study also found that albino F_2 mice are more resistant to OIR than their pigmented littermates. Albinism in the cross is caused by homozygous loss of function of tyrosinase, which is located within the identified QTL. Thus we sought to determine whether tyrosinase may be one of the quantitative trait genes (QTGs) underlying the QTL, and whether control of recruitment of endothelial progenitor cells (EPCs) into the retina may be part of the mechanism by which tyrosinase influences avascular area. The *B6(Cg)-Tyr$^{c\text{-}2J}$*/J ("*c-2J*") mouse strain is derived from the C57BL/6J strain with a spontaneous loss of function mutation in tyrosinase that has been bred to homozygosity. Pups from both strains were exposed to the OIR model and their retinal avascular area was measured immediately upon return to normoxia on P12, or four days later on P16. Tyrosinase-deficient *c-2J* mice were found to revascularize more rapidly after return to normoxia than do C57BL/6J mice ($p=2.5x10^{-10}$). *c-2J* mice were also found to recruit more AC133$^+$ endothelial progenitor cells (EPCs) to perivascular areas in the retina ($p < 0.01$), which was associated with greater numbers of CD45$^-$/AC133$^+$/CD34$^+$ EPCs both in the circulation ($p = 0.02$) and in the bone marrow ($p = 0.02$). As these strains are genetically identical except for a loss of function mutation in tyrosinase, the data confirm the role of tyrosinase as a QTG in OIR revascularization and suggest that tyrosinase activity modifies angiogenic repair mechanisms, including EPC recruitment.

Understanding The Impact of Body Mass Index and Associated SNPs on Serum Metabolites. *J. Kumar[1], R. Karlsson[1], J. Prince[1], M. Hong[1], C. Broeckling[2], J. Prenni[2,3], E. Ingelsson[1], F. Wiklund[1].* 1) Dept of Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm, Sweden; 2) Proteomics and Metabolomics Facility, Colorado State University, Fort Collins, USA; 3) Department of Biochemistry and Molecular Biology, Colorado State University, Fort Collins, USA.

Introduction: Obesity is a serious public health problem of increasing prevalence causing various disorders such as type 2 diabetes and cardiovascular diseases. Body mass index (BMI) is used as a surrogate marker to assess obesity. The present study integrating metabolomics and genomics data was performed to assess the impact of BMI and associated single nucleotide polymorphisms (SNPs) identified in another GWAS on various serum metabolites. Materials and Methods: Two case-control studies consisting of prostate cancer patients (diagnosed between year 2001 and 2003) and controls (all men) were recruited utilizing Swedish Cancer Register and Swedish Population Register, respectively. The first study had 275 cases and 182 controls (discovery group), while the second had 514 cases only (replication group). Ultra performance liquid chromatography coupled with mass spectrometry was employed for metabolic profiling in these individuals. Linear regression analysis was performed for metabolite peaks testing their association with BMI and adjusting for potential confounding factors like seasonal variation, storage, handling and fasting time, age and prostate cancer status. Significant metabolites were further studied for their association with BMI-associated SNPs. Results: Metabolite concentrations were log-transformed to normalize their distribution. 203 metabolite peaks were found to be significantly associated with BMI in the discovery stage (P<8.15x10-6, correcting for multiple testing), and of those, eighteen could be robustly replicated in the replication sample (P<2.4x10-4). Eighteen peaks corresponded to nine unique metabolites and four were putatively identified from these nine. The four peaks represented monoacylglycerol, diacylglycerol and two phosphocholine (34 and 36C). A total of 21 SNPs available (out of 32 from Speliotes EK et al Nat Genet 2010;42(11):937-48) associated with BMI or related traits were tested for their association with four putatively identified peaks. No SNP reached statistical significance after adjusting for multiple correction. Conclusion: In conclusion, four identified fatty acids and five unknown metabolites in an untargeted metabolomics experiment were found to be significantly associated with BMI. BMI associated genetic variants did not show association with these serum metabolites. Further analysis is underway to explore the impact of BMI on ratios between various metabolites to dissect obesity-related metabolic pathways.

1991F

Biological processes of human development and genome-wide linkage disequilibrium. *I. Culminskaya, A. Kulminski, A. Yashin.* Duke University, Durham, NC.

Recently (Age, 2012, PMID: 22282054) we documented two clusters of extensive intra- and inter-chromosomal linkage disequilibrium (LD) in the Framingham Heart Study families comprised of parents and their children. Both clusters were observed on two independent arrays, the Gene-Chip Human Mapping 500K (250K Sty and 250K Nsp) and the 50K Human Gene Focused arrays. The LD has unlikely been generated by stochasticity, population or family structure, or mis-genotyping. Alleles of SNPs in strong inter-chromosomal LD were inherited as an intact unit which was associated with complex heritable phenotype of premature death. The analyses suggested involvement of a large number of genes for SNPs in LD in fundamental biological processes in an organism. In this presentation we report on significant enrichment of genes for SNPs in genome-wide intra- and inter-chromosomal LD in Gene Ontology (GO) biological processes. Annotation of two (partly overlapping) clusters of SNPs in LD (r^2=0.02-1.0) with minor allele frequency 0.009-0.499 results in two reference sets of 1697 and 4637 genes. These gene sets have been categorized into biological processes using ArrayTrack and GoMiner classification tools. The evidences on enrichment have been validated by comparison of the results for the reference sets with those for randomly generated sets of the same number of genes. The analyses using the Fisher's exact test and the False Discovery Rate (FDR) approach reveal highly significant enrichment of GO terms linked to developmental process. The strongest associations have been observed for nervous system development/axonogenesis/axon guidance ($p<10^{-4}$, $FDR<10^{-4}$ for each category) for both sets and for cardiovascular system development for the largest set ($p\leq10^{-4}$, $FDR\leq0.007$). Both gene sets showed highly significant enrichment of biological processes which are tightly linked with neural development including cell differentiation, morphogenesis, adhesion, projection organization, signaling, chemotaxis ($p<10^{-4}$, $FDR<10^{-4}$ for each category). The results provide evidences on significant role of functional interactions and major biological processes of human development in generation of genome-wide LD.

1992W

The Type 1 Diabetes gene *CLEC16A* functions in NK cells to restrain secretory functions including cytokine release and cytotoxicity. *M. Bakay, R. Pandey, A. Mohamed-Hadley, P. Banerjee, H. Hakonasron.* Center for Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA.

Type 1 Diabetes (T1D) is a multifactorial childhood disease with a strong genetic component. Several GWAS have shown association of CLEC16A with T1D and other autoimmune diseases. CLEC16A has homology domains that identify it a C-type lectin, however the protein has no known function yet. The highest levels of CLEC16A expression were identified in NK cells, which are required for development of T1D. Therefore, defining the role of CLEC16A in NK cells may provide insight into the pathogenesis of T1D. We reported previously that protective alleles of CLEC16A [A/A] are associated with higher levels of mRNA. Thus, we hypothesize that CLEC16A functions in NK cells to restrain cytotoxicity after activation.

To address the role of CLEC16A in T1D we studied consequences of knockdown and overexpression of this protein in NK cell lines. Using a retroviral expression system, we created NK cell lines stably over-expressing the canonical form of CLEC16A with a GFP expression reporter. Expression was validated by Western blot analysis. Cytotoxicity assay revealed decreased killing in YTS-CLEC16A overexpression cell line. Optimized protocols using CLEC16A siRNA mediated knockdown enabled a 70% reduction in CLEC16A protein levels in NK cells and also resulted in a 35% increase in cytotoxicity compared to cells receiving control siRNA. Search for association partners of CLEC16A by immunoprecipitation (IP) pull down using anti-CLEC16A antibody (AB) with following protein sequencing revealed alpha-Centractin (ACTR1A) - an actin-related protein. ACTR1A encodes a 43kD subunit of dynactin, a macromolecular complex. Dynactin binds to both microtubules and cytoplasmic dynein and is involved in a diverse array of cellular functions, including ER-to-Golgi transport, the centripetal movement of lysosomes and endosomes. Preliminary microscopy data shows CLEC16A co-localization with tubulin. CLEC16A association with alpha-Centractin suggests it may impact on the process of translocation of the microtubule-organizing center (MTOC) and focused secretion of effector molecules to the synapse in NK cells. Our results indicate that CLEC16A may serve a role in restraining NK cell function. Studies are in progress to validate the proposed mechanism. Our improved understanding of this novel T1D-linked gene and the protein it codes may lead to new therapeutic interventions aimed at T1D prevention.

1993T

Influence of Ethnicity with Type 2 Diabetes in Association of UCP2 -866G/A, PGC1α (Gly 482 Ser) and SIRT1 -1400T/C Polymorphisms in North Indian Punjabi Population Groups. *A. Bhanwer[1], N. Kaul[1,2], R.N.K. Bamezai[2].* 1) HUMAN GENETICS, GURU NANAK DEV UNIVERSITY, AMRITSAR, PUNJAB, India; 2) National Centre of Applied Human Genetics, School of Life Science, Jawaharlal Nehru University, New Delhi 110067, India.

Type 2 Diabetes (T2D) involves complex disorder involving defects in insulin secretion and insulin action pathways. Several studies have reported the role of UCP2 -866G/A, PGC1α (Gly482Ser) and SIRT1 -1400T/C polymorphisms in development of T2D involving insulin secretary pathway. The association of above mentioned polymorphisms was investigated in 859 Type 2 diabetics and 954 normal healthy control subjects from Punjab. India exhibits different ethnic population structure comprising various caste groups existing from ages which have mostly remained endogamous even today. Thus to assess the impact of ethnicity, independent association of these polymorphisms was carried out in Brahmins, Backward Castes (BCs), Jat Sikhs, Khatris, Rajputs, Banias and Scheduled Castes (SCs). Binary logistic regression was applied to test the association after adjusting for age, sex and BMI. In total population UCP2-866AA [p=0.0001, OR-1.46 (1.2-1.78)] and PGC1α AA [p=0.000002, OR-1.46 (1.20-1.78)] significantly provided risk. Caste based stratification revealed UCP2 -866 A/ AA provided risk only in Banias [p=0.000004, OR- 4.7×10-6, OR- 4 (2-5.9)], BCs [p=0.01, OR- 2.2 (1.1-4.2)] and SCs [p=0.0001, OR- 1.9 (1.16-3.2)] while PGC1α A/AA provided risk in BCs [p=0.0003, OR- 3.3 (1.7-5.5)], Jat Sikhs [p=0.0003, OR- 1.7 (1.20-2.4)] and Khatris [p=0.03, 1.51 (1.02- 2.27)]. SIRT1 -1400T/C polymorphism does not seem to provide risk either in the total population or in any of the caste groups except Khatris [p=0.004, OR- 2.4 (1.3-4.5)] of Punjab. The present investigation concludes that differential pattern of association of polymorphisms is observed for different caste groups, suggesting the putative role of ethnicity. Thus, for risk calculation and proper medical intervention, knowledge of the ethnicity and nature of variation in risk factors needs serious attention.

1994F

Allelic variation in the protein stability of HLA shapes genetic association of HLA with type 1 diabetes. *H. Miyadera[1], J. Ohashi[2], K. Tokunaga[1].* 1) Department of Human Genetics, The University of Tokyo, Tokyo, Japan; 2) Molecular and Genetic Epidemiology, University of Tsukuba, Japan.

Among many disease-susceptibility loci, human leukocyte antigens (HLA) provide the most strong genetic risk for autoimmune and variety of immune disorders, but underlying mechanisms have not been fully explained by allelic variations of HLA in antigen presentation. We hypothesized that functional variation of HLA other than peptide binding spectrum might contribute to genetic association of HLA with autoimmune diseases. In the present study, we analyzed the stability of HLA class II (HLA-DQ) proteins and their contribution to genetic risk for type 1 diabetes (T1D). Through a newly devised protein stability assay, we measured the stability of DQ proteins that are encoded by major DQ alleles, including 10 alleles of DQA1 and 14 alleles of DQB1, that generate 140 different DQA1-DQB1 heterodimer combinations in total. We demonstrate over 100-fold of stability differences among DQ allele products. Polymorphic residues that regulate the intrinsic stability of DQ protein have been also identified through mutagenesis and by utilizing protein crystal data of DQ. Using case-control data for T1D of European and East Asian populations, we identified that DQ protein stability contributes to the genetic risk/protection for T1D. These findings indicate that the stability of HLA protein determines genetic risk for T1D. Our study provides a novel mechanistic basis of HLA associations with autoimmune diseases.

1995W

Functional characterization of gene regulatory elements associated with epilepsy. *R.Y. Birnbaum[1,2], Y. Zhang[3], C. Wei[3], N. Ahituv[1,2].* 1) Bioengineering & Therapeutic Sci, UCSF, San Francisco, CA; 2) Institute for Human Genetics, University of California San Francisco, San Francisco, CA, USA; 3) DOE Joint Genome Institute, Walnut Creek, CA, USA.

Epilepsy is a complex and heterogeneous disease making it difficult to precisely diagnose and provide effective treatments. Infantile spasms (IS) is an uncommon epilepsy syndrome that typically begins in infancy and is associated with ventral forebrain development and forebrain synapse function. Since a major cause of complex diseases, such as epilepsy, could be mutations in gene regulatory elements, we set out to identify these elements in the mouse forebrain at embryonic day 16.5 (E16.5) which could be associated with IS. Using chromatin immuneprecipitation followed by deep sequencing (ChIP-Seq) with enhancer marks (H3K27ac, p300, RNA-Poll2), we identified active enhancer candidates in the mouse E16.5 forebrain. In addition, using chromatin interaction analysis followed by paired-end tag sequencing (ChIA-PET) on mouse E16.5 forebrain we are determining the physical interactions of these enhancer candidates and IS-associated genes. Several enhancer candidates are then tested for their enhancer activity using both zebrafish and mouse transgenic enhancer assays. Our results provide a novel dataset of neuronal enhancers that could control the spatiotemporal expression of IS-associated genes. These sequences pose as great candidates for mutation analyses in IS patients, a screen which we are currently carrying out. Combined, this work will shed light on neuronal gene regulation in general and identify novel genomic regions that could be involved in epilepsy pathogenesis and brain development.

1996T

Differential Behavior of Splice Isoforms of the Asthma Susceptibility Gene *DENND1B*. *M.E. March, P.M.A. Sleiman, C. Hou, J. Bradfield, C.E. Kim, E.C. Frackleton, J.T. Glessner, H. Hakonarson.* Children's Hospital of Philadelphia, Philadelphia, PA.

Asthma is a chronic inflammatory condition of the lungs, characterized by excessive responsiveness of the lungs to stimuli, in the forms of infections, allergens, and environmental irritants. Currently, 22.9 million Americans suffer from asthma, and the prevalence has increased dramatically since 1980. Asthma is the leading chronic illness in U.S. children, with 6.8 million affected in 2006. Twin studies have shown that there is a genetic element to asthma susceptibility (with heritability of the condition estimated at between 0.36 and 0.77), but only a fraction of the heritability is explained with previously identified loci. In a genome wide association screen (GWAS), we identified *DENND1B* as a novel asthma susceptibility locus. At least two splicing isoforms of *DENND1B* exist, and we have attempted to examine the relative activities of these isoforms. Overexpression of the short or long isoform of DENND1B in 293T cells had opposite effects on the response of those cells to TNFα stimulation, with the long isoform enhancing the response and the short isoform diminishing it. Confocal microscopy with GFP-tagged versions of the DENND1B isoforms have revealed that the long isoform displays some localization to the plasma membrane of expressing cells, while the short isoform appears entirely cytoplasmic. Biochemical cell fractionation experiments show similar localization patterns. The DENND1B proteins possess a domain (the conserved DENN domain) that functions as a guanonucleotide exchange factor for the small GTPase Rab35. The DENN domain is identical in the long and short isoforms, however we find that the short isoform more readily interacts with Rab35, particularly when the Rab35 is expressed in a mammalian cell system. We are currently determining which of the splice isoforms is expressed in different cell types and to what relative levels, and if splicing is altered in individuals with either asthma-susceptible or -resistant genotypes.

Targeted resequencing identifies secretion-defective variants of decoy receptor 3 in pediatric-onset inflammatory bowel disease. *C. J. Cardinale[1], S. Panossian[1], F. Wang[1], E. C. Frackelton[1], C. E. Kim[1], F. D. Mentch[1], R. M. Chiavacci[1], K. E. Kachelries[2,3], R. Pandey[1], S. F. A. Grant[1,3], R. N. Baldassano[2,3], H. Hakonarson[1,3].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Gastroenterology, Hepatology, and Nutrition, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, Perelman School of Medicine at the University of Pennsylvania.

Tumor necrosis factor receptor superfamily *(TNFRSF)6B* encodes a secreted protein, decoy receptor (DcR)3, that binds to and neutralizes pro-inflammatory cytokines of the tumor necrosis factor superfamily, namely TL1A, LIGHT, and Fas ligand. Genome-wide association studies have implicated common variation in the *TNFRSF6B* locus in inflammatory bowel disease, particularly of the pediatric Crohn's type. We sought to enhance the evidence of DcR3′s role in pediatric IBD by identifying rare missense mutations with functional significance through Sanger sequencing in 592 cases. The variants uncovered in the cases went on to be assessed functionally for their ability to be secreted from 293T cells and to bind to their ligands. Our pediatric IBD cohort harbored 12 missense variants at the *TNFRSF6B* locus, with six affecting secretion of DcR3 from cultured cells. The load of missense variation in the TNFRSF6B gene was significantly enriched in our Caucasian Crohn's subclass (2%) than in publically-available control (0.34%) exomes (p less than 4.2×10^{-4}; odds ratio = 5.9;). Furthermore, the 3 missense variants that are seen in both cases and controls are all secretors, pointing to the fact that the majority of the variants exclusive to the cases are non-secretors, revealing a non-random pattern of mutation. As personalized medicine targeting IBD emerges, sequencing or genotyping of variants at the TNFRSF6B locus should be included. Development of therapeutics targeting this pathway is a priority for future research.

1998W

A population-based immunologic phenotype study for the identification of high risk individuals to childhood infectious diseases in Vietnam. *R. Miyahara[1], L.M. Yoshida[1], H. Nakamura[1], K. Takahashi[1], X.M. Trinh[2], D.A. Dang[3], N.H. Tran[4], K. Ariyoshi[1], M. Yasunami[1].* 1) Institute of Tropical Medicine, Nagasaki University, Nagasaki, Japan; 2) Pasteur Institute Nha Trang, Nha Trang, Vietnam; 3) National Institute of Hygiene and Epidemiology (NIHE), Hanoi, Vietnam; 4) Pasteur Institute Ho Chi Minh City, Ho Chi Minh City, Vietnam.

The susceptibility to certain infectious disease is attributable to augmented responsiveness to pathogen-derived stimulus in part. Accordingly, properties of host defense mechanism evaluated by *ex vivo* cellular response to stimuli mimicking microbial pathogens would be eligible to infer the individual predisposition to infectious diseases. A population-based study of such immune-related phenotype analysis was conducted. A cohort of 1,999 infants who were born at Khanh Hoa Provincial Hospital, a principal medical facility in Nha Trang, central Vietnam, was set from May 2009 to May 2010 to observe the incidence of severe infectious diseases. In the present study, the registered children were invited to medical check in the month they became two year old. Venous blood samples were collected upon their guardians' informed consent. A simple procedure of small-scale whole blood culture was established to obtain a reliable result under the situation where the amount of samples and manpower are limited; a fresh whole blood was mixed with cell culture medium at 1:9 ratio and incubated at 37 degree in the presence of LPS (a ligand for TLR4), Pam3CSK4 (a ligand for TLR2-TLR1 heterodimer) or other chemical stimulants of immune-competent cells. Twenty hours later, the cells were collected for RNA preparation. The levels of induced mRNA expression of cytokine genes such as IL8 and those of internal standards such as GAPDH were quantified by real time RT-PCR assay. Among 124 children examined in May and June 2011, 118 gave complete quantification data set. 11, 17, 2 and 11 of 118 children had a history of admission to the hospital because of respiratory infection, gastrointestinal infection, dengue virus infection and undefined fever, respectively, and the rest 77 were free of severe infectious disease in their first two years of life. Induction of IL8 mRNA expression by LPS (p=0.0075) and Pam3CSK4 (p=0.0095) was higher in children with a history of respiratory infection in comparison to those without history of admission by infectious disease, mainly because of lower basal expression level of IL8 in children with a history of respiratory infection (p=0.0069). Receiver-operator curve analysis indicated that the basal lower IL8 expression was a good predictor for admission by respiratory infection in this cohort (AUC=0.71). The results suggested that impaired regulation of inflammatory cytokine gene predisposes children to severe infectious diseases.

1999T

A birth-cohort study for the identification of genetic risk for childhood infectious diseases in Vietnam. *M. Yasunami[1], L.M. Yoshida[1], R. Miyahara[1], H. Nakamura[1], K. Takahashi[1], H. Moriuchi[2], D.A. Dang[3], N.H. Tran[4], K. Ariyoshi[1].* 1) Clinical Medicine, Inst Trop Med, Nagasaki Univ, Nagasaki, Japan; 2) Medical Virology, Grad Sch of Biomedical Sciences, Nagasaki Univ, Nagasaki, Japan; 3) National Institute of Hygiene and Epidemiology (NIHE), Hanoi, Vietnam; 4) Pasteur Institute Ho Chi Minh City, Ho Chi Minh City, Vietnam.

It has been generally accepted that individual susceptibility to certain infectious diseases are genetically determined in part. A large amount of information about association between common genetic variations and incidence and/or severity of infectious disease has been accumulated mainly as results of retrospective case-control studies. We conducted a prospective study to evaluate the predictive power of common genetic variation in candidate genes for infections/infectious diseases by employing all the newborn babies in a single core medical facility in urban-rural mixed area in Vietnam. A total of 1999 full-term newborns without apparent abnormality at birth, who were from 16 communes of Nha Trang city and adjacent suburban area which cover approximately one third of total population of the province, were enrolled from the beginning of May 2009 to the end of May 2010. Umbilical cord blood was collected to obtain plasma samples for testing congenital infections and nucleated cells for genomic DNA. All the children were provided with standard national immunization program composed with DPT+HBV and BCG after birth. Occurrence of severe illness was captured at the core hospital. Upon the admission to the hospital, the presence of certain viral and bacterial genome in the pharyngeal swab was examined for the patients with respiratory infection. All the participants were invited to medical check in their two year-old birth month and venous blood was collected after obtaining their guardians' informed consent. HLA and other 750 selected candidate genetic variations were genotyped by using genomic DNA isolated from cord blood. Venous blood collected at two year-medical check was used for blood cell count, plasma separation for antibody tests for HBV and other microbial pathogens, and blood cell phenotype analysis. Frequencies of HLA-A, -B and -DRB1 alleles of 1985 children of the cohort whose DNA was available were similar to those of healthy individuals of northern and southern Vietnam reported by Hoa (2007) and Nguyen (2008), respectively. During two years of observation, 33% of children had a history of severe disease which required hospitalization once or more, and incidence of severe respiratory infection was 86.9/1000 person;lbyears The effect of HLA and other polymorphisms on the incidence of severe respiratory infection and other infectious diseases was evaluated.

2000F

Variant genotypes of PKR1 and PKR2 in patients of recurrent pregnancy loss. *M. Su, L. Wu, P. Kuo.* National Cheng-Kung University Hospital, Tainan City, Taiwan.

Recurrent pregnancy loss (RPL) is a multi-factorial disorder and up to 50% of cases remain undetermined causes after detailed clinical examination. Angiogenesis plays a critical role in early gestation and endocrine gland-derived VEGF (EG-VEGF) is a tissue-specific angiogenesis-associated gene. The role of EG-VEGF and its two receptor genes (PKR1, PKR2) in human early pregnancy was believed to have a direct effect on both endothelial and trophoblastic cells and are likely to play important roles in placentation. We previously found gene polymorphisms of PKR1, PKR2 were significantly associated with human RPL using tag SNP analysis. We now direct sequenced these genes in 100 RPL patients and 100 normal controls, trying to fine map the variation sites that interfere with early pregnancy and further functional validate in vitro studies. We found allele and genotype frequencies of PKR1(I379V) and PKR2(V331M) were significantly higher in the normal controls and may play protective roles in RPL ($p<0.05$). Both variants induced nonsynonymous change of amino acids and located in the intracellular C-terminal domains of G protein-coupled receptors. We further demonstrated PKR1(I379V)- and PKR2(V331M)-overexpressed cell had altered intracellular calcium influx and significantly higher ability of cell invasiveness in both HEK293 and JAR (trophoblast) cell lines. We therefore concluded that PKR1(I379V) and PKR2(V331M) may play protective roles in preventing RPL by altering intracellular calcium signaling and enhancing cell invasion ability.

BCL11A transcription factor is one of the main genetic modifiers of both β-thalassemia and sickle cell anemia phenotypes. It functions as a developmental stage-specific repressor of fetal hemoglobin (HbF) expression, controlling globin switching, both in human and mouse. Several genome-wide association studies (GWAS) have identified a region of about 15 Kb in intron 2 of the *BCL11A* gene containing all variants associated with HbF levels as well as clinical severity of both diseases. Recently we performed a GWAS on 2343 individuals from the SardiNIA project, integrating, by imputation procedure, DNA microarray data and low pass whole-genome sequencing of 826 unrelated individuals. Our analysis revealed that two independent variants in the region, representing the strongest haplotypic signal, fully account for the association observed at this locus. Given that intron 2 shows chromatin signatures of functional genomic elements with a potential regulatory activity, we carried out functional analysis to assess the specific impact of associated variants in gene action. In particular we evaluated whether these SNPs might be themselves the causative variants at this locus or if their surrounding sequence has regulatory features. Furthermore, we conducted expression studies on erythroid cell lines (K562 and HEL) as well as BFU-E cells, isolated at different days of differentiation from 10 patients with β^0-thalassemia, a Mendelian disorder whose phenotype is ameliorated by these two HbF associated variants. To estimate differential expression of *BCL11A* transcripts, we selected a group of 5 patients with a milder phenotype carrying the high HbF levels haplotype, and the remaining 5 with a severe phenotype carrying the low HbF levels haplotype. Preliminary results revealed significant differential expression levels of the *BCL11A* main isoform between the two groups ($p = 0.006$), in BFU-E at day 9 of differentiation. Overall, our results suggest that genetic variants at intron 2 of *BCL11A* play a crucial role in modulating its expression and in turn HbF levels with consequent amelioration of β-thalassemia severity.

2002T

Additional Patients and an Association Study support a Role of SOX9 in CD-ACD-PRS Phenotypic Continuum and in CPO. *M. Quentric[1,2], L. Desmyter[1], M. Ghassibe[1], W. Courtens[3], S. Sox9 has an essential role in chondrogenesis. Nonsense mutations and deletions of Sox9 suggested haploinsufficiency to underly campomelic dysplasia (CD), a rare autosomal dominant disease characterized by campomelia, skeletal defects and Pierre Robin sequence (PRS). Translocations in the 350kb region upstream or downstream of SOX9 were reported in less severe CD patients. Some translocations and deletions further upstream have been identified in patients with acampomelic campomelic dysplasia (ACD) and PRS, suggesting that these three syndromes form a continuum of phenotypes. We report the identification of a translocation 600kb upstream of SOX9 in a patient with classical features of ACD. In parallel, we identified a deletion in a PRS family that overlaps a deletion reported in a patient with the same phenotype. These data and the literature lead us to test whether or not there is a genetic association between the SOX9 locus and cleft palate (CP) and/or PRS. We used three SNPs in a cohort of case-parent trios analyzed using TDT. While two SNPs, tagging a conserved region upstream of SOX9, were not associated, significant over-transmission of an intragenic SNP was detected in the combined CP+PRS cohort ($p=0.026$) and PRS cohort ($p=0.042$), with a relative risk of 0.54 under a dominant model. The association has been replicated in an independent Italian CP-cohort. Our data are in agreement with the hypothesis that removal or disruption of cis-regulatory elements upstream of SOX9 can lead to phenotypes of gradual severity. We show for the first time an association of SOX9 with CP and PRS.

2003F

The impact of amino acid polymorphisms in four genes of the tumor necrosis factor (TNF) and interferon-gamma (IFNG) pathways on BCG-triggered production of TNF. *T. Yu[1], L. de Léséleuc[2], A. Cobat[1], L. Simkin[1], G.F. Black[4], K. Stanley[4], P. van Helden[4], L. Abel[3], A. Alcaïs[3], E.G. Hoal[4], E. Schurr[1].* 1) McGill Centre for the Study of Host Resistance & Dept. of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Institute for Biological Sciences, National Research Council, Ottawa, Canada; 3) Université de Paris Descartes, Necker Medical School, Paris, France; 4) Faculty of Health Sciences, Stellenbosch University, Tygerberg, South Africa.

Tuberculosis (TB) is an infectious disease caused by *Mycobacterium tuberculosis* for which host genetic factors play an important role. Numerous cytokines participate in the immune pathway of TB, including tumor necrosis factor (TNF) and interferon gamma (IFNG). Prior genetic analyses detected four non-synonymous amino acid changes in the following four genes located in IFNG and/or TNF pathway that were significantly associated with BCG (*M. bovis* bacille Calmette-Guérin)-triggered TNF production in South African families: M594I (*STAT2*), N248S (*TLR1*), N75Y (*DNAJA3*) and H712Q (*NFKB1*). Our main research objective is to provide functional validation of these non-synonymous polymorphisms that are associated with TNF production. For this, we first assessed whether the corresponding human genes were modulators of TNF secretion in various *in-vitro* cell assays. The possible allelic influence on biological activity of the corresponding proteins was determined next. Previous study showed that N248S is in complete linkage disequilibrium (LD) with I602S in *TLR1*, which regulates NF-κB signaling and affects the innate immune response to lipopeptides (Hawn *et al*., 2007). This strongly suggests that the association of N248S with TNF production is mediated by I602S. While *DNAJA3* may affect TNF release, we did not observe any allelic impact of N75Y. Preliminary data indicates that H712Q (*NFKB1*) affects p50 conversion, supporting its potential function in NF-κB signaling. The possible allelic impact of H712Q (*NFKB1*) and M594I (*STAT2*) on TNF release is currently under investigation. In conclusion, our study helps to understand the underlying relationships among specific amino acid changes, their biological functions and TNF secretion.

[Purpose] The aims of study are 1) to confirm the association signals of our previous genome-wide association study (GWAS) for rheumatoid arthritis (RA) in Japanese population and 2) to search for disease causing variants in the candidate loci. [Methods] We selected 31 loci that showed moderate associations in the GWAS (2,303 cases and 3,380 controls, $5\times10^{-8}<P<5\times10^{-5}$) and performed replication studies of association using additional Japanese individuals (5,604 cases and 31,982 controls). To identify disease-causing nsSNPs, we sequenced the coding region of candidate genes in RA patients (n=48) and investigated their effects on protein function by NF-κB reporter assays. We next performed allele-specific transcript quantification (ASTQ) analysis by using TaqMan assays to investigate allelic imbalance of expression. In addition, we evaluated regulatory potential of SNPs in the region by *in silico* analyses using genomic and epigenomic databases as well as by *in vitro* analyses using gel-shift assays and reporter assays. [Results] We identified variants in two gene loci that were associated with RA susceptibility (rs2233434 in *NFKBIE*, OR=1.20, $P=1.3\times10^{-15}$; rs3125734 in *RTKN2*, OR= 1.20, $P=4.6\times10^{-9}$). We identified disease-associated nsSNPs (rs2233434 and rs2233433 in *NFKBIE*, rs3125734 and rs61850830 in *RTKN2*), which comprised a single common risk haplotype in each locus. The risk haplotype of *NFKBIE* showed higher NF-κB activity than non-risk haplotype, but no difference was detected in *RTKN2*. In the ASTQ analysis, the risk alleles showed 1.2-fold lower amounts of transcripts in *NFKBIE* and 1.5-fold higher amounts of transcripts in *RTKN2*, suggesting that both gene loci were eQTL. 14 SNPs in *NFKBIE* and 10 SNPs in *RTKN2* were selected as having regulatory potential by the *in silico* analysis, and 9 SNPs showed allelic differences in the gel-shift assays. In the reporter assays, the risk allele of rs2233424 in *NFKBIE* showed enhanced repressor activity, while the risk alleles of rs12248974 and rs61852964 in *RTKN2* displayed more enhancing activity than the non-risk alleles. [Conclusions] SNPs in *NFKBIE* and *RTKN2* genes were significantly associated with RA susceptibility. Through functional analysis, we identified candidate causal SNPs in *NFKBIE* (rs2233434, rs2233433 and rs2233424) and *RTKN2* (rs12248974 and rs61852964). The risk alleles of these SNPs were implicated in the enhancement of NF-κB activity, indicating the importance of this pathway in the etiology.

2005T

Resequencing *ITGAM* reveals two functionally deleterious rare variants in Systemic Lupus Erythematosus cases. *A.L. Roberts[1], E.R.A. Thomas[2], S. Bhosle[2], L. Game[2], O. Obraztsova[1], T.J. Aitman[2], T.J. Vyse[1], B. Rhodes[1].* 1) Dept. of Genetics & Molecular Medicine, King's College London, London, United Kingdom; 2) MRC Clinical Sciences Centre, Imperial College London, London, United Kingdom.

Systemic lupus erythematosus (SLE) is an autoimmune disease with a strong genetic basis. Despite notable gene discoveries in genome-wide association studies there remains a large amount of “missing heritability”, that may be accounted for by rare variants (MAF<1%) which these techniques are underpowered to detect. A genetically associated non-synonymous variant (R77H) in *ITGAM* (CD11b) impairs complement receptor 3 (CR3; CD11b/CD18) function, including the phagocytosis of iC3b-opsonised sheep erythrocytes ($sRBC_{iC3b}$). We screened *ITGAM* in an SLE cohort to identify functionally deleterious rare variants. 24Kb of the *ITGAM* gene, including all 30 exons, was PCR amplified in 75 SLE patients and 95 controls. PCR products were pooled and tagged with unique DNA barcodes using the Parallel Tagged Sequencing protocol and sequenced on the Roche 454 Titanium high-throughput sequencing platform. An average coverage of 105x (896,206 reads) for cases and 35x (542,867 reads) for controls was achieved. Identified variants were confirmed by Sanger sequencing. Two missense mutations were identified - one rare (F941V) and one private (G1145V) - in one patient sample each. Neither variant is found in the 1000 genomes database; F941V is described in 1/6707 chromosomes of European ancestry in the Exome Variant Server database but G1145V is not found. The variants were introduced into pcDNA3.1-*ITGAM* vectors using site-directed mutagenesis. Transfected COS-7 cells were challenged with $sRBC_{iC3b}$, using an identical technique to our published approach for R77H variant studies. We measured the association index (AI = mean number of engaged $sRBC_{iC3b}$/100 COS cells) and phagocytic index (PI = mean number of phagocytosed $sRBC_{iC3b}$/100 COS cells). Comparisons were made by paired t-test. We observed no difference in transfection efficiency (measured by surface expression of CD11b). Neither variant impaired iC3b binding (AI F941V P=0.61; AI G1145V P=0.74). However, both variants significantly impaired phagocytosis (PI F941V P=0.007; PI G1145V P=0.031). Through resequencing a candidate gene, we have identified two rare variants in SLE patients. We observed an under-functioning affect, of similar magnitude to the SLE-associated R77H, on phagocytosis of RBC_{iC3b}. Our work adds confirmatory evidence to the functional importance of CR3 in SLE pathogenesis, and provides a further example of a gene which harbours both rare and common variation predisposing to the same disease.

2006F

***DcR3* Mutations in Systemic Lupus Erythematosus Patients Lead to Enhanced Lymphocyte Proliferation.** *K. Suphapeetiporn[1,2], C. Chokdeemeeboon[2,3], P. Ammarinthnukrowh[2,3], S. Tongkobpetch[2,3], C. Srichomtong[1,2], T. Deekajorndech[1], P. Rianthavorn[1], P. Kingwattanakul[1], Y. Avihingsanon[4], V. Hoven[5], S. Edwards[6], N. Hirankarn[7], V. Systemic lupus erythematosus (SLE) is a multifactorial disorder. Although several of its underlying genes have been identified, many more remain to be discovered. Previous studies suggested that death decoy receptor 3 (DcR3) might play a role in pathogenesis of adult SLE. Here, we found that the serum DcR3 levels of juvenile SLE patients in active state (440.2 ± 169.3 pg/ml) were significantly higher than those in inactive state (181.7± 42.72 pg/ml; p = 0.003) and unaffected controls (65.52 ± 20.66 pg/ml; p = 0.001). This indicated an association between an increased serum DcR3 level and juvenile SLE. We then performed PCR-sequencing of the entire coding regions of *DcR3* in 100 juvenile and 100 adult unrelated SLE patients and found two heterozygous missense mutations (p.T56I and p.H122Y) in two patients. Using surface plasmon resonance assay, we found that the p.T56I mutant had a 2.4 fold greater, whereas the p.H122Y had 0.7 fold lower affinity to FasL than the wild-type DcR3. Although both mutations did not change the activation-induced apoptosis, they statistically significantly increased lymphocyte proliferation more than that of the wild-type. In summary,serum levels of DcR3 are elevated in juvenile SLE patients with active disease. These data demonstrate, for the first time, that polymorphisms in *DcR3* might play an etiologic role in human SLE pathogenesis via regulation of T cell function.

2007W

A *CD14* promoter polymorphism is implicated in tuberculosis susceptibility in a South African population. *M. Möller[1], C. Wagman[1], M. Daya[1], C. Kok[1], L. van der Merwe[2, 3], P.D. van Helden[1], E.G. Hoal[1].* 1) Biomedical Sciences, Stellenbosch University, Cape Town, Western Cape, South Africa; 2) Biostatistics Unit, Medical Research Council, Tygerberg, South Africa; 3) Department of Statistics, University of Western Cape, South Africa.

Tuberculosis is a multi-factorial disease dependent not only on the infectious agent *Mycobacterium tuberculosis*, but also affected by the environment and host genetic factors. The rs2569190 (C-159T) promoter polymorphism in the LPS-binding cell surface molecule CD14 gene (*CD14*) has been reported to be a risk factor for pulmonary tuberculosis in Mexico and Korea and is known to regulate promoter activity of *CD14*. We investigated the role of this polymorphism in tuberculosis susceptibility in a South African population. The variant was genotyped in 398 tuberculosis patients and 394 control individuals in a population-based case-control association study. Individuals carrying the T allele were protected against developing tuberculosis (p = 0.019, OR = 0.77, 95% CI 0.62 - 0.96). We investigated the functional significance of this polymorphism in gene expression experiments using qPCR and reporter gene assays and showed that the TT genotype of rs2569190 results in higher expression of CD14. Our results demonstrate that an association exists between a *CD14* polymorphism and tuberculosis and also affirmed its effect on gene expression.

2008T

Effects of IL9 and IL9 receptor(IL9R)gene polymorphisms on Allergic Rhinitis in Iranian females. *F. Fatahi, H. Khazraee, K. Ghatreh, M. Hashemzadeh.* Biochemistry and Genetic Center, Shahrekord University Of Medical Sciences, Shahrekord, Chaharmahal Va Bakhtiari, Iran.

Background and aims: The development of allergic rhinitis entails a complex interaction between genetic predisposition and environmental exposure to different factors that allergens are the most important. Responding molecules are; chemokines and their receptors, interleukins and their receptors, eosinophil peroxidase and leukotrienes, among others.The interleukin-9 cytokine and its reseptor are emerging as critical players in allergic diseases. This study investigated the association between single-nucleotide polymorphisms(SNP) in IL9 gene (rs2069885,)and IL9R (rs731476) and Rhinitis-related traits among the females in Chaharmahal va Bakhtiari province. Methods: DNA was extracted using standard phenol-chloroform method. The screening of mentioned polymorphisms were performed using PCR-RFLP procedure. A case- control association study was performed(rhinitis group;n=195 and control group;n=190). Chi- square test was performed to compare proportions of subjects with different clinical features among subjects with different genotypes.(All statisticall analyses were performed using SPSS). Result: There was significant association between rs731476 ;IL9R and allergic rhinitis (p=0.004) but no association between rs2069885;IL9 and cited disease between females in cases and controls goups in Chaharmahal va Bakhtiari province was found (p=0.991). Conclusions: Our data indicated that the IL9R may play an important role in the inflammatory response and promoting allergic rhinitis in females and rs 2069885 ;1L9 may not have a role in femals with rhinitis in Chaharmahal va Bakhtiari province. Keywords: Allergic Rhinitis ;polymorphism;Interleukin-9 and IL9R;Association study.

TRIB1 is involved in the susceptibility of non-alcoholic fatty liver disease. S. *Iwamoto, Y. Ishizuka, Y. Kitamura, S. Makishima, S. Boonvisut, K. Nakayama.* Human Genetics, Center for Molecular Medicine, Jichi Medical University, Shimotsuke, Tochigi, Japan.

Tribbles homolog 1 (TRIB1) is the gene associated robustly with plasma triglyceride (TG) and LDL cholesterol level. Moreover, association with myocardial infarction is also repeatedly shown. The hepatic over expression reduced plasma TG and LDL in mice. Conversely, those in TRB1 knockout mice were increased. The Trib1 over expression impaired VLDL production in liver through down regulation of lipogenesis. This study aims to assess the involvement of TRIB1 gene in the development of hepatic steatosis, which is a recently nominated risk factor of cardiovascular diseases. MATERIALS and METHODS: Japanese general population admitted to Hospital of Jichi Medical University for health checkup, 3013 (1623 males and 1390 females), was enrolled in this study with written informed consent as the first genome panel. Hepatic steatosis was diagnosed by the finding of diffuse ultrasonographic bright liver and hepatorenal contrast. The second panel was extracted from large scale Japanese genome bank (J. Med. Genet. 2009;46;370-374) on the condition of the attachment of ultrasonographic data. Genotyping of TRIB1 SNPs was performed by using TaqMan Genotyping Assay Systems and an ABI PRISM 7900 HT Sequence Detection System. The effects of copy numbers of minor alleles of each SNP on hepatic steatosis were assessed by logistic regression models. Age, sex, body mass index (BMI), status of alcohol consumption, and medication for diabetes mellitus were included in multiple linear regression models as covariates. The functional involvement of Trib1 in hepatic lipid storage was assessed by TRIB1 cDNA or shRNA transduction into mice liver via adenovirus vector system. Hepatic TG strage and plasma TG were measured at day4 and day8 after viral administration. RESULTS and DISCUSSION: The Japanese major allele of re17321515, G, correlated with higher plasma TG level (P= 4.8E-4 (panel 1), P=4.6E-6 (panel 2)) and with the ultrasonographic diagnosis of hepatic steatosis (P=0.001 (panel 1), P=0.019 (panel 2), P=3.87E-5 (combined)). The mice enforced the over expression of Trib1 in liver reduced the plasma TG level and the hepatic TG storage. The knockdown vector increased the mice plasma and hepatic TG. These results indicated that the expression level of TRIB1 is involved in the development of non-alcoholic fatty liver disease.

Alleles of a Rapidly-Evolving ETV6 Binding Site in *DCDC2* Confer Risk of Reading and Language Impairment. *N.R. Powers[1], J.D. Eicher[1], F. Butter[3], L.L. Miller[4], S.M. Ring[4], M. Mann[3], J.R. Gruen[1,2].* 1) Genetics Dept, Yale University, New Haven, CT; 2) Pediatrics Dept, Yale University, New Haven, CT; 3) Proteomics and Signal Transduction Dept, Max Planck Institute of Biochemistry, Martinsried, Germany; 4) School of Social and Community Medicine, University of Bristol, Bristol, UK.

Learning disabilities (LDs) are disorders involving a specific deficit in a particular mode of learning, such as reading, writing, math, or speech. The most common LDs involve language=mthe National Institute of Child Health and Development (NICHD) estimates that 15-20% of Americans have a language-based LD, and that the vast majority of these have reading disability (RD), also known as dyslexia. RD is a specific deficiency in ability to process written language. Another common LD, language impairment or LI, is a specific deficiency in ability to process spoken language. Comorbidity between RD and LI is common. Both disorders are substantially genetic, and their inheritance is typical of a complex trait. We here report two risk haplotypes in the RD-associated gene *DCDC2* that associate strongly with an RD and an LI endophenotype ($p = 6.068 \times 10^{-5}$ and $p = 3.98 \times 10^{-4}$, respectively). The haplotype block containing these haplotypes is almost directly adjacent to BV677278, a rapidly-evolving, highly polymorphic, compound short tandem repeat (STR) that we previously showed to associate with RD. Each of the two risk haplotypes is strongly linked to an allele of BV677278; 92% of RD risk haplotype carriers also carry BV677278 allele 5, and 78% of LI risk haplotype carriers also carry BV677278 allele 6. We also showed previously that BV677278 binds a nuclear protein with high specificity, and that it can modulate reporter gene expression from the *DCDC2* promoter in an allele-specific manner. Using stable isotope labeling of amino acids in cell culture (SILAC) based quantitative mass spectrometry, we have now identified the protein as the transcription factor ETV6. We confirmed the ETV6-BV677278 interaction *in vivo* via chromatin immunoprecipitation (ChIP). These data suggest that BV677278 is a regulatory element that influences risk of reading and language impairment. Intriguingly, the two *DCDC2* risk haplotypes interact synergistically with a previously described RD risk haplotype encompassing the 5′ and upstream region of *KIAA0319*, another RD-associated gene within 200kB of *DCDC2* on the chromosome, to adversely affect mean performance on several reading, language, and cognitive measures. These data lend support to the hypothesis that regulatory elements may be largely responsible for the variation seen in complex traits, and to the `phantom heritability' hypothesis, which explains missing heritability as resulting from non-additive gene-gene interactions.

Polymorphisms in phosphatidylethanolamine N-methyltransferase (PEMT) gene associates with obesity and gene expression. *S.K. Das, K.A Langberg, A.K. Mondal, N.K. Sharma.* Internal Medicine-Endocrinology, Wake Forest School of Medicine, Winston-Salem, NC.

Recent studies in animal models have shown a mechanistic link between the alteration of endoplasmic reticulum (ER) phospholipid composition and activation of ER stress in the development of insulin resistance in obesity. Expression of genes involved in phosphatidylcholine (PC) synthesis (*PCYT1A* and *PEMT*) was upregulated, while phosphatidylethanolamine (PE) synthesizing gene (*PCYT2*) was downregulated, leading to high PC/PE ratio in the livers of obese mice. Expression of *PEMT* is increased in adipose of high fat fed mice and is involved in lipid droplet biogenesis during adipocyte differentiation. To understand the role of genes involved in phospholipid biosynthesis in human obesity we have analyzed their expression in adipose and muscle from 170 individuals who spanned a broad range of insulin sensitivity (S_I) and body mass index (BMI). We have investigated the association of SNPs in these genes with obesity and glycaemic traits in large GWA studies. We found positive correlation of % fat mass with expression of *PEMT* (r= 0.46, p= 9.57E-09), *PCYT1A* (r= 0.36, p= 1.09E-05) and *PTDSS2* (r= 0.29, p= 4.72E-04), and negative correlation of *PCYT2* (r= -0.30, p= 4.15E-04) in adipose but not in muscle. Expression of *PEMT* (r = -0.33, p= 1.37E-04) and *PCYT2* (r= 0.34, p= 7.15E-05) in adipose was also correlated with S_I, but the correlation was reduced after adjustment for BMI. SNPs in these genes showed no significant association with glycaemic traits in Caucasian subjects from the MAGIC consortium. Interestingly nine SNPs in *PEMT* gene showed association (p<0.001) with Waist-to-hip ratio (WHR) in a meta-analysis of 77158 Caucasian subjects from the GIANT consortium. The strongest association of WHR was observed with intronic SNP rs4646404 (p= 3.1E-06). To evaluate the role of obesity associated SNPs in regulating the expression of *PEMT* gene in adipose we genotyped four tag-SNPs (including two nsSNPs) in 154 subjects. The SNP rs4646343 in intron1 showed the strongest association with *PEMT* expression (P_{res} = 3.21E-04). *PEMT* expression was higher in obese insulin resistant subjects and allele G of rs4646343 was associated with higher WHR (P= 2.47E-05) in Caucasians and with higher expression of *PEMT*. Significant positive correlation of BMI and % fat mass was observed with expression of *PEMT* in adipocytes but not in the stromal vascular cells of adipose tissue. Thus our study indicates an important function of *PEMT* gene and its regulatory polymorphisms in obesity.

Identification of a *cis* regulatory variant that binds a transcriptional repressor complex including PDX1 at the *JAZF1* type 2 diabetes locus. *M.P Fogarty[1], T.M Panhuis[1,2], S. Vadlamudi[1], M.L. Buchkovich[1], K.L. Mohlke[1].* 1) Dept Genetics, Univ North Carolina, Chapel Hill, NC.Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Zoology, Ohio Wesleyan University, Delaware, OH.

Genome-wide association studies (GWAS) have identified at least fifty genome-wide significant loci associated with type 2 diabetes (T2D). For many of these loci, association signals are localized to non-protein-coding intronic and intergenic regions, and the underlying functional variants and target genes remain unknown. For the T2D association signal in *JAZF1* intron 1, we hypothesized that the underlying risk variants(s) have a *cis* regulatory effect in islets or other T2D-relevant cell types. We prioritized variants for functional follow up studies of transcriptional activity using maps of experimentally-predicted open chromatin regions. All SNPs in strong linkage disequilibrium ($r^2 \geq .8$, 1000 Genomes CEU) with the GWAS index SNP rs849134 and also present in an islet FAIRE peak or DNase peak were tested for evidence of differential transcriptional activity in INS-1-derived 832/13 and MIN6 insulinoma cells. Twelve regions containing T2D-associated variants were tested for enhancer activity, including five located in regions of islet open chromatin. Three regions exhibited enhancer activity, and of these only rs1635852 displayed allelic differences in enhancer activity. The rs1635852 T2D risk allele T showed less transcriptional activity than the non-risk allele C (832/13 P = 7.8 x 10^{-5}, MIN6 P = 1.0 x 10^{-5}). We assessed whether alleles of rs1635852 differentially bind nuclear proteins using electromobility shift assays. The T2D risk allele showed increased binding to protein complexes, suggesting that it functions as part of a transcriptional repressor complex. We applied DNA affinity capture and mass spectrometry to identify factors in the complex and determined that the T allele preferentially binds the pancreatic master regulator PDX1. These data suggest that maps of open chromatin are useful to guide identification of variants with allelic differences in regulatory activity at T2D loci and that rs1635852 in *JAZF1* intron 1 is part of a *cis* regulatory complex that affects transcriptional activity through binding of a protein complex that includes PDX1.

Investigation of mtDNA mutations in non-syndromic hearing loss patients in Fars province, Iran, using PCR- RFLP procedure. *S. Heydari Sodjani[1], M. Montazer Zohori[2], E. Farokhi[3], A. Shirmardi[4], G. Banitalebi[3], S. Reisi[3], M. Abolhasani[3], M. Akbari[2], M. Hashemzadeh[3].* 1) Department of Genetics, shahrekord university, Shahrekord, chaharmahal va bakhtiyari, Iran; 2) Department of Medical Genetics, School of Medical Sciences, Tarbiat Modares University, Tehran, I. R. Iran; 3) Cellular and Molecular Research Center, Shrekord University of Medical Sciences, Shrekord, I. R. Iran; 4) Welfare Organization of Chaharmahal va Bakhtiari Province, Shrekord, I. R. Iran.

Abstract: Background: Hearing loss is a sensorineural disorder that affecting 1 in 500 newborns. It happens due to genetic or environmental causes, or both. More than 60% of cases are inherited and 80% of hereditary cases are non-syndrome with autosomal recessive inheritance. In the present study we investigated the frequency of mtDNA A1555G, A3243 and A7445G mutations in patients in Fars province. Materials and Methods: Seventy two non-syndromic hearing impaired subjects were studied. DNA was extracted using standard phenol-chloroform method. The screening of the mitochondrial gene mutations were performed by PCR-RFLP procedure. Finally, the possible mutations were confirmed by direct sequencing. Results: None of the A1555G, A3243G and A7445G mutations were detected in this study. However, destroying a MTTL1 restriction site for the investigation of A3243G mutation, revealed a G3316A allelic variant in 1.4% of deaf subjects studied. Coclusion: Our data indicated that the mitochondrial A1555G, A3243G and A7445G mutations have any role in deaf subjects studied.

Genetic and environmental predictors of serum vitamin D3 levels in African Americans. *R.A. Kittles[1,2,3], K. Batai[2], E. Shah[2], M. Ruden[2], J. Newsome[2], S. Agate[2], A. Murphy[4], HY. Chen[3].* 1) Dept Med, M/C 767, Univ Illinois at Chicago, Chicago, IL; 2) Institute of Human Genetics, University of Illinois at Chicago, Chicago, IL; 3) Division of Epidemiology and Biostatistics, School of Public Health, University of Illinois at Chicago, Chicago, IL; 4) Department of Urology, Feinberg School of Medicine, Northwestern University, Chicago, IL.

Vitamin D deficiency is more common among African Americans (AAs) than European Americans (EAs). Vitamin D has been shown to inhibit growth and induce apoptosis in several cancers. Also epidemiologic evidence has linked vitamin D status to cardiovascular disease, diabetes, and autoimmune disease. Several GWAS studies in EAs have found vitamin D metabolic pathway gene variants associated with serum 25(OH)D level, but few of these SNPs have been replicated in AAs. It has been difficult to replicate theses SNPs mainly because serum 25(OH)D levels are influenced by skin color, genetic ancestry, age, BMI, and environmental factors such as sunlight exposure and diet. Also studies fail to look at the interaction of these genetic and environmental factors. Here, we test if vitamin D pathway gene SNPs, genetic ancestry, sunlight (UV) exposure, skin color, season, geography, and education were associated with serum 25(OH)D concentration and/or vitamin D deficiency in AAs. Thirty-seven variants in *GC, DHCR7/NADSYN1, VDR, CYP2R1, CYP27A1, CYP27B1, CYP3A4, and CYP24A1*, including 19 GWAS identified variants were genotyped in 1,000 AAs from Washington, D.C. and Chicago. We performed linear and logistic regression analyses including genetic ancestry, age, skin color as measured using reflectance (M-index), season of blood draw, vitamin D intake, education, and geographic region. Thirteen SNPs (10 of which were GWAS identified; four in *GC*, four in *CYP2R1*, and two in *DHCR7/NADSYN1*) were associated with serum 25(OH)D levels and/or vitamin D deficiency. The *CYP2R1* SNP, rs2060793 revealed the strongest association (P<0.001) with serum 25(OH)D levels. Three SNPs, including the *VDR* SNP rs11568820 (*Cdx2*), were also significantly associated in our full model. Significant interactions were observed between several genetic and environmental factors. Among darker pigmented AAs (M-index >58.6), rs12800438 in *DHCR7/NADSYN1*, had the strongest association (P=0.004) with the risk of vitamin D deficiency (<20 ng/ml) (OR=0.40; CI 0.22-0.75). Our study replicated the findings from previous GWAS in EAs and found that many of the same variants were associated with serum 25(OH)D and/or vitamin D deficiency in AAs if skin color, vitamin D intake, and UV exposure were included in the model. Our findings provide insights on the biological and environmental modifiers of serum vitamin D3 and will help guide future studies on the role of vitamin D in high risk populations such as AAs.

2015F

Vitamin D receptor ChIP-seq in human CD4+ T-cells and association with multiple sclerosis. *A. Handel[1,2], G. Disanto[1,2], G. Giovannoni[2], G. Ebers[1], S. Ramagopalan[1,2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Blizard Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, London, United Kingdom.

Vitamin D insufficiency has been associated with risk of multiple sclerosis (MS) in prospective case-control studies. We recently demonstrated an association between MS genetic risk loci and vitamin D receptor (VDR) binding in a lymphoblastoid cell line. However, no studies have examined the relationship between MS risk loci, chromatin architecture, gene expression and VDR binding in primary immune cells. We extracted CD4+ T-cells from peripheral blood in nine healthy Caucasian individuals by MACS. We studied genome-wide VDR binding using chromatin immunoprecipitation and massively parallel DNA sequencing (ChIP-seq). RNA-seq was undertaken on a subset of these samples. Vitamin D levels for each sample were determined by LC/MS. VDR binding peaks were determined by ZInba. MS risk SNPs were obtained from the Wellcome Trust Case Control Corsortium (Sawcer et al. Nature 2012). Overlap with MS risk intervals (100kb either side of each SNP), DNase I hypersensitivity sites (from UCSC) and RNA-seq peaks was performed in the Genomic Hyperbrowser. The number of VDR binding sites was far higher in the 5 individuals with 25-hydroxyvitamin D levels >75 nmol/L than in the 4 individuals with levels <75 nmol/L. There was significant enrichment for VDR binding near MS risk loci, DNase I hypersensitivity peaks and RNA-seq expression peaks. There was significant overlap between VDR binding in primary CD4+ T-cells and our previously published lymphoblastoid cell line VDR ChIP-seq. There is good a priori evidence for an epidemiological association between vitamin D levels and MS susceptibility. Our VDR ChIP-seq data support a potential role for vitamin D in gene-environment interactions determining MS risk. VDR-binding is associated with underlying chromatin architecture. Importantly the association between VDR binding sites and MS risk loci is observed both in cell lines and in primary CD4+ T-cells.

2016W

Gene-Gene Interaction in disease association for systemic lupus erythematosus in Asian populations. *J. Yang[1], Y. Zhang[1], X. Zhang[2], Y. Lau[1], W. Yang[1].* 1) University of Hong Kong, Pokfulam, Hong Kong; 2) Anhui Medical University, Hefei, China.

Systemic lupus erythematosus (SLE) is characterized as an autoimmune disorder with unclear etiology. Genome-wide association study (GWAS) has been proved to be a powerful approach for uncovering association between genetic variation and disease risk. Single locus analysis is widely used in most GWAS to date. However, all the confirmed susceptibility genes still only explain a small fraction of disease heritability. Gene-gene interaction may play a role in disease association, but has so far been missing in the bigger picture of connection between genetic factors and complex diseases. In this study, genome-wide gene-gene interaction was analyzed based on two GWAS data sets from two different regions in China, namely Hong Kong and Anhui. Three statistical methods installed in PLINK and MDR were used to calculate the genetic epistasis using logistic regression, machine learning and information gain theory. First, logistic regression was used for preliminary genome-wide selection of pairwise variant-variant interactions in the two independent GWAS datasets. A number of SNP pairs showed statistically significant P value on genetic interaction. These SNP pairs were kept for further validation if one or both of which are located in a region with annotated biological function. Selected SNP pairs were then analyzed by two MDR methods. By machine learning method, new variables were constructed to classify high risk and low risk genotype combinations. Further, information gain theory was used to detect whether the information between two SNPs were redundant. A number of variant pairs were found to have significant epistatic interaction in disease association in both Hong Kong and Anhui GWAS, such as interaction between SNPs in MTHFR and CXCR4. Interactions between established loci were also confirmed by our data, such as that between BANK1 and BLK. These findings are currently being replicated by a larger data set in independent cohorts.

2017T

Prevalence of diabetes-associated gene variants and its association with blood glucose levels in the Algarve population, Portugal. *M. Barreto da Silva[1], V. Gaio[1], A. Fernandes[2], F. Mendonça[3], F. Orta Gomes[3], A. Beleza[2], A. Gil[1], M. Bourbon[1], A.M. Vicente[1], C.M. Dias[1].* 1) Instituto Nacional de Saúde Doutor Ricardo Jorge, Lisboa, Portugal; 2) Laboratório de Saúde Pública Dra. Laura Ayres, Faro, Portugal; 3) Administração Regional de saúde do Algarve, Faro, Portugal.

The global rise in incidence of type 2 (T2D) has been called a pandemic, constituting a major public health concern. Although environmental factors play a substantial role in the etiology of T2D, genetic susceptibility has been established as a key component in T2D risk. Given the absence of studies regarding the prevalence of T2D associated variants in the Portuguese population, our aim was to determine the prevalence of disease-associated variants and determine its relative contribution to this phenotype. For this purpose, we have recruited 221 individuals (93 males and 128 females), between 26-91 years old (mean age 57.1), who were enrolled in the Health Centre of S. Brás de Alportel (Algarve). For each participant, we have measured total glucose levels and collected DNA. In addition, each participant has answered an exhaustive questionnaire including socio-demographic information, health history and lifestyle. We have selected and analysed three of the most significant loci previously reported to be associated with T2D in Caucasian populations (*TCF7L2* rs7903146, *PARPG* rs1801282 and *FTO* rs9939609) and performed an association analysis between glucose levels in this population and the selected gene variants. The mean total population glucose level was 103.85±35.3 g/dl. We found a significant difference in the mean glucose levels between males (mean = 111.5±51.3 g/dl) and females (mean = 98.4±17.6 g/dl) (Mann-Whitney test $P < 0.001$). The relative allele frequencies of the genotyped variants have been established. Genotype distribution for all investigated SNPs was in Hardy-Weinberg equilibrium. We found a marginal association between glucose levels and genotypes at the *TCF7L2* locus (Mann-Whitney test $P = 0.045$) in females but not in males, with carriers of the T allele displaying higher levels of blood glucose than homozygous for the A allele. This difference is also observed in males, although not reaching significance. No association was found between glucose levels and the other genotyped variants. These results suggest that the pathophysiology of the disease may be different between males and females, or that environmental factors are influencing this trait in males. We are currently investigating the later hypothesis by increasing our sample size and by analysing lifestyle information provided by the participants in order to evaluate gene-environment interactions influencing glucose levels in the Portuguese population.

2018F

Genome-wide methylation analysis of DNA from offspring exposed to a diabetic intrauterine environment. *M. del Rosario, R.L. Hanson, V. Ossowsky, W.C. Knowler, C. Bogardus, L.J. Baier.* Phoenix Epidemiology and Clinical Research Branch, NIDDK, NIH, Phoenix, AZ.

The offspring of mothers who had diabetes during pregnancy have high risk of developing type 2 diabetes and obesity. We explored the possibility of DNA methylation as a mechanism through which epigenetic signals are passed on to the offspring. We studied DNA methylation in peripheral blood leukocytes from 14 non-diabetic Pima Indians who were offspring of diabetic mothers (ODM) and 14 offspring of nondiabetic mothers (ONDM). These two groups were matched for age (mean±SD=16.1 ± 5.4), sex, age of mother, and fraction of Pima ethnicity to reduce confounding from other factors. To find regions that are differentially methylated between the two groups, a MeDIP-chip assay was performed on the Affymetrix Human Tiling 2.0R Array. Data were analyzed using the model based analysis of tiling arrays (MAT) algorithm implemented in the Partek Genomic Suite using the mean of the corrected probe on 600 bp window to asses methylation (quantified by the MAT score). Differences in MAT score between ODM and ONDM groups were assessed by ANOVA. Initially we restricted the analysis to 50,726 regions that overlap with known promoter regions (between -2 kbp and +500 bp of Refseq Bld 36 transcription start sites), resulting in analysis of 50,726 regions across 35,830 different promoters. We analyzed 80 permutations to generate the expected distribution of p-values under the null hypothesis for determination of the empirical False Discovery Rate. Based on the one-sided Kolmogorov-Smirnov test, there is a significant enrichment of low p-values in the observed data compared with the expected distribution if there was no differential methylation between the two groups ($p<0.001$). 54% of the differentially methylated regions were hypomethylated in ODM. A total of 5,975 promoters that were differentially methylated (nominal $p<0.005$, FDR~90%) were subjected to KEGG pathway analysis using DAVID. The top pathway results were Type II Diabetes ($p<0.003$) and maturity onset diabetes of the young (MODY) ($p<0.005$). These preliminary findings support the hypothesis that epigenetic dysregulation of genes known to be involved in glucose metabolism mediate the increased risk for diabetes in ODM.

2019W

HNF1α and ABCA1 genes polymorphisms in gestational diabetes mellitus. *E. Zamarron-Licona[1], M.C. Martinez-Lopez[1], R. Diaz-Martinez[1, 2]*. 1) DIAGNOSTICO MOLECULAR, UNIVERSIDAD JUAREZ AUTONOMA DE TABASCO, VILLAHERMOSA, TABASCO, Mexico; 2) Especialidad en Genética de la Universidad de Guadalajara.

Gestational Diabetes Mellitus (GDM) is defined as any degree of glucose intolerance with onset or first recognition during pregnancy. Hepatocyte nuclear factor-1 homeobox A (HNF1A) single-nucleotide polymorphisms (I27L, S487N) are associated with monogenic diabetes with early-onset. ATP binding cassette A1 (ABCA1) single-nucleotide polymorphisms (R230C) have been associated with Tangier's disease and familial high-density lipoprotein deficiency. This study aims to investigate the relationship of HNF1A and ABCA1 SNPs with gestational diabetes mellitus, as well as to characterize them in contrast with non-diabetics and family history of type 2 Diabetes Mellitus. 91(age at onset > 40 y.o.; diabetes in 3 contiguous generations) along with 58 non-diabetic and family history patients and 60 normoglycemic controls (N group) have been evaluated for gestational diabetes mellitus and SNPs of HNF1A and ABCA1. HNF1α (L27L) GDM group 43%, N group 26% and T2DM family history group 24%. (I27I) GDM group 21%, N group 32% and T2DM family history group 24%. (I27L) GDM group 36%, N group 42% and T2DM family history group 52%. p: 0.027695 (N487N) GDM group 27%, N group 7% % and T2DM family history group 2%. (S487S) GDM group 41%, N group 18% and T2DM family history group 22%. (S487N) GDM group 32%, N group 75% % and T2DM family history group 76%. p: 0.025427 ABCA1 (R230C) GDM group 18%, N group 23% and T2DM family history group 22%. (C230C), GDM group 82%, N group 77% and T2DM family history group 78%. (R230R) Not found p: 0.097375. HNF1α polymorphisms I27L and S487N are associated to gestational diabetes mellitus. In spite of R230C variant of ABCA1 appeared in a higher frequency for that described for Mexican population, It does not contribute to gestational diabetes mellitus. 1.Villarreal-Molina, M. T., et al(2008) Diabetes 57, 509-513 2.Bjorkhaug, L., et al J. Clin. Endocr. Metab. 88: 920-931, 2003. 3.Fernando MA Giuffrida,et al. Cardiovascular Diabetology 2009, 8:28.

External sources of vitamin D modify the effects of the GC and CYP2R1 genes on 25-hydroxyvitamin D concentrations: CAREDS. *C. D. Engelman[1], K. J. Meyers[2], S. K. Iyengar[3], Z. Liu[2], C. Karki[2], R. P. Igo, Jr.[3], B. Truitt[3], J. Robinson[4], G. E. Sarto[5], R. Wallace[4], L. Tinker[6], E. LeBlanc[7], Y. Song[8], J. A. Mares[2], A. E. Millen[9]*. 1) Population Health Sciences, University of Wisconsin, Madison, WI; 2) Ophtalmology and Visual Sciences, University of Wisconsin, Madison, WI; 3) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 4) Epidemiology, University of Iowa, Iowa City, Iowa; 5) Obstetrics and Gynecology, University of Wisconsin, Madison, WI; 6) Fred Hutchinson Cancer Research Center, Seattle, WA; 7) Kaiser Permanente Center for Health Research, Portland, OR; 8) Division of Preventive Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 9) Social and Preventive Medicine, University at Buffalo, Buffalo, NY.

Vitamin D deficiency (defined by the blood concentration of 25-hydroxyvitamin D [25(OH)D]) has been associated with many adverse health outcomes. Genetic and non-genetic factors account for variation in [25(OH)D], but the role of interactions between these factors is unknown. To assess this, we examined 1,204 women of European descent from the Carotenoids in Age-Related Eye Disease Study (CAREDS), an ancillary study of the Women's Health Initiative Observational Study. Twenty-nine SNPs in 4 genes, *GC*, *CYP2R1*, *DHCR7* and *CYP24A1*, from recent meta-analyses of genome-wide association studies of [25(OH)D], were genotyped. Associations between these SNPs and [25(OH)D] were tested using generalized linear regression under an additive genetic model adjusted for age, blood draw month and ancestry. Results were stratified by season of blood draw and, separately, vitamin D intake for 6 SNPs showing a significant association with [25(OH)D] at the $p<0.01$ level. Two non-synonymous SNPs in *GC* and 4 SNPs in *CYP2R1* were strongly associated with [25(OH)D] in individuals whose blood was drawn in summer ($p\leq0.0001$ for the most significant SNP in each gene) but not winter months ($p>0.05$ for all SNPs) and, independently, in individuals with vitamin D intake ≥400 ($p<0.0001$) but not <400 IU/day ($p\geq0.04$). Only one SNP in each of these genes was independently associated with [25(OH)D]: rs4588 in *GC* and rs2060793 in *CYP2R1*. A genetic risk score summing the number of risk alleles at these two SNPs was significantly associated with [25(OH)D] ($p<0.0001$). The analysis was, again, stratified by high and low external sources of vitamin D. Women with all 4 risk alleles (from the genetic risk score) had low mean [25(OH)D], regardless of summer/winter season or high/low vitamin D intake (46.5-47.6 nmol/L for all 4 groups); however, women with no risk alleles and either summer season or high vitamin D intake (≥400 IU/day) attained a mean [25(OH)D] of 71.4 and 71.9 nmol/L, respectively, compared to only 53.8 and 55.3 nmol/L, respectively, for women with no risk alleles and either a winter blood draw or low vitamin D intake (<400 IU/day), indicating a stronger genetic effect in the presence of external sources of vitamin D. This effect modification has important implications for the design of discovery and replication genetic studies for all health outcomes and for public health recommendations and clinical practice guidelines regarding achievement of adequate vitamin D status.

Mapping variation in the response to vitamin D in peripheral blood. *C. Jeong, J.C. Maranville, S. Baxter, A. Di Rienzo.* Department of Human Genetics, University of Chicago, Chicago, IL., USA.

Vitamin D (VD) functions as a critical regulator of the immune system and is likely to play a role in a variety of diseases such as asthma, autoimmune diseases, and cancers. In addition, because of the known inter-ethnic differences in circulating vitamin D levels, it has been proposed that variation in the vitamin D pathway underlies inter-ethnic differences in disease risk. The main mechanism of VD action is through activation of the vitamin D receptor (VDR), which in turn acts a transcription factor to induce transcriptional changes at its target genes. This initiates a cascade that, in the immune system, results in suppression of antigen-driven inflammatory reactions, such as proliferation of lymphocytes. To elucidate the genetic bases of inter-individual variation in VD response, we measured changes in gene expression levels and in the suppression of cell proliferation in cultures of peripheral blood mononuclear cells (PBMCs) from 88 healthy African American donors. Each PBMC sample was treated, in paired aliquots, with vehicle control or with VD. In a genome-wide association mapping of the suppression of cell proliferation by VD, we found two QTLs, one on chromosome 5 (p=9.10×10-8, Bonferroni-corrected p=0.045), and the other on chromosome 18 (p=1.06×10-7, Bonferroni-corrected p=0.053). Gene expression data suggest that these associations are mediated by transcriptional responses because: 1) association between suppression of cell proliferation and log2 fold change of gene expression was found at 857 genes (FDR=0.10), 2) a large proportion of these genes showed association between their log2 fold change and either of the two proliferation QTLs (650 of 857 genes with FDR = 0.05). In addition, we used a Bayesian method to identify polymorphisms that interact with VD treatment to influence transcriptional response. This method detected 5 high-confidence interaction eQTLs (posterior p > 0.7), which show an effect of genotype on expression only in the VD-treated expression, but in the vehicle control. Together, these findings provide new information on the genetic bases of variation in the physiological response to VD treatment, with important implications for the risk to common diseases and their inter-ethnic disparities as well as for the assessment of response in VD supplementation trials.

The Interaction between Adolescent Parental Knowledge and Genetic Risk for Alcohol Dependence Predicts Adult Alcohol Dependence. *J.L. Meyers[1], J.E. Salvatore[1], R.J. Rose[5], J. Kaprio[2, 3, 4], D.M. Dick[1].* 1) Human Genetics, Virginia Commonwealth University, Richmond, VA; 2) Institute for Molecular Medicine Finland FIMM, University of Helsinki, Finland; 3) Department of Public Health, Hjelt Institute, University of Helsinki, Finland; 4) Department of Mental Health and Substance Abuse Services, National Institute for Health and Welfare, Helsinki, Finland; 5) Indiana University, Bloomington, Indiana.

Background. Previous studies demonstrate that parental knowledge moderates latent genetic influences on adolescent externalizing behavior and alcohol use (Dick et al., 2007, Latendresse et al., 2010) as well as specific genetic predispositions, such as CHRM2, to predict adolescent externalizing behavior (Dick et al., 2009). Little is known however, about the longitudinal effects of the parental knowledge in moderating genetic risk for alcohol problems from adolescence into adulthood.**Methods.**This study examines whether parental knowledge in adolescence continues to moderate genetic influences on alcohol use in young adulthood. We approached this question using data from a longitudinal, population based twin sample, Finntwin12 (Kaprio et al., 1999). We first conducted twin analyses to examine whether parental knowledge (measured at age 14) moderated genetic and environmental influences on alcohol dependence symptoms at age 22. We then created genetic risk sum scores (Yang et al., 2009) using GWAS data available on the twins (scores were comprised of all SNPs associated at p<0.01 with DSM-IV Alcohol Dependence symptoms). Next, we examined the interaction between this aggregate measure of risk genes and parental knowledge, and its effect on age 22 alcohol dependence symptoms. **Results.** The twin analyses indicated that parental knowledge significantly moderates the genetic influences on alcohol dependence symptoms at age 22 (χ2=10.31, p<0.0001). The genotypic analyses indicated that the interaction between genetic risk sum scores and parental knowledge significantly predicted alcohol dependence symptoms at age 22 (β=0.308, p<0.001). **Conclusion.** Converging evidence from two analytic methods suggests that parental knowledge in adolescence has an enduring moderating influence on genetic predispositions to alcohol use disorders in young adulthood. Parental knowledge may be an important proxy for some stable aspect of the individual's environment from adolescence into early adulthood, or may scaffold the adolescent's burgeoning behavioral regulation skills. There is a need for future research to elucidate the depth and limitations of the lasting effects of this aspect of adolescent parenting throughout development.

2023T

Association study of FUT2 (rs601338) with celiac disease and inflammatory bowel disease in the Finnish population. *A.S. Parmar[1], N. Alakulppi[2], P. Paavola-Sakki[3], K. Kurppa[7], L. Halme[4], M. Färkkilä[3], U. Turunen[3], M. Lappalainen[1], K. Kontula[5], K. Kaukinen[6], M. Mäki[7], K. Lindfors[7], J. Partanen[2], P. Sistonen[2], J. Mättö[2], P. Wacklin[2], P. Saavalainen[1], E. Einarsdottir[1].* 1) Research Program for Molecular Medicine and Department of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland; 2) Finnish Red Cross Blood Service, Helsinki, Finland; 3) Department of Gastroenterology, Helsinki University Hospital, Helsinki, Finland; 4) Department of Surgery, Helsinki University Hospital, Helsinki, Finland; 5) Department of Medicine, Helsinki University Central Hospital, Helsinki, Finland; 6) Department of Gastroenterology and Alimentary Tract Surgery, Tampere University Hospital and School of Medicine, University of Tampere, Tampere, Finland; 7) Pediatric Research Center, University of Tampere and Tampere University Hospital, Tampere, Finland.

Homozygosity for a non-sense mutation in the fucosyltransferase2 (FUT2) gene (rs601338G>A) leads to the absence of secreted Lewis blood group antigens and consequently ABH blood groups in body fluids. FUT2 non-secretor status has previously been associated with risk of type-1 diabetes and Crohn's disease (CD). We studied the association of rs601338-FUT2 with celiac disease (CelD) and inflammatory bowel disease (IBD) in the Finnish population. rs601338 was genotyped in CelD (n=909), dermatitis herpetiformis (DH) (n=116), ulcerative colitis (UC) (n=496) and CD (n=280) patients and healthy controls (n=2738). CelD showed significant genotypic (P=0.0074, OR:1.28) and recessive (P=0.015, OR:1.28) association with the rs601338-AA genotype. This was also found in the combined CelD+DH dataset (genotype association: P=0.0060, OR:1.28; recessive association: P<0.011, OR:1.28). The A allele of rs601338 showed nominal association with dominant protection from UC (P=0.044, OR:0.82) and UC+CD (P= 0.035, OR: 0.84). The frequency of non-secretors in controls, CelD, DH, UC and CD datasets was 14.7%, 18%, 18.1%, 14.3% and16.1% respectively. No association was evident in the DH or CD datasets alone, possibly due to lack of power. FUT2 non-secretor status is associated with CelD susceptibility and FUT2 secretor-status may also play a role in UC in the Finnish population.

2024F

Identifying novel gene-environment interactions for HDL-cholesterol. *L. Parnell, K. Richardson, C.Q. Lai, J.M. Ordovas.* Nutrition & Genomics, JM-USDA Human Nutrition Research Center on Aging, Boston, MA.

Many genetic variants associating with clinical measures of metabolic diseases have been uncovered by genome-wide association studies (GWAS). While many of those associations replicate, many fail to validate in other populations, likely due to genetic and environmental differences. However, a substantial number of gene-environment (GxE) interactions have been described from approaches examining specific genes where environment equals diet, physical activity (PA), tobacco/alcohol use and sleep. Mining our database of over 500 GxE interactions involving obesity and blood lipids from disparate research reports, we built a gene network for interactions involving PA. This network of interacting genes and proteins was then supplemented with exercise-based gene expression data, HDL metabolism pathway membership, and main effect associations for HDL from GWAS all to prioritize candidate genes to test for novel GxE interactions for HDL-cholesterol and physical activity. Further refinement of the list of candidate HDL-PA interaction genes was done by measuring the distance across the network from the candidate gene to a known HDL-PA gene as identified in our GxE database. This resulted in 43 top candidate genes, which have been selected for analysis in a deeply phenotyped population. While analysis of the GxE interactions is ongoing, initial results suggest this is a viable approach to identify novel GxE interactions.

Genetically-determined differences in arsenic metabolism efficiency influence risk for arsenic-induced skin lesions: A Mendelian Randomization Study. *B. Pierce, L. Tong, M. Argos, F. Jasmine, M. Kibriya, H. Ahsan.* Health Studies, Univ Chicago, Chicago, IL.

Arsenic is a class-I human carcinogen, and arsenic contamination of drinking water is a serious public health issue in many countries, increasing risk for a wide array of diseases, including cancers of the bladder, kidney, lung, and skin, as well as neurological and cardiovascular diseases. There is substantial inter-individual variation in arsenic metabolism efficiency, as some individuals are able to methylate, and thus excrete, arsenic more efficiently than others. Consumed arsenic enters the blood as inorganic arsenic (iAs) and undergoes a series of methylation steps to produce monomethylarsonic acid (MMA) and then dimethylarsinic acid (DMA). Using data on urinary arsenic metabolite concentrations of iAs, MMA, and DMA and genome-wide single nucleotide polymorphisms (SNPs) for 2,060 arsenic-exposed Bangladeshi individuals, we show genome-wide significant associations for urinary concentrations of both MMA% ($P=2x10^{-11}$) and DMA% ($P=2x10^{-14}$) in a large linkage disequilibrium block containing the AS3MT gene (arsenite methyltransferase; 10q24.32), with five genetic variants showing evidence of independent association. Although the association signals for MMA% and DMA% appear to be driven by different SNPs, haplotype analysis of these five variants suggests that MMA and DMA are to a large degree influenced by the same underlying variants. In a Mendelian randomization analysis of 2,073 skin lesion cases (the classical sign of arsenic toxicity) and 3,267 controls, we used two-stage regression methods to assess the effect of genetically-determined differences in arsenic metabolism efficiency on skin lesion risk. Results from both SNP-based and haplotype-based Mendelian randomization analysis support the hypothesis that iAs and MMA are more toxic than DMA (i.e., increased methylation efficiency decreases risk for arsenic toxicity, presumably because DMA is more readily excreted in urine and expelled from the body). For example SNP-based MR analyses produce causal ORs of 1.25 (CI: 1.17-1.33) for a 1-unit change in iAs%, 1.15 (CI: 1.09-1.21) for a 1-unit change in MMA%, and 0.89 (CI: 0.87-0.92) for a 1-unit change in DMA%). Our results support a causal role for arsenic methylation efficiency in arsenic toxicity. Knowledge of these biological processes could be used to develop intervention and pharmacological strategies aimed at preventing large numbers of arsenic-related deaths in arsenic-exposed populations.

The Ubiquitin Proteasome System: Gene-Environment Interactions in Parkinson's Disease. *S. Rhodes[1], B. Ritz[1,2].* 1) Dept Epidemiology, UCLA Sch Public Hlth, Los Angeles, CA; 2) Dept Neurology, Geffen Medical School, UCLA, Los Angeles, CA.

The underlying causes of Idiopathic Parkinson's disease (PD) are likely complex interactions between environmental exposures and genetic variants that confer a predisposition towards damage resulting from the relevant environmental exposure. Pesticide exposure or its proxy (e.g. rural living, well-water consumption, farming occupation) are regularly observed in association with PD. Animal studies have demonstrated that multiple different types of pesticides are toxic to dopamine neurons and that the mechanisms of toxicity tend to fall in one or the other known biologic pathways implicated in PD etiology including mitochondrial dysfunction, oxidative stress, and ubiquitin proteasome system (UPS) disruption. We investigated in the population-based Parkinson's Environment and Genes (PEG) study possible gene-environment (GxE) interactions between five genes hypothesized to have a role in UPS or mis-folded protein trafficking and five pesticides determined to inhibit the UPS in an SK-N-MC GFP^u model assessing 26S activity in living cells. The PEG study is unique in that pesticide exposure was assessed using state-mandated pesticide use reports, land use maps, and residential and occupational histories from each subject, thereby minimizing subject recall bias with regards to pesticide exposure. 354 cases and 543 controls were genotyped for single nucleotide polymorphisms (SNPs) in PARK2, UCHL1, SKP1, UBA1, and UBA6; pesticides considered included benomyl, endosulfan, ziram, dieldrin, and rotenone. Four SNPs, one in each gene except UCHL1, were suggestive ($p<0.10$) of a 30-40% change in PD risk per variant allele and were considered for GxE interaction with pesticides. Two SNPs, rs2284312 in SKP1 and rs354872 in UBA6, were associated ($p<0.05$) with a 2- to 2.5-fold increase in PD risk under the additive genetic model but only in the presence of one or more UPS-inhibiting pesticides. These SNPs were not associated ($p>0.15$) with any increase in PD risk in the absence of pesticide exposure. rs9365292 in PARK2 was suggestive of a GxE interaction. These findings are consistent with the multi-factorial etiology of PD and are suggestive of a greater need to integrate genetic investigations with epidemiologic studies so as to better understand the combined impact of genes and environment.

2027F

GENETIC TRADE-OFFS MAY EXPLAIN SOME PARADOXES OF GENETICS OF HUMAN LONGEVITY. *S. Ukraintseva, K. Arbeev, A. Kulminski, I. Akushevich, D. Wu, A. Yashin.* Duke University, Durham, NC.

Chronic diseases, such as CVDs, cancer, diabetes and AD, are major contributors to mortality in old age. It might therefore be expected that genetic factors which increase risks of such diseases will negatively affect person's survival. However, several studies suggested that the presence of "risk alleles" in individual genomes does not necessary compromise longevity, and that the proportion of such alleles among centenarians is often similar to that in younger controls (e.g., Beekman et al. 2010; Sebastiani et al. 2011). It has also been shown that the frequency of some "risk alleles" may change non-monotonically with age, e.g., decrease from youth to the age 80, and increase afterwards (Yashin et al. 1999; Bergman et al. 2007). Few explanations of this phenomenon have been suggested (Yashin et al. 1999, 2001; Bergman et al. 2007), while more comprehensive investigation of its mechanism is required and critically important for understanding the relationships between genetic factors influencing health and longevity. Here we propose that the apparent paradox of accumulating "harmful" alleles in long-living individuals can plausibly be explained by "genetic trade-offs". The latter in our case includes the situations when a genetic variant: (i) increases the risk of a disease (e.g. cancer) in middle/old age, but decreases that risk at the oldest old ages; (ii) increases the risk of one disease (e.g. CHD) at middle/old age, but decreases the risk of another life-threatening condition (e.g., internal bleeding) at older ages; (iii) increases the risk of a disease (e.g. cancer), but slows/postpones some physiological aging changes, so it becomes advantageous for person's survival at the very old age, when senescent state itself becomes leading cause of death. We provide evidence from our recent research and work of others in support of this explanation and conclude that the paradoxical accumulation of "risk alleles" in long-living individuals may in fact be a common consequence of a normal change in phenotypic effects of genes with age in constantly changing environment in aging human body, as well as be a result of antagonistic pleiotropic influence of some genes on different health traits.

2028W

Interaction analysis of exogenous estrogen in age-related macular degeneration (AMD): new gene-based 2-degree-of-freedom (2df) joint test finds joint effects within the VEGF signaling pathway. *MD. Courtenay[1,2], WH. Cade[1], PL. Whitehead[1], SG. Schwartz[3], JL. Kovach[3], G. Wang[1], A. Agarwal[4], JL. Haines[5], MA. Pericak-Vance[1,2], WK. Scott[1,2].* 1) Human Genetics and Genomics, Hussman Institute for Human Genomics, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 3) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL; 4) Ophthalmology, Vanderbilt University, Nashville, TN; 5) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

AMD is the leading cause of irreversible vision loss in developed countries. Its multifactorial etiology includes both genetic and environmental risk factors. Overexpression of VEGF promotes angiogenesis, making it a key influence on the choroidal neovascularization (CNV) found in advanced AMD. Anti-VEGF therapy is the primary treatment for CNV. VEGF expression can be modulated by exposures to exogenous estrogen, and women who take exogenous estrogen in the form of hormone replacement therapy (HRT) have reduced risk of AMD. This study tested the association of 74 genes in the VEGF pathway for association with AMD, accounting for genetic effects and HRT use using a new gene-based test of genetic and environmental factors. SNPs (N=1119) were selected from a previous AMD GWAS that included 312 Caucasian women with AMD (AREDS Grade 5 CNV) and 179 unaffected women controls (AREDS Grade 1). History of ever taking HRT was collected with a self-administered questionnaire. The gene-based test was conducted as an extension of the set-test implemented in PLINK, using the chi-square statistic at each SNP derived from Kraft's 2 degree of freedom (df) joint test of genetic and environmental factors. Using a function written in R, the 2 df joint test utilized a likelihood ratio test computed from a "full" logistic regression model with SNP and HRT main effects, a pairwise interaction term, age, and smoking status, and a "restricted" model excluding the SNP and interaction terms. Gene-based chi-square test statistics were calculated as the mean of all independent ($r2<0.8$) joint test statistics. The analysis was then repeated 10,000 times, permuting phenotype labels to generate an empirical p-value. The same set-test was conducted without incorporating HRT. Although no results reached Bonferroni corrected significance ($p<3.4x10\text{-}4$) for either analysis, nominally significant results were obtained at five genes: NFATC1 (joint test p=0.0036), VEGFA (p=0.0043), MAPKAPP3 (p=0.0072), PLA2G6 (p=0.0288), and RAF1 (p=0.032). Only the test incorporating HRT detected the effect at PLA2G6, (main effects gene-based set test p=0.1239). PLA2G6 plays a role in arachidonic acid metabolism which leads to inflammation, a feature of AMD pathogenesis. These results illustrate the utility of incorporating environmental exposures in tests of genetic association in complex diseases, at the SNP, gene, or pathway level.

Heritability and host SNP associations of microbial species in the human gut. *J.K. Goodrich[1,2], R. Blekhman[1,3], J.T. Bell[4], T.D. Spector[4], A.G. Clark[1], R.E. Ley[1,2].* 1) Dept of Molecular Biology & Genetics, Cornell University, Ithaca, NY, USA; 2) Dept of Microbiology, Cornell University, Ithaca, NY, USA; 3) Dept of Neurology & Neuroscience, Weill Cornell Medical College, New York, NY USA; 4) Dept of Twin Research & Genetic Epidemiology, King's College London, U.K.

The composition of the human gut microbiome is shaped by several factors including environment, diet, and host disease status. Variation in the human genome would also be expected to impact many aspects of the gut environment that in turn should impact microbiome composition, but this aspect is under-explored. In order to determine the degree to which species composition of the microbiome is heritable, and to identify associations of specific regions of the genome with particular attributes of the human gut microbiome, we characterized the gut microbial communities of 165 dizygotic (DZ) twin pairs and 118 monozygotic (MZ) twin pairs from the United Kingdom Adult Twin Registry (TwinsUK). Each individual provided a single stool sample. The environmental stability of the gut microbiota over time was assessed through repeat sampling of a subset of the individuals. The 16S rRNA gene sequences from microbes in the stool samples were sequenced in sufficient abundance to produce a phylogenetic representation of the microbiota species composition. We determined the degree to which the microbial tree is heritable using the classical ACE twin model, which partitions the total variance of a phenotype into additive genetic effects (A), common environment (C), and unique environment (E). We identify specific regions of the tree with moderate heritability such as members of the families Ruminococcaceae, Lachnospiraceae, and Catabacteriaceae, while other regions have little to no heritability. An assessment of the twin-pair correlations of microbial abundances throughout the phylogenetic tree, showed on average that MZ twin pair correlations were significantly greater than the DZ twin pair correlations, further indicating heritability of the microbiota. To determine specific regions of the genome influencing microbial composition we performed an association analysis of attributes of the microbiota including diversity measures and relative abundance of shared bacterial taxa. The genes near loci that are significantly associated with the composition of the gut microbiome are enriched in pathways involved in host immune response. This analysis opens a window into the unexplored world of host-genetic control over the microbiome, begging further investigation into specific genes and pathways and exploration of the interaction of host-genetics and the microbiome in the context of disease.

2030F

SNPs for BMI demonstrate consistent results through the lifecourse. *N. Heard-Costa[1,2], L.D. Atwood[1,2], C. Jaquish[3], C.T. Liu[4], L.A. Cupples[1,4], C.S. Fox[1,5].* 1) Division of Intramural Research, National Heart, Lung and Blood Institute, Framingham Heart Study, Framingham, MA; 2) Department of Neurology, Boston University School of Medicine, Boston, MA; 3) Division of Prevention and Population Sciences, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD; 4) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 5) Division of Endocrinology, Metabolism, and Diabetes, Department of Medicine, Harvard Medical School, Boston MA.

Introduction: Body mass index (BMI) has a substantial genetic component, and 32 common genetic variants have been reported in association with BMI. However, few studies have investigated whether the associations of these variants with BMI are consistent throughout the lifecourse. In this study we take advantage of multiple observations available for participants in the Framingham Heart Study (FHS) to assess whether the genetic association of each of the 32 SNPs with BMI changes with age. Methods: We analyzed the association of BMI with 32 confirmed SNPs (Speliotes, 2010) in 8379 FHS participants. We grouped participants into 15 distinct 5 year intervals, beginning at age 15 and ending with those ≥ 85 years of age. For each participant, a single observation was chosen in each interval; if multiple observations were available, the one with the minimum age was retained for those under 50 and the one with maximum age was retained for those 50 and above. This resulted in a total of 33048 observations, with an average of 2203 observations per age interval. To account for familial relatedness, we used pedigree-based mixed effects models that allow for repeated measure analysis; the model included an age interaction term. To account for multiple testing, we considered a p-value < 0.0016 to be significant. Results: Mean BMI levels increased from 23.1 kg/m^2 at age 15, peaked at 27.6 kg/m^2 in the sixth decade of life, and declined after age 65 to 25.8 kg/m^2. Of the 32 SNPs tested, we generally observed consistent associations with BMI by age. For example, for SNP rs4836133, in ZNF608, the average effect size was 0.019 ± 0.086. Only 1 SNP, rs10150322 at NRXN3, revealed a significant interaction with age (p value 1.203 x 10^{-4}) with stronger effects observed in older individuals, with estimated mean BMI difference per copy of the risk allele ranging from 0.01 kg/m^2 at age 20 years to 0.51 kg/m^2 at age 70. Conclusion: These findings highlight how the majority of SNPs known to be associated with BMI show remarkable robustness of association through the lifecourse.

2031W

Examining the roles of diet, age, and sex on the composition of the human fecal microbiome. *ER. Davenport[1], O. Mizrahi-Man[1], LB. Barreiro[2], C. Ober[1], Y. Gilad[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Sainte Justine Hospital Research Centre, Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, QC, Canada.

The composition of the human microbiome is known to be influenced by many environmental factors, particularly diet. Host genetic variation also likely plays a role in shaping the composition of the microbiome. However, this has not yet been demonstrated in humans and it is important to minimize the strong influence of inter-individual dietary differences when attempting to identify the potentially small, multifactorial genetic effects. In this study, we sought to understand the relative importance of environmental and genetic factors on the composition of the gut microbiome by examining the bacterial communities of feces from members of an isolated population, the Hutterites of South Dakota. This communal-living, farming population prepares and eats all meals in a common dining room. Although their diet differs seasonally with respect to the proportion of fresh fruits and vegetables consumed, it is remarkably uniform among individuals within seasons. This allowed us to investigate the roles of both genetics (by examining inter-individual genetic variation within season, diets controlled) and the environment (by examining the same individuals between seasons, with diets differing) in shaping microbiome composition. To this end, we collected fecal samples from 138 adult Hutterites (51 men, 87 women; ages 16-76 years) in winter and summer months (33 men and 55 women sampled at both times). DNA was extracted from feces in duplicate, the 16S rRNA V4 region was amplified, each sample was sequenced to high depth (mean: 2,721,718 ± 1,451,405 reads per replicate) using Illumina HiSeq technology;, and reads were classified using mothur's classify.seq function. We observed high correlation between replicates (median spearman r=0.85-0.95, depending on taxonomic rank). As a first step, we examined age and sex effects on microbial diversity, controlling for season. Microbial diversity decreased with age (F-test; p=0.018). Additionally, in contrast to reports of mice and Rhesus macaques, there were no significant differences in Shannon diversity between males (n=48; mean= 2.27) and females (n=75; mean=2.28) (t-test; p=0.94). Our next steps include analyzing genome-wide SNP information to identify associations with microbiome abundance and diversity measures, in order to assess the role of genetics in maintaining microbiome composition.

2032T

Gene-to-gene interaction in the development of gout. *A. Taniguchi, W. Urano, N. Ichikawa, H. Yamanaka.* Institute of Rheumatology, Tokyo Women's Medical University, Shinjuku-ku, Tokyo, Japan.

Background: More than ten genetic loci have been reported to be associated with serum levels of uric acid (SUA). Most of those are polymorphisms in genes of renal transporters or genes associated with metabolic syndrome (MetS). Gout is a disease based on hyperuricemia and some of those genetic factors are expected to be associated with gout. In gout, renal excretion of uric acid is impaired and it is well known that more than half of gout patients have MetS. Some of renal transporters are responsible of renal reabsorption or excretion of urate. Furthermore, previous reports indicate the relationship between impaired renal urate excretion and metabolic syndrome. Therefore, it is important to investigate gene-to-gene interactions between genetic factors associated with SUA or gout. Purpose: To investigate gene-to-gene interactions between genetic factors associated with gout in Japanese. Method: 153 patients with gout and 534 Japanese male controls were subjects of the study. We first investigated the association of gout with genetic factors that have been reported the association with SUA by GWAS. Then, we investigated gene-to-gene interaction. Gene-to-gene interactions between pairwise combinations of SNPs were tested using logistic regression. For each pair of genetic variant, two models were developed. The model (A) was developed based on the assumption of interaction, while the model (B) developed without it. Model (A): g(P) = SNP1 risk allele (+) + SNP2 risk allele (+) + {SNP1 risk allele (+) x SNP2 risk allele (+) }; Model (B): g (P) = SNP1 risk allele (+) + SNP2 risk allele (+). A comparison between model (A) and (B) were performed using χ^2 test. Bonferroni correction for multiple testing was carried out where appropriate. Results: 12 polymorphisms in genes such as *PDZK1, GCKR, ABCG2, LRRC16A, LRP2, SLC17A1, SLC2A9, SLC16A9, SLC22A11* and *SLC22A12* were selected for this study. Polymorphisms in *GCKR, ABCG2, LRRC16A, LRP2, SLC17A1, SLC2A9* and *SLC22A12* showed significant association with gout. Then, we evaluated gene-to-gene interaction for each pair of those loci. The interaction between *SLC16A9* and *ABCG2* was shown with the p-value of 0.018. However, Bonferroni correction removed the significance. We did not detect significant gene-to-gene interaction between genetic polymorphisms of renal transporters. Conclusion: In gout, the role of gene-to-gene interaction between renal transporters or between renal transporters and MetS might be small.

The genetic basis of preeclampsia in populations adapted to high altitude. *P. Ortiz-Tello[1], K. Sandoval Mendoza[1], V. Villanueva Dávalos[2], A. Moreno Estrada[1], J. Manzaneda[4], F. Manzaneda[4], A. McKenney[5], L. Enriquez Lencinas[2,3], C. Bustamante[1], J. Baker[1].* 1) Dept Genetics, Stanford Univ Sch Med, Stanford, CA; 2) Dept of Obstetrics and Gynecology, Hospital Regional “Manuel Núñez Butrón”, Puno, Peru; 3) Dept of Pathology, Hospital Regional “Manuel Núñez Butrón”, Puno, Peru; 4) Universidad Nacional del Altiplano, Puno, Peru; 5) Dept Pathology, Stanford Univ Sch Med, Stanford, CA.

Preeclampsia - a disorder of pregnancy characterized by the sudden onset of maternal hypertension and proteinuria - complicates 3-8% of all pregnancies and is the largest killer of pregnant women worldwide. Preeclampsia also poses a risk to newborns, particularly in areas of the world where resources are limited. The heterogeneity of the disorder has posed a challenge in our understanding the molecular basis of the preeclampsia. High altitude populations provide an untapped resource to understand the genetics underlying preeclampsia due to the relative homogenous population living under strong selective forces. Moreover, at high altitudes, pregnant women have a 2-3 fold higher rate of preeclampsia than women at low altitudes. Importantly, it has been known for hundreds of years, and recently documented, that Native populations living in the Andes are far more equipped for pregnancy at high altitudes than their European counterparts. This is similarly true for the Native Tibetans compared to the recently immigrated Han Chinese. Thousands of years of genetic adaptation to the low oxygen environment at high altitudes may have conferred protection to these individuals against preeclampsia, although the mechanisms for this protection have not been elucidated. In order to investigate the genetic basis of preeclampsia at high altitude, we have embarked in an international collaboration with the Regional Hospital “Manuel Núñez Butrón” and the National University of the Altiplano (UNA) in Puno, Peru to sample affected individuals living at nearly 4,000 m.a.s.l. We have consented and collected maternal, paternal, and cord blood for genotyping and sequencing, as well as associated sections of placenta cut and embedded for histopathology on more than 400 trios (mother, father, baby), as well as pertinent medical records. We are applying admixture mapping, as well as methods of detecting positive selection, in combination with RNAseq data, histopathology, and quantifiable phenotype data, in order to identify new loci correlated with preeclampsia and shed light on better understanding human physiopathology.

The effect of race, sex, age, socioeconomic, behavioral factors, and genetics on dental caries in different tooth surfaces. *D. Lewis[1], E. Feingold[1,2], Z. Zeng[1,2], J. Shaffer[1], X. Wang[3], R. Weyant[4], D. McNeil[5], M. Marazita[1,3,6].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 2) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 3) Center for Craniofacial & Dental Genetics, Department of Oral Biology, School of Dental Medicine, Pittsburgh, PA, USA; 4) Department of Dental Public Health and Information Management, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 5) Dental Practice and Rural Health, West Virginia University, Morgantown, WV, USA; 6) Clinical and Translational Science, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA.

Dental caries (cavities) is a multifactorial disease that involves many interacting variables to promote its development. It constitutes a major public health problem that begins in childhood. The prevalence of dental caries in adults from underserved and minority populations in the U.S can be over 90%. Risk factors associated with dental caries include environmental, behavioral, socioeconomic, and genetic factors. Many studies have demonstrated caries varying by race, gender and socioeconomic status (SES) and several genetic risk factors have been established as well. In this study, we ask whether these predictive factors have different effects on caries in different tooth surfaces (smooth surfaces vs. pit and fissure surfaces).

Families were recruited by the Center for Oral Health Research in Appalachia (COHRA) for a collection of demographic data, biological samples, and clinical assessment of oral health. There were a total of 1,129 Black and White adults examined in this study. We used exploratory statistics and regression analyses to examine the relationships among various demographic, SES, genetic and behavioral variables.

We confirmed associations between a number of known risk factors and caries, including sex, race, age and tooth brushing frequency. We also found that these risk factors are different for different tooth surfaces. Regression modeling was used to reach conclusions not only about which predictors are important and the size of their effects but, also the independence of predictors simultaneously affecting different tooth surfaces. Supported by; DE018903 and DE014899.

2035T

Telomere length in human blood cells and the prediction of survival. *J. Deelen[1,2], M. Beekman[1,2], V. Codd[3,4], H.E.D. Suchiman[1], A.J.M. de Craen[5], N.J. Samani[3,4], J.J. Houwing-Duistermaat[6], P.E. Slagboom[1,2].* 1) Section of Molecular Epidemiology, Leiden University Medical Center, Leiden, The Netherlands; 2) Netherlands Consortium for Healthy Ageing, Leiden University Medical Center, Leiden, The Netherlands; 3) Department of Cardiovascular Sciences, University of Leicester, Glenfield Hospital, Leicester, UK; 4) NIHR Leicester Cardiovascular Biomedical Research Unit, Glenfield Hospital, Leicester, UK; 5) Department of Gerontology and Geriatrics, Leiden University Medical Center, Leiden, The Netherlands; 6) Section of Medical Statistics, Leiden University Medical Center, Leiden, The Netherlands.

Telomere length (TL) in human leukocytes declines with age and several studies have shown that decreased TL is associated with increased mortality, although not in all studied populations. Previous studies had a relatively small sample size and follow-up in larger populations is warranted. In addition, it is not clear whether telomere shortening measured in blood cells marks merely a history of cell division induced by infections or whether there is a causal contribution of length reduction to mortality. We measured TL in peripheral blood of 870 nonagenarian siblings (mean age 93 years), 1,580 of their offspring (mean age 59 years) and 725 spouses thereof (mean age 59 years.) from the Leiden Longevity Study. These participants have been followed up for vital status during 7.56 years on average. Mean TL was measured as a ratio (T/S) of telomere repeat length (T) to the copy number (S) of the single-copy gene *36B4*. There was no difference in TL between the offspring and spouses ($P = 0.927$), so we could analyse them as one group. Survival analysis, using Cox regression, in the nonagenarians showed that longer telomeres are associated with better survival into very old age (HR = 0.66, $P = 0.028$). This effect is even more pronounced in the offspring and their spouses (HR = 0.24, $P = 0.001$). To determine whether the association could be based on TL marking a history of infections, we determined the association between TL and markers for immune response (white blood cell counts, hsCRP and incidence of CMV infection) and a marker for cell replication (IGF1/IGFBP3) in the offspring and spouses. We conclude that decreased TL is significantly associated ($P < 0.05$) with decreased neutrophil counts, basophil counts and IGF1/IGFBP3 ratio, increased lymphocyte counts and a higher incidence of CMV infection. When the survival analysis of TL among the nonagenarians was adjusted for the mentioned parameters of cell replication and immune response, we found that TL still showed an independent association with survival (HR = 0.60, $P = 0.007$). We conclude that TL predicts survival in very old and middle age and that this effect is independent from markers for immune response and cell replication. This observation is currently being replicated in independent cohorts in which we will also determine the impact of known genetic determinants of TL on survival.

Early life infection associated with shorter adult blood telomere lengths in Cebu, the Philippines. *D.T.A. Eisenberg[1,2,3], J. Borja[4], M.G. Hayes[2,5,6], C.W. Kuzawa[2,3].* 1) Department of Anthropology, University of Washington, Seattle, WA; 2) Department of Anthropology, Northwestern University, Evanston, Illinois, 60208, USA; 3) Cells 2 Society: the Center for Social Disparities and Health, Institute for Policy Research, Northwestern University, Evanston, IL 60208; 4) Office of Population Studies Foundation, University of San Carlos, Cebu City, Philippines; 5) Division of Endocrinology, Metabolism and Molecular Medicine, Department of Medicine, Northwestern University Medical School, Chicago, Illinois, 60611, USA; 6) Center for Genetic Medicine, Northwestern University, Chicago, Illinois, 60611.

Telomeres are repetitive DNA sequences found at the ends of chromosomes. Telomere lengths (TL) shorten with age in proliferating human tissues due to the `end-replication problem' and oxidative stress. This shortening is implicated in senescence, with previous work suggesting that shorter TL impairs immune and cardiovascular function and results in increased mortality. Repeat activation of cellular immune responses, each involving extensive clonal expansion, is necessary to defend against rapidly reproducing and evolving pathogens. Because cellular division shortens telomeres and shortened telomeres are related to increased infections and subsequent mortality, ecologies in which immune activation are more extensive might also limit later immune function. Studies examining associations between infectious diseases and TL are primarily limited to clinical contexts in developed countries. To our knowledge, no study has evaluated the effect of infectious diseases on TL within the context of a non-clinical, low-income country nor examined the influence of early life infections on TL. To test the hypothesis that increased infections early in life cause shortened TL, TL from young men and women from Cebu, Philippines were measured (N = 1,639) from DNA extracts of blood using a qPCR method. Mothers were asked every two months for the first two years of the child's life how many diarrheal episodes the child had over the past week. Consistent with expectations, increased incidence of early life diarrheal episodes was associated with shorter TL (P = 0.04). On closer examination the association was most marked for diarrheal episodes which occurred when the individuals were between 8 and 12 months old=ma time when probably due to weaning and increased interaction with the environment diarrheal incidence is greatest. In order to consider the biological importance of this association we compared it to the age related decline in blood TL in 36 -69 year old Filipino women measured in our laboratory. The effect of having one more diarrheal episode in the past week before a survey in the second half year of life is equivalent to approximately three years worth of decrease in TL in adulthood. These results imply that infections early in life might predispose toward later life development of senescence and chronic disease mediated via TL shortening. This work was supported by NSF and Wenner Gren Foundation grants. DNA extracts generously provided by Karen Mohlke.

Characterization and generalization of HFE rs1800562 genotype-phenotype relationships in the diverse National Health and Nutrition Examination Surveys (NHANES) as part of the Epidemiologic Architecture for Genes Linked to Environment (EAGLE). *K. Brown-Gentry, B. Niloufar, J. Hailing, B. McClellan, J. Boston, C. Sutcliffe, H. Dilks, D. Crawford.* Ctr Human Gen, Vanderbilt Univ, Nashville, TN.

Hemochromatosis (HFE) rs1800562 (C282Y) is known for its strong association with hemochromatosis, a disease of excess iron storage from diet, and iron status biomarkers in European (EA) populations. In genome-wide association studies (GWAS) in EA descent populations, HFE rs1800562 has also been associated with red blood cell traits, cardiovascular risk factors, and markers of metabolic syndrome. Despite characterization of this common variant in EA descent populations, little is known about its frequency and genetic associations in diverse populations. To fill these gaps in knowledge, the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) genotyped HFE rs1800562 in 14,998 participants from the National Health and Nutrition Examination Surveys (NHANES) III and 1999-2002. NHANES, a nationally representative sample of the United States is conducted by the National Center for Health Statistics at the Centers for Disease Control and Prevention. Among 6,634 non-Hispanic whites (NHW), 3,458 non-Hispanic blacks (NHB), and 3,950 Mexican Americans (MA), the minor allele was observed at a frequency of 6.28%, 1.88%, and 1.68%, respectively. Tests of association were performed using linear regression assuming an additive genetic model for the following dependent variables, stratified by self-reported race/ethnicity and adjusted for sex and age: serum transferrin saturation (%), serum iron (ug/dL), ln(serum ferritin)(ng/mL), mean cell volume (MCV; fL), and fasting plasma glucose (mg/dL). As expected, among NHW, serum iron (β=13.3), serum transferrin saturation (β=5.9), and MCV (β=1.2) were strongly associated with rs1800562 (p<2.0x10-7). Also associated in NHW was ln(serum ferritin) (β=0.12 and p=3.1x10-4). Among both NHB and MA, rs1800562 was associated with serum iron (p<0.01) and serum transferring saturation (p<3.0x10-4) with similar genetic effect sizes compared with NHW. MCV was associated with rs1800562 in MA (β= 2.3; p=1.5x10-7), but MCV was not associated in NHB possibly due to power. Neither glucose nor ln(serum ferritin) was associated with rs1800562 in NHB nor MA. Despite generalizing known associations between rs1800562 and iron trait markers to diverse populations, we failed to generalize all GWAS-identified genotype-phenotype relationships described in EA descent populations highlighting the need for further genetic association studies for HFE in large non-EA populations.

2038T

Analysis of Established Type 2 Diabetes Associated Variants in American Indians. *R. Hanson, S. Kobes, W. Knower, C. Bogardus, L. Baier.* Diabetes Epidemiology Clin Res, NIDDK, Phoenix, AZ.

Variants at several genetic loci have recently been reproducibly associated with type 2 diabetes mellitus (T2DM) in European and Asian populations. There is little information, however, on the relationship of these variants with T2DM in American Indian populations, many of which are at high risk for the disease. We genotyped a “sentinel” single nucleotide polymorphism (SNP) at 39 of these loci in 3401 Pima Indians (47% with diabetes) from a population-based study; acute insulin secretion was measured by an intravenous glucose tolerance test in 287 individuals. Generalized estimating equations, which account for familial relationships, were used to calculate the odds ratio (OR) for the association of T2DM with each risk allele, as determined by previous studies. Heterogeneity between Pimas and Europeans was assessed by comparison of the OR in Pimas with that published for Europeans. A multiallelic risk score, constructed by summing the number of risk alleles over all loci, was also analyzed. Stouffer's method for combining p-values was used to construct a summary test of heterogeneity across all loci. In analysis of the multiallelic score, the number of risk alleles was associated with higher risk of diabetes (OR=1.05 per risk allele, $p=8.3\times10^{-5}$); the multiallelic score was also strongly associated with reduced acute insulin secretion (r=-0.32, $p=3.1\times10^{-8}$). Nominally significant (p<0.05) associations with diabetes were observed for SNPs in *GCKR* (OR=1.38), *KCNQ1* (OR=1.32), *FTO* (OR=1.24), *CDKAL1* (OR=1.15) and *ZBED3* (OR=1.15). The summary test for heterogeneity across all 39 loci indicated that the effects in Pimas were weaker than in Europeans ($p=3.0\times10^{-4}$). Nominally significant heterogeneity between Pimas and Europeans was observed for SNPs in *IRS1*, *ADAMTS9*, *PTPRD*, *TCF7L2* and *DUSP9*. When allele frequencies were compared with the HapMap CEU population, differences with genome-wide significance ($p<5\times10^{-8}$) were seen for 27 SNPs; however at 14 of these the risk allele was at lower frequency in Pimas. These analyses suggest that in general type 2 diabetes risk loci identified in other populations also influence risk of T2DM in Pima Indians, and that risk is mediated in part through an effect on acute insulin secretion. However, the effects on T2DM risk are generally weaker in Pimas than in Europeans, and systematic differences in allele frequencies at these variants do not appear to account for differences in population risk of T2DM.

Describing the contribution of Multiple Sclerosis genetic risk factors in Sardinian Multiple Sclerosis cases. *A. Hadjixenofontos[1], L. Foco[2], V. Bakthavachalam[3], P-A. Gourraud[3], A. Ticca[5], P. Bitti[6], R. Pastorino[2], L. Bernardinelli[2,4], J.L. McCauley[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Public Health, Neurosciences, Experimental and Forensic Medicine, Medical Statistics and Epidemiology Unit, University of Pavia, 27100, Pavia, Italy; 3) Department of Neurology, School of Medicine, University of California at San Francisco, San Francisco, CA, USA; 4) Statistical Laboratory, Centre for Mathematical Sciences, Wilberforce Road, Cambridge CB3 0WA, UK; 5) Divisione di Neurologia, Ospedale S. Francesco, Nuoro, Italy; 6) Immunohaematology and Blood Transfusion Department, Ospedale S. Francesco, Nuoro, Italy.

Multiple Sclerosis (MS) is an autoimmune, demyelinating disease that constitutes the leading cause of neurological disability in young adults. Prevalence rates follow a latitude gradient with the lowest prevalence in countries closest to the equator. Sardinia, in Insular Italy defies this gradient with a prevalence range of 150-200 per 100,000 people. The involvement of genetic risk factors has been established through twin, adoption and migration studies. Dissections of the genetic risk factor landscape have focused on populations with Northern European ancestry. The geographical isolation of Sardinia presents a unique opportunity to study a relatively homogeneous population; however, the underlying genetic risk factors for MS in Sardinia remain largely unknown. Clinical expression studies suggest overlapping risk factors across these populations, and population genetics coupled with Sardinian population history suggest that fewer variants act at the population level. To qualify the involvement of Northern European-identified variants we assess the effectiveness of the MS genetic burden (MSGB) calculated on the basis of established MS susceptibility variants to differentiate between Sardinian MS cases and controls. Using genotypes from a custom Illumina genotyping chip dubbed the “Immunochip” we built a logistic regression model with disease status as the outcome, and MSGB, and sex as predictors/covariates. An increase in the Northern European derived MSGB was not associated with MS case status in our preliminary analysis of cases from 16 Sardinian families, and 94 unrelated Sardinian controls (OR=1.136, 95% CI 0.857-1.493, P > 0.05). This suggests that perhaps a separate set of genetic risk factors, are driving MS in Sardinia. A more conclusive analysis is currently underway. This analysis will include additional cases from each family, using Generalized Estimating Equations to correct for correlations between relatives, and additional controls from the SardiNIA Medical Resequencing Project (NIH). Furthermore, we will assess the extent to which the MSGB can differentiate between Northern European and Sardinian MS cases.

2040W

Heritability and Linkage Analysis of the Health Aging Index (HAI) in the Long Life Family Study. *M.M. Barmada[1], J.L. Sanders[2], A.M. Matteini[3], K. Christensen[4], R. Mayeux[5], T. Perls[6], I. Borecki[7], Q. Zhang[7], A.B. Newman[2], Long Life Family Study.* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Division of Geriatric Medicine and Gerontology, School of Medicine, Johns Hopkins University, Baltimore, MD; 4) Department of Epidemiology, University of Southern Denmark, Odense, Denmark; 5) Department of Neurology, College of Physician and Surgeons, Columbia University, New York, NY; 6) Department of Medicine, School of Medicine, Boston University, Boston, MA; 7) Division of Statistical Genomics, School of Medicine, Washington University in St. Louis, St. Louis, MO.

A goal of gerontology research is to find longevity assurance genes that affect many specific conditions leading to age-related chronic disease and death, providing clues to an underlying aging process. We constructed a Healthy Aging Index (HAI) and determined its association with death and heritability to validate it as a longevity phenotype in the Long Life Family Study (LLFS). LLFS is a two-generation, family-based cohort designed to study sibships of exceptionally healthy older individuals and their adult offspring. LLFS comprises a total of 480 families with information measured on 3770 individuals; 1294 in the older generation (mean age = 89 yr), and 2476 in the offspring generation (mean age = 61 yr). The HAI includes systolic blood pressure, pulmonary vital capacity, serum creatinine, fasting glucose, and Modified Mini Mental Status Exam score, each scored as 0, 1 or 2 using approximate tertiles. Scores were summed from 0 (healthy) to 10 (unhealthy) using either equal weighting, or with mortality-optimized component weights. Using maximum likelihood methods, heritability of this trait was estimated in LLFS (overall age-adjusted h^2 = 0.285, P=8.2e-11; probands h^2 = 0.369, P=9e-7; offspring h^2 = 0.248, P=0.00078). We next performed variance components linkage analyses using multipoint identity by descent estimates derived from three sets of SNPs. Significant linkage (LOD > 3.0) was detected on chromosome 8 and suggestive linkage (LOD > 2.5) was observed on chromosome 19. These findings support further evaluation of the genetic and environmental factors contributing to this phenotype of healthy aging in the elderly.

2041T

Genetic determinants of Age-related Macular Degeneration in Diverse Populations: the Population Architecture using Genomics and Epidemiology (PAGE) Study. *N. Restrepo[1], K. Spencer[3], R. Goodloe[1], T. Garrett[4], G. Heiss[4], P. Buzkova[5], N. Jorgensen[5], R. Jensen[5], T. Matise[6], B. Klein[7], R. Klein[7], W. Tien Yin[8], B. Cornes[8], E. Shyong Tai[9], M. Ritchie[10], J. Haines[1], D. Crawford[1,2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Vanderbilt Department of Molecular Physiology & Biophysics; 3) Department of Biology, Heidelberg; 4) Department of Epidemiology, University of North Carolina, Chapel Hill; 5) Department of Biostatistics, University of Washington, Seattle; 6) Department of Genetics, Rutgers University, Piscataway; 7) Office of Population Genomics, National Human Genome Research Institute, national Institutes of Health, Bethesda, MD; 8) Department of Ophthalmology and Visual Sciences, University of Wisconsin, Madison, WI; 9) Singapore Eye Research Institute, Singapore national Eye Centre, Singapore; 10) PennState Department of Biochemistry and Molecular Biology.

Age-related Macular Degeneration (AMD) is the third leading cause of visual impairment worldwide. Unlike many other common, complex disorders, substantial progress has been made in identifying susceptibility variants for AMD. The most widely replicated loci are Complement Factor H (CFH) Y402H and Age-related Maculopathy Susceptibility-2 (ARMS2), both of which were discovered in populations of mainly European-descent. To date, little data exist for these AMD-associated variants in diverse populations. A major goal of the Population Architecture using Genomics and Epidemiology(PAGE) study is to describe the underlying genetic architecture of common, complex diseases such as AMD across diverse populations. The PAGE study consists of several epidemiologic collections including the National Health and Nutrition Examination Surveys (NHANES), the Atherosclerosis Risk in Communities Study (ARIC), and the Cardiovascular Health Study (CHS). Also included in this study are the Singapore Prospective Study Programme (SP2) and the Singapore Malay Eye Study (SiMES). Targeted genotyping was performed for AMD-associated SNPs in CFH, CFI, ARMS2, VEGF, and lipid trait loci. All cases of AMD were >60 years of age and presented with early or late AMD as determined by fundus photography. A total of 830, 95, 107, and 21 cases and 5,710, 1,172, 863, and 206 controls from European Americans, African Americans, Malays, and Chinese, respectively, were available for study. We performed a meta-analysis following logistic regression assuming an additive genetic model performed at each study site and adjusted for age, sex, body mass index, smoking status, and HDL cholesterol. In European Americans, rs1061170 (CFH) and rs10490924 (ARMS2) replicated at p=3.7x10-10 (OR= 1.61, 95% CI= 1.85and 1.41) and p=1.8x10-5 (OR = 1.49, 95% CI= 1.78 and 1.25), respectively. None of the CFH or ARMS2 SNPs tested generalized to African Americans (p>0.05). Interestingly, HDL associated variant CETP rs1800775 (OR=0.55; 95% CI=0.86 and 0.35; p=0.009) associated with AMD in African Americans but not European Americans or Asians suggesting a potential risk modifier in lipid pathways to AMD in this population. Further studies are needed to determine if lack of generalization in major CFH and ARMS2 variants is due to statistical power or differences in linkage disequilibrium and allelic distribution across these diverse populations.

Age at menarche (AM) and age at natural menopause (ANM) define the boundaries of the reproductive lifespan in women. The timing of these events has been associated with various diseases, including cancer and cardiovascular disease. Genome-wide association studies have identified several genetic variants associated with either AM or ANM in populations of largely European or Asian descent women. The extent to which these associations generalize to diverse populations remains unknown. Therefore, we sought to replicate previously reported AM and ANM findings and also performed a large scale association study to identify novel AM and ANM variants using Metabochip data (161,098 SNPs) genotyped in 4,159 and 1,860 African American women, respectively, in the Women's Health Initiative (WHI) and Atherosclerosis Risk in Communities (ARIC) studies, as part of the Population Architecture using Genomics and Epidemiology (PAGE) Study. We were able to generalize only one previously identified variant each for AM and ANM to our African American cohort, rs1361108/*CENPW* and rs897798/*BRSK1*, respectively. Overall, generalization of the majority of previously-identified variants for AM and ANM, including *LIN28B* and *MCM8*, was not observed in this African American sample, though these loci were not well covered in the array. In our discovery analysis, we identified three loci associated with ANM that reached significance after accounting for multiple testing (*LDLR* rs189596789, $p=5x10^{-08}$; *KCNQ1* rs79972789, $p=1.9x10^{-07}$; *COL4A3BP* rs181686584, $p=2.9x10^{-07}$) as well as ninety-two additional SNPs suggestively associated with ANM, $p<1x10^{-4}$. Our most significant AM association was upstream of *RSF1*, a gene implicated in ovarian and breast cancers (rs11604207, $p=1.6x10^{-06}$). We identified suggestive AM and ANM associations in or near genes implicated in obesity, type 2 diabetes, cancer, or cardiovascular traits (*HEXIM2* rs59622946, *LPL* rs4922116, *PPP2R3A* rs11922097, *CYP4F22* rs1273516), which, in part, likely reflects the Metabochip focus on cardiometabolic loci. While most associations were unique to either AM or ANM, we also identified novel associations in genes common to both: *PHACTR1* (rs117124693(ANM) and rs73725617(AM)) and *ARHGAP42* (rs11224401(ANM) and rs11224447(AM)). The lack of generalization coupled with the potentially novel associations identified here emphasize the need for additional genetic discovery efforts for AM and ANM in diverse populations.

2043W

African Ancestry Is a Risk Factor for Asthma and High Total IgE Levels in African Admixed Populations. *C.I. Vergara[1], T. Murray[2], N. Rafaels[1], R. Lewis[1], M. Campbell[1], C. Foster[1], L. Gao[1], M. Faruque[3], R. Riccio Oliveira[4], E. Carvalho[4], M.I. Araujo[4], A.A. Cruz[5], H. Watson[6], D. Mercado[7], J. Knight-Madden[8], I. Ruczinski[9], G. Dunston[3], J. Ford[2], L. Caraballo[7], T. Beaty[2], R.A. Mathias[1], K.C. Barnes[1].* 1) Division of Allergy and Clinical Immunology, Johns Hopkins University, Baltimore, MD; 2) Department of Epidemiology, Bloomberg School of Public Health, JHU, Baltimore,MD 21225; 3) National Genome Center at Howard University, Washington, D.C; 4) Servico de Imunologia, Hospital Universitario Professor Edgard Santos, Salvador, Bahia, Brazil; 5) ProAR-Nucleo de Excelencia em Asma, Federal University of Bahia and CNPq, Salvador, Bahia, Brazil; 6) Faculty of Medicine, Univesity of the West Indies, Cave Hill Campus, Barbados; 7) Institute for Immunological Research, University of Cartagena, Cartagena, Colombia; 8) Tropical Medicine Research Institute, The University of West Indies, Mona Kingston 7, Jamaica, West Indies; 9) Johns Hopkins School of Public Health, Biostatistics, Baltimore, Maryland.

Characterization of genetic admixture of populations in the Americas and the Caribbean is of interest for anthropological, epidemiological and historical reasons. Asthma has a higher prevalence and is more severe in populations with a high African component. Association of African ancestry with asthma has been demonstrated. We estimated admixture proportions of samples from 6 trihybrid populations of African descent and determined the relationship between African ancestry and asthma and total serum IgE levels (tIgE). We genotyped 237 ancestry informative markers in asthmatics and non-asthmatic controls from Barbados (190/277), Jamaica (177/529), Brazil (40/220), Colombia (823/941), African Americans from New York (207/171) and African Americans from Baltimore/Washington, D.C. (625/757). We estimated individual ancestries and evaluated genetic stratification using STRUCTURE and principal component analysis. Association of African ancestry and asthma and tIgE was evaluated by regression analysis. Mean ± SD African ancestry ranged from 0.76 ± 0.10 among Barbadians to 0.34 ± 0.14 in Colombians. The European component varied from 0.14 ± 0.05 among Jamaicans and Barbadians to 0.25 ± 0.07 among Colombians. African ancestry was associated with risk for asthma in Colombians (OR: 4.3; 95% CI: 2.1-8.6; P = 0.0001)), Brazilians (OR= 136.5; 95% CI: 5.4-3406; P = 0.003) and African Americans of New York (OR: 4.7; 95% CI: 1.07-21.04, P=0.040). African ancestry was also associated with higher tIgE levels among Colombians (β=1.3, 95% CI: 1.1-2.6, P = 0.003), Barbadians (β= 3.8, 95% CI: 1.1-13.1; P = 0.03) and Brazilians (β = 1.6, 95% CI: 1.1-2.6; P = 0.03). Our findings indicate that African ancestry can account for, at least in part, the association between asthma and its associated trait, tIgE levels.

Validation of the HELIC population isolate collections as cohorts for complex trait association mapping. *E. Zeggini[1], I. Tachmazidou[1], A. Farmaki[2], L. Southam[1,3], N.W. Rayner[1,3], K. Daoutidou[2], A. Kolb-Kokocinski[1], K. Panoutsopoulou[1], E. Tsafantakis[4], M. Karaleftheri[5], G. Dedoussis[2].* 1) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Harokopio University, Athens, Greece; 3) Wellcome Trust Centre for Human Genetics, Oxford, UK; 4) Anogia Medical Centre, Greece; 5) Echinos Medical Centre, Greece.

Over the last five years, genome-wide association studies (GWAS) have been successful in identifying multiple robustly replicating complex trait genetic loci. The field is now shifting focus from common to low frequency and rare sequence variation. Population isolates can enhance power to detect association at these sites, as rare variants may have risen in frequency and linkage disequilibrium tends to be extended. We have collected samples from two isolated populations in Greece under the auspices of the HELIC (HELlenic Isolated Cohorts) study (HELIC-Pomak and MANOLIS cohorts), both accompanied by information on a wide array of anthropometric, cardiometabolic, biochemical, haematological and diet-related traits. We recently established these cohorts as genetic isolates based on measures of extended haplotype sharing derived from GWAS data and have whole-genome sequenced 250 individuals from MANOLIS at 6x to enable imputation and subsequent association testing. To date, we have carried out a GWAS for glycaemic traits and compared results at established trait loci (Dupuis et al, Nat Genet, 2010) to validate the utility of these cohorts in complex trait mapping. 747 and 1118 individuals were typed on the Illumina OmniExpress platform for HELIC-Pomak and MANOLIS respectively. Fasting glucose (total n=1566) and fasting insulin (total n=1759) trait values were inverse-normal transformed and residualized using age, age^2 and the kinship matrix as covariates. A fixed-effects meta-analysis across ~665,000 SNPs was performed across the two cohorts. Of the 18 established glucose-associated variants, 14 were present in our analysis and all had the same direction of effect as the published data (binomial p=6.1x10^{-5}). The strongest association was observed for the *MTNR1B* SNP rs10830963 (p=8.7x10^{-5}), followed by rs560887 at the *G6PC2* locus (p=1.1x10^{-4}). Of the 2 established insulin loci, one (rs780094 at the *GCKR* locus) went in the same direction and showed evidence for association with the trait (p=4.2x10^{-3}). These data provide validation of the HELIC-Pomak and MANOLIS cohorts for use in complex trait association mapping. Phasing of the 250 sequenced individuals and imputation into the full analysis cohorts will enable assessment of low frequency and rare variant associations with quantitative traits of cardiometabolic relevance.

2045F

Evidence of Natural Selection at Crohn's GWAS Loci Based on Population Genetic Variation. *B.M.P.M. Bowen, J.H. Cho.* Department of Genetics, Yale University, New Haven, CT.

Crohn's Disease (CD) is an inflammatory bowel disease (IBD) affecting 150 per 100,000 Americans on average; however, the prevalence of CD among American subpopulations varies with ancestry. In particular, the prevalence of CD is four to seven-fold higher in Ashkenazi Jews (AJs) than in non-Jewish individuals of European descent (NJs). Using available genotype data from a previous genome-wide association study (GWAS), as well as data from the recently completed Immunochip IBD association study (IC), we found an enrichment of derived risk alleles in AJs and an enrichment of derived protective alleles in NJs. Further, for shared risk alleles, the risk allele frequency was higher in AJs. For shared protective alleles, the protective allele frequency was lower in AJs. We examined whether the allele frequency differences between AJs and NJs could be explained in part by natural selection. We examined population genetic patterns in AJ and NJ CD cases. AJ and NJ individuals were identified by self-report and ancestry was confirmed by principal components analysis. Admixed individuals were omitted from subsequent analyses. Each individual's GWAS data was phased using BEAGLE and was used to calculate extended haplotype homozygosity (EHH). We identified a number of genes for which cores of EHH differed between the two populations. We also observed more extensive EHH in AJs. We noted an enrichment of genes from the tumor necrosis factor super family (TNFSF) and its receptors in cores of EHH in AJs compared to NJs including *TNFSF8*, *TNFRSF8*, and *TNFRSF18*, among others. We then looked for evidence of coevolution for receptor-ligand pairs based on the correlation of receptor and ligand allele frequencies using a merged dataset of the Human Genome Diversity Panel and HapMap populations as well as our own sample populations, totaling a sample of 65 populations covering 7 geographic regions around the world. We found an inverse correlation between the frequency of the CD-associated *TNFSF18* and *TNFRSF18* alleles, as well as the *TNFRSF8* allele and the CD-associated *TNFSF8* allele, with the former driven largely by a selective sweep at *TNFSF18* in East Asians. These data support that natural selection has acted on CD loci in multiple populations and that such events may explain population-specific differences in disease prevalence.

Systemic lupus erythematosus (SLE) is a highly heterogeneous disorder characterized by production of autoantibodies directed at particular self-antigens in the cell nucleus. These autoantibodies are an important molecular sub-phenotype of SLE and are directly pathogenic. Prevalence of these autoantibodies varies by ancestral background, and genetic variation may play a role in these differences. We followed up a previous case-only GWAS which identified loci that were also associated with particular autoantibodies in SLE patients. We genotyped 43 tag SNPs from 10 regions identified in the above GWAS in a multi-ancestral SLE cohort of over 8000 patients split between African-American, European, Hispanic, and Asian ancestral backgrounds. The MAPK4 gene was associated with autoantibodies across multiple ethnic groups: rs2051308 was strongly associated with anti-dsDNA in African-Americans (OR=0.784, $p=5.49x10^{-4}$), rs7242442 was significantly associated with anti-RNP in Hispanic-Americans (OR= 1.578, $p= 3.18x10^{-4}$) while rs8097986 was strongly associated with anti-Ro (OR= 0.8248, $p= 4.14x10^{-3}$) in European-Americans. We also detected associations which were specific to one ancestral background: in African-Americans, rs310230 SNP in JAK1 was significantly associated with both anti-dsDNA and anti-RNP antibodies (OR=1.63, $p=6.20x10^{-05}$); in Asians, rs12202764 in the PRL gene was significantly associated with anti-La (OR= 4.681, $p= 1.53x10^{-4}$). We demonstrate one locus which is associated with diverse autoantibody specificities across multiple ancestral backgrounds, and other loci that are uniquely associated with a particular autoantibody profile in a specific ancestral background. The various SNP-autoantibody associations identified in this study highlight important molecular pathways that predispose to the characteristic serologic autoimmunity which contributes to the pathogenesis of SLE.

2047T

HLA DRB1 amino acid position 11 is highly associated with rheumatoid arthritis in African-Americans. *R.J. Reynolds[1], S. Raychaudhuri[2], P.I.W. de Bakker[2,3], X. Jia[2], M.I. Danila[1], A.F. Ahmed[4], L.W. Moreland[5], R. Brasington[6], L.F. Callahan[7], E.A. Smith[8], R.M. Plenge[2], S.L. Bridges Jr.[1], CLEAR Investigators.* 1) Department of Medicine, Division of Clinical Immunology and Rheumatology University of Alabama at Birmingham, Birmingham, AL; 2) Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, MA; 3) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 4) University of Alabama School of Medicine, Birmingham, AL; 5) Department of Medicine, Division of Rheumatology and Clinical Immunology, University of Pittsburgh, Pittsburgh, PA; 6) Washington University School of Medicine, St. Louis, MO; 7) University of North Carolina, Chapel Hill, NC; 8) Department of Medicine, Division of Rheumatology and Immunology, Medical University of South Carolina, Charleston, SC.

Although more than 30 non-major histocompatibility complex risk loci for rheumatoid arthritis (RA) have been identified in populations of European descent, of the known variants, 75% of the genetic variance for RA is confined to three human leukocyte antigen (HLA) loci. Compared to peoples of European descent, African-Americans have a lower prevalence of RA, the highest risk HLA DRB1 classical alleles (e.g. *04:01, *04:04) are found at lower frequency, and the effect size of the high risk alleles with RA is lower. Here we test the hypothesis that the source of the risk among HLA DRB1 alleles with RA in African-Americans is amino acid positions 11, 71, and 74, as shown in populations of European descent. Using Allele SEQR HLA-DRB1 (Abbot), we sequenced 665 African American autoantibody-positive RA cases and 976 healthy controls and assigned four digit alleles using Assign SBT v 3.5 (Conexio Genomics). Alleles were converted to binary variables indicating the presence/ absence of a specific amino acid residue at a given position. A series of linear models were fit to assess whether the joint effect of amino acid residues within each position was a significant source of variation for the presence of RA. Of 30 amino acid positions examined, amino acid position 11 (P=7.8E−23) was most highly associated with RA followed by position 13 (P=2.7E−19), 71 (P = 2.2E−04), 70 (1.9E−03) and 74 (P= 3.5E−03). After conditioning on position 11, the effects at the other positions were diminished, suggesting that in this sample amino acid position 11 was the primary contributor to the association with HLA DRB1. Within position 11 the multivariate odds ratios (+, − 95% CI) of association were: Val 3.3 (2.4, 4.5); Asp 2.4 (1.6, 3.5); Leu 1.5 (1.1, 2.1); Gly 1.4 (0.98, 1.9); Ser 1.0 (0.80, 1.3), with Pro as the referent. Two of the three high risk residues, Val and Leu, were also reported to be high risk residues in populations of European descent (Val 3.8, Leu 1.3). The odds ratio for Asp (2.4) was substantially higher for African-Americans than for Europeans (Asp 1.0). The finding that amino acid position 11 is most strongly associated with RA in African-Americans validates the association for this position described in populations of European descent. However, substantial differences are noted among amino acid residues within position 11, which can partly be attributed to differences in the frequencies of the presence of the residues between the ethnic groups.

***GCKR* Polymorphism and Insulin Resistance in Americans of Mexican origin.** *Y. Lu[1], H.Q. Qu[1], Q. Li[2], S.P. Fisher-Hoch[1], J.B. McCormick[1].* 1) The University of Texas School of Public Health, Brownsville, TX; 2) The McGill University Health Center (Montreal Children's Hospital), Montreal, QC, Canada.

Our previous study of the community based Cameron County Hispanic Cohort (CCHC) consisting of Mexican Americans showed that elevated homeostasis model assessment-estimated insulin resistance (HOMA-IR) is significantly more frequent in our adult and adolescent Mexican American population than in European populations(Qu et al., 2011, Rentfro et al., 2011). Using a set of ancestral informative markers (AIM) comprised of 103 single nucleotide polymorphisms (SNP) we then conducted a genetic ancestral analysis in which we demonstrated that elevated HOMA-IR levels are highly correlated with Amerindian ancestry, highlighting ethnic effects in this admixed Mexican American population(Qu et al., 2012). We are now investigating possible molecular mechanisms associated with this ethnic effect. An interesting candidate genetic mechanism is suggested by recent genome-wide association studies (GWAS), i.e. a SNP rs780094 of the glucokinase regulatory protein gene (*GCKR*) that is significantly associated with HOMA-IR (Dupuis et al., 2010). GCKR is an inhibitor of glucokinase (GCK) in liver and pancreatic islets, while GCK catalyzes the first step of glycogen synthesis and glycolysis, and serves as a metabolic glucose sensor in liver and pancreatic islets and thus plays a key role in glucose metabolism. Significant differences in rs780094 frequencies occur among different human populations according to the HapMap phase 3 study (http://hapmap.ncbi.nlm.nih.gov/), which therefore suggested to us as one possible mechanism mediating our reported ancestral effect on HOMA-IR. To test this hypothesis we genotyped rs780094 in 1551 CCHC participants who were also genotyped for the 103 AIMs. We found that, rs780094 is highly significantly associated with HOMA-IR levels (β=0.088, P=6.43E−05) after correction for population structure, body mass index (BMI), age, and gender, and also associated with Amerindian ancestry (β=0.081, P=1.48E−03). This DNA marker alone explains 6.14% of the ancestral effect on HOMA-IR levels in Mexican Americans. We are currently pursuing this approach to systematically identify other potential molecular mechanisms involved in the ancestral effect of HOMA-IR in people of Mexican origin.

Characterization of clinical characteristics and genetic burden of Multiple Sclerosis in Hispanics. *I. Konidari[1], A. Hadjixenofontos[1], C.P. Manrique[1], A.H. Beecham[1], P.L. Whitehead[1], V. Bakthavachalam[2], P-A. Gourraud[2], M.A. Pericak-Vance[1], L. Tornes[3], M. Ortega[3], K.W. Rammohan[3], S. Delgado[3], J.L. McCauley[1].* 1) John P. Human Genomics, University of Miami - Miller School of Medicine, Miami, FL; 2) Department of Neurology, School of Medicine, University of California at San Francisco, San Francisco, CA, USA; 3) Multiple Sclerosis Division, Department of Neurology, Miller School of Medicine, University of Miami, Miami, FL, USA.

Multiple Sclerosis (MS) is a demyelinating disease with autoimmune etiology and variable expression across populations. The influence of race and ethnicity is suggested by the differences in disease presentation among African Americans, Asians, Hispanics and non-Hispanic Whites (NHW). Hispanic populations were considered to be less susceptible to MS, however, recent studies suggest that the incidence and prevalence of MS in this admixed population is increasing. Studies of Hispanics in the US with primarily Mexican origin note a preponderance of opticospinal MS at first presentation, with a younger age at onset, and a progression of disability that is similar to that of NHW. The primary purpose of our study was to describe the expression of MS in a sample of Hispanics from the South Florida community with primarily Caribbean origin. Chi-squared tests were used to identify statistically significant differences in sex, disease type, symptoms at initial presentation, site of initial presentation, Expanded Disability Status Scale score, and interferon response. Age at onset, age at diagnosis, diagnostic lag, disease duration, MS genetic burden score (MSGB) and genetic burden due to HLA-DRB1*1501 were tested for differences by race/ethnicity using t-tests. Since the MSGB is designed to capture the genetic load attributed to variants identified in populations of European ancestry, it is expected that an admixed population will be characterized by a partly-overlapping set of genetic variants and/or environmental influences. In our studies, we observe a significantly younger age at onset (P=0.016) and age at diagnosis (P=0.016) in Hispanics (n=251) when compared to NHW (n=247). Interestingly, we also observe a significantly lower MSGB (P<0.001) in Hispanics as compared to NHW. When we excluded HLA-DRB1*1501 from the analysis, this difference was no longer significant (P=0.126). Our study highlights the need for further studies of MS risk factors among Hispanics with the goal of understanding the underlying causes of MS in this population in hope of improved disease management and treatment of MS in all populations.

2050T

Investigating a role for functional variation in HIV-1 control through exome sequencing. *P.J. McLaren[1, 2], P. Shea[3], I. Bartha[1, 2], K.V. Shianna[3], D.B. Goldstein[3], J. Fellay[1, 2].* 1) School of Life Sciences, Ecole Polytechnique Fédérale de Lausanne, Lausanne, VD, Switzerland; 2) Institute of Microbiology, University Hospital Lausanne, Lausanne, VD, Switzerland; 3) Center for Human Genome Variation, Duke University School of Medicine, Durham, NC, USA.

Background: Genome-wide association studies (GWAS) of HIV-1 infected individuals have identified variants in the MHC and CCR5 regions as associated with viral load and disease progression, but none elsewhere. However, these studies are limited to analyzing common genetic variation represented on commercial arrays. Here we investigate the role of rare and functional variants in mediating HIV-1 control through exome sequencing.

Methods: We captured and sequenced all coding exons to high coverage (> 70x) in 131 HIV-1 infected individuals of recent Western European ancestry using the SureSelect Human All Exon 50Mb enrichment kit and the Illumina HiSeq2000. Paired-end, 120 bp reads were aligned using the Burrows-Wheeler Aligner (BWA) and quality control and variant calling were performed using a combination of Picard and Samtools. Variant functional annotation was performed using snpEff version 2.1. As a correlate of HIV-1 control, we used viral load at set point (spVL), calculated as the average of at least 3 longitudinal measurements obtained during the chronic phase of infection, in absence of antiretroviral therapy.

Results: An average of 10,109 non-synonymous variant alleles were observed per individual. No association was observed between mean virus load and genome-wide burden of non-synonymous variants after accounting for the top eigenstrat coordinates (from GWAS), age and sex. In total, 358 genes were found to carry homozygous stop gain mutations in at least 1 individual. Of these genes, 22 are reported as having a direct interaction with at least one viral protein in the HIV-1, Human Protein Interaction Database (http://www.ncbi.nlm.nih.gov/RefSeq/HIVInteractions). No association was observed between presence of a homozygous stop-gain mutation in a known HIV-1 interacting gene and spVL.

Conclusions: Preliminary analysis shows no association between spVL and genome-wide burden of missense variants or carriage of a homozygous stop mutation in a gene known to directly interact with HIV-1. Addition of further samples and other testing methods (e.g. individual variant testing, collapsing of variants by gene and pathways) will be required to fully address the role of rare, functional sequence variants in controlling HIV-1 infection.

2051F

The effect of genetic and interaction factors for risk prediction in type 2 diabetes. *D. Shigemizu[1], T. Abe[1], T. Morizono[1], TA. Johnson[1], KA. Boroevich[1], M. Kubo[1], Y. Nakamura[2], S. Maeda[1], T. Tsunoda[1].* 1) Center for Genomic Medicine, RIKEN, Yokohama, Kanagawa, Japan; 2) Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Many genome-wide association studies (GWAS) have recently identified and validated novel single nucleotide polymorphisms (SNPs) associated with type 2 diabetes (T2D). Numerous models and scores using genetic risk factors have been developed for T2D risk prediction, such as a prognostic model, because multiple genetic and clinical risk factors are expected to contribute the pathogenesis of T2D. However, risk prediction models composed of genetic factors have shown only a low ability to predict the development of T2D compared to models composed clinical risk factors. To our knowledge, exhaustive analysis considering not only algorithms for risk factor detection but also regression methods for model construction and, in furthermore, interactions of the risk factors have not been investigated so far. Here, we exhaustively examined risk prediction models considering three algorithms for risk factor detection, three regression methods for the model construction and interactions of risk factors. The best risk prediction model was constructed using a Bayes factor approach, considering information of the square of the correlation coefficient between SNPs and the lasso method. This method achieved a highest area of a receiver operating characteristic curve (AUC), an improvement over analysis composed of only clinical risk factors. With the addition of two significant interaction factors, the model was further improved with an increase in AUC. Our results suggest that current risk prediction models can be improved by taking into consideration genetic risk factors and interaction factors.

Genome-Wide Association Study of Structural Foot Disorders (lesser-toe deformity, hallux valgus and plantar soft-tissue atrophy) in Older Caucasian Populations. *YH. Hsu[1, 2], CH. Cheng[1], Y. Liu[3], LA. Cupples[4], J. Jordan[3], M. Hannan[1].* 1) HSL Institute for Aging Res and Harvard Medical School, Boston, MA; 2) Molecular and Integrative Physiological Sciences, Harvard School of Public Health, Boston, MA; 3) University of North Carolina, Chapel Hill, NC; 4) Boston Univ. Sch Pub Hlth, Boston, MA.

Structural foot disorders, such as lesser-toe deformity, hallux valgus and plantar soft-tissue atrophy, commonly affect ~ 60% of older adults and are associated with chronic mobility limitations, disability and foot pain. Although, ageing is considered the most important cause of these foot disorders, the importance of genetics is commonly suspected in clinical observations of family aggregation. Previously, we reported strong heritability (h^2) for lesser-toe deformity (61% in men; 85% in women) and moderate h^2 for hallux valgus (~35%) and plantar soft-tissue atrophy (~20%) in older men and women, suggesting potential genetic predisposition to structural foot disorders. To identify their genetic determinants, we have undertaken a GWAS using 2.5M imputed SNPs (HapMapII CEU reference panel) to localize susceptible genes in the Framingham Study. Structural foot disorders were indicated as present or absent and were assessed based on an atlas of pictorial depictions. Plantar soft tissue atrophy was determined by standardized palpatory clinical examination. Among 2,446 Framingham participants (mean age 66 yrs; 57% women; Caucasian), we identified 753 (31%), 764 (31%) and 665 (27%) participants with lesser-toe deformity, hallux valgus and plantar soft-tissue atrophy, respectively. A mixed-effect regression model was performed and adjusted for age, sex, weight and principal components of ancestral genetic background. A kinship covariance matrix was used to take into account within family correlations among siblings. We filtered out SNPs with low imputation quality (O/E variance ratio of allele frequency < 0.3) and SNPs with MAF < 1%. In addition, p-values were also adjusted for λGC. We found several associations achieved genome-wide significance ($p < 5x10^{-8}$), i.e. SNPs on TBC1D22A and OR5D13 gene for lesser-toe deformity. For hallux valgus, the most significant SNP ($p= 4.9x10^{-7}$) is located in GATAD2B gene. For plantar soft-tissue atrophy, the most significant SNP ($p=4.76x10^{-7}$) is located near ADAMTS16 gene. Pathway and gene-set analyses for the genome-wide significant and suggestive genes suggested significant clustering of genes involved in connective tissue disorders (such as oligoarticular arthritis, osteoarthritis and osteosclerosis). Of note, few SNPs reported to associate with longevity. The replication in independent samples is undergoing. In conclusion, our results reveal novel genes to further elucidate the etiology of structural foot disorders.

2053T

Multi-stage genome-wide association meta-analyses identified two new loci for bone mineral density. *L. Zhang[1,2], J. Li[2], YF. Pei[1,2], Y. Lin[1], H. Shen[2], K. Estrada[3,4,5], F. Rivadeneira[3,4,5], AG. Uitterlinden[3,4,5], CS. Shin[6], HJ. Choi[6], EL. Duncan[7,8], PJ. Leo[7], MA. Brown[7], YZ. Liu[2], YJ. Liu[2], JG. Zhang[2], Q. Tian[2], YP. Wang[2], XZ. Zhu[1], SY. Wu[1], CJ. Papasian[9], HW. Deng[1,2].* 1) Center of System Biomedical Sciences, University of Shanghai for Science and Technology, Shanghai, China; 2) Center for Bioinformatics and Genomics, Department of Biostatistics and bioinformatics, Tulane university, New orleans, LA; 3) Department of Internal Medicine, Erasmus Medical Center, Rotterdam, The Netherlands; 4) Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 5) Netherlands Genomics Initiative (NGI)-sponsored Netherlands Consortium for Healthy Aging (NCHA), Leiden, The Netherlands; 6) Department of Internal Medicine, College of Medicine, Seoul National University, Seoul, Korea; 7) Human Genetics Group, University of Queensland Diamantina Institute, Brisbane, Queensland, Australia; 8) Department of Endocrinology, Royal Brisbane and Women's Hospital, Brisbane, Queensland, Australia; 9) Department of Basic Medical Science, University of Missouri-Kansas City, Kansas City, USA.

Aim: Bone mineral density (BMD) is a highly heritable trait and a major risk factor for osteoporosis. We aim to identify genetic variants associated with BMD. Methods: We conducted a multi-stage genome-wide association (GWA) meta-analysis in 26,988 individuals. In Stage 1, we meta-analyzed 7 GWA samples and 11,140 individuals for BMDs at the lumbar spine, hip, and femoral neck. In Stage 2 we analyzed in silico a selected set of single nucleotide polymorphisms (SNPs) from Stage 1 in 3 independent samples encompassing 9,185 individuals. Novel SNPs at or near the genome-wide significance (GWS, $5.0x10^{-8}$) level in joint analyses of Stages 1+2 were replicated de novo in 2 additional samples encompassing 6,663 individuals. Results: Combining evidence from all stages, we have identified 2 novel loci at the GWS level: 14q24.2 (rs227425, p-value $3.98x10^{-13}$, SMOC1) and 21q22.13 (rs170183, p-value 4.15x10−9, CLDN14) that were associated with BMD in the combined sample of males and females and in the female specific sample respectively. We have also replicated 12 previously reported loci at the GWS level: 1p36.12 (ZBTB40), 1p31.3 (GPR177), 4p16.3 (FGFRL1), 5q14.3 (MEF2C), 6q25.1 (C6orf97, ESR1), 7q21.3 (FLJ42280, SHFM1), 7q31.31 (FAM3C, WNT16), 8q24.12 (TNFRSF11B), 11p15.3 (SOX6), 11q13.4 (LRP5), 13q14.11 (AKAP11), and 16q24 (FOXL1). Gene expression analysis in osteogenic cells implied some potential functions of the newly identified genes in bone metabolism. Conclusion: In total, these findings contribute to uncover the biological pathways underlying bone metabolism, and thus provide valuable insights into the intervention and treatment of osteoporosis.

Genetics of left- and right-hemisphere subcortical structures in the human brain. *M.E. Renteria[1,2], A. Wallace[1], L. Strike[1], K. Johnson[1], D.P. Hibar[3], J.L. Stein[3], G. De Zubicaray[2], K.L. McMahon[4], G.W. Montgomery[1], P.M. Thompson[3], N.G. Martin[1], S.E. Medland[1], M.J. Wright[1].* 1) Queensland Inst Medical Research, Herston, Queensland, Australia; 2) Laboratory of Neuro Imaging, UCLA School of Medicine, Los Angeles, CA, USA; 3) School of Psychology, University of Queensland, Brisbane, QLD, Australia; 4) Center for Advanced Imaging, University of Queensland, Brisbane, QLD, Australia.

The human brain displays great individual variation in its morphology and function. Subcortical structures such as the hippocampus, caudate nucleus, amygdala, putamen or pallidum play important roles in both basic and higher-order cognitive functions and behaviour. Previous studies have reported that individual differences in subcortical volumes are highly heritable and that significant phenotypic correlation exists between them. In this study, we obtained whole-brain MRI scans and extracted in a sample of 1032 twins and their siblings (655 females and 377 males). MRI images were processed with the FSL/FIRST software package to calculate volumes of 7 subcortical structures. We performed univariate and multivariate twin modelling to study the genetic contributions to variation and covariation across structures. Furthermore, DNA was extracted from blood samples, followed by SNP genotyping with the Illumina 610K Quad Bead chip and imputation to the latest reference panel of the 1000 Genomes Project was carried out using Mach. Finally, we performed 14 genome-wide association studies in our sample (7 left-hemisphere structures and 7 right-hemisphere structures).

Variant in the HLA-DPB1 region inversely associated with follicular lymphoma risk in meta-analysis of two genome-wide association studies. *L. Conde[1], K.E. Smedby[2], J.N. Foo[3], J. Riby[1], K. Humphreys[4], F.C.M. Sillé[1], H. Darabi[4], S. Sanchez[1], H. Hjalgrim[5], J. Liu[3], P.M. Bracci[6], C.F. Skibola[1].* 1) School of Public Health, Division of Environmental Health Sciences, University of California, Berkeley, CA 94720; 2) Unit of clinical epidemiology, Dept of Medicine Solna, Karolinska Institutet, Stockholm, Sweden; 3) Human Genetics, Genome Institute of Singapore, A*STAR, Singapore 138673; 4) Dept of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 5) Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 6) Department of Epidemiology and Biostatistics, University of California, San Francisco, CA 94143.

Introduction: Follicular lymphoma (FL) represents the second most common form of B-cell non-Hodgkin lymphoma (NHL). An important role for inherited genetic susceptibility in FL has been supported by recent genome-wide association studies (GWAS) where three independent susceptibility alleles have been identified on chromosome 6p21.33–32 in the HLA class I and class II regions. To identify new genetic variants, we conducted a meta-analysis of the top 1000 SNPs from existing GWAS data in 592 FL cases and 1541 controls from Denmark/Sweden (SCALE) and the San Francisco Bay Area (SF-NHL2). Validation genotyping of associated SNPs was conducted in 107 FL cases and 681 controls from an independent NHL case-control study population (SF-NHL1). The effect of validated SNP genotypes on gene expression levels was also investigated using publicly available microarray data.

Methods: We selected for meta-analysis the top 1000 SNPs most significantly associated with FL in the SF-NHL2 and SCALE GWAS. Selected SNPs in one dataset that were not genotyped or did not pass direct genotyping quality control in the other, were imputed using BEAGLE 3.0.3 and IMPUTEv1 with haplotype data from HapMap phase II-CEU or 1000 Genomes pilot1 CEU as reference. Odds ratios (ORs) for each individual study were estimated using unconditional logistic regression under an additive model in PLINK. OR estimates were combined in a meta-analysis under fixed- and random-effects inverse variance models using the metagen function from the meta package in R. Heterogeneity across studies also was tested with the Cochran's Q test and quantified with the I2 heterogeneity index.

Results: An additional SNP in the 6p21.32 HLA class II region was validated and strongly inversely associated with FL risk (OR=0.66, 95CI=0.57–0.77, p=1.02x10-7). The association was independent of previously established FL SNPs, but not of HLA-DPB1*0301 and also correlated significantly with HLA-DPB1 expression.

Conclusion: These results further support a major role for HLA genetic variation in FL pathogenesis.

2056T

Genome-wide linkage and association analyses in uterine leiomyomata reveal *FASN* as a risk gene. *S.L. Eggert[1], K.L. Huyck[4], P. Somasundaram[2], R. Kavalla[2], E.A. Stewart[5], A.T. Lu[6], J.N. Painter[7], G.W. Montgomery[7], S.E. Medland[7], S.A. Treloar[7,8], K.T. Zondervan[9], D.R. Nyholt[10], A.C. Heath[10], P.A.F. Madden[10], L. Rose[11], P.M. Ridker[11,12], D.I. Chasman[11,12], N.G. Martin[7], R.M. Cantor[6], C.C. Morton[2,3,12].* 1) Dept Genetics, Harvard Med Sch, Boston, MA; 2) Dept of Obstetrics, Gynecology and Reproductive Biology, Brigham and Women's Hospital, Boston, MA; 3) Dept of Pathology, Brigham and Women's Hospital, Boston, MA; 4) Dept of Medicine, Dartmouth-Hitchcock Medical Center, Lebanon, NH; 5) Dept of Obstetrics and Gynecology and Surgery, Mayo Clinic and Mayo Medical School, Rochester, MN; 6) Dept of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 7) Queensland Institute of Medical Research, Brisbane, Australia; 8) The University of Queensland, Centre for Military and Veterans' Health, Herston, Australia; 9) Wellcome Trust Centre for Human Genetics and Nuffield Dept of Obstetrics and Gynaecology, University of Oxford, UK; 10) Washington University School of Medicine, St. Louis, MO; 11) Division of Preventive Medicine, Brigham and Women's Hospital, Boston, MA; 12) Harvard Medical School, Boston, MA.

Uterine leiomyomata (UL), the most prevalent pelvic tumors in women of reproductive age, pose a major public health problem given their high frequency, associated morbidities and most common indication for hysterectomies. A genetic component to UL predisposition is supported by analyses of ethnic predisposition, twin studies, and familial aggregation. A genome-wide SNP linkage panel was genotyped and analyzed in 261 white UL sister pair families from the Finding Genes for Fibroids study (FGFF). Two significant linkage regions were detected in 10p11 (LOD=4.15) and 3p21 (LOD=3.73) while five additional linkage regions were identified with LOD scores >2.00 in 2q37, 5p13, 11p15, 12q14 and 17q25. Genome-wide association studies were performed in two independent cohorts of white women and a meta-analysis was conducted. One SNP was identified with a p-value that reached genome-wide significance (rs4247357, P = 3.05E-08, odds ratio (OR) = 1.299). The candidate SNP is under a linkage peak and in a block of linkage disequilibrium in 17q25.3 which spans the genes fatty acid synthase (*FASN*), coiled-coil domain containing 57 (*CCDC57*) and solute carrier family 16, member 3 (*SLC16A3*). By tissue microarray immunohistochemistry, we found FAS protein expression elevated (3-fold) in UL when compared to matched myometrial tissue. *FAS* transcripts and/or protein levels are up-regulated in various neoplasms and implicated in tumor cell survival. *FASN* represents the first UL risk allele identified in white women by a genome-wide, unbiased approach and opens a path to management and potential therapeutic intervention.

X Chromosome markers associated with COPD: a meta-analysis in 3 cohorts. *M. Hardin[1], M. McDonald[1], M. Matthiessen[1], M. Cho[1], E. Wan[1], P. Castaldi[1], D. Lomas[2], P. Bakke[3], A. Gulsvik[3], J. Crapo[4], T. Beaty[5], C. Lange[1,6], E.K. SIlverman[1], D. DeMeo[1], The COPDGene and ECLIPSE investigators.* 1) Network Medicine, Brigham and Womens Hospital, Boston, MA; 2) Cambridge Institute for Medical Research, University of Cambridge, UK; 3) Institute of Medicine, University of Bergen, Norway; 4) Department of Medicine, University of Colorado, Denver CO; 5) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 6) Harvard School of Public Health, Boston, MA.

Rationale: Chronic obstructive pulmonary disease (COPD) is a progressive disorder of the lungs. COPD susceptibility is influenced by genetic factors. Several GWAS have identified genes associated with COPD. However, these studies have generally excluded variants on the X Chromosome. Analysis of the X chromosome poses challenges compared to standard approaches to analyzing the autosomes. Recently, several investigators have developed methods to address these issues. We hypothesized that by utilizing methods specifically addressing X chromosome analysis, we would identify previously unrecognized associations between X chromosome SNPs and COPD. Methods: We analyzed the non-pseudo-autosomal region of the X chromosome in three Caucasian case/control cohorts of COPD. The three cohorts included ECLIPSE (1763 cases and 178 controls), GensKOLs (850 cases and 855 controls), and COPDGene (2774 cases and 2493 controls). All cases had COPD with GOLD stage II or higher. All controls were current or former smokers with normal lung function. Genotyping was performed using Illumina SNP arrays. Our primary analysis was via the method of Clayton et al as implemented in INTERSNP, using an allele-based test with 1 degree of freedom, counting hemizygous males as equivalent to homozygous females and adjusting for age, pack-years, and X-chromosome specific MDS components, followed by a meta-analysis of all three cohorts. A second analysis was performed using the logistic regression in PLINK with autosomally derived PCs. Results: 132,77 SNPs and 1941 subjects were analyzed from ECLIPSE, 12,014 SNPs and 1705 subjects were analyzed from GenKOLS, and 16966 SNPs and 5354 subjects were analyzed from COPDGene. The most significant associations included variants in PASD1 (ECLIPSE, OR 1.6, p = 9.96x10-5), MAGEB2 (COPDGene, OR 0.87, p=4.21x10-5), and DMD (GensKOLs, OR 0.81, p=4.9x10-4). The most significant variant in a meta-analysis of all cohorts was located in the PHEX gene (OR=1.15, P=4x10-4). In a meta-analysis of the results using logistic regression in PLINK, the most significant association was in the PASD1 gene (OR 0.8, p=1x10-4). Conclusions: Although no single variant achieved genome-wide significance, several associations were present among all three cohorts and using both analytical methods. Extending these analyses to a larger sample size and imputed data could improve statistical power to detect associations between markers on the X chromosome and COPD.

2058W

Periodontitis shares *IL2RA* as a genetic risk factor with rheumatoid arthritis, multiple sclerosis, type 1 diabetes, and Crohn's disease. *A.S. Schaefer[1], M. Nothnagel[2], C. Graetz[3], Y. Periodontal diseases are highly prevalent and the major cause of tooth loss in adults above 40 years. The oral cavity is colonized by myriads of bacteria, which grow as complex colonies on tooth surfaces and on the oral mucosa. To some extent, it can be considered as a gateway for pathogens to other parts of the body, which may induce the development of systemic diseases. Periodontal diseases have been associated with a higher incidence of autoimmune conditions like rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and indirectly, of multiple sclerosis (MS). In the last five years, many disease-associated variants of genome-wide significance were identified, which contributed to the genetic basis of these autoimmune diseases, some of which showed a considerable overlap between different phenotypes. These factors often cluster within known regulatory pathways, and expose pathophysiologically relevant networks that are centered on specific transcriptional regulators. In an interdisciplinary medical research approach, we conducted the to date most comprehensive evaluation of the oral inflammatory disease periodontitis to identify shared genetic risk factors with the autoimmune diseases RA, SLE, and MS. We finemapped all major genetic risk loci (N=51) including their complete -cis regulatory regions by genotyping single nucleotide polymorphisms (SNPs) and insertions/deletions within these regions using the Illumina custom genotyping array immunochip. By a genetic association study of the 51 candidate regions in a total of 1,032 cases of the most severe and early-onset form aggressive periodontitis (AgP), further 1,351 cases of the more moderate but widespread form chronic periodontitis (CP), and 3,917 controls, we provide evidence for the intronic SNP rs11597237 of *IL2RA* to be associated with AgP (p=0.002, odds ratio=0.7 [95% confidence interval 0.6–0.9]). Our findings propose a genetic link between the oral cavity and the organism and further suggest the interrelation of inflammation and autoimmune disease.

2059T

Genetic factors underlying birth weight and cardiovascular disease: a study of 17 048 Finns. *K. Auro[1,2], E. Widen[3], J. Eriksson[1,4], A. Palotie[5], T. Lehtimäki[6], O. Raitakari[7], M. Perola[1,2].* 1) National Institute for Health and Welfare, Helsinki, Finland; 2) Helsinki University Central Hospital, Helsinki, Finland; 3) Institute for Molecular Medicine, Finland; 4) University of Helsinki, Finland; 5) Welcome Trust Sanger Institute, Cambridge, UK; 6) University of Tampere, Finland; 7) University of Turku, Finland.

Low birth weight has been solidly linked to cardiovascular diseases (CVD) at epidemiological level. Genetic factors linking birth weight and CVD are, however, poorly recognized. Our aim was to elucidate possible common genetic background underlying both fetal growth and CVD burden with combined genome and metabolome approach in large Finnish cohorts containing detailed phenotypic information. The study sample consists of three Finnish cohorts: The Young Finns Study, Helsinki Birth Cohort Study, and a subcohort of FINRISK 2002 sample. Together these cohorts contain total of 17 048 individuals having reliable birth measurements and data of CVD risk factors. Information of CVD events was gathered from hospital registers. Genome-wide genotypic (GWAS) data was available for 5 752 participants and metabolome data containing >100 serum metabolites for 8 288 participants. The study cohorts were pooled to gain statistical power. Gestation age, sex and maternal smoking were used as covariates. Only singleton pregnancies were included. The total amount of cardiovascular events in our study sample is 1800. Genotypic or metabolome data was available for 443 CVD cases. Birth weight associated with a novel gene locus (p=2.37x10-8) in CVD cases. In controls free of CVD, no association was seen. Birth weight also associated with several serum metabolites. With lipid particles, associations were seen with VLDL, LDL, and HDL levels measured in adulthood (P=0.0023–0.019). In addition, birth weight showed association with serum leptin (P=0.0013) and creatinine (p=0.0064) levels. Our results suggest a genetic link for fetal growth and CVD. Birth weight, when stratified for CVD status, associated with a novel gene locus with genome-wide statistical significance in a pooled study sample. Metabolome analysis also revealed association of birth weight with several serum metabolites, many involved in lipid metabolism. Since dyslipidemias significantly contribute to the CVD risk, these findings may indicate underlying, yet unknown genetic mechanisms common for both CVD and fetal growth. These novel findings elucidate the importance of fetal environment in future disease burden: factors affecting fetal growth may also guide the metabolic signals of the fetus into certain paths, contributing to the CVD risk in later life.

2060F

Genome-wide association study of orthostatic hypotension and supine-standing blood pressure changes in two Korean populations. *K. Hong, Y. Kim.* Center for Genome Science, Korea National Institute of Health, Cheongwon-gun, Chungbuk, South Korea.

Orthostatic hypotension is the failure of the cardiovascular reflexes to maintain blood pressure on standing from a supine position. The prevalence of orthostatic hypotension varies from 5% to 30% greatly depending on the population being studied. In the current study, we conducted genome-wide association studies for orthostatic hypotension case-control using the genome-wide SNP genotypes and also tested the supine-standing blood pressures as the quantitative traits. The study subjects were consisting of two population-based cohorts, Ansung and Ansan. The phenotypes and genotypes were obtained from Korean Genome and Epidemiology Study. The genome-wide association studies were conducted for each cohort, and the target phenotypes were the blood pressure differences in supine-standing systolic (dtSBP) and diastolic (dtDBP) and orthostatic hypotension. Among the target phenotypes, genome-wide association study for dtSBP detected a significant SNP, rs6736587 (meta-analysis p-value: 5.3 × 10-8) that located on chromosome 2p12. Interestingly, this region is known as the chromosome 2p12-11.2 deletion syndrome region and reported mental or psychomotor retardations. There is only one gene, CTNNA2 (alpha-N-catenin) around rs6736587±1Mbp. The CTNNA2 is a linker between cadherin adhesion receptors and the actin cytoskeleton, and is essential for stabilizing dendritic spines in rodent hippocampal neurons. Although there is no report about the function at blood pressure regulation, the hippocampal neurons interact primarily with the autonomic nervous system and might be related to the orthostatic hypotension.

2061W

Genetic association of erythrocyte and platelet phenotypes in Mexican Americans. *P.E. Melton[1], J.E. Curran[2], M. Carless[2], M.P. Johnson[2], T.D. Dyer[2], J.W. MacCluer[2], E.K. Moses[1], H.H.H. Goring[2], R. Duggirala[2], D. Glahn[3], J. Blangero[2], L. Almasy[2].* 1) Centre for Genetic Epidemiology and Biostatistics, University of Western Australia, Crawley AU; 2) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 3) Department of Psychiatry, Yale University School of Medicine, New Haven, CT.

Erythrocyte and platelet measurements are associated with risk of hematological disorders and early onset of cardiovascular disease. Most genetic studies on these phenotypes have been conducted in cohorts of European ancestry and little is known regarding genetic variants influencing these traits in other populations. This study reports family based genome-wide association study (GWAS) results for seven erythrocyte (hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, and red blood cell count) and three platelet (platelet count, mean platelet volume, plateletcrit) phenotypes in 827 Mexican Americans from the Genetics of Brain Structure (GOBS) Study. Erythrocyte and platelet measures were averaged over three readings taken at time of blood draw. GWAS was conducted utilizing 931,219 SNPs from Illumina microarrays under an additive genetic model. Covariates included age, sex, their interactions as well as the first 10 principal components to account for population stratification. The strongest association identified was for plateletcrit on chromosome 17q24 with the intergenic SNP rs10853057 (p=2.45x10e-10) near GNA13. We found three additional significant intergenic signals for plateletcrit on chromosomes 1q43 (rs1361277, p= 2.0x10-8), 6p12 (rs7751328, p=2.0x10-8), and 8q24 (rs7006137, p=1.0x10-8). QQ plots were done for all phenotypes demonstrating significant SNPs and lambda values did not exceed 1.02. None of these observed SNPs for plateletcrit have been identified in other GWAS analyses. Additional associations were detected in intronic SNPs for mean platelet volume in STK38 on chromosome 6p21 (rs4236051, p =1.0x10-8) in a previously identified region for platelet function. Analysis of hematocrit (rs6807319, p= 5x10e-8) demonstrated a previously unidentified significant association in SLC9A9 on chromosome 3q23. This SNP also demonstrated suggestive association (p=2x10e-7) with hemoglobin. Further analysis of these results is being undertaken with whole-genome sequencing in a subset of GOBS participants. This study identified new genetic regions that may have important implications for better understanding of genetic variants influencing erythrocyte and platelet variation.

2062T

GWAS in an isolated Sardinian population contribute to elucidate the genetic control of serum Angiotensin Converting Enzyme (ACE) level. *I. Persico[1], M.P. Concas[1], G.B. Maestrale[1], L. Portas[1], F. Murgia[1], M. Cosso[2], D. Serra[2], M. Pirastu[1,2].* 1) Institute of Population Genetics, CNR, Sassari, Italy; 2) SharDNA Life Science, Pula, Italy.

INTRODUCTION: ACE, encoded by DCP1 gene, plays a key role in the Renin Angiotensin System which is involved in the control of fluid electrolyte balance and cardiovascular system. A QTL at DCP1 is the major determinant of serum ACE levels and more recently the AB0 locus was found associated with ACE levels by GWAS in hypertensive patients. However these two loci do not fully explain the variability of the trait suggesting a role of other genetic factors. PURPOSE: We aimed to detect the genetic components which determine the serum ACE levels in healthy individuals through GWAS of a genetically homogeneous population. METHOD. Talana is an isolated village characterized by centuries of isolation and high genetic homogeneity. We phenotyped 517 individuals (>18 yrs), genotyped with 2.5 million SNPs, without diseases and not taking medications that may interfere in ACE levels. The GWAS for discovery was carried out in two steps: 1) log10-transformed ACE levels adjusted for sex and principal components; 2) adding the DCP1 gene as covariate. The best hits were replicated in two villages of the same area (Baunei, N=848; Seulo, N=346), with different genetic structure and almost absent intermarriages with Talana, and in 1000 unrelated individuals from outbreed population, all selected with the same criteria. RESULTS: We confirmed the DCP1 locus on chr 17q23 (rs4311, p = 2.3E-18). We identified several loci with p values < 5.0E-8 spread in 10 Mb region (17q23.2–17q24.2) containing the DCP1. We did not observe linkage disequilibrium between all these loci. In addition we observed suggestive signals on chr 9q34.2, in 180 Kb region spanning AB0-SURF4-ADAMTS13 genes which reached a significant p value adding the DCP1 as covariate in GWAS second stage. We replicated the signals of the entire region 9q34.2 both in the two villages and in the outbreed population and we observed a strong effect of the A, B and O alleles on ACE levels. Finally we replicated some of the chr 17 hits (i.e. rs9895941, p=2.18E-9, MARCH10) in the two villages but not in the outbreed population. CONCLUSION: This study confirms the independent role played by DCP1 and AB0-Surf4-ADAMTS13 loci in the genetic control of the ACE level. It is interesting to note that both loci have been associated with cardiovascular disease. We also highlighted, thanks to the peculiar genetic structure of our isolated population, new genes/loci that should be confirmed with new genetic and functional studies.

GWAS is a routine approach to detect the genetic determinants of complex traits, but requires a large sample size in order to overcome multiplicity and subtle effect sizes. Successful GWAS are often conducted through meta-analysis by large consortia, which usually operate by sharing summary statistics from cohorts with the same phenotypes. When multiple correlated phenotypes, such as hypertension status, systolic and diastolic blood pressure (BP) are available, multivariate analysis is often more powerful than single trait analysis. However, it is difficult to perform multivariate analysis with summary statistics. We propose a novel permutation procedure, META (Multiple-outcome Empirical Trait Analysis), for multiple correlated traits using GWAS summary statistics. META preserves the linkage disequilibrium patterns among SNPs as well as the correlation structure among traits, and adjusts significance for both multiple testing and trait correlation. META accomplishes this by randomly flipping the sign of regression effect estimates from each cohort to obtain the distribution of meta-analysis test statistics for each SNP under the null hypothesis and empirically estimating significance. Our simulations show that the proposed permutation method can improve power up to 40%; compared to single trait analysis. We applied our method to the GWAS summary statistics from the Continental Origins and Genetic Epidemiology Network (COGENT) consortium study of BP traits, which includes 19 African ancestry cohorts. The proposed method identified two additional novel BP/hypertension loci that were not detected by the single trait analysis. Our results suggest that a multivariate approach should be used when multiple correlated traits are studied, and furthermore that this enhanced analysis can also be done using summary statistics.

Association study on the X chromosome identifies novel genes associated with systemic lupus erythematosus (SLE) in Asian populations. *W. Yang[1], Y. Zhang[1], N. Hirankarn[3], X. Zhang[2], Y. Lau[1].* 1) Paediatrics & Adolescent Med, Univ Hong Kong, Hong Kong, Hong Kong; 2) Anhui Medical University, Hefei, China; 3) Chulalongkorn University, Bangkok, Thailand.

SLE is an autoimmune disease with striking female predominance. The sex chromosomes may play an important role in the increased female prevalence of the disease. The prevalence rate of SLE increases by 14 folds in males with Klinefelter's syndrome (47, XXY), to a level similar to that of females. Several genes on the X chromosome were confirmed by candidate gene approach as associated with SLE. In this study, we performed a meta-analysis of X chromosome variants of the two Genome-wide association studies (GWAS) in Asian populations from Hong Kong and Anhui, China. Based on the GWAS data, together with replication from more samples from different research centers in Hong Kong, Anhui and Bangkok, Thailand, we have shown a much clearer picture of X-linked genes related to lupus. A novel locus, PRPS2 (P=3.9E-09, OR=0.84), and a risk haplotype spanned a region from ARHGAP4 to MECP2 (P=1.8E-05) were confirmed by the meta-analysis and replication in three cohorts. Clear difference between the susceptibility loci identified in Asians and those from Caucasians is also demonstrated. These results may help us understand the gender difference and the role of the X chromosome in this disease.

2065T

Genetic modifiers of the palatal phenotype in 22q11 microdeletion syndrome. Preliminary results of a genome-wide association study. *C. Vial[1], G.M. Repetto[1,2], M. Palomares[3,4], S. McGhee[5], N.K. Henderson-MacLennan[6], M.L. Guzman[1], K. Espinoza[1], G. Lay-Son[1,2].* 1) Center for Human Genetics, Facultad de Medicina, Universidad del Desarrollo-Clinica Alemana, Santiago, Chile; 2) Hospital Padre Hurtado, Santiago, Chile; 3) Fundación Gantz, Chile; 4) Hospital Calvo Mackenna, Santiago, Chile; 5) Stanford University, Stanford, CA;; 6) UCLA, Los Angeles, CA.

Chromosome 22q11 microdeletion syndrome (del22q11) is one of the most common pathogenic genomic rearrangements in humans, with an estimated frequency of 1/4000 live births. Most patients share a common 3Mb deletion, but the clinical phenotype shows marked variable expressivity. Approximately 70–80% of patients have palatal anomalies, ranging from overt cleft palate to occult submucous cleft leading to velopharyngeal insufficiency and hypernasal speech. The cause of the incomplete penetrance of the palatal anomalies is unknown. We performed a genome wide association study (GWAS) to search for genetic modifiers of the palatal phenotype in Chilean patients with del22q11. DNA samples from 91 Chilean patients with del22q11 demonstrated by FISH with TUPLE1 probe (Abbott) and known palate anatomy by physical examination and nasopharyngoscopy were analyzed with Affymetrix ® v. 6.0 SNP array. We compared cases with any palate anomaly (n=69) to controls with normal palates (n=22). After filtering, genotypes, over 728,000 SNPs were analyzed with PLINK v1.07, using Fisher exact test for association. A population stratification analysis was done using the principal component multi-dimensional scaling (MDS) test. This results were used to perform an association with MDS information using the Cochran-Mantel-Haenszel test. A Bonferroni-corrected p value of 1 x 10-7 was considered as evidence of association. Two regions were found to have an association with the palatal phenotype. The first one was between 7q11.23–7q21.11 and included 4 SNPs with a p value between 7 x 10-8 and 1.3 x 10-5. Another region of 120kb in 20q13.12 included 8 SNPs with p values between 1.3 x 10-6 and 5.6 x 10-5. Although a larger sample size is needed to reach statistical significance in the latter region, these results point out two potential regions of interest, both within gene rich regions which will have to be further studied. Funded by Fondecyt-Chile Grant #1100131.

2066F

Genome-wide copy number variation in anorectal malformations. *S.S. Cherny[1], E.H.M. Wong[1], L. Cui[2], C.L. Ng[2], C.S.M. Tang[1], M.T. So[2], B.H.K. Yip[1], G. Cheng[2], V.C.H. Liu[2], P.C. Sham[1], P.K.H. Tam[2], M.M. Garcia-Barcelo[2].* 1) Psychiatry, Univ Hong Kong, Pokfulam, Hong Kong; 2) Surgery, Univ Hong Kong, Pokfulam, Hong Kong.

Anorectal malformations (ARMs, congenital obstruction of the anal opening) are among the most common birth defects requiring surgical treatment (2–5/10,000 live-births) and carry significant chronic morbidity. ARMs present either isolated or as part of the phenotypic spectrum of some chromosomal abnormalities or monogenic syndromes. The etiology is unknown. To assess the genetic contribution to ARMs, we investigated single nucleotide polymorphisms (SNPs) and copy number variants (CNVs) at genome-wide scale. A total of 363 Han Chinese sporadic ARM patients and 4,006 Han Chinese controls were included. Overall, we detected a 1.3-fold significant excess of rare CNVs in patients. Stratification of patients by presence/absence of other congenital anomalies showed that while syndromic ARM patients carried significantly longer rare duplications than controls ($p < .05$), non-syndromic patients were enriched with both rare deletions and duplications when compared to controls ($p < .0004$). Twelve chromosomal aberrations and 114 rare CNVs were observed in patients but not in 868 controls or 11,943 healthy individuals from the Database of Genomic Variants (DGV). Importantly, the aberrations were observed in isolated-ARM patients. Gene-based analysis revealed 79 genes interfered by CNVs in patients only. In particular, we identified a *de novo DKK4* duplication and an *INTU* hemizygous deletion. These genes are members of pathways (*Shh* and *Wnt*, respectively) involved in the development of the anorectal region. In mice, *Shh* or *Wnt* disruption results in ARMs. Our data suggest a role for rare CNVs not only in syndromic but also in isolated ARM patients and provides a list of plausible candidate genes for the disorder.

2067W

A genome-wide meta-analysis of copy number variation identifies novel childhood obesity loci. *D. Hadley[1], J. Bradfield[1], H. Hakonarson[1,2], S. Grant[1] on behalf of the Early Growth Genetics Consortium.* 1) The Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, USA; 2) Division of Genetics and Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA.

Recently, single nucleotide polymorphisms (SNPs) have been associated with the common form of early-onset obesity through a collaborative meta-analysis of North American, Australian and European pediatric populations (Bradfield et al, 2012). However, only limited progress has been made in understanding the influence of copy number variants (CNVs) in common childhood obesity. To that end, we developed a novel method to perform CNV meta-analyses and applied it to a large subset of the same three global populations studied by Bradfield et al to conduct the first meta-analysis of CNVs in common early-onset obesity. We compared over 2.2K cases to over 5.8K controls that passed quality control to discover genome-wide significant signals of association. We found common (frequency ≥ 5%) deletions at chromosomes 4q13.1 ($P \leq 2.32x10^{-6}$, OR = 1.31) and 6q14.1 ($P \leq 7.85x10^{-6}$, OR = 1.25), rare (frequency < 5%) deletions at chromosomes 6p22.3 ($P \leq 3.02x10^{-5}$, OR = 3.37), 14q11.2 ($P \leq 8.05x10^{-7}$, OR = 1.76), and 20q13.2 ($P \leq 8.69x10^{-5}$, OR = 2.71), and rare duplications at chromosome 1p32.2 ($P \leq 3.95x10^{-5}$, OR = 6.54). Most notably, the deletions at chromosome 6p22.3 were highly penetrant and span 25Kb of the intergenic region immediately downstream of *SOX4* which encodes a HMG box transcription factor best known to contribute to the development of the endocrine pancreas. Moreover, the deletions at *SOX4* were robustly identified from at least one site across all three continental populations analyzed. Our work is significant not only because it sheds light on the contributions of CNVs in the pathophysiology of common, early-onset childhood obesity, but also because, to the best of our knowledge, it is the first multi-site, genome-wide meta-analysis of CNVs performed for any trait.

Copy number variation analysis implicates locus 5q21.2 with raised intra-ocular pressure. *A. Nag[1], P.G. Hysi[1], C. Venturini[2], S. MacGregor[3], A.W. Hewitt[4], T.L. Young[5], P. Mitchell[6], A.C. Viswanathan[2], D.A. Mackey[7], C.J. Hammond[1], WTCCC2.* 1) King's College London, London, United Kingdom; 2) NIHR Biomedical Research Centre for Ophthalmology, Moorfields Eye Hospital NHS Foundation Trust and UCL Institute of Ophthalmology, London, UK; 3) Genetics and Population Health, Queensland Institute of Medical Research, Brisbane, Australia; 4) Centre for Eye Research Australia, University of Melbourne, Royal Victorian Eye and Ear Hospital, Melbourne, Australia; 5) Centre for Human Genetics, Duke Univ Med Ctr, Durham, NC; 6) Centre for Vision Research, Westmead Millennium Institute, University of Sydney, Australia; 7) Lions Eye Institute, University of Western Australia, Perth, Australia.

Glaucoma is a major cause of visual impairment and the second leading cause of blindness in the world. Rare sequence mutations in the genes myocilin (MYOC) and optineurin (OPTN) explain about 2–5 percent of primary open angle glaucoma cases. Lately, GWAS have identified common genetic variants for glaucoma, but still a significant heritability gap remains. We hypothesized that copy number variants (CNVs) might influence part of the susceptibility to glaucoma or its related quantitative phenotypes. The study examined the association between CNV and intra-ocular pressure (IOP), the major modifiable risk factor for glaucoma, in a sample of 781 unrelated individulas from the TwinsUK cohort. The samples were genotyped with the Illumina Human Hap610 Quad. The software package PennCNV was used to detect CNV regions for each sample. Appropriate quality control measures were implemented and CNV regions encompassing less than 10 SNPs were filtered out. Association testing between the CNVs detected and IOP was carried out using the software package GenABEL. Regression was performed to test for the association between a CNV and IOP. CNV regions which were less than 1% in frequency were excluded from further analysis. We found association with IOP for two CNV regions: 5q21.2 (p=0.013) and 22q11.2 (p=0.03). All the 5q21 CNVs overlapped the gene RAB9BP1 and all the 22q11 CNVs overlapped the gene CRYBB2P1. Replication studies were carried out in a sample of 467 Australian twins and in a sample 1620 individuals from the Blue Mountains Eye Study (BMES) cohort. Both studies successfully replicated the 5q21.2 CNV association and direction of effect (p=0.001 and p=0.003 respectively). A meta-analysis of this locus across the 3 cohorts showed that per allele copy number change increased the IOP by 1.62mmHg (p=8.67 x 10-7). The frequency of this CNV region in the TwinsUK cohort, the Australian twins cohort and the BMES cohort was 1.3%, 2.8% and 1% respectively. Interestingly, this IOP locus overlaps the previously widely replicated GLC1G linkage locus for glaucoma, for which subsequent studies have not reached consensus on the causal gene (including WDR36). Our results suggest that copy numbers changes of the RAB9BP1 gene may explain the linkage signal at this locus. .

Genome-wide Analysis of Copy Number Variants in Down Syndrome Associated Congenital Heart Defects. *D. Ramachandran[1], J. Mulle[2], AE. Locke[3], P. Bose[1], LJ. Bean[1], S. Le[1], T. Rosser[1], K. Dooley[4], DJ. Cutler[1], E. Feingold[5], SY. Cheong[6], CL. Cua[7], CL. Maslen[8], RH. Reeves[9], SL. Sherman[1], ME. Zwick[1].* 1) Human Genetics, Emory University, Atlanta, GA; 2) Epidemiology, Rollins School of Public Health, Emory University, Atlanta, GA; 3) Center for Statistical Genetics and Department of Biostatistics, University of Michigan School of Public Health, MI; 4) Sibley Heart Center Cardiology, Children's Hospital of Atlanta, GA; 5) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 6) Battelle Center Mathematical Medicine, Nationwide Children's Hospital, Columbus, OH; 7) Heart Center, Nationwide Children's Hospital, Columbus, OH; 8) Department of Molecular and Medical Genetics, Division of Cardiovascular Medicine, Oregon Health & Science University, Portland, Ore; 9) Department of Physiology, McKusick Nathans Institute for Genetic Medicine, School Of Medicine, John Hopkins University, MD.

Our project is focused on identifying genetic variants contributing to congenital heart defects (CHD), especially atrioventricular septal defect (AVSD) among individuals with Down Syndrome (DS). Non-syndromic AVSDs occur in approximately 1 in 10,000 births in the general population. However, among infants with DS nearly 20% have an AVSD, representing a nearly 2000-fold increased risk of AVSD compared to the general population. We hypothesize that in the presence of extra chromosome 21, otherwise benign copy number variants (CNVs) become susceptibility alleles and hence could explain the variable penetrance observed in DS-associated AVSD. We have used Affymetrix SNP 6.0 genotyping platform to comprehensively characterize the CNVs in a large DS population to test this hypothesis. The samples were collected through a multi-site recruitment effort. Cases were individuals with DS and a complete AVSD (DS+AVSD) and controls were those with DS and the documented absence of CHD (DS-CHD). We have developed an analysis pipeline for the quality control (QC) of samples and CNV calling aimed at minimizing false positive calls, including 3 algorithms to make the CNV calls, namely BEAST, GADA and GLAD. After QC filtering, we have a total of 831 samples consisting of 239 cases, 268 controls and 324 case parents for downstream analyses. Preliminary analyses identified a total of 434 CNVs. Among those, 139 CNVs were common to both cases and controls, 114 were present only in cases and 119 in controls. The size of the CNVs range from 964bp to 29.9Mb. In-depth analyses of these loci are presently underway for DS cases, controls and parents. Any interesting candidate loci identified will be validated independently. This study has the potential to shed light on as-yet unknown pathways that give rise to AVSD.

Rare genetic variation in relation to circulating adiponectin. *S. Gustafsson[1], L. Lind[2], A. Mahajan[3], S. Söderberg[4], A. Flyvbjerg[5], C.M. Lindgren[3], A.P. Morris[3], I. Ingelsson[1].* 1) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 2) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 4) Department of Public Health and Clinical Medicine, Cardiology and Heart Centre, Umeå University, Umeå, Sweden; 5) The Medical Research Laboratories, Department of Clinical Medicine, Faculty of Health, Aarhus University, Aarhus, Denmark.

Background: Previous studies have identified genetic variants associated with the phenotypic variance of adiponectin, mainly focusing on common genetic variation which to date explains a small fraction of the expected adiponectin variance. Our aim was to investigate the impact of rare genetic variants on circulating adiponectin. **Methods**: We investigated the relationship between circulating adiponectin levels and the proportion of minor alleles at rare genetic variants within a gene carried by an individual in two population-based cohorts, including 948 individuals from the Prospective Investigation of the Vasculature in Uppsala Seniors (PIVUS) and 1106 individuals from the Uppsala Longitudinal Study of Adult Men (ULSAM). Samples were genotyped on Illumina OmniExpress (PIVUS), Illumina Omni 2.5M (ULSAM) and Illumina Metabochip (both samples), and further imputed using haplotypes from the 1000 Genomes, June 2011 release. The software GRANVIL was used to perform the regression analysis and the results were combined across cohorts in a fixed-effect sample size-weighted Z-score meta-analysis. **Results**: In models adjusted for population stratification the proportion of minor alleles at rare variants within a transcript of *RPS27L* was significantly and positively associated with levels of adiponectin (P-value=$5.1\text{x}10^{-7}$), which remained significant after adjustment for BMI (P-value= $2.3\text{x}10^{-7}$), but more modestly associated in a subset of non-diabetic individuals. The transcripts of *FBXL14* and *WNT5B* were significantly associated with adiponectin in models adjusting for population stratification and BMI in a subset of non-diabetic individuals, when restricting the analysis to non-synonymous markers. With these settings only one non-synonymous marker at chr12:1702929 was included in the analysis of transcript regions of *FBXL14* and*WNT5B*. **Discussion**: Our results indicate that individuals who carry a larger proportion of rare alleles within a transcript of *RPS27L* have on average higher levels of adiponectin. A significant positive association was observed for each of the overlapping transcript regions of *FBXL14* and *WNT5B*, all adjacent to *ADIPOR2*, which included only one non-synonymous marker which is equivalent with a dominant effect single-marker association test. Prior studies have not been able to establish these regions to be associated with circulating adiponectin levels, so our results are of importance for understanding of adiponectin biology if replicated.

2071T

Comprehensive evaluation of type 2 diabetes susceptibility loci in East Asians by using 1000 Genomes Project data. *K. Hara[1], H. Fujita[1], T.A. Johnson[2], S. Maeda[2], T. Tsunoda[2], M. Kubo[2], T. Kadowaki[1].* 1) Department of Diabetes and Metabolic Diseases, Graduate School of Medicine, University of Tokyo, Tokyo 113-8655, Japan; 2) RIKEN Center for Genomic Medicine, Yokohama Kanagawa 230-0045.

Although over 50 type 2 diabetes (T2D) loci have been identified through genome-wide association studies (GWAS), the vast majority of the genetic predisposition to T2D still remains to be clarified. One explanation is that despite the use of high-throughput genotyping arrays, only a small proportion of genetic variants in the human genome are actually surveyed, especially in non-European populations. We explored the comprehensive catalog of genomic variations provided by the 1000 Genomes Project to identify variations conferring susceptibility to T2D in the Japanese population that were not detected in previous scans. We imputed 10,524,368 variants derived from 194 East Asian subjects (June 2011 release) into 5,976 cases and 20,829 controls genotyped by 610K single-nucleotide polymorphism (SNP) array. Overall concordance was good, although imputed SNPs with minor allele frequency (MAF) below 5 % apparently contained poorly imputed SNPs. We then tested associations for T2D before and after adjusting for age, sex, and body mass index. We confirmed that 8 previously reported loci were associated with T2D at the level of genome-wide significance ($P<5\times10^{-8}$). To briefly assess the similarities of genetic architecture between ethnic groups, we compared the effect sizes of previously reported and newly discovered variants between European and East Asian populations. There was significant concordance in the direction of effects among the two populations, indicating that the genetic factors contributing to T2D were substantially shared among these populations. In addition, we found 30 loci harboring multiple variants associated with T2D at $P<5\times10^{-5}$, seven of which had been reported previously. The remaining 23 previously unreported loci were subsequently selected for in silico (2,799 cases and 3,793 controls) and de novo genotyping (10,319 cases and 6,795 controls) follow-up studies focused on East Asian subjects. We also sought to define the most relevant SNPs for susceptibility to T2D in the previously identified genes. We did not find any stronger association with T2D than the originally reported SNPs in our population. Our study highlights the benefit of using data derived from next-generation sequencing of the human genome such as the 1000 Genomes Project to explore T2D loci more comprehensively.

Age-related macular degeneration (AMD) is the commonest cause of blindness in Western populations. Susceptibility is influenced by age, environmental and genetic factors. Known genetic risk loci do not account for all the heritability. We therefore carried out a genome-wide association study of AMD in the UK population with 893 cases of advanced AMD and 2199 controls. This showed association with the well established AMD risk loci ARMS2-HTRA1 ($P = 2.7 \times 10^{-72}$), CFH ($P = 2.3 \times 10^{-47}$), C2-CFB ($P = 5.2 \times 10^{-9}$), C3 ($P = 2.2 \times 10^{-3}$) and CFI ($P = 3.6 \times 10^{-3}$) and with more recently reported risk loci at VEGFA ($P = 1.2 \times 10^{-3}$) and LIPC ($P = 0.04$). Using a replication sample of 1411 advanced AMD cases and 1431 examined controls we confirmed a novel association between AMD and single nucleotide polymorphisms on chromosome 6p21.3 at TNXB-FKBPL (rs12153855/rs9391734; discovery $P = 4.3 \times 10^{-7}$, replication $P = 3.0 \times 10^{-4}$, combined $P = 1.3 \times 10^{-9}$, OR = 1.4, 95% CI = 1.3–1.6) and the neighbouring gene NOTCH4 (rs2071277; discovery $P = 3.2 \times 10^{-8}$, replication $P = 3.8 \times 10^{-5}$, combined $P = 2.0 \times 10^{-11}$, OR = 1.3, 95% CI = 1.2–1.4). These associations remained significant in conditional analyses which included the adjacent C2-CFB locus. Further research will be needed to identify the causal variants and determine whether any of these genes are involved in the pathogenesis of AMD. TNXB, FKBPL and NOTCH4 are all plausible AMD susceptibility genes, and NOTCH4 in particular merits further investigation as the Notch signalling pathway has already been suggested as a potential therapeutic target for AMD.

2073W

Evidence for association and biologic support of a novel locus for serum albumin. *N. Franceschini[1], F.J.A. van Rooij[2], B.P. Prins[3], M.F. Feitosa[4], M. Karakas[5], Q. Wu[6], C.A. Winkler[7], J. Kopp[8], J.F. Felix[2], K.E. North[1], B.Z. Alizadeh[3], L.A. Cupples[9], J.R.B Perry[10], A.P. Morris[11] on behalf of the CHARGE Consortium Protein Working Group.* 1) Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) ErasmusAGE, Department of Epidemiology, Erasmus MC, Rotterdam, the Netherlands; Netherlands Consortium for Healthy Aging (NGI-NCHA), The Netherlands Genomics Initiative, Leiden, the Netherlands; 3) Department of Epidemiology, University Medical Center Groningen, University of Groningen, Groningen, the Netherlands; 4) Division of Statistical Genomics, Department of Genetics, Washington University School of Medicine, St. Louis, MO, USA; 5) Department of Internal Medicine II-Cardiology, University of Ulm Medical Center, Ulm, Germany; 6) Molecular Cardiology/Nephrology & Hypertension Lerner Research Institute/NB20 Cleveland Clinic, Cleveland, OH, USA; 7) Molecular Genetics Epidemiology Section, National Institute of CancerFrederick National Laboratory for Cancer Research, National Institutes of Health, Frederick, MD, USA; 8) National Institute of Diabetes and Digestive and Kidney Diseases, National Institute of Health, Bethesda, MD, USA; 9) Department of Biostatistics, Boston University School of Public Health, Boston, MA, USA and National Heart, Lung, and Blood Institute's (NHBLI's) Framingham Heart Study; 10) Genetics of Complex Traits, Peninsula Medical School, University of Exeter, UK; 11) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

Serum protein concentrations are highly heritable and are altered in many disorders including kidney diseases, malnutrition, cancer, and inflammatory diseases. To identify loci associated with serum albumin concentration, the major plasma protein, we performed a genome-wide association study of up to 53,190 European ancestry individuals from 19 studies. Each study performed association analysis using linear regression or mixed models (for family data) while adjusting for age, sex and measures of population stratification. These results were then combined using fixed-effects inverse-variance weighted meta-analysis. We identified four novel loci for serum albumin at genome-wide significance ($p<5\times10^{-8}$), including *HPN-SCN1B*($p=3.3\times10^{-15}$) which showed evidence of two independent association signals using approximate conditional analyses (GCTA): rs4806073, $p=1.6\times10^{-12}$ and rs11671010, $p=1.5\times10^{-11}$; CEPH Europeans from Utah $r^2=0.02$, 4.3kb apart). The lead SNP at the *HPN-SCN1B* locus maps to an intron of *HPN*, a gene encoding hepsin, a membrane-bound serine protease with substrate specificity for basic amino acids, similar to those involved in proalbumin processing to albumin. In *hepsin* -/- mice, we observed reduced serum albumin concentration compared with wild-type litter-mates ($p=9.1\times10^{-12}$). We also confirmed the previously reported associations in East Asian populations at *GCKR-FNDC4* ($p=2.9\times10^{-14}$) and *RPS11-FCGRT* ($p=3.2\times10^{-8}$) for serum albumin. *FCGRT* encodes the heavy alpha chain of the FcRn, which prevents lysosomal degradation of albumin and immunoglobulins in lysosomes and thereby extends their serum half-life. KO *fcgrt* mice manifest low serum albumin. Our findings support a biologic role for the *HPN* locus on serum albumin homeostasis and confirm the *RPS11-FCGRT* locus identified in animal models. These loci may have potential roles in disease states.

Gene-based meta-analysis of genome-wide association studies implicates new susceptibility loci for obesity. *S. Hägg, Y. Pawitan, E. Ingelsson on behalf of the GIANT consortium.* Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden.

Genome-wide association studies (GWAS) have identified 36 loci associated with body mass index (BMI) to date. The majority of these have been identified through standard meta-analyses of single variants. This approach may miss loci with allelic heterogeneity. Therefore, the aim of the present study was to discover additional susceptibility loci for BMI using gene-based meta-analysis to identify regions with high allelic heterogeneity. We included data from ~124,000 adult individuals of European descent from 46 cohorts of the Genetic Investigation of Anthropometric Traits (GIANT) consortium in the discovery stage, and data from additionally 112,000 individuals from 43 cohorts in the replication stage. Each cohort was tested for association between ~2.4 million imputed or genotyped single nucleotide polymorphisms (SNPs) and BMI, and summary statistics were subsequently meta-analyzed in 17,941 autosomal genes based on UCSC Genome Browser hg18 assembly. We used a software package called `Versatile gene-based test for genome-wide association studies' (VEGAS), which assigns SNPs to genes by accounting for LD-block structure using simulations, to calculate gene-based p-values. The VEGAS method was applied to each cohort separately before a gene-based meta-analysis using the Fisher sum statistics with chi-squared distribution was performed. Of all genes tested, two loci which have already associated with BMI (*FTO* and *TMEM18*), as well as six novel loci (*TXNDC12, PEX2, FAM54A*, *SSFA2*, *IARS2* and *KIAA1731*) were associated with BMI at genome-wide significance (p-value < $2*10^{-6}$). Further, replication following the same procedure confirmed six of the eight loci to be genome-wide significant, and all eight loci well below a Bonferroni-corrected threshold of replication (alpha=0.00625 for eight tests). Using a new approach to do gene-based meta-analyses of large-scale GWAS data, we have reproduced results for two already identified BMI susceptibility loci, as well as contributed with six novel potential target genes associated with BMI. Our results indicate that gene-based meta-analysis of GWAS can provide a useful strategy to find additional susceptibility loci that are not identified in standard single-marker analyses due to high allelic heterogeneity.

2075F

Homozygosity mapping in a Sindh Pakistan family identifies new candidate regions for primary autosomal recessive microcephaly. *P. Lemay[1], M. Sindhi[2], N. Sehar[2], S. Kashif[3], Q. Brohi[4], J. Michaud[1], Z. Kibar[1].* 1) CHU Ste-Justine, Montreal, Quebec, Canada; 2) Department of Zoology, University of Sindh Jamshoro, Sindh, Pakistan; 3) Autism Institute Karachi Sindh, Pakistan; 4) Sir Cowasjjee Jehangir Institute of Psychiatry, Hyderabad, Sindh, Pakistan.

Microcephaly is defined as a condition in which the head circumference of an affected individual is >3 standard deviation below the population age and sex related mean. Autosomal recessive primary microcephaly (MCPH) is a neurodevelopmental disorder which is characterized by two principal features, microcephaly present at birth and non-progressive mental retardation. Primary microcephaly is further defined by the absence of other syndromic features or significant neurological deficits (other than mild-to-moderate mental retardation. MCPH has an estimated incidence of 1 in 1 000 000 in the Caucasian populations but is particularly frequent in northern Pakistan where it occurs in approximately 1 in 10 000 individuals. To date, 8 loci and 5 genes were associated with microcephaly in the Northern Pakistan region. We have recruited 10 extended families affected with MCPH from the Sindh Pakistan region. This southern region of Pakistan was never investigated for MCPH and could result in identification of new associated loci. A homozygosity mapping analysis was performed using the Illumina Human660w quad beadchip and the HomozygocityMapper program on 2 distantly related affected individuals from one large family of our Pakistani cohort. A total of 7 homozygous regions were identified: chr5: 27564–1936443, chr10: 53806602–58948207, chr10:113735304–116047921, chr11:7714879–115 31547, chr11:11592794–14944645, chr13: 101755185–104391808, chr19: 48557013–51595182. No known MCPH genes were found in these regions. Using a combination of homozygosity mapping and whole exome sequencing, we will reduce the number of identified potentially pathogenic coding variants facilitating the identification of the causative MCPH gene in this family.

Genome-wide association studies (GWAS) have been successful in identifying loci contributing to a range of complex human traits. However, there is still large proportion of unexplained trait heritability. Current large-scale association studies have mainly been targeting common variants due to the design of genome-wide genotyping arrays. Nevertheless, it is possible to gather information about rare variants by imputing markers up to high-density reference panels. We have tested for association between eight quantitative traits and accumulations of minor alleles at rare variants with minor allele frequency (MAF)<1% within gene regions (defined by the UCSC Human Genome database) using GRANVIL software. 14 cohorts with genome-wide association data contributing to the ENGAGE Consortium were imputed up to the cosmopolitan reference panel from the 1000 Genomes Project (June 2011 release). Altogether 17,098 men and 16,616 women were used in analyses for 8 traits: high density lipoprotein, low density lipoprotein, triglycerides, total cholesterol, body-mass index (BMI) and waist-to-hip ratio (WHR), fasting glucose and fasting insulin (FI) adjusted for BMI. Association summary statistics were combined across studies in a weighted Z-score based meta-analysis. We observed genome-wide significant evidence ($p<1.7x10^{-6}$, Bonferroni correction for 30,000 genes) for association with two traits. For triglycerides, associations with *ZNF259* ($p=1.4x10^{-11}$) and *APOA5* ($p=4.7x10^{-8}$) genes were detected. The excess of rare variants in *APOA5* has already been described for hypertriglyceridemia. Both, *ZNF259* and *APOA5*, are also associated with metabolic syndrome. For fasting insulin, a male-specific association was observed with *TAS2R60* ($p_{men}= 6.2x10^{-10}$; $p_{women}=0.22$, $p_{men+women}=0.00084$). This gene belongs to a family of taste receptors that may play a role in the perception of bitterness, and is gustducin-linked. Our results highlight the potential of imputation into exiting GWAS data up to high-density reference panels as a tool for discovering rare-variant associations with complex traits and an alternative to costly re-sequencing experiments.

2077T

Common genetic variants underlie endometriosis and fat distribution but not overall adiposity. *N. Rahmioglu[1], S. Macgregor[2], H.R. Harris[3], A. Morris[1], S.A. Missmer[3], G.W. Montgomery[2], C.M. Lindgren[1], K.T. Zondervan[1], The International EndoGene Consortium (IEC), The GIANT Consortium.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Queensland Institute for Medical Research, Herston, Queensland, Australia; 3) Brigham and Women's Hospital and Harvard Schools of Medicine and Public Health, Boston, MA, USA.

Lower body mass index (BMI) and waist-hip ratio (WHR) have been associated with increased risk of endometriosis in epidemiological studies. Both endometriosis and these obesity-related traits are heritable. The top endometriosis associated risk increasing SNP on chromosome 7, had a p-value of 4.4x10-5 in the GIANT consortium WHRadjBMI and marked one of 14 loci associated with lower WHRadjBMI. Therefore, we aimed to investigate the potential commonality in genetic variants underlying their aetiology through, (1) genetic enrichment analysis comparing three large-scale GWAS of endometriosis (3194 cases; 7060 controls; 12.5m SNPs imputed using 1000G), WHRadjBMI (n=77,167; 2.85m SNPs imputed using HapMap2) and BMI (n=123,865; 2.85m SNPs imputed using HapMap2), to identify potential pleiotropic regions, (2) polygenic prediction analysis, to evaluate the aggregate effect of WHR alleles on endometriosis risk, and (3) pathway analysis using the PANTHER database, to investigate potential common etiological pathways between enriched loci underlying endometriosis and WHR. The genetic enrichment analyses revealed significant enrichment of genetic variants between endometriosis and fat distribution (p-values for binomial tests 0.02–0.004) but not with overall adiposity (p-values 0.12–0.98). However, the directions of effect of the enriched variants associated with endometriosis and WHRadjBMI was not consistently in either the same or opposite direction (p=0.31–0.60). Some of the enriched variants include: (1) the endometriosis risk increasing allele at PPARG on chromosome 3, showing a strong association with higher WHRadjBMI, (2) the endometriosis risk increasing allele upstream of WNT4, showing an association with lower WHRadjBMI. Polygenic prediction revealed no en mass shared common genetic component between endometriosis and fat distribution. Pathway analysis generated some evidence for over-representation of developmental processes (p=1x10-4), WNT signaling (p=1.7x10-3) and cadherin signaling (p=1.2x10-3) pathways. We have identified support for potential pleiotropy underlying endometriosis and fat distribution, and identified several genetic loci with plausible biological candidacy. Even though the overall polygenic component of fat distribution does not contribute to the risk of endometriosis, there is evidence for the presence of some key pleiotropic loci contributing to the endometriosis risk and regulation of fat distribution, which require replication.

2078F

Genome-wide association of single nucleotide polymorphisms with weight loss outcomes following Roux-en-Y Gastric Bypass surgery. *E. Rinella[1], C. Still[2], Y. Shao[3], G.C. Wood[2], X. Chu[2], B. Salerno[2], G.S. Gerhard[2], H. Ostrer[4].* 1) New York University Langone Medical Center, New York, NY; 2) Geisinger Obesity Research Institute, Geisinger Clinic, Danville PA; 3) Division of Biostatistics, New York University School of Medicine, New York, NY; 4) Department of Pathology, Albert Einstein College of Medicine, Bronx, NY.

Objective: Bariatric surgery offers an effective treatment for obesity and obesity-related complications when other interventions fail. However, despite its success, many patients do not maintain sufficient weight loss following bariatric surgery. In order to better understand the long-term response to Roux-en-Y Gastric Bypass (RYGB) we designed a genome-wide association study (GWAS) to examine the genetic component of variable weight loss after RYGB. **Subjects:** 175 obese patients (BMI>35) receiving RYGB were selected for a Discovery cohort: 86 “Regainers” who lost the least excess body weight (EBW) and 89 “Retainers” who lost the most EBW at 2 years post-surgery and genotyped using Affymetrix 6.0 SNP arrays. A second cohort of 164 Regainers and 169 Retainers was selected to validate the Discovery cohort results using custom SNP arrays. **Results:** We identified 111 SNPs in the Discovery cohort whose frequencies were significantly different between Regainers and Retainers (allelic χ^2-test p<0.0001). Linear regression of %EBW remaining at 2 years post-surgery revealed 17 SNPs that were validated in the Replication cohort. These SNPs cluster in or near several genes with potential biological relevance including HTR1A, IGF1R, NMBR andPKHD1. **Conclusion:** We conclude that there are genetic components in addition to known clinical factors with utility in predicting weight loss outcome following RYGB.

2079W

Identification of common and specific genetic determinants to skin prick test reactivity using genome-wide association study and gene-based test approaches. *P-E. Sugier[1,2,3], A. Vaysse[1,2,3], C. Loucoubar[1,2,3], C. Sarnowski[1,2,3], P. Margaritte-Jeannin[1,2,3], M-H. Dizier[1,2,3], M. Lathrop[3], F. Demenais[1,2,3], E. Bouzigon[1,2,3], the EGEA collaborative group.* 1) U946, INSERM, Paris, France; 2) Université Paris Diderot, Sorbonne Paris Cité, Institut Universitaire d'Hématologie, France; 3) Fondation Jean Dausset-Centre d'Etude du Polymorphisme Humain (CEPH), France.

The prevalence of allergic diseases such as asthma has reached pandemic proportions in industrialized countries. The genetic component of allergy is substantial but it has been rarely investigated at the genome-wide level. Two genome-wide association studies (GWAS) of atopy defined by increased specific IgE levels or skin prick test (SPT) reactivity to allergens have been conducted in population-based cohorts with inconsistent results. We aimed to identify common and specific genetic determinants of SPT response to a panel of aeroallergens using a GWAS approach combining a single SNP analysis and gene-based association tests. We conducted GWAS of atopy phenotypes in 1,660 subjects (925 atopics and 735 non-atopics) from the French Epidemiological study on the Genetics and Environment of Asthma (EGEA) which includes families ascertained through asthmatics. These subjects were genotyped by Illumina 610K Array. Four atopy traits were investigated: 1) atopy as a whole and defined by a positive SPT response to at least one of 11 aeroallergens, and then three groups of aeroallergens: 2) indoors (Dermatophagoides pteronyssinus, cat, Blattella germanica), 3) outdoors (timothy grass, olive, birch, Parietaria judaica, ragweed), and 4) molds (Cladosporium herbarum, Aspergillus, Alternaria tenuis). For each phenotype, we used logistic regression for the single SNP analysis followed by gene-based association tests using VEGAS (Lui et al Am J Hum Genet 2010). Six atopy loci were detected at P-value$\leq 5x10^{-7}$ by single SNP analyses. One gene in 3q24 region was strongly associated to atopy as a whole ($P=3x10^{-7}$) and in a lesser extend to each SPT group (P ranging from $5x10^{-6}$ to $3x10^{-4}$), suggesting this locus harbors common genetic determinants shared across SPT responses to allergens. Five loci were mainly detected in sub-groups of allergens: 5q13 with indoors, 12q24 with outdoors and 4q24, 15q13 and 19q13 with molds. Gene-based tests both strengthened the evidence for association of 19q13 locus with SPT to molds and increased evidence for two other loci on chromosome 19 with this phenotype. Further investigation will be needed to confirm our findings in order to reliably identify key genetic factors underlying atopy predisposition. This study highlights that combining at the genome-wide level single SNP analyses and gene-based tests may facilitate the identification of new susceptibility genes. Funding: ANR-11-BSV1-027-01 grant.

Insulin-like growth factor-I (IGF-I) and its predominant carrier IGF binding protein 3 (IGFBP-3) are implicated in a complex biological system important in diverse biological processes including cell replication, proliferation or differentiation, protein synthesis and carbohydrate and bone metabolism. IGF-I and IGFBP-3 serum concentrations are associated with cardiovascular disease, cancer and all-cause mortality. IGF-I and IGFBP-3 levels are known to have a high degree of heritability.

We conducted a genome-wide association study (GWAS) of circulating concentrations of IGF-I and IGFBP-3, in a meta-analysis of up to 22,000 middle-aged adults of European ancestry. Analyses were adjusted for age and sex, and sex-specific associations were also investigated. Because most circulating IGF-I is bound to IGFBP-3, the concentration of free circulating IGF-I may be estimated by adjusting blood IGF-I concentrations for the concentrations of circulating IGFBP-3. Therefore, we also performed GWAS of IGF-I concentrations after adjustment for IGFBP-3 concentrations, and vice versa.

In analysis of men and women together, we identified two new loci *GCKR* (rs780093) and *NUBP2* (rs1065656) where variants reached genome-wide significance ($p<5x10^{-8}$) for association with IGF-I, and one new locus *CELSR2* (rs12740374) where variants were associated with IGFBP-3 concentrations. In analysis of women only, variants at one additional locus *VPS13C*(rs12593844) were significantly associated with IGF-I adjusted for IGFBP-3. SNPs near *IGFBP3* showed effects on IGFBP-3 concentrations that differ by sex.

The findings revealed potential new loci which gene products are related to glucokinase and insulin-like growth factor binding. Furthermore, the associations of known variants with both IGF-I and IGFBP-3 concentrations near *IGFBP3* (rs11977526) and *TNS3* (rs700752) as well as the associations with IGFBP-3 concentrations in *SORCS2* (rs4234798) and in close vicinity of*NUBP2/IGFALS* (rs1065656) were confirmed.

Phenotypic refinement and genome-wide association analysis identifies a functional variant in ADCY3 associated with BMI. *N.J. Timpson[1], R. Gaillard[2], E. Stergiakouli[1], HR. Taal[2], DM. Evans[1], F. Rivadeneira[3], B. St Pourcain[5], AG. Uitterlinden[3], J. Kemp[1], A. Hofman[4], S. Ring[5], VWV. Jaddoe[2], G. Davey Smith[1].* 1) MRC CAiTE Centre, University of Bristol, Bristol, Bristol, United Kingdom; 2) Erasmus Medical Centre, Department of Epidemiology, Rotterdam, Netherlands; 3) Erasmus Medical Centre, Department of Internal Medicine and Epidemiology, Rotterdam, Netherlands; 4) Erasmus Medical Centre, Department Epidemiology & Biostatistics, Rotterdam, Netherlands; 5) School of Social and Community Medicine, University of Bristol, Bristol, Bristol, United Kingdom.

Genomewide association studies tend to be undertaken for recognised phenotypes based on either convention or available instrumentation. Body mass index (BMI; weight(kg)/height(m)2) is a routine measure of weight given height despite the known failure of the square of height to precisely account for this covariable. Work here aimed to re-assess the contribution of common genetic variation to BMI taking into account height. Genomewide association analysis (GWA) for BMI was undertaken in 6076 non-related participants from the Avon Longitudinal Study of Parents and Children (mean age 7.5 years) adjusting for height, age and sex. rs1172294 in the 3' UTR of RBJ was the strongest of a clear association signal on chr2, showing a 0.204kg/m2(0.133,0.274)p=1.1e-08 change per common allele. This signal contained rs11676272 (0.201kg/m2(0.132,0.270)p=1.4e-08), a missense SNP coding for a ser/pro change in exon1 of ADCY3. This association is larger then the established association at FTOrs9939609 for BMI at this age (0.128kg/m2(0.054,0.202)p=0.0007) and equivalent to that seen at later ages where the full effect of rs9939609 is realised. Results could be re-created when using a revised version of BMI based on the equation weight(kg)/height(m)3.05 which removed residual correlation with height in this population. In 2089 non-related participants from an independent study (Generation-R, average age 6.1 years) there was consistent evidence for association between rs11676272 and BMI adjusted for height (0.14kg/m2(0.056,0.224)p=0.0001; meta-analysis 0.177(0.123,0.230)p=7.6e–11, I217.4). Transformed lymphocyte derived analysis of the ADCY3 transcript showed evidence of association between the coding variant rs11676272 and levels of ADCY3 expression (r2=0.21, p<1x10-30). Furthermore, analyses conditional on rs11676272 obliterated both this signal and phenotypic association across this region of chr2. The ser/pro change coded by rs11676272 lies within the second transmembrane spanning alpha-helix of this membrane associated adenylate cyclase. It incorporates a helix-breaking residue into an important regulatory region of the enzyme and is likely to disrupt cAMP formation and triglyceride metabolism in adipose tissue. Together this provides evidence of a direct link between GWA results and a functional genetic change in ADCY3. Analyses serve as an important reminder as to the value of precise measurement in undertaking genetic association studies.

2082W

A genome-wide association study of kidney transplant survival: Donors recipients and interactions. *C. Franklin[1], M. Hernandez Fuentes[2], J. Mollon[2,3], I. Rebollo Mesa[2], E. Perucha[2], P. Conlon[4], N. Anyanwu[2], S.H. Sacks[2], M.E. Weale[2,3], N. Soranzo[1], G. Lord[2], United Kingdom and Ireland Renal Transplant Consortium, the Wellcome Trust Case-Control Consortium 3.* 1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 2) MRC Centre for Transplantation, King's College London, London, UK; 3) Department of Medical and Molecular Genetics, King's College London, London, UK; 4) Royal College of Surgeons in Ireland, Dublin, Ireland.

Approximately 1,600 kidney transplants from cadaveric donors are performed in the UK each year. There is a large variance in the survival times of these transplants with some grafts failing in the first few months, whereas around 70% survive 10 years or longer. Matching of donor and recipient for blood group and HLA types is used routinely to reduce the risk of rejection. However, the 100% acceptance rate for transplants between monozygotic twins indicates that other genetic influences on graft survival must exist.

We have genotyped samples from the UK and Ireland Renal Transplant Consortium collected from 24 transplant centres between 1981 and 2007. Samples were genotyped on Illumina 660 or 610 chips and after QC 512,535 SNPs were retained for analysis. Extensive post transplant phenotype information was collected on these samples through the NHS blood and transplant service and individual transplant centres. Genotype and phenotype data for a total of 2,678 transplant recipients, 2,200 donors and 2,081 complete transplant pairs was available.

We have conducted survival analysis of the time to graft failure using cox proportional hazards models to estimate the effect of each SNP. Effects were estimated for three models: recipient genotype, donor genotype and the interaction between donor and recipient genotype. Likelihood ratio tests were then used to estimate the significance of each effect. Several strong signals were found. The strongest was a recipient-only effect, but several weaker donor-only and interaction effects were also identified. None of the signals overlap with the HLA or ABO loci. This study represents the discovery phase of the first genome-wide association analysis of genetic effects on kidney transplant survival. Replication is on-going.

Admixture mapping of Vitamin D in African Americans. *I. Halder[1], L. Pearson[2], .S. Mulukutla[1], M. Shriver[2], V. Causer[1], G. Huggins[3], S. Reis[1].* 1) Cardiovascular Institute, Univ Pittsburgh, Pittsburgh, PA; 2) Dept. of Anthropology, Pennsylvania State University, State College, PA; 3) Tufts University Medical Center, Boston, MA.

Background: Vitamin D is crucial for a multitude of Cardiovascular and musculoskeletal functions. African Americans (AAs) generally have lower circulating levels of 25 hydroxyvitamin D [25(OH)D] than Whites, the cause for which is unknown. While darker skin pigmentation and dietary factors have been attributed to this difference, little is known about genetic determinants of 25(OH)D in AAs. Neither GWAS nor admixture mapping studies of 25(OH)D have been reported in AAs. We examined whether genetic ancestry was associated with 25(OH)D in AAs and performed genome wide admixture mapping. Methods: Circulating 25(OH)D was assessed by radioimmunoassay in 220 unrelated AAs from the HeartSCORE study. All individuals were genotyped for 1695 ancestry informative markers as part of a novel CVD gene chip. Individual admixture was ascertained by maximum likelihood method and admixture-phenotype associations were performed. The ADMIXMAP software was used for admixture mapping with age, gender, BMI, vitamin D supplementation status and season of blood draw as covariates. Results: Mean West African individual admixture in the sample was 69% (SD 16%). Covariate adjusted 25(OH)D levels showed a significant negative association with increasing individual African admixture (B = -12.5, SE = 3.7, t = -3.4, P = 0.001). Measured genetic ancestry explained ~ 5% of variation in vitamin D levels. In admixture mapping studies, significant excess European ancestry was observed in one region on chromosome 4 (4q), with largest excess seen at locus rs2545258 (Z score: -2.79, P = 9.47E-07); and one on chromosome 11 with largest excess seen at locus rs12289502 (Z score: -2.51, P = 6.61E-05). Excess West African ancestry was observed in one region on chromosome 22 with largest excess seen at locus rs1009787 (Z score: 2.3, P = 0.002). Conclusions: Genetic ancestry explains part of the variability in circulating 25(OH)D levels in AAs. Two loci associated with 25(OH)D in this study are near candidate genes identified in populations of European ancestry: *GC* (4q) and *CYP2R1* (11p). The SNP on chromosome 22 is in the *HIRA* gene which has been associated with the histone chaperone complex. *HIRA* in association with other cellular regulators acts as a transcriptional regulator of vitamin D receptors. In conclusion, we have identified three regions which appear to be associated with circulating 25(OH)D levels in AAs. We are in the process of confirming these results in other independent cohorts.

2084F

A genome-wide association study establishes multiple susceptibility loci for Sjögren's syndrome. *C.J. Lessard[1], H. Li[1], I. Adrianto[1], J.A. Ice[1], R. Jonsson[2], G.G. Illei[3], M. Rischmueller[4], G. Nordmark[5], X. Mariette[6], C. Miceli-Richard[6], M. Wahren-Herlenius[7], T. Witte[8], M. Brennan[9], R. Omdal[2], P.M. Gaffney[1], J.A. Lessard[10], W.-F. Ng[11], N. Rhodus[12], B. Segal[12], R.H. Scofield[1], J.A. James[1], J.-M. Anaya[13], J.B. Harley[14], C.G. Montgomery[1], K. Moser Sivils[1].* 1) Arthritis & Clinical Immunology, OMRF, Oklahoma City, OK; 2) University of Bergen, Norway; 3) National Institute of Dental and Craniofacial Research, NIH, Bethesda, MD; 4) The Queen Elizabeth Hospital and Health Service, Australia; 5) Uppsala University Hospital, Sweden; 6) Université Paris-Sud, France; 7) Karolinska Institute, Sweden; 8) Hannover Medical School, Germany; 9) Carolinas Medical Center, Charlotte, NC; 10) Valley Bone and Joint Clinic, Grand Forks, ND; 11) Newcastle University, England; 12) University of Minnesota, Minneapolis, MN; 13) Center for Autoimmune Diseases Research (CREA), Universidad del Rosario, Colombia; 14) Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Sjögren's syndrome (SS) is a common (0.7–1.0% of the European population), clinically heterogeneous autoimmune disease characterized by exocrine gland dysfunction that involves both innate and adaptive immune responses. A complex genetic architecture has been hypothesized; however, genetic studies to date have been limited to candidate gene approaches. We used high-density Illumina OMNI1-Quad genotyping arrays in a discovery cohort of 424 European-derived SS cases and 2120 healthy controls to perform the first genome-wide association scan (GWAS) in an unbiased manner to identify SS susceptibility loci. Stringent quality control (QC) criteria, adjustments for population stratification, and standard GWA statistical methodologies were used to compare allele frequencies between cases and controls. A total of ~650,000 single nucleotide polymorphisms (SNPs) were tested for association to SS (P_{omni}). For replication, an independent cohort of 1194 SS cases and 2930 healthy controls were genotyped using the ImmunoChip (IC; P_{IC}) with ~26,000 overlapping SNPs with the GWAS after QC. Meta-analysis between the GWAS and IC was done using METAL (P_{meta}). The most significantly associated region with risk of SS was the major histocompatibility complex (MHC), with 1071 overlapping SNPs exceeding a genome-wide significance (GWS) threshold of 5x10E-8, and the peak association was observed in MSH5 (rs3117574 P_{meta}=5.33x10E-79). Additional results across the extended MHC support association with multiple loci throughout this region. In the GWAS, two SNPs, rs485497 and rs4680536, were identified near IL12A with P_{omni}<6x10E-4. Both rs485497 (P_{IC}=1.88x10E-7) and rs4680536 (P_{IC}=2.06x10E-5) replicated yielding P_{meta}=4.81x10E-10 and P_{meta}=1.69x10E-8, respectively. In addition, we observed associations surpassing GWS for the first time with loci previously implicated in SS, including IRF5 (rs10488631 P_{meta}=5.25x10E-13), BLK (rs922483 P_{meta}=1.50x10E-8), and STAT4 (rs10168266 P_{meta}=3.59x10E-8). IL12A, IRF5 and STAT4 are involved in type 1 interferon responses. IL12A encodes the p35 subunit of IL12 and is secreted by monocytes and dendritic cells ultimately stimulating the production of IFN-γ. Interestingly, responses to IL12A are mediated through STAT4. We present the first GWAS of SS identifying and confirming IL12A as a novel susceptibility locus. We also observed IRF5, BLK and STAT4 for the first time at GWS confirming them as risk loci for SS.

2085W

Pooling-based genome-wide association study for intracranial aneurysms in the Portuguese population. *P.C. S. Abrantes[1,2,3], I. Sousa[1,2], M. M. Santos[4], V. Francisco[1,2], T. Krug[1,2], J. M. Xavier[1,2], A. Jacinto[3], D. Coiteiro[4], S. A. Oliveira[1,2].* 1) Instituto Medicina Molecular, Lisbon, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Centro de estudos de Doenças Crónicas, Lisbon, Portugal; 4) Hospital de Santa Maria, Lisbon, Portugal.

Subarachnoid hemorrhage is a life-threatening event that most frequently leads to severe disability and death. Its most frequent cause is the rupture of an intracranial aneurysm (IA), which is a dilation of a blood vessel caused by disease or weakening of the vessel wall. Although the genetic contribution to IA is well established, to date no single gene has been unequivocally identified as responsible for IA formation or rupture. The main goal of this work was to identify for the first time new IA susceptibility genes in the Portuguese population. To this end, we conducted a pooling-based GWAS in 100 IA cases and 92 controls matched for age and gender. Pool-based GWAS is an efficient strategy to reduce the high costs associated with individual-based GWAS but is also effective at identifying major genetic contributions to disease that could be lost in individual underpowered studies. In the present study, 2 pools of cases and 2 pools of controls were genotyped in triplicate using the Affymetrix Human SNP Array 6.0. Probe intensities were analyzed using the SNPMaP package and the R freeware. Two methods were used to select variants that increase IA risk: a) a Welch t-test between cases and controls and b) the absolute differences of averaged normalized RAS (Relative Allele Score) between cases and controls. Top 50 hits from the Welch t-test and RAS difference approach, as well as the convergent SNPs from both methods, were analyzed. We replicated the 9p21.3 region found in previous IA GWAS, and identified 29 novel loci associated with IA (P-value $<5x10^{-8}$ or RAS difference $\geq$ 15%). Moreover, we found 6 putatively loci that were convergent in both analyses and due to their biological function could have a role in IA etiology. With a better understanding of the contribution of causative variants in the IA Portuguese population, we expect to contribute to unravel the genetic etiology of IA.

2086T

Genetic variants at the IGHC locus are associated with IgG levels in multiple sclerosis patients. *E. Albrecht[1], D. Buck[2], M. Aslam[2], A. Goris[3], N. Hauenstein[2], A. Jochim[2], S. Cepok[2], V. Grummel[2], B. Dubois[3], A. Berthele[2], P. Lichtner[4,5], C. Gieger[1], J. Winkelmann[2,4,5], B. Hemmer[2].* 1) Institute of Genetic Epidemiology, Helmholtz Center Munich - German Research Center for Environmental Health, Neuherberg, Germany; 2) Department of Neurology, Technische Universität München, Munich, Germany; 3) Laboratory for Neuroimmunology, Section of Experimental Neurology, KU Leuven, Leuven, Belgium; 4) Institute of Human Genetics, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 5) Institute of Human Genetics, Technische Universität München, Munich, Germany.

Multiple Sclerosis (MS) is considered a chronic inflammatory disease of the central nervous system of autoimmune origin involving T and B cells. Intrathecal IgG synthesis is observed in the majority of patients with MS. Whereas the amount of intrathecal IgG synthesis varies largely between patients, intrathecal IgG remains rather constant in the individual patient. Based on this observation it seems reasonable to assume that genetic factors may impact on the extent of intrathecal IgG synthesis. To investigate the genetic determinants of intrathecal IgG synthesis in MS patients, we performed a genome-wide association study (GWAS) based on 526,014 SNPs of the Human660-Quad chip in 229 MS patients. For replication, we genotyped 18 SNPs, showing an association with intrathecal IgG synthesis (p<1E-5), in an independent validation sample of 256 MS patients using Sequenom. Five of the 18 SNPs, which could be replicated in the first validation sample, were additionally analyzed in a second validation sample containing 152 MS patients genotyped on the Illumina Human660-Quad chip. Patients of all three samples are of European descent. We identified five SNPs showing a significant association with intrathecal IgG synthesis in the discovery and replication samples. These SNPs are in high LD and are located on the IGHC locus on chromosome 14. The strongest effect is seen for rs10136766 with a combined p-value of 7.5E-16 and 8.9% explained variance. The results of this study suggest that intrathecal IgG synthesis in MS patients is genetically influenced by variants in the IGHC gene cluster, with a remarkably high proportion of explained variance.

2087F

A web-based initiative to accelerate research on genetics and disease in African Americans. *K.E. Barnholt[1], A.K. Kiefer[1], H.L. Gates, Jr.[2], M. Nelson[1], M. Mullins[1], E. Baker[3], J. Frank[1], C.D. Bustamante[4], T.W. Love[5], R.A. Kittles[6], N. Eriksson[1], J.L. Mountain[1].* 1) 23andMe, Inc., Mountain View, CA; 2) W.E.B. Du Bois Institute for African and African American Studies, Harvard University, Cambridge, MA; 3) 23andYou.com; 4) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 5) Onyx Pharmaceuticals, Inc., South San Francisco, CA; 6) College of Medicine, University of Illinois at Chicago, Chicago, IL.

Little is known about the connections between DNA and disease in African Americans, in part because most genetics research has involved only those of European ancestry. Greater understanding of such connections could improve diagnoses and lead to opportunities for more personalized health care. In 2011 23andMe, Inc., a personal genomics and research company, launched the Roots into the Future initiative, which aims to enroll 10,000 African Americans in an innovative research project. The study seeks to determine whether genetic associations previously identified in Europeans are relevant to African Americans and to discover other genetic markers linked to conditions of particular relevance to the African American community. Currently the 23andMe cohort includes nearly 10,000 African Americans, over 5700 of whom were recruited through the Roots into the Future initiative. Each of these individuals (58% female, 42% male; mean age: 44) has submitted a saliva sample for genotyping via 23andMe's custom genotyping array, which includes approximately 1 million single nucleotide polymorphisms. Participants are currently contributing information about their health and traits through online surveys. To date over 6200 participants have completed an average of 10.6 surveys. Using the genetic data we estimated the percent African and European ancestry of each participant. Median estimates were 73% and 23% respectively (with 4% uncertain). As expected, the higher a person's proportion of European ancestry, the greater the chance that person carries variants that are more common among Europeans than among Africans, such as those linked to HIV-resistance and alpha-1 antitrypsin deficiency. Furthermore, the higher a person's proportion of African ancestry, the more likely that person reported having curly hair, high blood pressure and type 2 diabetes, and the less likely that person reported having facial wrinkles, rosacea and Parkinson's Disease. Based on data for over 8700 individuals likely to self-identify as African American, we replicated over 25 genetic associations reported previously for African Americans, including those for body-mass index, type 2 diabetes, lupus, height, and osteoporosis. For conditions for which we have already accrued at least 500 cases among this cohort, such as asthma, migraines, and uterine fibroids, we anticipate having power either to replicate associations identified through previous studies of Europeans or to find new associations.

2088W

First systematic association study of achalasia points to a strong involvement of the *HLA* region in the disease process. *J. Becker[1,2], M. Knapp[3], M.M. Wouters[4], G. Trynka[5], V. Kumar[5], L. Franke[5], H.-J. Westra[5], C. Wijmenga[5], G.E. Boeckxstaens[4], M.M. Nöthen[1,2], I. Gockel[6], J. Schumacher[1].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 3) Institute for Medical Biometry, Informatics, and Epidemiology, University of Bonn, Bonn, Germany; 4) Translational Research Center for Gastrointestinal Disorders, Catholic University of Leuven, Leuven, Belgium; 5) Genetics Department, University Medical Center and University of Groningen, Groningen, The Netherlands; 6) Department of General and Abdominal Surgery, University of Mainz, Mainz, Germany.

Achalasia is a severe disorder of the lower esophageal sphincter (LES) characterized by degeneration of neurons in the myenteric plexus. This leads to the development of a megaesophagus with irreversible loss of LES function. Furthermore, the retention of food can result in aspiration pneumonia and esophagitis, which is a precancerous condition leading to esophageal carcinoma. Although the cause of achalasia is mainly unknown, autoimmune processes appear to be involved in individuals with a genetic susceptibility. The purpose of the present study was to identify genes contributing to achalasia. We therefore performed the first systematic association study using Illumina's Immunochips, which capture genetic variants at immune-relevant loci. To the best of our knowledge, we analyzed the largest achalasia sample that has been studied so far. Our sample consisted of 633 cases and 2,653 controls from Central Europe. After quality control 126,899 markers remained for association testing. The analysis yielded 24 markers reaching genome-wide significance (P<5x10^{-08}) which are all located within the *HLA* region on chromosome 6p. The most significant marker reached a P-value of 7.53x10^{-15} and a relative risk (RR) of 2.84. Of all markers, a total of four association signals are contributing independently from each other to achalasia according to a stepwise logistic regression analysis. The markers are located within or near the genes *HLA-DPA1*, *HLA-DQA2*, *HLA-DQB2*, and *MUC21*. In order to investigate whether the associated variants have an effect on gene expression, we analyzed one of the largest available expression quantitative trait loci (eQTL) data sets (Fehrmann *et al*., 2011 PLoS Genetics). This study indicates that achalasia risk variants represent significant eQTLs for transcripts that are functionally involved in immunological processes. Finally, we performed an interaction analysis using all 126,899 markers and observed one marker-pair that showed epistatic association reaching the threshold of Bonferroni-corrected significance (P=4.67x10^{-12}, RR=5.47). Both markers are located upstream of the genes *HLA-DQA1* and *HLA-DQB1*, respectively. Interestingly, the corresponding proteins are also interacting on the cellular level by forming the HLA-II molecule on antigen-presenting cells. In summary, we have identified the first risk genes for achalasia and our data emphasize the hypothesis that autoimmune-relevant processes are involved in the disease process.

2089T

Genetic variants associated with breast size also influence breast cancer risk. *G. Benton, N. Eriksson, C.B. Do, A.K. Kiefer, J.L. Mountain, D.A. Hinds, U. Francke, J.Y. Tung.*23andMe, Mountain View, CA.

While some factors of breast morphology, such as density, are directly implicated in breast cancer, the relationship between breast size and cancer is less clear. Breast size is moderately heritable, yet the genetic variants leading to differences in breast size have not been identified. To investigate the genetic factors underlying breast size, we conducted a genome-wide association study (GWAS) of self-reported bra cup size, controlling for age, genetic ancestry, breast surgeries, pregnancy history and bra band size, in a cohort of 16,175 women of European ancestry.

We identified seven single-nucleotide polymorphisms (SNPs) significantly associated with breast size ($p < 510^{-8}$): rs7816345 near ZNF703, rs4849887 and (independently) rs17625845 flanking INHBB, rs12173570 near ESR1, rs7089814 in ZNF365, rs12371778 near PTHLH, and rs62314947 near AREG. Two of these seven SNPs are in linkage disequilibrium (LD) with SNPs associated with breast cancer (those near ESR1 and PTHLH), and a third (ZNF365) is near, but not in LD with, a breast cancer SNP. The other three loci (ZNF703, INHBB, and AREG) have strong links to breast cancer, estrogen regulation, and breast development.

These results provide insight into the genetic factors underlying normal breast development and show that some of these factors are shared with breast cancer. While these results do not directly support any possible epidemiological relationships between breast size and cancer, this study may contribute to a better understanding of the subtle interactions between breast morphology and breast cancer risk.

2090F

Meta-analysis of genetic associations in up to 339,224 individuals identify 67 new loci for BMI, confirming a neuronal contribution to body weight regulation and implicating several novel pathways. *S.I. Large-scale genome-wide association studies (GWAS) have identified > 50 loci unequivocally associated with obesity-susceptibility traits, including body mass index (BMI), waist-hip ratio, percent body fat, and extreme obesity. Of these, 32 loci were reported to be associated with BMI in our most recent meta-analysis, including 123,865 individuals at the discovery stage and 125,931 individuals at the follow up stage. To identify additional genetic loci for overall adiposity, we expanded the GIANT Consortium to include a total of 236,231 individuals from 82 GWAS as well as 103,046 individuals from 43 studies that were genotyped with the Metabochip, a custom-designed array comprised of SNPs with prior evidence of suggestive associations with metabolic traits. Summary statistics of the study-specific BMI-SNP association analyses assuming an additive genetic model were combined using a fixed-effects inverse variance meta-analysis approach. We confirmed 31 established BMI loci and identified 67 new independent loci (separated by at least 500 kb) associated with BMI ($P < 5x10^{-8}$). Joint conditional analyses from summary statistics identified additional independently associated common variants ($P < 5x10^{-8}$ for the secondary variant) at five loci (*MC4R*, *BDNF*, *GPRC5B*, *FANCL*, and *ADCY9*); analysis of rare variants at these loci may reveal additional independent genetic variants associated with BMI and help elucidate the nature of important functional units at each locus. Furthermore, we observed that among 1,929 independent variants with $P < 0.0001$ in our original GWAS and now included on the Metabochip, 1,608 demonstrated directionally consistent association signals, suggesting there are likely ~1,246 additional loci with BMI-associated common variants. Consistent with previous GWAS, many of the genome-wide significant BMI loci contain genes that have a potential neuronal role (e.g., *GRID1*, *NAV1*). However, this extended analysis also reveals loci near genes in pathways that were previously less apparent, such as those related to glucose and insulin homeostasis (e.g., *TCF7L2*, *GIPR*, *ADPGK*), mitochondrial processes (e.g., *MTCH2*, *MTIF3*, *PDK4*), lipid metabolism (e.g., *APO*-cluster, *NPC1*), and hormone regulation (*HSD17B12*). This large-scale meta-analysis has more than doubled the number of identified obesity-susceptibility loci and implicated additional pathways that further elucidate the complex biology of adiposity regulation.

2091W

Selective Immunoglobulin A Deficiency is Associated with IFIH1, TNFAIP3, PVT1, FAS, CDH23 and TM7SF3 in a Genomewide Association Study and Meta-Analysis. P.*G. Bronson[1], A.P. Manoharan[1], T.R. Bhangale[1], W. Ortmann[1], R.C. Ferreira[2], Q. Pan-Hammarström[3], L. Hammarström[3], R.R. Graham[1], T.W. Behrens[1].* 1) Genentech, Inc, South San Francisco, CA; 2) Cambridge Institute for Medical Research, Cambridge, UK; 3) Karolinska Institutet, Stockholm, Sweden.

The etiology of selective immunoglobulin A deficiency (IgAD) is unknown but a strong genetic component has been established. The most consistent associations are with HLA genes. We previously conducted a GWAS that tested 286k genotyped and 1.8M imputed variants in 430 cases and 1,090 controls (N=1,520) and a meta-analysis of three samples with 772 cases and 1,976 controls (N=2,748). IFIH1 rs1990760*T, a missense mutation associated with type 1 diabetes (T1D) and systemic lupus erythematosus (SLE), was associated with IgAD. The current GWAS tested 505k genotyped and 6.3M imputed variants (529 cases; 6,964 controls; N=7,493) and conducted a meta-analysis of four independent samples (1,289 cases; 8,932 controls; N=10,181). IFIH1 rs1990760*T was over-represented in cases (0.70) vs. controls (0.62) (OR=1.4, P=$3x10^{-14}$). In addition, 5 novel non-HLA loci were significant: TNFAIP3, CDH23, TM7SF3, FAS and PVT1. TNFAIP3 rs2230926*G, a missense mutation associated with SLE and rheumatoid arthritis (RA) in the opposite direction, was under-represented in cases (0.013) vs. controls (0.035) (OR=0.5, P=$4x10^{-9}$). CDH23 rs4747179*T was under-represented in cases (0.17) vs. controls (0.22) (OR=0.7, P=$1x10^{-8}$). Rs77540050*T (near TM7SF3) was under-represented in cases (0.003) vs. controls (0.013) (OR=0.3, P=$1x10^{-8}$). FAS rs2234978*T was over-represented in cases (0.37) vs. controls (0.32) (OR=1.3, P=$2x10^{-8}$). Rs72722767*A (near PVT1) was under-represented in cases (0.20) vs. controls (0.25) (OR=0.8, P=$5x10^{-8}$). Of 48 loci with suggestive results in the previous GWAS (P<$1x10^{-4}$), 6 loci were still suggestive in this GWAS (AHI1, CLEC16A, ADAM29, CD86, BCL6 and ODZ4). Over half of these loci are associated with autoimmunity. FAS is associated with a rare autoimmune lymphoproliferative syndrome. PVT1 and AHI1 are associated with multiple sclerosis (MS). CLEC16A is associated with MS and T1D. There is suggestive evidence that SLE is associated with CD86. The observed vs. expected numbers of low P-values in 278 independent autoimmune variants were examined. The expected number of P<$1x10^{-5}$ was 0.00278 and 18 were observed; the expected number of P<0.01 was 2.78 and 47 were observed (P<$1x10^{-5}$). In conclusion, results provide strong evidence for association with IFIH1, TNFAIP3, FAS, CDH23, PVT1 and TM7SF3, suggest that the AHI1, CLEC16A, ADAM29, CD86, BCL6 and ODZ4 may be involved, and provide additional support for the enrichment of association between IgAD and autoimmune disease loci.

2092T

Three new susceptibility loci for hyperuricemia identified through a genome-wide association analysis in Han Chinese. *C.-H. Chen, Y.-T. Chen, Y.-T. Chen, J.-Y. Wu.* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Background: Previous studies showed genetic variants contributed to hyperuricemia in various populations.

Objective: To investigate the genetic components of hyperuricemia, this study aimed to identify genes that might affect the level of uric acid in the blood in the Han-Chinese population.

Methods: DAN samples of a total of 1,947 unrelated subjects were extracted from a population-based study in the Taiwan. All subjects were of Han-Chinese ancestry and genotyped using the Axiom Genome-wide CHB Array. After excluding subjects with cryptic relatedness and population outliers, 471 subjects were classified into the hyperuricemia group for their levels of uric acid were equal to or greater than 7 mg/dL and 1,410 for the control group. Genome-wide association analysis was carried out using logistic regression models, adjust for age, sex and BMI.

Results: Several SNPs were found to be associated with hyperuricemia (P < 10^{-6}) and located in or near three gene loci, which were not previously reported to be susceptibility to hyperuricemia. In addition, several SNPs clustering in ABCG2, a previously reported major regulator of hyperuricaemia, showed nominal signals (P < 10^{-5}). SNPs in SLC2A9, another reported major regulator, however, did not show any significance in this study (P > 10^{-4}).

Summary: Our results identified 3 novel loci and 1 reported locus susceptible to hyperuricemia. Our findings might lead to a better understanding of differences in the molecular pathogenesis of hyperuricemia among various populations.

2093F

Candidate genetic loci for telomere length: A family based association study of Long Life Family Study (LLFS). *R. Cheng[1,2], J.H. Lee[1,2,3], M.S. Kang[1], M. Province[5], R. Mayeux[1,2,3,4], L.S. Honig[1,2,4].* 1) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY, USA; 2) Sergievsky Center, Columbia Univ, New York, NY, USA; 3) Department of Epidemiology, School of Public Health, Columbia Univ, New York, NY, USA; 4) Departments of Neurology and Psychiatry, P&S, Columbia Univ, New York, NY, USA; 5) Div. of Statistical Genomics, Dep. of Gen., Washington U. School of Med., St. Louis, MO, USA.

Shortening of chromosomal telomeres is a consequence of cell division, and is a biological factor that relates to cellular aging. Since shorter telomeres may relate to more rapid biological aging, we hypothesize that genetic and environmental factors contribute to shorter telomere length. To identify genetic factors that contribute to telomere length, we examined families participating in the Long Life Family Study (LLFS), which includes primarily white families from four different sites, including New York, Boston, Pittsburgh, and Denmark. To identify genetic factors that contribute to telomere length, we performed a family based genome wide association. For this purpose, we examined 4163 individuals from 586 families that are part of the Long Life Family Study (LLFS). Using 2.5M SNPs from the Illumina HumanOmni2.5, we applied an additive genetic model with linear mixed effects while taking into account kinship. The model adjusted for potential confounders, including age, sex, site, PCAs, a history of heart disease, smoking and drinking, and marriage. Heritability of telomere length was estimated to be 54.1% (SE=3.5%). One SNP (rs7680468) on chromosome 4 reached a genome-wide significant level (p=4.7x10E-8). Multiple SNPs had p-values less than 1x10E-5. Among them, two SNPs on chromosome 14 were located within the SYT16 gene. Other SNPs were located in TRDMT1, TMPRSS7, TRDMT1, ASCC2, and TSHZ2. In the present family based genome wide association study, we identified several candidate loci that are associated with telomere length. These loci are currently being confirmed in two independent datasets.

Common variations at chromosome 21q22 influences the risk of age-related nuclear cataract: The Singapore Malay Eye Study. *C.Y. Cheng[1,2,3], J. Liao[1], X. Li[3], C.C. Khor[2,4], W.T. Tay[3], A.G. Tan[5], J.J. Wang[5,6], P. Mitchell[5], Y.Y. Teo[2,7,8,9], E.S. Tai[2,10], S.M. Saw[2,3], T. Aung[1,3,11], T.Y. Wong[1,3,6,11].* 1) Dept of Ophthalmology, National University of Singapore, Singapore, Singapore; 2) Saw Swee Hock School of Public Health, National University of Singapore; 3) Singapore Eye Research Institute, Singapore; 4) Human Genetics, Genome Institute of Singapore; 5) Centre for Vision Research, Department of Ophthalmology, University of Sydney, Australia; 6) Centre for Eye Research Australia, University of Melbourne, Australia; 7) Centre for Molecular Epidemiology, National University of Singapore, Singapore; 8) Dept of Statistics and Applied Probability, National University of Singapore, Singapore; 9) Graduate School for Integrative Science and Engineering, National University of Singapore, Singapore; 10) Dept of Medicine, National University of Singapore; 11) Singapore National Eye Centre, Singapore.

Age-related cataract is the most common cause of blindness in the world. Although several mutations have been identified as causative for congenital and juvenile cataracts, little is known about the genes that influence the susceptibility of age-related cataract. We conducted a genome-wide association study on 2,259 individuals aged 40 years and older enrolled in the Singaporean Malay Eye Study (SiMES). Participants underwent a comprehensive eye examination including slit-lamp lens photography and provided a blood sample for genotyping. Lens photographs were graded using the Wisconsin Cataract Grading System based on 1 to 5 scale. Genotyping was performed with Illumina's 610K Quad Bead Chips. After standard quality control filtering, the association of nuclear cataract and 55,7824 genotyped SNPs was tested using ordered logistic regression analysis with adjustment for age, sex, and population substructure. The strongest evidence was observed at chromosome 21q22 (OR=1.48, *P*=$1.81x10^{-8}$), reaching genome-wide significance. The results were similar after further adjustment for smoking status. An additional SNP at 10q26 was suggestively associated with age-related nuclear cataract (*P*<$5x10^{-7}$). Further replication tests in other cohorts are needed to confirm these associations.

2095T

A genome-wide association study on progressive and bout-onset multiple sclerosis patients. *F. Clarelli[1], P. Brambilla[1], F. Esposito[1], G. Giacalone[1], M. Rodegher[1], M. Sorosina[1], C. Guaschino[1], N. Barizzone[5], P. Cavalla[3], E. Patti[2], D. Galimberti[4], E. Scarpini[4], S. Lupoli[8], R. Capra[6], G. Tedeschi[11], G. Mancardi[9], G. Coniglio[7], L. Grimaldi[10], A. Ghezzi[12], D. Cusi[8], V. Martinelli[1], M. Leone[5], S. D'Alfonso[5], G.C. Comi[1], F. Martinelli Boneschi[1].* 1) Department of Neurology, Scientific Institute and University Hospital San Raffaele, Milan, Italy; 2) Department of Neurological Sciences, University of Catania, Italy; 3) Department. of Neurology, University of Turin, Italy; 4) IRCCS Ospedale Maggiore Policlinico, Milan, Italy; 5) Department of Neurology, Ospedale Maggiore della Carità, Novara, Italy; 6) Department of Neurology, Spedali Civili, Brescia, Italy; 7) Department of Neurology, Madonna delle Grazie Hospital, Matera, Italy; 8) Department of Health Sciences, University of Milan, Italy; 9) Department of Neurological Sciences and Neurorehabilitation - University of Genova, Italy; 10) San Raffaele Hospital Giglio, Cefalù, Italy; 11) Department of Neurological Sciences, Second University of Naples, Italy; 12) Department of Neurology, S. Antonio Abate Hospital, Gallarate, Italy.

Background The role played by genetic factors in distinguishing between progressive multiple sclerosis (PrMS) and bout-onset multiple sclerosis (BOMS) is not yet well estabilished.**Objective** To identify genetic risk modifiers loci which could drive the risk of developing a progressive-onset versus a bout-onset course of multiple sclerosis. **Methods** We conducted a genome-wide association study (GWAS) in 530 patients affected by primary progressive (PPMS) and progressive-relapsing (PRMS) patients recruited in the context of a multicentric project conducted in continental Italy and compared the genetic profiling of these patients with 540 patients affected by a relapsing-remitting (RRMS) and secondary progressive (SPMS) multiple sclerosis of continental italian origin. Samples were genotyped on two different Illumina platforms (OmniExpress 700k, OmniQuad 610k), so only common markers across chips have been taken into account. **Results**. Results highlight the existence of a signal of weak association on chromosome 9p22.2 ($p=3.09 * 10^{-6}$),which needs to be validated and confirmed. While there are no evidences of any signal from the HLA region, supporting the knowledge that the contribution exerted by this region is independent of disease course. Further statistical analyses are ongoing to stratify results across platform type and other covariates. Other association studies are going to be conducted: genetic profiles of PrMS patients and Italian healthy controls are going to be compared, and the relation between genetic loci and PrMS progression index is going to be investigated. **Conclusions** This study represents one of the largest cohort study performed on PPMS. Results still need to be finalized to confirm or not the conclusion that the difference between disease courses can't be explained by genetic factors.

2096F

Novel loci for caffeinated coffee consumption revealed by a genome-wide meta-analysis of 91,000 individuals. *M. Cornelis on behalf of the Coffee & Caffeine Genetics Consortium.* Nutrition, Harvard School of Public Health, Boston, MA.

Background: Coffee, a major dietary source of caffeine, is one of the most widely consumed beverages in the world and has been implicated in various health conditions. We previously identified variants near *AHR* and *CYP1A2* associated with habitual caffeine and coffee intake. To identify additional loci, we now focus specifically on coffee consumption in an expanded sample. Methods: We included 28 population-based studies of European ancestry with self-reported intake of predominantly caffeinated coffee and genotype data imputed to ~2.5 million SNPs. A genome-wide (GW) analysis was performed for association of SNP allele dose with coffee consumption (cups/day) among coffee drinkers adjusting for age, sex, and smoking within each study. A secondary GW analysis was performed comparing high coffee consumers to none/low consumers. For both phenotypes, genetic effect estimates across studies were combined using an inverse-variance fixed-effects approach after applying quality control filters to the GW results. Results: Among ~91,000 coffee drinkers, coffee intake was associated at GW-significance (p<5E-8) with SNPs near *AHR* (7p21), *CYP1A2* (15q24), *POR* (7q11.2) and *MLXIPL* (7q11.23). SNPs near *BDNF* (11p13) reached GW-significance in the secondary analysis. These 5 loci have effect sizes of 0.05 to 0.15 cups/day per allele and together explain ~1.1% of the phenotypic variance of coffee intake. POR encodes an electron transfer protein that catalyzes the activity of CYP450 enzymes and is plausibly linked to caffeine metabolism. Brain-derived neurotrophic factor (BDNF) regulates synaptic transmission and plasticity in the central nervous system and thus may facilitate the psychostimulant effects of caffeine. The role of *MLXIPL* in coffee drinking behavior is unknown. SNPs associated with increased coffee consumption have previously been associated with smoking initiation (*BDNF*), higher adiposity (*BDNF*) but lower blood pressure (*CYP1A2*), and favorable lipid, inflammatory and liver enzyme profiles (*MLXIPL*)(genome.gov/gwastudies). Replication of these 5 loci and ~40 more with sub-GW significance are currently underway in populations of European, African American and South Asian descent as are functional studies of all genes spanning these regions. Conclusions: SNP associations for habitual coffee intake reinforce the role of the caffeine metabolic pathway and suggest new pathways related to neuronal function.

2097W

Genome-wide association study of Tanner puberty staging in males and females. *D. Cousminer[1], N. Timpson[2], D. Berry[3], W. Ang[4], I. Ntalla[5], M. Groen-Blokhuis[6], M. Guxens[7], M. Puberty is a complex trait with large variation in timing and tempo in the population, and extremes in pubertal timing are a common cause for referral to pediatric specialists. Recently, large genome-wide association studies (GWAS) have revealed 42 common variant loci associated with age at menarche (AAM), and some implicated genes are known from severe single-gene disorders. However, little remains known of the genetic architecture underlying normal variation in the onset of puberty, especially in males.

Tanner staging, a 5-stage scale assessing female breast and male genital development, is a commonly used measure of pubertal development. While AAM is a late event during puberty, Tanner staging during mid-puberty may correlate more closely with the central activation of puberty. With Tanner scale data at the comparable ages of 11–12 yrs in girls and 13–14 yrs in boys, we performed GWAS meta-analyses across 10 cohorts with up to 9,900 samples. The combined male and female analysis showed evidence for association near *LIN28B* ($P=1.95 \times 10^{-8}$), previously implicated in AAM and height growth in both sexes. Our data confirms that this locus is also important for male pubertal development and may be part of the pubertal initiation program upstream of sex-specific mechanisms. A novel signal ($P= 4.95 \times 10^{-8}$) with a consistent direction of effect across contributing datasets locates on chromosome 1 at an intronic transcription factor binding-site cluster within the gene *CAMTA1*. Furthermore, the primary analyses revealed suggestive evidence for male-specific loci, e.g. nearby *MKL2* ($P= 4.68 \times 10^{-7}$), which may be confirmed by follow-up genotyping. MAGENTA gene-set enrichment analysis of the combined-gender GWAS results showed enrichment of genes involved in expected pathways given the known biology underlying activation of puberty via the HPG axis. Novel genes near suggestively associated loci may also pinpoint novel regulatory mechanisms; *CAMTA1* is a calmodulin-binding transcriptional activator, while *MKL2* is also a transcriptional activator involved in cell differentiation and development. These results suggest the presence of multiple real signals beneath the genome-wide significant threshold, and further exploration of enriched pathways may reveal new insights into the biology of pubertal development.

Jarvik[1,19].* 1) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 2) Fred Hutchinson Cancer Research Center, Public Health Sciences Division, Seattle WA; 3) Group Health Research Institute, Center for Health Studies, Seattle, WA; 4) Department of Biostatistics, University of Washington, Seattle, WA; 5) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 6) Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 7) Essentia Institute of Rural Health, Duluth, MN; 8) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 9) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 10) Divisions of General Internal Medicine and Preventive Medicine, Northwestern University, Chicago, IL; 11) Division of Endocrinology, Metabolism, and Molecular Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 12) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA; 13) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 14) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 15) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 16) Division of General Internal Medicine, University of Washington, Seattle, WA; 17) Office of Population Genomics, National Human Genome Research Institute, Bethesda, MD; 18) Program in Medical & Population Genetics, Broad Institute of Harvard & MIT; Cambridge, MA; 19) Department of Genome Sciences, University of Washington, Seattle, WA.

With white blood cell count (WBC) emerging as an important risk factor for chronic inflammatory diseases, genetic associations of differential leukocyte types, specifically monocyte count, are providing novel candidate genes and pathways to further investigate. Circulating monocytes play a critical role in vascular diseases such as in the formation of atherosclerotic plaque. We performed a joint and ancestry-stratified genome-wide association analyses to identify variants specifically associated with monocyte count in 13,923 subjects in the electronic Medical Records and Genomics (eMERGE) Network. In the joint and European ancestry samples, we identified novel significantly-associated variants on chromosome 16 from the interferon regulatory factor 8 (*IRF8*) gene (p-value = 2.78e-16, β = -0.22.) Other findings include novel missense variants in the chemokine binding protein 2 (*CCBP2*) gene (p-value = 1.88e-7, β = 0.30) and a region replication found in ribophorin I (*RPN1*) (p-value = 2.63e-16, β = –0.23) on chromosome 3. The *CCBP2* and *RPN1* region is located near GATA2 gene, which has been previously shown to be associated with coronary heart disease. On chromosome 9 we found a novel association in the prostaglandin reductase 1 (*PTGR1*) gene (p-value = 2.29e-7, β = 0.16,) which is downstream from lysophosphatidic acid receptor 1 (*LPAR1*.) This region has previously been shown to be associated with monocyte count. We also replicated monocyte associations of genome-wide significance (p-value = 5.68e-17, β = -0.23) at the *ITGA4* gene on chromosome 2. The novel *IRF8* results and further replications provide excellent candidate genes and pathways to further investigate.

2099F

A Genome-wide Association Study of Systemic Lupus Erythematosus in North Americans of European Ancestry. *F.Y. Demirci[1], X. Wang[1], A.H. Kao[2], A. Clarke[3], R. Ramsey-Goldman[4], S. Manzi[2], M.M. Barmada[1], M.I. Kamboh[1].* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA, USA; 2) Medicine, West Penn Allegheny Health System, Pittsburgh, PA, USA; 3) Medicine, McGill Univ, Montreal, Quebec, Canada; 4) Medicine, Northwestern Univ, Chicago, IL, USA.

Systemic lupus erythematosus (SLE) is a complex autoimmune disease that is influenced by the interplay of heritable, hormonal, and environmental factors. Genome-wide association studies (GWAS) in individuals of European ancestry have identified a number of SLE susceptibility loci using moderate-size samples and earlier versions of Illumina or Affymetrix platforms. Follow-up studies on GWAS regions showing suggestive associations using larger samples and more markers have implicated additional loci. In this study, we report the results of a genome-wide association analysis of SLE in a North American case-control sample of European ancestry (n= 1,166) genotyped by using the Affymetrix Genome-Wide Human SNP Array 6.0 consisting of 906,600 SNPs. As expected, the most significant associations were observed at the major histocompatibility complex (MHC) locus on chromosome 6p21, from which the SNPs easily surpassed the stringent genome-wide significance threshold of $5x10^{-8}$. Among several other previously implicated SLE loci also supported in our study, the strongest associations were observed in the *STAT4* (2q32) and *BLK* (8p23) regions (p= $4.9x10^{-7}$ and $5.0x10^{-6}$, respectively). We also observed several novel loci with p<$5x10^{-5}$ and the most compelling ones were at 2p22 (p=$2.1x10^{-6}$) and 12p13 (p=$6.7x10^{-6}$). These new suggestive loci harbor candidate genes potentially relevant to SLE and related subphenotypes based on their functions. The newly implicated SLE loci in our GWAS warrant further investigation and confirmation in other SLE case-control samples.

2100W

Genome Wide Association Study of Sexual Orientation in a Large, Web-based Cohort. *E.M Drabant, A.K. Kiefer, N. Eriksson, J.L. Mountain, U. Francke, J.Y. Tung, D.A. Hinds, C.B. Do.* 23andMe, Mountain View, CA.

There is considerable variation in human sexual orientation. Heritability studies have differed on the exact scope of genetic contributions for sexual orientation, but it appears that both genetics and environment play a role. Though a few linkage studies have pointed at a possible role for certain genes on the X chromosome, the strength of that evidence is limited due to the conflicting nature of the reports and small sample sizes. We sought to clarify some of the questions surrounding the possible genetic underpinnings of sexual orientation by deploying a web-based survey to the large 23andMe database and conducting the first ever genome-wide association study (GWAS) on sexual orientation.

We adapted the Klein Sexual Orientation Grid to examine seven elements of sexual orientation. All items were rated on a seven point scale by participants. Initial analyses focused on the "self identification" item as a continuous variable in response to the question "How do you label, identify or think of yourself?" In a sample of 7,887 men and 5,570 women, 77.2% of men 74.6% of women identified as heterosexual only, 7.3% of men and 15.3% of women as heterosexual mostly, 1.1% of men and 2.7% of women as heterosexual somewhat more, 1.3% of men and 3.5% of women as bisexual, 0.7% of men and 0.5% of women as homosexual somewhat more, 2.9% of men and 1.6% of women as homosexual mostly, and 9.5% of men and 1.8% of women as homosexual only. In both men and women, sexual identity was most significantly correlated with sexual attraction (men r=0.97, women r=0.90), sexual behavior (men r=0.95, women r=0.83), sexual fantasies (men r=.96, women r=.75), and emotional attraction (men r=0.79, women r=0.45), and the least strongly correlated with heterosexual/homosexual lifestyle (men r=.54, women r=.37), and social preference (men r=.15, women r=.08).

We carried out GWAS stratified by sex in a cohort of 7887 unrelated men and 5570 unrelated women of European ancestry collected in the two months since the initial survey release. No clear genome-wide significant associations have been found thus far, and the current data do not show any direct association for markers within chromosome band Xq28. However, data collection is still ongoing, and increased sample size may help to clarify the roles for currently suggestive associations.

2101T

Identification of multiple novel susceptibility regions for primary sclerosing cholangitis through dense genotyping of autoimmunity risk loci. *E. Ellinghaus[1,4], J.Z. Liu[2,4], T. Folseraas[3,4], A. Franke[1,5], C.A. Anderson[2,5], T.H. Karlsen[3,5] on behalf of The International Primary Sclerosing Cholangitis Study Group &The Immunochip Consortium.* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University Kiel, Kiel, Germany; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK; 3) Medical Department, Rikshospitalet University Hospital and University of Oslo, Oslo, Norway; 4) These authors contributed equally; 5) Shared senior authorship.

Primary sclerosing cholangitis (PSC) is a rare bile duct and liver disease of unknown etiology. In lack of medical therapy, PSC has become a major indication for liver transplantation in Northern Europe and the USA. An important clinical feature of PSC is the frequent occurrence of inflammatory bowel disease (IBD), which is reported in 60% to 80% of PSC patients of Northern European descent. So far, two genome-wide association studies (with up to 715 patients included at the discovery stage of analysis) have identified four genome-wide significant (P<5×10^{-8}) associations for PSC (HLA, *MST1*, *IL2RA* and *MMEL1*).

To identify additional PSC risk loci and systematically interrogate the genetic relationship between PSC and other immune-mediated diseases, we performed genotyping at 186 distinct risk loci previously implicated in 12 autoimmune diseases using a custom high-throughput SNP genotyping array, the Immunochip. This array was specifically designed to perform fine-mapping and deep replication of previously established risk loci by investigating both common and rare SNPs.

After genotyping of 196,524 SNPs in 4,228 PSC cases and 27,077 controls from throughout Europe, Canada and the USA, stringent quality control left 3,788 PSC cases and 25,079 controls for association analysis by logistic regression with the first 10 principal components included as covariates. Our analysis yielded seven novel PSC risk loci at genome-wide significance (P<5×10^{-8}) within or near the following genes: *CTLA4*, *PSMG1*, *BACH2*, *PRKD2*, *IL2*/*IL21*, *SH2B3* and *CLEC16A*. Six of the seven newly identified PSC risk loci overlap with previously established susceptibility loci for type 1 diabetes, with a less pronounced overlap with celiac disease, rheumatoid arthritis and IBD. Further analysis of the obtained data is ongoing and will be presented. The outcome is likely to provide unprecedented insight into the biological pathways underlying PSC as well as the relationship between PSC and several more prevalent autoimmune diseases, both of which may lead to the development of novel therapeutic strategies for a rare, but debilitating, condition.

Genome wide association studies (GWAS) have provided great insight into the genetic architecture of complex diseases. Unfortunately, huge samples sizes will be needed to detect all the multiple low-risk variants likely to play a role in disease at the significance threshold required in GWAS. Therefore, a major challenge is the identification of new risk factors among the thousands of markers that show evidence for association but do not reach genome-wide significance (the so called “GWAS grey zone”). The parallel increase in prevalence observed in common inflammatory disorders together with the identification of SNPs simultaneously influencing the risk of multiple diseases points to overlapping etiological factors among these disorders. We aimed to use this overlap in order to identify new risk factors for the chronic inflammatory skin disease Atopic Dermatitis (AD). We inspected the GWAS repository (http://www.genome.gov/gwastudies/) and selected all 318 SNPs associated to any immune-related trait at genome-wide significance. These markers were then screened for association with AD in a GWAS meta-analysis including 2890 cases and 2030 controls. Interestingly a strong enrichment on AD-associated markers was observed among these 318 candidate SNPs (p<2x10-7), confirming our hypothesis of an overlap among the genetic determinants of AD and inflammatory traits. Eight markers moderately associated to AD (GWAS_p<0.01) were selected for follow-up in 3 cohorts including 4235 cases and 6805 controls. A missense functional variant in the IL6 receptor (rs2228145) affecting the shedding of the soluble IL6R (sIL6R) was significantly associated with AD (OR=1.15; P=5x10-9). rs2228145 correlated with serum sIL6R levels (P=4x10-14) and sIL6R was increased in AD patients (P=0.001). This finding suggests that targeted blocking of IL6R signaling with Tocilizumab may be a novel target for clinical intervention in AD, especially for individuals carrying this variant. Additionally variants in RAD50, RUNX3, and ERBB3 were also associated with AD. Strikingly, all 4 risk SNPs reported here showed only modest association with AD in the GWAS and would have been missed if selecting markers based on significance level alone. This study demonstrates that inclusion of relevant biological information is a valuable tool for GWAS prioritization and may help to identify novel susceptibility genes in already-existing GWAS data sets.

2103W

A novel sarcoidosis risk locus for Europeans on chromosome 11q13.1. *A. Fischer[1], B. Schmid[1], D. Ellinghaus[1], M. Nothnagel[2], K.I. Gaede[3], M. Schürmann[4], S. Lipinski[1], P. Rosenstiel[1], G. Zissel[5], K. Höhne[5], M. Petrek[6], V. Kolek[7], S. Pabst[8], C. Grohé[9], J. Grunewald[10], M. Ronninger[11], A. Ecklund[10], L. Padyukov[11], C. Gieger[12], H.-E. Wichmann[13,14,15], A. Nebel[1], A. Franke[1], J. Müller-Quernheim[5], S. Hofmann[1], S. Schreiber[1,16,17].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts University, Kiel, Germany; 2) Institute of Medical Informatics and Statistics; Christian-Albrechts University; Kiel, Germany; 3) Department of Pneumology, Research Center Borstel, Borstel, Germany; 4) Institute of Human Genetics, University of Lübeck, Lübeck, Germany; 5) Department of Pneumology, University of Freiburg, Freiburg, Germany; 6) Laboratory of Immunogenomics and Immunoproteomics, Faculty of Medicine and Dentistry, Palacky University Olomouc, Czech Republic; 7) Dept. of Respiratory Medicine, Faculty of Medicine and Dentistry, Palacky University Olomouc, Czech Republic; 8) Medical Clinic II, Department of Pneumology, University of Bonn, Germany; 9) Department of Respiratory Medicine, Evangelische Lungenklinik Berlin-Buch, Germany; 10) Respiratory Medicine Unit, Department of Medicine, Karolinska Institutet, Stockholm, Sweden; 11) Rheumatology Unit, Department of Medicine, Karolinska Institutet, Stockholm, Sweden; 12) Institute of Genetic Epidemiology, Helmholtz Centre Munich, German Research Center for Environmental Health, Neuherberg, Germany; 13) Institute of Epidemiology I, Helmholtz Centre Munich, German Research Center for Environmental Health, Neuherberg, Germany; 14) Institute of Medical Informatics, Biometry and Epidemiology, Ludwig-Maximilians-University, Munich, Germany; 15) Klinikum Grosshadern, Munich, Germany; 16) Department of General Internal Medicine, University Hospital Schleswig-Holstein, Kiel, Germany; 17) Popgen Biobank, University Hospital Schleswig-Holstein; Kiel, Germany.

Sarcoidosis is a complex inflammatory disease with a heterogeneous clinical picture. Amongst others, an acute and chronic clinical course can be distinguished, for which specific genetic risk factors are known. In order to identify additional risk loci for sarcoidosis and its acute and chronic subforms, we analyzed imputed data from a genome-wide association scan (GWAS) for these phenotypes.

After quality control, the GWAS comprised nearly 1.3 million imputed single nucleotide polymorphisms based on an Affymetrix 6.0 Gene Chip dataset of 564 German sarcoidosis cases, including 176 acute and 354 chronic cases and 1575 controls. We identified chromosome 11q13.1 as a novel locus influencing susceptibility to sarcoidosis with genome-wide significance. The lead marker was significantly associated in three distinct German case-control populations and in an additional German family sample with ORs ranging from 0.67 to 0.77. This finding was further replicated in two independent European case-control populations from the Czech Republic (OR = 0.75) and from Sweden (OR = 0.79). In a meta-analysis of the included European case-control samples the marker yielded a p value of 2.68×10^{-18}. The locus was previously reported to be associated with Crohn's disease and alopecia areata. For sarcoidosis, fine-mapping and expression analysis suggest several transcripts as candidates for the underlying risk gene in the associated region.

In summary, this study provides striking evidence for association of chromosome 11q13.1 with sarcoidosis in Europeans, and thus identified a further genetic risk locus shared by sarcoidosis and Crohn's disease. Full results, including marker and gene names, will be shown in the oral presentation or on the poster, respectively.

2104T

A GWAS on Age-Related Hearing Impairment in a European population. *E. Fransen[1], S. Bonneux[1], I. Schrauwen[1], F. Di Berardini[2], I. Dhooge[3], J.J. Corneveaux[4], J.D. Ohmen[5], P.H. Van de Heyning[6], R. Friedman[5], M.J. Huentelman[4], G. Van Camp[1].* 1) Center Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Dipartimento di Scienze Chirurgiche Specialistiche, Università degli Studi di Milano, Milan, Italy; 3) ENT department, University Hospital of Ghent, Ghent, Belgium; 4) Neurogenomics Division, The Translational Genomics Research Institute, Phoenix, AZ, USA; 5) House Ear Institute, Gonda Research Center for Cell and Molecular Biology, Los Angeles, CA, USA; 6) ENT department, University Hospital of Antwerp, Antwerp, Belgium.

Age-related hearing impairment (ARHI) is characterized by a gradual, symmetric and sensineural loss of hearing acuity beyond age 50. Hearing loss is sensorineural, symmetric and primarily affecting the high frequencies. Heritability studies have indicated that ARHI is a complex trait, with approximately half of the variance attributable to genetic factors, and the remainder to environmental risk factors. There where several environmental risk factors have been identified including noise exposure and smoking, the genetic basis of ARHI remains to be elucidated. We and others have already performed several large-scale association studies into ARHI, pointing at several interesting candidate genes, but none of these candidate genes has ever shown a consistent replication across multiple studies. Here we present the results of a genome-wide association study on a population of 2161 samples collected in and around Antwerp, Belgium. We report the most promising candidate genes as scored by classic association test, show the results of pathway analysis and compare our results to the results of previous association studies into ARHI.

2105F

An extensive literature-based multilocus genetic score is associated with all-cause-mortality and major diseases: The Rotterdam and TwinGene studies. *A. Ganna[1], A. C. Janssens[2], A. Hofman[2], F. Rivadeneira[2], A. G. Uitterlinden[2], P. K. E. Magnusson[1], N. L. Pedersen[1], E. Ingelsson[1], H. Tiemeier[2].* 1) Department of medical epidemiology and biostatistics, Karolinska institutet, Sweden; 2) Department of epidemiology, Erasmus Medical Center, The Netherlands.

Background: Twin studies have shown that approximately 20–30 % of the overall variation in lifespan is caused by genetic differences, and that the genetic influence on lifespan increase with age. Moreover, centenarians' offspring have lower risk of all-cause mortality and cause-specific mortality from cancer and coronary heart disease than controls. Genome-wide association (GWA) studies have revealed a large number of single nucleotide polymorphisms (SNPs) associated with diseases and their risk factors, but have failed to robustly identify any longevity loci besides the well-established APOE locus. Objectives: To create a multilocus genetic score including SNPs that have been found to be associated with mortality-related traits in GWA studies, and to test for association of this score with all-cause-mortality and incidence of major diseases. Methods: Using the NHGRI-GWAS catalog, six medical doctors with expertise in epidemiology independently selected 125 traits moderately or highly associated with overall mortality. After extensive quality control, we included 709 SNPs in a unweigthed multilocus genetic score by adding the number of risk alleles. We prospectively studied the association of this multilocus genetic score with: (1) time-to-death; and (2) incidence of at least one of nine major diseases (coronary heart disease, stroke, heart failure, diabetes, dementia, lung, breast, colon and prostate cancers) in two population-based cohort studies of Dutch and Swedish individuals (Rotterdam study and TWINGENE; total N=15,039). We further investigated whether the strength of associations varied with age. Results: During a median follow-up of 6.0 years (max, 22.2 years), we observed 4,267 deaths and 2,132 incident disease events. The multilocus genetic score was significantly associated with time-to-death, but the association was very modest (hazard ratio [HR] per added risk allele, 1.002; P-value=0.01). The association remained significant after removing APOE rs2075650 from the multilocus genetic score, which was our top association in the single-marker analysis. The association between the multilocus genetic score and incidence of major diseases was stronger (HR per added risk allele, 1.005; P-value=0.002). Associations were more pronounced for individuals died at average life expectancy. Conclusions: Genetic determinants of longevity are partially overlapping with those of commons diseases.

2106W

Large-scale meta-analysis in up to 40,429 Europeans identifies genetic loci associated with non-fasting plasma glucose and reveals links to glucose uptake in muscle. *KS. Gutierrez[1], V. Lagou[2,3], A. Isaacs[1,4], JB. Meigs[6,7], YS. Aulchenko[1,5], I. Prokopenko[2,3] for MAGIC (the Meta-Analyses of Glucose and Insulin-related traits Consortium) investigators.* 1) Genetic Epidemiology Unit, Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 4) Centre for Medical Systems Biology, Leiden, The Netherlands; 5) Laboratory of Recombination and Segregation Analysis, Institute of Cytology and Genetics SD RAS, Novosibirsk, Russia; 6) General Medicine Division, Massachusetts General Hospital, Boston, Massachusetts, USA; 7) Department of Medicine, Harvard Medical School, Boston, Massachusetts, USA.

Levels of circulating plasma glucose are strictly regulated. An unusually high non-fasting (random) plasma glucose (RG) level (measurement of plasma glucose at any time point during the day) might indicate abnormal glucose homeostasis and can be used to suggest a diagnosis of diabetes. We sought to identify genetic variants contributing to the variability of RG and to elucidate the genetic relationship between RG, other glycemic traits and type 2 diabetes (T2D). We conducted an inverse variance fixed-effects meta-analysis of genome-wide association studies (GWAS) for RG, adjusted for age and sex, at ~2.5M European HapMap II reference panel-imputed SNPs and SNPs genotyped on the Metabochip platform. Up to 40,429 non-diabetic European individuals from 14 studies were available for analysis. We found three variants associated with RG at a genome-wide significance level: at *G6PC2* (rs573225,P=1.27x10^{-20}), *GCK* (rs2908282, P=1.18x10^{-17}) and the muscle-specific tyrosine-protein kinase receptor (*MuSK*) (rs4500149, P=1.57x10^{-8}). The first two were also associated with fasting glucose (FG) and HbA1c in previous studies. Association at the *MuSK* gene locus is novel and a promising biological candidate, due to its important role in muscle contraction through increased glucose uptake leading to improved cellular insulin efficiency. We observed suggestive associations (P<10^{-5}) within *ADCY5* (rs7613951, P=2.43x10^{-7}), *SLC2A2* (rs16847990,P=1.21x10^{-6}), both previously associated with FG, and at *ANKRD32* (rs7718956, P=1.09x10^{-6}) and *TMEM132D* (rs10847533, P=1.09x10^{-6}). A model with an additional adjustment for the time since last meal produced similar results, but was available only in a subset of studies. We also evaluated consistency between the effects of known T2D and glycemic variants on T2D, FG and RG. To that end, using Kolmogorov-Smirnov test we revealed that T2D, fasting insulin, FG and 2 hours post load glucose (2hGlu) variants are enriched for the RG association signals (P=5.77x10^{-15}, N=158). Consistently, T2D (P=1.53x10^{-6}, N=57), FG (P=2.81x10^{-10}, N=39) and 2hGlu (P=0.001, N=7) loci also overlapped with RG associations when analyzed separately. In conclusion, RG shares genetic background with T2D and other glycemic traits. Association at the *MuSK* gene locus needs to be confirmed and suggests that analysis of RG will provide additional insights into regulation of glucose homeostasis and muscle glucose uptake.

2107T

Genome-wide association study detects multiple novel loci associated with Nuclear Magnetic Resonance spectroscopy detected metabolites in human serum. *P. Henneman[1], A. Verhoeven[2], H. Dharuri[1], J. van Klinken[1], A. Meissner[2], S. Göraler[2], A. Deelder[2], R. Frants[1], L. Karssen[3], B. Oostra[3], K. Willems van Dijk[1,4], C. van Duijn[3].* 1) Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Dept. Parasitology, Leiden University Medical Center, Leiden, The Netherlands; 3) Dept. Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 4) Dept. Internal Medicine, Leiden University Medical Center, Leiden, The Netherlands.

Introduction: Recently reported GWA studies on classical Metabolic Syndrome (MetS) traits showed that only moderate proportions of the heritability of these traits could be explained. Recent reports hypothesized and showed that one possible approach to tackle this problem of "missing heritability" is to make use of intermediate or endo-phenotypes. Here we aim to find novel loci involved in MetS-related traits using intermediate metabolomic phenotypes detected by state of the art NMR technology. Methods: The present study applies to a Dutch genetically isolated population: The Erasmus Rucphen Family (ERF) study. Two-dimensional J-resolved NMR spectroscopy experiments were performed on human sera using a 14.09T 600 MHz ultra shield Plus from Bruker. Forty-three metabolites for 2482 ERF participants were successfully quantified and QC-ed. Heritability estimates were performed using SOLAR software. Genome-wide association was based on 300K genotypes imputed at 2.5 million SNPs. Association analysis was performed using the GenABEL "R" packages that enables adjustment for kinship. 265 ratios were derived from concentrations using novel bioinfomatic techniques, which selected ratios of metabolites only in the vicinity of a metabolite. Gene-based association was performed using VEGAS. Results: Heritability estimates for metabolites or the derived measures ranged between 10% and 70%. Genome-wide association for 43 metabolites and 265 derived measures were performed. Thirty-four SNPs in 23 metabolite traits showed P-value < 1e -8 of which 15 SNPs were located at genes that were reported earlier (e.g. *LPL*, *GCKR*, *ABO*). Six SNPs showed P-value < 1e-10. Moreover, a gene-based approach using the genome-wide results, detected 7 additional loci in 6 of the 43 metabolites. For the derived traits we found 268 SNPs in 30 traits associated with a P-value < 1e0–10. Novel bioinformatic techniques indentified promising MetS-related biochemical reactions and metabolic pathways. Replication (Finish cohorts of Kettunen et al. 2012, N~8000) and meta-analysis analysis are ongoing. Conclusion: Here we show successful detection of several novel and confirmation of earlier associated loci with NMR detected metabolites, which may provide substantial contribution to basal physiological knowledge of metabolic syndrome and cardiovascular disease.

2108F

Ontology, visual, and informatics enhancements to the NHGRI Genome-wide Association Study (GWAS) catalog. *L.A. Hindorff[1], J.A.L. MacArthur[2], D. Welter[2], T. Burdett[2], P. Hall[1], H.A. Junkins[1], H. Parkinson[2].* 1) Population Genomics, NHGRI, NIH, Bethesda, MD; 2) EMBL-EBI, Wellcome Trust Genome Campus, Hinxton, UK.

The National Human Genome Research Institute's (NHGRI) GWAS Catalog (http://www.genome.gov/gwastudies) contains over 1,300 publications and 6,400 disease- or trait-associated genetic variants, which have been manually curated from published genome-wide association studies (GWAS). The availability of this curated, regularly updated, and downloadable resource contributes to the knowledge base of genetic variants associated with important diseases and conditions and enables cross-linking with other commonly used resources such as Ensembl, Database of Genotypes and Phenotypes (dbGaP), the Phenotype-Genotype Integrator (PheGenI) and UCSC Genome Browser. We have implemented several improvements to increase the usability of catalog data and ease of integration with other resources. First, catalog traits have been integrated into the Experimental Factor Ontology (Malone et al., 2010), an application ontology based on a paradigm of reusing elements from reference ontologies including PATO and ChEBI. This standardization of trait organization will facilitate increased integration of NHGRI GWAS catalog data with other sources and improved querying of the catalog. Building upon this ontology, generation of the iconic GWAS catalog diagram has been automated (http://wwwdev.ebi.ac.uk/fgpt/gwas) such that visual representations of GWAS associations across the human genome are now available filtered by different criteria, including disease category and p-value. These customized diagram images can be downloaded for use in publications and presentations. SNP-trait associations in the online version of the diagram are also interactive, with dynamic links to the GWAS catalog entry and to external resources such as Ensembl and dbSNP. Informatics improvements have also increased the efficiency and quality of the curation process. For example, the previous limit of 50 SNP-disease associations per paper is no longer in effect, with all qualifying associations with a p-value < $1x10^{-5}$ now included in the catalog. Ultimately, the benefits of standardized disease annotation, customized views of the GWAS catalog diagram, and efficient curation will yield an enhanced user experience and facilitate further integration of GWAS catalog data with other resources.

2109W

Genome-wide association study of time-to diabetic retinopathy. *S.M. Hosseini[1,2], A.P. Boright[3], L. Sun[4], K. Howard[5], A.J. Canty[6], S.B. Bull[4,7], B.E. Klein[5], R. Klein[5], A.D. Paterson[1,2,4], the DCCT/EDIC research group.* 1) Gen & Genomic Biol, Rm 15–701, Hosp Sick Children, Toronto, ON, Canada; 2) Inst of Medical Science, Univ Toronto, Toronto, Canada; 3) Dept of Medicine, Univ Toronto and LMC Diabetes & Endocrinology, Toronto, Canada; 4) Dalla Lana School of Public Health, Univ Toronto, Toronto, Canada; 5) Dept of Ophthalmology & Visual Sciences, Univ Wisconsin, Madison, WI, USA; 6) Dept of Mathematics & Statistics, McMaster Univ, Hamilton, Canada; 7) Samuel Lunenfeld Research Institute, Toronto, Canada.

Diabetic retinopathy (DR) is a major health problem affecting up to 82% of patients with type 1 diabetes (T1D). Duration of diabetes and poor glycemic control are the major known risk factors for DR. Consistent with a genetic contribution, the severity of DR clusters in families, yet few genetic variants have shown convincing and consistent associations with DR.

White T1D participants in the Diabetes Complications and Control Trial (DCCT, n=1304) and Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR, n=627) were genotyped by Illumina Human1M and HumanOmni1-Quad assays, respectively. Following quality control procedures, genotypes of ~1.5M autosomal SNPs from HapMap3 were imputed in both studies. Time-to severe non-proliferative DR [level 53/<53 or worse on ETDRS scale or panretinal laser photocoagulation treatment] was defined by examination of repeated retinal photographs taken over more than 2 decades (average 4.5 photos in WESDR and 16.8 in DCCT/EDIC). To address both left and interval censoring, survival analysis was performed using a complementary log-log model. Multivariate models were built to account for glycemia (measured by A1C), diabetes duration and other relevant covariates in the association analysis of time-to-DR with genotype. Analyses were performed separately in WESDR and the 3 subgroups of DCCT (primary cohort, secondary cohort by treatment group - conventional or intensive) before combining the results in a meta-analysis.

Two SNPs on 8q23.3, upstream of *TRPS1*, showed significant association with risk of DR (p<5E-8). Suggestive associations (p<1E-6) were also observed for SNPs on: 2q14.1 in *DPP10*, a member of voltage gated potassium channels, associated with asthma; 5q31.3 in protocadherin beta gene cluster (*PCDHB1–16*); 11p14.3 near *NELL1*; and 6p22.3 (intergenic). Attempts to replicate the results in independent cohorts are in progress.

This first GWAS of time-to diabetic retinopathy illustrates the value of survival analysis with explanatory covariates in genetic studies of diabetic complications.

2110T

Genome-wide screen for telomere length loci identifies a cancer risk associated gene in Finnish cohorts. *I. Hovatta[1,2,3], I. Surakka[2,3], I. Sirén[1], J. Kettunen[2,3], J.G. Eriksson[2,4,5,6,7], P. Knekt[2], V. Salomaa[2], J. Kaprio[2,3,8], S. Ripatti[2,3,9].* 1) Molec Neurology Program, University of Helsinki, Helsinki, Finland; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) Institute for Molecular Medicine Finland, FIMM, University of Helsinki, Helsinki, Finland; 4) Dept of General Practice and Primary Health Care, University of Helsinki, Helsinki, Finland; 5) Helsinki University Central Hospital, Helsinki, Finland; 6) Folkhälsan Research Centre, Helsinki, Finland; 7) Vasa Central Hospital, Vasa, Finland; 8) Dept of Public Health, University of Helsinki, Helsinki, Finland; 9) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

We carried out a genome-wide association study to identify loci influencing leukocyte telomere length (LTL) in four Finnish sample sets with 5133 individuals. The relative LTL was measured using a qPCR based methods. We tested genome-wide associations between 38 million markers and LTL. In a meta-analysis of the results three SNPs in the intron of the telomerase transcriptase (TERT) gene associated (p-value <5×10–8) with LTL. Additionally, we found 10 suggestive loci from which the best SNP per area, together with the most significant TERT SNP, rs7726159, were taken forward to the replication genotyping of 3452 individuals from Health 2000 and 4031 individuals from FINRISK92-07 cohorts. In the replication analyses the association of TERT locus was replicated separately in both replication datasets leading to a screening and replication stage combined P-value of 6.0×10–10. Variants in TERT have previously been associated with multiple types of cancer. We therefore investigated the TERT SNP, LTL and risk of cancer in the Health 2000 data (447 incident cancer cases and 4939 controls) in which we observed a suggestive association between LTL and cancer risk (P-value = 0.03) with a simple logistic regression with age and sex as covariates. We also investigated if individuals with shorter LTL have higher mortality. We saw a significantly higher risk of mortality for individuals with shorter telomeres (P-value = 0.003) when combining data from Health 2000 and one of the screening datasets with 914 incident death cases altogether. Longitudinal studies, such as ongoing in the Health 2000, will be essential to understand the causal relationship between LTL, cancer risk, mortality, and genetic variation in the TERT locus.

GWAS Identifies 13 Polymorphisms Associated with Motion Sickness. *B.S. Hromatka, E.R. Chang, J.Y. Tung, J.L. Mountain, U. Francke, C.B. Do, N. Eriksson.* 23andMe, Inc., Mountain View, CA.

Motion sickness and its underlying causes are not well understood and yet this condition affects many; between 7% and 28% of people experience acute motion sickness while traveling. This condition is also medically relevant, as individuals who experience motion sickness while traveling are more likely to experience nausea and vomiting after surgery. A better understanding of this common condition could perhaps lead to improved travel and surgery experiences. Twin studies on motion sickness suggest high heritability (57–70%), but to date there are no known genetic factors associated with motion sickness. To discover which genes may be involved, we conducted a genome-wide association study on over 33,400 individuals who were genotyped on the 23andMe platform and surveyed on motion sickness. We found thirteen SNPs associated with motion sickness at a genome-wide-significant level. Of these 13 SNPs, several are found near genes associated with eye, ear, and neurological development. Of note is rs6926953 (p = 1.95 x 10-9), which is 300 kb upstream from the gene MUTED; mutations in the mouse homolog of MUTED are implicated in balance problems. In addition, rs4891066 (p = 3.24 x 10-9) is 99 kb downstream from TSHZ1, a gene involved in inner ear development. Furthermore, rs17720662 (p = 2.69 x 10-27), which was the most significant association found, is 1.1 Mb upstream from the gene PVRL3, which plays a role in eye development. One prevailing theory of motion sickness is that nausea results from contradictory information the brain receives while traveling. The inner ear, which can perceive acceleration and influences balance, signals "moving" to the brain, while the eye signals "stationary" because the car or boat is stationary relative to the viewer. The proximity of several of these motion sickness-associated SNPs to genes associated with eye, ear, and neurological development suggests that these genes may be involved in motion sickness. These findings are an important first step towards understanding the biological basis of not only motion sickness, but of conditions such as post-operative nausea and vomiting as well.

2112W

Identification of Leprosy Host Genetic Susceptibility Loci. *A. Irwanto[1,2], L. Hong[3], F. Zhang[3], J. Liu[1].* 1) Human Genetics, Genome Institute of Singapore, Singapore, Singapore; 2) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 3) Shandong Provincial Institute of Dermatology and Venereology, Provincial Academy of Medical Science, Jinan, China.

Interaction among the pathogen, environmental factors and host genetic makeup determine the success of an infection and its disease outcome. Genome-wide association studies (GWAS) have been successful in identifying host susceptibility genes that show significant association with the development of leprosy, including *CCDC122*, *LACC1* (*C13orf31*), *NOD2*,*TNFSF15*, *HLA-DR-DQ*, *LRRK2*, *RIPK2*, *IL23R*, *RAB32* in the Chinese population and *TLR1*, *HLA-DRB1*, *HLA-DQA1* in the Indian population, but many more remain to be discovered. Further GWAS analysis with better coverage of genetic variation through imputation and better statistical power through enlarged samples size can help to identify additional novel susceptibility loci for leprosy. Here we performed a large GWAS analysis of leprosy by analyzing over 2 million SNPs in 1623 cases and 6580 controls of Northern and Southern Chinese as well as Chinese minority population through a whole genome imputation using 1000 Genomes phased-haplotype information (from 1092 individuals of multiple ethnicities) and association analysis adjusting for population stratification via logistic regression. Our GWAS analysis replicated most of the previously identified loci and revealed additional novel suggestive associations at 48 novel loci (p-value < 10^{-4}; I^2 < 30). The validation study of the novel association signals is carried out using Sequenom MassArray platform in independent datasets and will likely discover additional new susceptibility genes to provide further biological insight into the pathogenic mechanism of leprosy.

2113T

Genetic risk score in Multiple Sclerosis: Back to the individual in the post-GWAS era. *N. Isobe[1], P. KhanKhanian[1], B. Vinod[1], S. Cailler[1], H. Harbo[2], A. Santaniello[1], S. Hauser[1], J. Oksenberg[1], P. Gourraud[1].* 1) UCSF, San Francisco, CA; 2) Department of Neurology University Hospital, Oslo Norway.

By the end of 2011, after 9 GWAS in Multiple Sclerosis (MS), there were more than 50 genomic regions associated with MS. In the well-known genomic region of HLA-DRB1, the description of the associations of multiple MS genetic variants with susceptibility, disease severity and response to treatment has become extremely elaborated. We are thus facing a new situation: the discovery of additional MS genes increase the critical need for summary metrics of the MS-specific genes configuration of patients. As of 2012, we developed a log-additive weighted statistical model, termed Multiple Sclerosis Genetic Burden, to take into account as many as 64 single nucleotide polymorphisms (SNPs). In addition, if real HLA typing is available, the contribution of the MHC region can be flexibly taken into account to provide a more accurate risk model. When computed in over 3,000 samples of the USCF MS repository, the MSGB analysis demonstrates a higher aggregation of susceptibility variants in multi-case compared to sporadic MS families (p=4.72.10-4). A greater MSGB score in siblings of MS patients was associated with an increased risk of MS (odds ratio, 2.1; p = 0.001), but MSGB differences between probands and their sibs show that case-control status cannot be predicted with the currently available genetic data. Using this score we applied another original statistical method, the equivalence test (Gourraud et al 2011 Gen. Epi.) to prove that the primary progressive and relapsing remitting forms of MS share common genetic architecture. Finally, we used MSGB score as a simplified way to evaluate the genetic contribution to various aspects of MS such as age of onset (p=2.4e-2) and presence of oligo-clonal band (p= 4.21e-6). The 2012 version of the MSGB analyses underline the high variability of individual and family load with known common variants. The primary interest of aggregated genetic risk score, such as MSGB resides in its capacity to integrate genetic contributions to MS risk in a summarized yet genome-wide way.

2114F

A genome-wide association study of HIV-1 infection in African American and European American injection drug users. *E. Johnson[1], D. Hancock[1], J. Levy[2], G. Page[3], S. Novak[1], C. Glasheen[1], N. Gaddis[2], N. Saccone[4], J. Rice[5], Q. Wang[6], M. Moreau[6], K. Doheny[7], J. Romm[7], A. Brook[6], L. Bierut[5], A. Kral[8].* 1) Behavioral Heallth Epidemiology, RTI International, Research Triangle Park, NC; 2) Research Computing Division, RTI International, Research Triangle Park, NC;; 3) Genomics, Statistical Genetics, and Environmental Research Program, RTI International, Atlanta, GA; 4) Department of Genetics, Washington University in St. Louis, MO; 5) Department of Psychiatry, Washington University in St. Louis, MO; 6) Rutgers University Cell and DNA Repository (RUCDR), Riscataway, NJ; 7) Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD; 8) Urban Health Program, RTI International, San Francisco, CA.

Nearly 40 million people worldwide are infected with HIV. Host genetic factors likely influence susceptibility to acquiring HIV upon exposure. However, the only validated genetic association with HIV-1 infection is the 32 base-pair deletion in the CCR5 gene, which is rare in the population. To identify and characterize novel genetic risk factors, we conducted GWA studies of HIV-1 infection in African American and European American injection drug users. Unlike the prior genetic studies, we focused on injection drug users whose transmission may be primarily parenteral rather the than mucosal or mother-to-infant, and used HIV-1 negative controls with individually assessed high probability of exposure. HIV-1 positive cases and negative controls were frequency-matched on behavioral and demographic risks of exposure. DNA was extracted from stored serum at RUCDR and treated with Illumina FFPE restoration prior to genotyping at CIDR on the Illumina Omni1-Quad array. Following quality control procedures for genotyped SNPs and participants, the analysis data set included ~700,000 autosomal SNPs in 2,010 African Americans (630 cases, 1,380 controls) and 1,149 European Americans (335 cases, 814 controls). In the separate ethnic groups, additive SNP genotypes were tested for association with HIV-1 infection using logistic regression models adjusted for age, gender, behavioral risk class, recruitment pre- or post- availability of antiretroviral therapy, and 10 principal component eigenvalues for population stratification. The ethnic-specific GWA results were then combined in a fixed-effects meta-analysis. The lowest P-value (meta-analysis P=1.88x10-6) was observed for a regulatory SNP on chromosome 9p13, located in a transcription factor binding site upstream of a gene essential to B-cell differentiation. B cells, a primary component of the adaptive immune system, may play a role in cell-to-cell transmission of the HIV virus and are known to be affected during disease progression (e.g., expansion of immature transitional B-cells and B-cell exhaustion). The SNP is associated with HIV-1 infection in both ethnic groups, but occurs more frequently in African Americans (MAF=21.9%) than in European Americans (MAF=1.3%). Analyses using 1000 Genomes imputed SNPs and genotyping of Hispanic American samples are underway to further characterize this biologically plausible gene region and others that may help determine the complex etiology of host response to HIV-1.

Genetics of Myopia in a Participant Driven, Web-Based Cohort. *A.K. Kiefer, J.Y. Tung, C. Do, D.A. Hinds, J.L. Mountain, U. Francke, N. Eriksson.* 23andMe, Inc., Mountain View, CA.

Myopia, or nearsightedness, is the most common eye disorder worldwide. Myopia results from the elongation of the eye axis, which causes images to be focused in the vitreous part of the eye instead of on the retina. In the United States, roughly a third of the adult population has clinically relevant myopia (more severe than -1 diopter), and its prevalence has increased in recent decades. The etiology of myopia is largely unknown, but is believed to have a substantial genetic component, with prior heritability estimates ranging from 0.60–0.90. Education, reading, and lack of time spent outdoors are known environmental risk factors for myopia, and may contribute to its rapidly increasing prevalence. We collected self-reported information on myopia from the 23andMe participant cohort. We describe the results of a genome-wide association analysis on this convenience sample consisting of approximately 23,000 cases, defined as anyone who reported a diagnosis of nearsightedness, and 16,000 controls, who reported that they had not been diagnosed with nearsightedness, all of European ancestry. We replicate the only two previously identified associations with myopia in Europeans, in GOLGA8B, which belongs to a family of Golgi auto-antigens, and in RASGRFI, a transcription initiation site that is highly expressed in neurons and the retina. We also find novel genome-wide-significant associations ($P < 5E-08$) in 13 regions. Notable among the novel findings are variants in LAMA2 (rs12193446,) a gene coding for laminin, an extracellular protein that is a major component of the basement membrane and believed to be involved in the development and maintenance of different eye structures; in RDH5 (rs3138142), which encodes a retinol dehydrogenase that catalyzes the final step in the biosynthesis of 11-cis retinaldehyde; and in KCNQ5 (rs7744813), a member of the KCNQ potassium channel gene family that produces an M-type K(+) current channel and is expressed in monkey retinal pigmentation epithelial cells. This largest ever GWAS on myopia in Europeans—by an order of magnitude—identifies many new potential biological pathways involved in the development of myopia.

Background: Leptin is an adipocyte-derived hormone for which the circulating levels correlate closely with body fatness. Leptin acts as a chronic signal to inform the brain about the stored body fat and as such it is involved in the regulation of long-term energy homeostasis. Complete leptin deficiency due to mutations in the leptin (*LEP*) gene causes severe obesity. We aimed to identify genetic variants associated with leptin levels in the general population. **Methods:** We performed a meta-analysis of associations between ~2.5 million SNPs and circulating leptin levels in 32,061 individuals from 22 studies and followed up SNPs in the six most significant loci ($P<10^{-6}$) in 20,278 additional individuals from 12 studies. To account for the effect of body fatness in the results, we performed the meta-analyses with and without adjustment for BMI. **Results:** We identified five loci reaching genome-wide significance ($P<5x10^{-8}$) for their association with leptin in the combined discovery and follow-up analyses. Variants near the *LEP*, *CCNL1*, and *SCL32A1* genes and in the *GCKR* gene showed a similar association with leptin between the BMI-unadjusted ($P=3x10^{-6}$, $P=1x10^{-9}$, $P=1x10^{-6}$, and $P=7x10^{-11}$, respectively) and BMI-adjusted ($P=1x10^{-13}$, $P=6x10^{-8}$, $P=2x10^{-8}$, $P=1x10^{-10}$, respectively) models. In contrast, variants in the *FTO* gene showed association with leptin in the BMI-unadjusted analysis only ($P=2x10^{-9}$); no association was observed after adjusting for BMI ($P=0.63$). **Conclusions:** Variation near the *LEP*, *CCNL1*, and *SLC32A1* genes and in the *GCKR* gene is associated with circulating leptin levels irrespective of the overall body fatness, whereas the association of the *FTO* locus with leptin is attributed to BMI. Interestingly, the near-*CCNL1* and *GCKR* loci have previously been reported to robustly associate with other metabolic or anthropometric phenotypes (near-*CCNL1* with birth weight; *GCKR* with e.g. lipids, glucose- and insulin levels) in previous meta-analyses of genome-wide association studies, whereas the near-*LEP* and near-*SLC32A1*loci have not been reported for association with such phenotypes. Further follow-up of the confirmed loci is ongoing. The identification of loci regulating leptin levels may provide new insights into the genetic regulation of obesity and metabolism.

Pathway-based analysis of genome-wide association studies for the personality traits. *H. Kim[1], S. Roh[1], C. Hong[4], E. Lee[4], Y. Sung[2], H. Lee[2], H. Chung[3], J. Lee[4], H. Kim[1].* 1) Dept Biochem, Sch Med, Ewha Womans Univ, Seoul, South Korea; 2) Dept Internal Medicine, Sch Med, Ewha Womans Univ, Seoul, South Korea; 3) Dept Obstetrics and Gynecology, Sch Med, Ewha Womans Univ, Seoul, South Korea; 4) Center for Genome Science, Korea National Institute of Health, Korea Centers for Disease Control and Prevention, Cheongwon.

Genome-wide association studies (GWAS) are now used as a major tool to identify SNPs associated with complex traits. In the initial GWAS, only a few SNPs within or near the *PTPRD*showed significant association and other loci showed the moderate association with personality. Single-marker-based analysis will miss many SNPs with moderate genetic effects. We performed pathway-based analysis on GWAS data sets of the Five Factor Model (FFM) personality trait to overcome these limitations and to find missing heritability of personality. We found pathways and gene sets with statistical significance of FDR< 0.05. More than 10 pathways associated with behavior and neurotransmitter pathway showed highly significance for Neuroticism, Extraversion, Openness, and Agreeableness, respectively. They include the association of Neuroticism with axon guidance (FDR< 1×10^{-5}), Extraversion with toll like receptor signaling pathway, nicotinate and nicotinamide metabolism and exon guidance (FDRs< 1×10^{-5}), Openness with adrenergic and monoamine G protein-coupled receptors (FDRs< 1×10^{-5}), and Agreeableness with adrenergic and monoamine G protein-coupled receptors (FDRs< 1×10^{-5}). Conscientiousness wasn't shown significant association. Personality trait is polygenic and at least 10,000 genes expressed in brain, so it is necessary to consider how many genes might conceivably influence personality traits. Interestingly, we also found that some significant pathways were overlapped in four personality traits regardless factor. Therefore we suggest that there may be common pathways associated with general personality which is not limited factors of personality. This research was supported by NRF (2010-0026606) and KNIH (4845-301).

A genome-wide association study identifies a novel susceptible locus for refractive error at 19q13.12 in Korean. *W.R. Kim[1], T.Y. Chung[2], Y.M. Song[3], K. Lee[4], J. Sung[1].* 1) Department of Epidemiology, School of Public Health and Institute of Health and Environment, Seoul National University, Seoul, Korea; 2) Department of Ophthalmology, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea; 3) Department of Family Medicine, Samsung Medical Center and Center for Clinical Research, Samsung Biomedical Research Institute, Sungkyunkwan University School of Medicine, Seoul, Korea; 4) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Seoul, Korea.

Introduction: Refractive error is the most common ocular disorder worldwide and the prevalences of myopia in Asians are much higher than those in Caucasians. In Korea, the prevalence of myopia is 53.7±0.6%. Although environmental factors such as sustained near visual work, higher education level and lack of outdoor activities have been reported to increase the risk of myopia, myopia is a highly heritable trait (h2=0.60~0.90) but the mechanism of myopia is not fully understood. Previous genome-wide association studies in Asian countries have identified risk variants for refractive error; in a Japanese population, 11q24.1 were linked with high myopia, which was not replicated in Chinese; in a Chinese population, 13q12.12 and 4q25 were associated with high myopia; in a Singapore Chinese population, variants at 5p15 were suggested. In Europeans whose myopia prevalence is generally lower than that of Asians, 15q14 and 15q25 were identified to be responsible for refractive error. To add to and compare with the existing body of evidence, we performed a GWA study involving the general families in Korea.**Method**: Among 3461 adult individuals (1493 men) who have participated in the Healthy Twin study Korea, full eye examination was undertaken on 1960 individuals. Refractive error was measured by Auto-Refractor (Canon Full Auto Ref-keratometer RK-F1, Japan). The spherical equivalent was calculated from the standard formula: spherical equivalent = sphere + (cylinder/2). We investigated the spherical equivalent as a quantitative trait. Individuals with history of corneal surgery such as cataract, LASIK and LASEK were excluded. The Affymetrix GeneChip Array version 6 (1 million SNPs) platform was used for generating genetic marker information. A GWA study was conducted by combining p-values of within-family information and population mean effects of between-families. Complete data on refractive error were available on 1022 persons with 537158 SNPs. **Result**: We identified a significant association between refractive error and a variant at 19q13.12 (P=7.95E-8). On the 8q21.11, loci also showed a suggestive association (P=4.18E-6). In a European population, 15q14 was reported to be a susceptibility locus for refractive error measured as a quantitative trait. In our study, rs688220 on 15q14 was not significantly associated with refractive error. (Psmallest=0.20) **Conclusion**: Our data suggests that a susceptible locus at 19q13.12 would be associated with refractive error.

2119T

A Genome-Wide Association Study on Hallux Valgus Angle (HVA) identifies candidate loci: The Healthy Twin Study Korea. *SJ. Lee[1], D. Lee[1], JH. Hwang[2], YM. Song[3], K. Lee[4], J. Sung[1].* 1) Department of Epidemiology, Graduate School of Public Health and Institute of Environment and Health, Seoul National University, Seoul, South Korea; 2) Department of Physical & Rehabilitation Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, South Korea; 3) Department of Family Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, South Korea; 4) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Busan, Korea.

Introduction: Hallux valgus (HV) is one of the most common chronic structural foot deformities known to be associated with genetic predisposition, age, sex and constricting footwear. Genetic influences on foot structure, particularly HV, play an important role, with the heritability of 0.55. However, specific genetic variants underlying HV have not yet been identified. The objective of this study is to investigate common genetic variants that confer susceptibility to the degree of HVA a genome-wide association (GWA) study. **Methods**: Among the 3461 participants of The Healthy Twin Study Korea, 837 individuals (312 men, 525 women, aged 44.8 ± 13.7 years), who have taken the weight-bearing anteroposterior (AP) and lateral foot X-ray examinations with genetic information (Affymetrix GeneChip v6) were included. Hallux valgus angle (HVA) was measured from each foot X-ray film, and HVA exceeding 20 degree was defined as having HV. Information about narrow-toed high-heeled shoe use was collected through a self-reported questionnaire. A meta-analysis of GWA results was executed by combining the p-values of population mean effects using founders between families (PLINK) and those of generalized transmission disequilibrium test based on familial relations (FBAT). **Results**: We identified potential candidate loci at 5q34 (p=2.86 x 10-7), 7q11.21 (p=3.77 x 10-7), and 4p16.1 (p=2.53 x 10-6). These regions comprise a gene related to limb and bone formation in Drosophila, which may be a potential target not only for HV, but general foot development and disorders. **Conclusion**: Our study could successfully identified potential genetic loci influencing HV, of which functions are of potential interests in foot development. Our findings are waiting for further validation through replications studies, however, it is challenging because of the lack of compatible measurements in other studies.

2120F

Sciatica in young adult population: A genome-wide association study in the Young Finns. *S. Lemmelä[1], S. Solovieva[1], R. Shiri[1], T. Lehtimäki[2,3], I. Seppälä[2,3], M. Kähönen[2,3], M. Juonala[4,5], J. Viikari[4,5], O. Raitakari[4,5], E. Viikari-Juntura[1], K. Husgafvel-Pursiainen[1].* 1) Finnish Institute of Occupational Health, Helsinki, Finland; 2) Tampere University Hospital, Tampere, Finland; 3) University of Tampere, Tampere, Finland; 4) University of Turku, Turku, Finland; 5) Turku University Hospital, Turku, Finland.

Sciatic pain is one of the leading causes of disability in the working age population. Epidemiological data suggest a strong genetic component and complex genetic etiology. This study is part of the research consortium focused on musculoskeletal disorders (MSD) and risk factors MSDs may share with cardiovascular diseases. The current study is based on the follow-up of the Young Finns Study carried out in 2007 (subjects 30–45 years), where the question on sciatica diagnosed by physician was included. A Genome wide association study (GWAS) was conducted in 2442 Finnish individuals (46% men, 54% women) using custom-built Illumina 670K beadcip at Wellcome Trust Sanger Institute (UK). Study sample comprised 180 Finnish sciatica cases and 1840 unaffected controls. A total 546 674 SNP's passed quality control and were analysed for association using PLINK. Further imputation to ~23 million SNPs (1000 Genomes imputation reference) was performed using IMPUTE. After excluding SNPs with minor allele frequency <0.01 and/or with imputation quality <0.7, ~8 million SNPs were available for the analysis. The GWA analysis was performed using SNPTEST with additive genetic model and adjustment for age and parental socioeconomic status based on occupation. The locus 1q32.2 was the most significantly associated with sciatica ($p=8.7 \times 10^{-7}$) in the genotyped SNP set. After imputation, in total 21 additional SNPs in three loci (4q23, 6p25.1 and 21q22.3) were identified with p-values below genome wide significance level ($p<5 \times 10^{-8}$). The analysis further indicated that partially different SNPs were associated with sciatica in men and women. In women, 2q21.2 and 1q32.2 were the most significantly associated loci with the p-value level of 10^{-6}. After imputation, 29 additional SNPs on 4q28.3 and 6p25.1 showed associations with genome-wide significance ($p<5 \times 10^{-8}$). In men, locus 1q43 yielded significant p-values in genotyped SNP set; in total 21 additional SNPs in the same locus and 25 SNPs on the locus 16q23.2 showed association ($p<5 \times 10^{-8}$) after imputation. In summary, our preliminary GWAS results identified a number of novel candidate regions for sciatica that warrant further investigation. Replication of these new association signals in GWAS in another Finnish population is ongoing. The study received financial support from the Academy of Finland (project no 129364, MSDs@Lifecourse, SALVE).

GWAS of Blood Cell Traits Identifies Novel Associated Loci and Epistatic Interactions in Caucasian and African American Children. *J. Li[1], J.T. Glessner[1], H. Zhang[1], C. Hou[1], Z. Wei[2], J.P. Bradfield[1], F.D. Mentch[1], Y. Guo[1], C. Kim[1], Q. Xia[3], R.M. Chiavacci[1], K.A. Thomas[1], H. Qiu[1], S. Grant[3], S.L. Furth[4], H. Hakonarson[1,3,4], P.M.A. Sleiman[1,3,4].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ; 3) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA.

Hematological traits are important clinical indicators. Commonly measured hematological traits include white blood cell count (WBC), red blood cell count (RBC), hemoglobin concentration (Hgb), percentage of erythrocyte cells (Hct), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), mean corpuscular volume (MCV) and platelet count (PLT). More than 100 loci have been reported to be associated with hematological quantitative traits in populations of European ancestry and East Asian ancestry. However, the genetic determinants of hematological traits have not been fully investigated in African Americans. We carried out a GWA study of the eight common hematological traits in two pediatric cohorts which consist of 7943 African American and 6234 Caucasian children respectively, followed by meta-analysis of both cohorts. In African Americans, we replicated four previously reported loci at genome wide significance level. In addition, we identified five novel associations, including association of HBE1 variants with HCT and MCHC, the alpha globin gene cluster variants with RBC and MCHC, and an ARHGEF3 variant with PLT. In Caucasians, we report novel significant association between COPZ1 variants and PLT as well as replication of five previously reported loci at genome wide significance. In total, we replicated 95 out of 107 previously reported loci at nominal significance following meta-analysis of both cohorts. Finally, through detailed analysis of the association between MCH and variants at the alpha globin gene cluster in African Americans, we not only identified variants with independent effects on MCH at the locus but also show epistatic interaction between them. Individuals homozygous for the minor alleles of the SNPs that show epistasis had extremely low MCH values and were at significantly increased risk of iron deficiency anemia.

2122T

A genome-wide analysis of longitudinal forced expiratory volume in one second in the framingham heart study. *S.-Y. Liao, X. Lin, D. C. Christiani.* Harvard School of Public Health, Boston, MA.

Background: Chronic Obstructive Pulmonary Disease (COPD) has become a globally prevalent disease, with occurrence between 6% and 20% worldwide. The Forced Expiratory Volume in One Second (FEV1) is a stable measure of lung function and has been shown to predict clinical outcome, grade the severity, and follow up the natural history of disease. In addition to the well-known environmental risk factor, tobacco smoking, many studies have shown that genetic factors also play an important role in COPD. COPD is founded to aggregate in families, and the spirometric measurements of pulmonary function are also heritable. Previous studies always focused on cross-sectional FEV1, in the study, we explore the association between the quantitative trait (FEV1) and SNPs using a longitudinal genome-wide analysis. With longitudinal analysis, we are able to characterize aging and normal development, as well as growth or decline of the FEV1. In addition, we can observe individual patterns of change. Methods: The study population is the Offspring cohort from Framingham Heart Study. A total of 2,238 participants have both genotype and spirometry measurements with 9032 observations (around 4 measurements per person) and the mean follow-up year is 15.77 years. In the study, we used participants' 3, 5, 6, 7, 8 examination of FEV1 as the outcomes. Age, height (inches), pack-years, and smoking status at the point of the each examination were used as time-varying covariates. The longitudinal genome wide analysis used for individual SNPs was a linear mixed effect model for association between FEV1 and allele “dose” with adjustment for these covariates. We used family random intercept and individual random intercept/random age slope for the issue of both within and between subjects' correlation. Results: In our longitudinal genome wide analysis, we identified several genome-wide significant risk loci. The four top significant SNPs are located at chromosome 17q25 (rs3924256, P = 4.67 x 10-9), chromosome 14q32.11 (rs4904670, P=3.64 x 10-8), chromosome 6q25.1 (rs9397997, P=1.15 x 10-7), chromosome 9q34.3 (rs3125786, P=6.22 x 10-7) Conclusions: Longitudinal analysis is a more powerful way to identify disease risk SNPs. These SNPs are worthy of further investigation. We will attempt to replicate the analysis in other cohorts, though to date there are few longitudinal cohort studies with genetic data.

2123F

Hundreds of loci contribute to body fat distribution and central adiposity. *A.E. Locke[1], D. Shungin[2,3,4], T. Ferreira[5], T.W. Winkler[6], D.C. Croteau-Chonka[7], R. Magi[5,8], T. Bronfman Institute of Personalized Medicine, Child Health and Development Institute, Department of Preventive Medicine, Mount Sinai School of Medicine, New York, NY.

Central adiposity and body fat distribution are risk factors for type 2 diabetes and cardiovascular disease and can be measured using waist circumference (WC), hip circumference (HIP), and waist-to-hip ratio (WHR). Adjusting for body mass index (BMI) differentiates effects from those for overall obesity. We performed fixed effects inverse variance meta-analysis for these traits with 72,919 individuals from 30 studies in a prior genome-wide association study (GWAS) meta-analysis, 71,139 individuals from 24 additional GWAS, and 67,163 individuals from 28 studies genotyped on Metabochip by the GIANT consortium. We identified 48 independent genome-wide significant ($p<5x10^{-8}$) associations for WHR adjusted for BMI, including all 14 previously published signals. Twelve signals are located near genes for transcription factors, including developmental homeobox-containing proteins. Among them, two are in the *HOXC* gene cluster near *HOXC8* and *miR-196a2*. *HOXC8* is expressed in white adipose tissue and is a regulator of brown adipogenesis, while miR-196a inhibits *Hoxc8* expression. Signals are located near*PPARG*, encoding a transcription factor known to regulate adipocyte differentiation, and near *HMGA1* and *CEPBA*, encoding transcription factors that act downstream of insulin receptor and leptin signaling, respectively. Further novel signals are located near genes involved in angiogenesis (*PLXND1, VEGFB,* and *MEIS1*). Among the other five traits, we estimate that a significant proportion of the genetic effects for WC and HIP adjusted for BMI are correlated with height (0.59, $p<5x10^{-79}$ and 0.83, $p<2x10^{-40}$, respectively). Despite this strong correlation, an appreciable proportion of the genetic contributions to these traits will be independent of height. Association meta-analysis for the five additional traits identified an additional 148 independent signals ($p<5x10^{-8}$), 32 of which have not been reported previously for an anthropometric trait. These novel signals suggest regulation of adipose gene expression (*KLF14*) and transcriptional control of cell patterning and differentiation in early development (*HLX, SOX11, ZNF423,* and *HMGXB4*) affect fat distribution. Meta-analyses for WHR, WC, and HIP, with and without adjustment for BMI, identified a total of 196 independent loci, 66 novel, affecting fat deposition and body shape, and implicating genes involved in development, adipose gene expression and tissue differentiation, response to metabolic signaling, and angiogenesis.

Significant evidence for association in genome-wide analyses of lipid levels in Pima Indians. *A. Malhotra, S. Kobes, W.C. Knowler, L.J. Baier, R.L. Hanson.* Phoenix Epidemiology and Clinical Research Branch, NIDDK, NIH, Phoenix, AZ.

Genome-wide association studies (GWAS) for lipid levels have been performed in multiple ethnic groups including Caucasians, African Americans, and Asians. However, to date, no GWAS in American Indians has been published. We performed GWAS analyses for total cholesterol (TC; N= 1135), low-density lipoprotein cholesterol (LDL; N=965), high-density lipoprotein cholesterol (HDL; N=976), and triglycerides (TG; N=970) using longitudinal Pima Indian data. Using SAS (Statistical Analysis Software), a mixed model was used which incorporates multiple tests per individual (ranging from 1 to 19 exams). We performed association analyses for 454,194 SNPs with these lipid traits. One SNP (rs1532625) reached genome-wide significance (estimated at 4.94×10^{-7}) for HDL (p-value: 1.53×10^{-7}). The *cholesterylester transfer protein* gene is located close to this SNP; the protein facilitates lipid transport. Analysis of TC (three SNPs) and LDL (two SNPs) identified a region on chromosome 1 (109,619,829–109,623,689bp) with p-values ranging from 2.48×10^{-9} to 4.72×10^{-8}. This region has been identified in other ethnic groups. Furthermore, a cluster of candidate genes is present at this locus, of these most notably, the *sortilin-1* gene. A previously published study of *sortilin-1* showed an association between increased expression levels in the liver and decreased LDL levels. For TG, seventeen SNPs on chromosome 11 (116,024,099–116,585,850bp) showed significant evidence for association, with p-values ranging from 5.86×10^{-11} to 4.35×10^{-7}. The *apolipoprotein A-V* gene is located in this region, which has been identified in previous TG association studies. The current GWAS in Pima Indians provides significant evidence for association that replicates previously identified regions with strong candidate genes that might affect lipid levels. Replication and fine-mapping studies are required to confirm these associations and to identify potential functional variants.

2125T

Investigation of Lipid Pathway Genes in Late Onset Alzheimer's Disease. *L.L. McClain[1], X. Wang[1], M.M. Barmada[1], F.Y. Demirci[1], O.L. Lopez[2,3], M.I. Kamboh[1,2].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Alzheimer's Disease Research Center, University of Pittsburgh, Pittsburgh, PA; 3) Department of Neurology, University of Pittsburgh, Pittsburgh, PA.

Alzheimer's disease (AD) is the most common type of dementia and affects about 5.4 million Americans with symptoms of memory loss, depression, and profound neurological atrophy in the advanced stage. Recent genome-wide association studies have identified 10 loci for late-onset of AD, including *APOE, PICALM, CR1, BIN1, CLU, CD2AP, CD33, ABCA7, EPHA1, MS4A4*, and *MS4A6E*. Three of these genes are involved in cholesterol metabolism (*APOE*, *CLU*, and *ABCA7*), indicating that cholesterol-related genes may play an important role in the etiology of AD. In this study, we examined the association of 4,838 SNPs in 212 cholesterol-related genes in 1291 AD cases and 958 controls, adjusted for age, sex, and principal components. Analyses were carried out using PLINK software. In the single-locus analysis, 225 SNPs in 75 genes revealed significant associations (P<0.05) with *APOE* /rs429358 being the top hit (P=2.49E-53). The five other top hits were: *CETP*/ rs9930761 (P=5.57E-04), *PCTP*/ rs2912558 (P=6.02E-04), *PPP1R3B*/ rs6998837 (P=6.75E-04), *UBASH3B*/ rs1894084 (P=7.09E-04), and *ABCA7*/ rs4147920 (P=8.12E-04). Three of the 75 significant genes (*ABCA1, UBASH3B*, and *CUBN*) had 24% of the significant SNPs. In the haplotype analysis, our most significant result was in the *ABCA7* gene (P=1.16E-04). Our data reinforce the importance of the cholesterol-related genes in AD pathology and resequencing of these genes may identify rare and common functional SNPs.

2126F

Genome-wide association study identifies genetic loci associated with iron overload in HFE hemochromatosis. *J. Mosser[1], R. Bouvet[2], J. Morcet[3], M. Perrin[3], A.M. Jouanolle[4], M.P. Roth[5], E. Génin[6], Y. Deugnier[3], M. de Tayrac[1].* 1) CNRS, UMR 6290, Laboratoire de génomique Médicale, CHU Rennes, France; 2) Plateforme Génomique Santé Biogenouest Rennes Biogenouest, Rennes; 3) Centre d'investigation clinique (CIC INSERM 0203) Hôpital de Pontchaillou, Rennes; 4) Laboratoire de Génétique Médicale, Hôpital de Pontchaillou, Rennes; 5) Inserm U563, CHU Purpan, Toulouse, France; 6) INSERM U946, Fondation Jean Dausset - CEPH, Paris.

In Humans, hemochromatosis, the most common form of genetic iron loading disease, may result in severely damaging the liver, heart, endocrine organs, bones and articles. HFE hemochromatosis accounts for more than 95% of hemochromatotic phenotypes in populations of European descent and is chiefly related to the HFE C282Y/C282Y (p.Cys282Tyr/p.Cys282Tyr) genotype. C282Y homozygosity is highly frequent in Europe (up to 1‰ in Northern Europe). However, its expressivity is variable in terms of both iron burden and iron-related organ damage and, as a whole, its clinical penetrance is low, ranging from 1% in females to 25% in males. Previous studies suggest that, in addition to environmental factors, a genetic component could explain a substantial part of such a phenotypic variation. However, a few genetic factors have been identified so far. We thus search for such modifier genes studying associations between common variants and hemochromatosis penetrance defined using iron burden and/or iron-related organ damage indices. A cohort of 500 unrelated C282Y homozygotes were genotyped using a high-throughput process based upon tagSNP-CNV arrays (Human660W-Quad; Illumina). For these patients, four biological variables and two clinical variables were studied: amount of iron removed, serum ferritin, transferrin saturation, serum iron, disease staging and fibrosis. The GenABEL R package (http://www.r-project.org/) was used to perform genetic association analyses on common variants (MAF > 5%) considering additive models for both quantitative and qualitative traits. These models were adjusted for age, gender. Population stratification was also taken into account by adjusting models for the two principal components issued from the PCA of the whole genotype data. These analyses have identified a catalog of 30 SNPs. Among these markers, our results replicate the SNP rs3811647 within intron 11 of *TF* gene ($p=1.10^{-6}$) and identify new genes likely to modulate iron overload. Specifically, 3 loci (4p16.2, 10q26.12 et 16q21) have been identified associated with ferritin and amount of iron removed ($p<10^{-5}$). The replication phase is currently performed on an independent cohort of 700 patients and is will allow the selection of the polymorphisms most associated with hemochromatosis expressivity. These results may impact the development of new means for preventing, diagnosing and treating hemochromatosis and other iron-related disorders, notably iron deficiency.

2127W

Not a stretch: Variant near the dermal gene elastin is associated with stretch marks. *M.E. Mullins, N. Eriksson, A.K. Kiefer, J.Y. Tung.* 23andMe, Inc., Mountain View, CA.

Striae distensae, or stretch marks, are a common skin condition that appear as red or white lines on the skin. Though stretch marks are only harmful in extreme cases, even mild stretch marks can cause distress. The portions of cosmetic/pharmaceuticals and maternity-care industries that offer stretch mark prevention and treatment products are estimated to be worth $5–10 billion annually.

Despite the range of products claiming to prevent and treat stretch marks, the causes of stretch marks are not well understood. Skin distension, such as that which occurs during pregnancy or puberty; prolonged exposure to cortisols, such as in individuals with Cushing syndrome; and genetics have all been implicated. A small number of monogenic diseases, including Marfan syndrome and Ehlers-Danlos syndrome, count stretch marks amongst their characteristics. Both these syndromes are caused by mutations in genes that encode dermal proteins. To date, no genes are known to be associated with the stretch marks that afflict the general population.

We conducted a genome-wide association analysis of stretch marks using approximately 7 million SNPs imputed from about 1 million SNPs genotyped. Phenotypic data was self-reported by over 30,000 23andMe customers who responded to the following question on the 23andMe website: “Do you have stretch marks on your hips, thighs, or backs of your arms? Yes/No/I'm not sure”. We found a genome-wide significant association (p-value 1.28E-12) with rs6946106, which is upstream of elastin (ELN). Defects in ELN are known to affect the integrity of the skin and cause aortic defects.

We also detected a second association (p-value 3.86E-8) with rs35318931, a missense mutation in sushi-repeat containing protein, X-linked (SRPX). These results show a genetic component to stretch marks: defects in ELN may influence skin remodeling after stress. Many stretch mark sufferers spend hundreds of dollars on stretch mark treatments that offer minimal results. A better understanding of the etiology of stretch marks could help develop more targeted and effective treatment or prevention strategies.

2128T

Identification of three new genes associated to serum Butyrylcholinesterase activity by GWAS in two genetically distant isolated populations. *F. Murgia[1], L. Portas[1], S. Ulivi[3], N. Pirastu[2], S. Vaccargiu[1], D. Parracciani[4], P. Gasparini[2], M. Pirastu[1].* 1) Institute of Population Genetics, CNR, Sassari, Italy; 2) Institute for Maternal and Child Health - IRCCS "Burlo Garofolo" - Trieste, University of Trieste, Trieste, Italy, 34137; 3) Institute for Maternal and Child Health - IRCCS "Burlo Garofolo" - Trieste, Trieste, Italy, 34137; 4) Genetic Park of Ogliastra, Perdasdefogu, Italy.

Introduction: Great interest in the physiological role of BuChE has been given since it was demonstrated the correlation of its serum activity levels with Metabolic Syndrome (MS). Many variants in the BuChE locus have been described which influence the serum activity level and more recently other QTL were identified by GWAS in a large cohorts of outbreed populations. However it is not known the genetic link between this enzyme and the MS. **Objectives**: To investigate the phenotypic correlation between serum BuChE activity levels and MS endophenotypes and to identify genetic determinants of the trait in homogeneous populations. **Methods**: We analyzed 2,500 participants from two Italian isolated populations representing the Ogliastra (N=1272) and Friuli Venezia Giulia (N=1226) Genetic Parks. A comparison of continuous variables was performed by ANOVA. Factor Analyses to illustrate the relationship between BuChe activity and other variables was performed using Principal Components method. GWAS was carried out in each cohort with 2.5M genotyped or imputed SNPs using a mixed linear regression model taking into account sex, age, BMI and genomic kinship. In conditional analyses SNPs with the GWAS lowest P values were selected and included as covariates in the linear regression. Meta-analyses were conducted using the inverse variance weighted method. **Results**: A significant (P<0.05) phenotypic correlation was detected between BuChE levels and BMI, LDL and HDL cholesterol, fasting glucose, triglycerides, diastolic and systolic blood pressure, MS (ATPIII). Factor analysis confirmed these results. We identified five genome wide significant loci: two (rs1803274 BuChE K variant P=4.7e-68 on 3q26 and rs11686036 ABI2-RAPH1P=2.2e-9 on 2q33) described in recently GWAS and three (rs2911262 ANKRD11 P=6.1e-9 on 16q24, rs1244509 TAF3 P=3.4e-8 on 10p15 and rs4308478 SPOCK1 P=1.7e-8 on 5q31) novel. Some of the several suggestive loci reached a significant P value in meta-analysis with previously published GWAS data. We tested the effects of loci previously reported to affect MS components such as GALNT and LPIN (P<0.01 bonferroni corrected). **Conclusions**: We confirmed a strong correlation of BuChE activity with MS. We add new genetic data which may help to better understand the BuChE pathway complexity. Additional Next-gen sequencing and functional studies are required to elucidate the role of this increasingly interesting enzyme in physiology and disease.

2129F

Common genetic variants of primary open-angle glaucoma in Japanese population. *M. Nakano[1], Y. Ikeda[2], Y. Tokuda[1], M. Fuwa[1], R. Sato[1], N. Omi[1], H. Adachi[1], M. Ueno[2], K. Mori[2], S. Kinoshita[2], K. Tashiro[1].* 1) Dept Genomic Med Sci, Kyoto Prefectural Univ Med, Kyoto, Japan; 2) Dept Ophthalmol, Kyoto Prefectural Univ Med, Kyoto, Japan.

Purpose: Glaucoma is a neurodegenerative ocular disease and one of the leading causes of irreversible blindness worldwide. Although it has been suggested that genetic factors play an important role for the pathogenesis and it would be a great benefit if the risk of developing glaucoma could be predicted based on a simple blood test assessing the genetic markers, only a small portion of the genetic variation for glaucoma has been elucidated. Therefore, in order to identify authentic common variants for the major type of glaucoma, primary open-angle glaucoma (POAG), in Japanese, we performed two genome-wide association studies (GWAS), and additionally analyzed the variants of candidate genes, some of which were uncovered by the GWAS.

Methods: We performed a GWAS by analyzing 653,519 autosomal common variants in 833 POAG patients and 686 controls after the quality control. We also combined the data set with those from 411 POAG patients and 289 controls of our previous GWAS by Mantel-Haenszel test. We then constructed a custom DNA chip with the probes to detect 612 autosomal variants of 24 glaucoma related genes that have been reported previously, and genotyped the genomic DNA derived from 521 POAG patients and 519 controls for the association study.

Results: As for the GWAS, we identified 5 variants that passed the Bonferroni correction in *CDKN2B-AS1* on chromosome 9p21. All of the significant variants whose probes were designed in the microarrays of both GWAS showed stronger association with POAG after combining the two data sets. Moreover, some of the variants from candidate genes, including the four variants in *WDR36*, showed suggestive association (P<0.05) for POAG in our population.

Conclusions: In this study, we have successfully identified the reliable variants in 9p21 locus strongly associated with POAG by means of GWAS. Since glaucoma has been regarded as a typical multifactorial disease, it should be important to continue the comprehensive identification of genetic variants that could explain the disease etiology and apply them to the glaucoma diagnosis.

2130W

The associations of HLA-DP locus with chronic hepatitis B and viral clearance are widely replicated in East-Asian populations. *N. Nishida[1,2], Y. Tanaka[3], H. Sawai[2], Y. Mawatari[1,2], M. Yamaoka[2], A. Koike[4], K. Matsuura[3], M. Sugiyama[1], K. Murata[1], M. Korenaga[1], N. Masaki[1], K-H. Han[5], K. Tokunaga[2], M. Mizokami[1].* 1) Research Center for Hepatitis and Immunology, NCGM, Ichikawa, Chiba, Japan; 2) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Bunkyo-ku, Tokyo, Japan; 3) Department of Virology & Liver unit, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 4) Central Research Laboratory, Hitachi Ltd., Kokubunji, Japan; 5) Department of Internal Medicine, Yonsei University College of Medicine, Seoul, South Korea.

Overall, one-third of the world's population (2.2 billion) is infected with hepatitis B virus (HBV), and about 15% of these are chronic carriers. About 75% of the chronic carriers live in the east-south Asia and east pacific area, and there are 1.3–1.5 million chronic carriers living in Japan. Of chronic carriers, 10–15% develop liver cirrhosis (LC), liver failure and hepatocellular carcinoma (HCC), and the remaining individuals eventually achieve a state of nonreplicative infection, resulting in hepatitis B surface antigen (HBsAg) negative and hepatitis B core antibody (anti-HBc) positive, i.e. HBV-resolved individuals. We performed a GWAS using samples from Japanese HBV carriers, healthy controls and spontaneously HBV-resolved individuals in order to confirm or identify the host genetic factors related to CHB and viral clearance. In the subsequent replication analysis, we validated the associated SNPs in the GWAS using two independent sets of Japanese and Korean individuals. In our study, healthy controls were randomly selected with clinically no evidence of HBV exposure, therefore, HBV-resolved individuals were prepared to clearly identify the host genetic factors related with CHB or HBV clearance. Association analysis in the Japanese and Korean data identified the *HLA-DPA1* and *HLA-DPB1* genes with $Pmeta = 1.89 \times 10^{-12}$ for rs3077 and $Pmeta = 9.69 \times 10^{-10}$ for rs9277542. We also found that the *HLA-DPA1* and *HLA-DPB1* genes were significantly associated with protective effects against chronic hepatitis B (CHB) in Japanese, Korean and other Asian populations, including Chinese and Thai individuals ($Pmeta = 4.40 \times 10^{-19}$ for rs3077 and $Pmeta = 1.28 \times 10^{-15}$ for rs9277542). These results suggest that the associations between the HLA-DP locus and the protective effects against persistent HBV infection and with clearance of HBV were replicated widely in East Asian populations; however, there are no reports of GWAS in Caucasian or African populations. Based on the GWAS in this study, there were no significant SNPs associated with HCC development. To clarify the pathogenesis of CHB and the mechanisms of HBV clearance, further studies are necessary, including functional analyses of the HLA-DP molecule. URLs. The results of the present GWAS will be registered at a public database: https://gwas.lifesciencedb.jp/cgi-bin/gwasdb/gwas_top.cgi.

Obesity is a well-established risk factor for several chronic diseases and presents a substantial public health challenge. Thirty six loci influencing body mass index (BMI) have been discovered through genome-wide association studies (GWAS) in individuals of European and Asian descent. Far fewer GWAS have been conducted in individuals of other ancestries, and have so far not identified new BMI loci. Our study addresses two key issues: are loci identified in populations of European and Asian ancestry important in those of African ancestry, and can novel associations be detected by studying individuals of African ancestry? Our study included 39,144 African ancestry adults from 19 studies that each tested ~2.5 million SNPs for association with BMI; individual study results were meta-analyzed (Stage 1). All analyses were adjusted for global ancestry, and imputation was performed using a combination of the HapMap YRI and CEU panels. To further validate associations, we selected the 1,500 most significantly associated SNPs from Stage 1 and tested them in a second stage (Stage 2) of 7,954 men and women of African ancestry from eight additional studies and a third stage (Stage 3) in ~250,000 European descent individuals in the GIANT consortium. We identified seven loci associated with BMI at genome-wide significance ($p<5.0x10-8$); two novel loci at 5q33 (GALNT10, rs7708584, $p=3.2x10-11$) and 6q16 (KLHL32, rs974417, $p=2.0x10-8$) and five signals at previously established loci in or near BDNF, RP11/GNPDA2, FTO, MC4R, and PCSK1/CAST. In Stage 3, after meta-analysis with data from the GIANT consortium, a third locus at 7p15 (rs10261878, $p=4.5x10-8$) was identified. We also confirmed that 32 of 36 of loci previously associated with BMI in European and Asian descent populations showed directional consistency in our Stage 1 data (p-value for binomial test of direction=4.05x10-7), with similar effects on BMI. At eight loci (PTBP2, TMEM18, RBJ, FLJ35779, NUDT3, BDNF, FTO, MC4R) we identified SNPs that are more strongly associated than are the previously reported index SNPs (to at least one order of magnitude), which may eventually aid in fine mapping and identification of underlying functional variants. Taken together, we identified novel BMI-associated variants by studying individuals of African ancestry, demonstrating the utility of studying populations with distinct ancestries and environmental influences to better understand obesity risk factors.

2132F

Genetic Determinants of IL-1 Receptor Antagonist in the Circulation. *ML. Nuotio[1,2], K. Kristiansson[1], M. Perola[1,2,3], V. Salomaa[1].* 1) National Institute for Health and Welfare Helsinki, Finland; 2) Institute for Molecular Medicine Finland; 3) University of Tartu Estonia.

Interleukins play an essential role in human immunity system acting as important mediators of inflammation and tissue damage in various organs. The interleukin-1 superfamily consists of two agonists, IL-1alpha and IL-1beta, two receptors, IL-1RI and IL-1RII, and a specific receptor antagonist, IL-1Ra. IL-1Ra gene (IL1RN) maps into the chromosome 2 and has long been under a careful research, since the level of IL-1Ra concentration in circulation may have clinical significance and possibly associates for example with diabetes and cardiovascular diseases. Systemic administration of recombinant human IL-1Ra has been shown to enable a better control of type 2 diabetes mellitus. Furthermore, IL-1Ra concentrations predict the progression of metabolic syndrome to clinically incident diabetes. Recombinant form of IL-1-receptor antagonist (anakinra) is also a commonly used drug in the treatment of rheumatoid arthritis and gout. In this study we wanted to test genome-wide association with IL-1Ra concentrations in circulation measured in several independent Finnish population- and case-control-cohorts, and meta-analyze the results further in collaboration with European population cohorts. Currently we seek to replicate variants remaining genome-wide significant in various European population cohorts. We also wanted to test the association of top SNPs with leukocyte transcriptome data. We performed the primary GWAS in a Finnish sample consisting in total of 7200 adults. Independent association studies were combined using inverse-variance weighted meta-analysis. As a result of the discovery phase meta-analysis, the best 17 SNPs were associated with IL-1Ra at $p < 10E-12$, when adjusting for age, sex, BMI and waist/hip-ratio. Most of these variants were located in genes belonging to the interleukin cluster in chr 2. While testing the association of the Finnish top SNPs with leukocyte transcriptome data, one polymorphism in IL1F10 was shown to act as cis-eQTL to the gene PAX8 and trans-eQTL to ALDH2 in chromosome 12 and LILRB4 in chromosome 19. Interleukin-1-receptor antagonist has shown a clinical significance and an association with a number of medical conditions. Identifying genetic variants associated with IL-1-Ra level in circulation provides further information about related pathophysiological pathways and enables the evaluation of its potential effects on cardiovascular disease and diabetes.

Endometriosis (MIM131200) is a common gynecological disease associated with severe pelvic pain, affecting 6–10% of women in their reproductive years and 20–50% of women with infertility. Endometriosis risk is influenced by genetic factors and has an estimated heritability of around 51%. We conducted a multi-ethnic genome-wide association (GWA) meta-analysis of 4,604 endometriosis cases and 9,393 controls of European[1] and Japanese[2] ancestry. In addition to showing that rs12700667 on chromosome 7p15.2 previously found in Europeans replicates in Japanese ($P = 3.6 \times 10^{-3}$), we confirmed association of rs7521902 on 1p36.12 near *WNT4*, established association of a SNP on 2p25.1, and identified a novel locus on 12q22. Excluding endometriosis cases with minimal (rAFS stage I-II) or unknown severity, we identified additional novel loci on 2p14, 6p22.3 and 9p21.3. All seven SNP effects were replicated in an independent cohort and produced $P < 5 \times 10^{-8}$ in a combined analysis of 5,648 endometriosis cases and 13,410 controls. A gene-based GWA analysis using VEGAS[3] revealed two genome-wide significant genes and implicated other genes associated with endometriosis. Finally, we found a significant overlap in polygenic risk for endometriosis between the European and Japanese GWA cohorts ($P = 8.8 \times 10^{-11}$), indicating that many weakly associated SNPs represent true endometriosis risk loci. To our knowledge, this is the first report confirming a shared polygenic risk for a complex trait such as endometriosis across different ethnic populations, signifying risk prediction and future targeted disease therapy may be transferred across these populations.

Genome-wide association study reveals new candidate loci for hand osteoarthritis. *A. Näkki[1,2,3], J. Eriksson[4,5,6], E. Widen[1], A. Palotie[1,7], U.M. Kujala[8,9], J. Saarela[1].* 1) Institute for Molecular Medicine Finland FIMM, Helsinki, Finland; 2) Unit of Public Health Genomics, National Institute for Health and Welfare, Helsinki, Finland; 3) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 4) Department of General Practice and Primary Health Care, University of Helsinki, Helsinki, Finland; 5) Helsinki University Central Hospital, Unit of General Practice, Helsinki, Finland; 6) Folkhalsan Research Centre, Helsinki, Finland; 7) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 8) ORTON Orthopedic Hospital, Invalid Foundation, Helsinki, Finland; 9) Department of Health Sciences, University of Jyväskylä, Jyväskylä, Finland.

Objective. Osteoarthritis (OA) is a complex disease common in the elderly. Our aim was to study single nucleotide polymorphisms (SNPs) using a genome-wide association (GWA) data in a setting of hand OA cases versus healthy controls. Methods. The study subjects were over 56 years of age and were part of Finnish Helsinki Birth Cohort Study sample genotyped using Illumina HumanHap 610 GWA chip. Hand joints of the study subjects were visually evaluated and individuals with Heberden's nodes in at least one DIP joint were graded as affected (n=524). Individuals graded as healthy (n=970) had visually healthy symptomless finger joints. Association with individual SNPs was monitored using the Plink program. Age, sex and two principal components differed between the cases and controls and were used as covariates. Results. In our hand OA GWA analysis the most significant results were for SNP flanking the CD28 gene in 2q33 (p=4.37x10-6, OR=1.68, 95% CI 1.35-2.10); SNP in the SUCLG2 gene in 3p14 (p=6.15x10-6, OR=0.62, 95% CI 0.50–0.76) and SNP in the SLC22A3 gene flanking lipoprotein genes LPAL2 and LPA in 6q25 (p=1.61x10-5, OR=1.41, 95% CI 1.20–1.64). Conclusion. Variants in regions harbouring CD28, SUCLG2, SLC22A3, LPAL2 and LPA genes showed suggestive evidence for association with hand OA. CD28 has been shown to affect T-cell functions and IL2 production. CD28 and LPA genes have been shown to play role in rheumatoid arthritis. Results did not reach genome-wide significance in the initial screening phase.

Genome-wide Association Study and Meta-Analysis of Intraocular Pressure in Primary Open-Angle Glaucoma Cases and Controls in the NEIGHBOR, GLAUGEN and AMD-MMAP MI Consortia. *A.B. Ozel[1], S. Moroi[2], D. Reed[2], E. Trager[2], K. Scott[2], J. Gilbert[2], S. Garnai[2], S. Akbari[2], M. Nika[2], C. Schmidt[2], B. Yaspan[3], K. Branham[2], W. Chen[4], J. Heckenlively[2], A. Swaroop[5], G. Abecasis[6], A. Ashley-Koch[7], M. Ulmer[7], M. Hauser[7], J. Haines[3], L. Pasquale[8], J. Wiggs[8], J. Richards[2], J.Z. Li[1], NEIGHBOR Consortium.* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Ophthalmology and Visual Sciences, University of Michigan, Ann Arbor, MI; 3) Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN; 4) Children's Hospital of Pittsburgh, University of Pittsburgh Medical School, Pittsburgh, PA; 5) National Eye Institute, National Institutes of Health, Bethesda, MD; 6) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 7) Center for Human Genetics, Duke University School of Medicine, Durham, NC; 8) Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA.

Intraocular pressure(IOP) is determined by intraocular fluid production, fluid drainage and venous pressure of the eye. The IOP range of 10–20mmHg is regulated by physiological pathways and influenced by environmental factors that are not fully understood. In many forms of glaucoma, including the most common form, primary open angle glaucoma (POAG), there is relative obstruction to intraocular fluid drainage that causes elevated IOP. In susceptible individuals, this leads to glaucomatous nerve damage with vision loss and even blindness. We performed genome-wide association studies of IOP from healthy individuals (controls, n=3,386) and glaucoma patients (cases, n=805) of European ancestry from three studies: (1) NEIGHBOR, with 350 untreated cases and 2,189 controls genotyped on Illumina Human660W_Quad_v1 array (~510K SNPs); (2) GLAUGEN, with 325 untreated cases and 325 controls genotyped on Illumina Human660W_Quad_v1 array (~484K SNPs after QC); and (3) AMD-MMAP (the MI subset), with 130 untreated cases and 872 controls genotyped on Illumina HumanCNV370v1_C platform and ~2.5 million imputed SNPs based on the HapMap2 CEU data. IOP was defined as the maximum value from one of the two eyes. The effect of variables including age, gender, central cornea thickness (CCT), and vertical cup-to-disc ratio (vCDR), on IOP was assessed by linear regression. Significant variables were included as covariates in association tests. We performed meta-analyses using cases and controls or only controls from the three studies, and a two-study meta-analysis using only cases from NEIGHBOR and GLAUGEN. No signal of genome-wide significance (p<5E-8) was revealed. A candidate gene analysis (~100K SNPs) was undertaken to specifically investigate previously reported IOP or glaucoma genes or those expressed in ciliary body or trabecular meshwork. This analysis identified a SNP (rs10037649,p=5.6E-07) at 5q23.2, which is within GLC1M, a novel locus for autosomal dominant juvenile-onset open angle glaucoma (JOAG) previously identified from family-based linkage studies.

Haplotype Association Mapping In 33 Inbred Mouse Strains Identifies Genetic Regions Contributing To Chronic Hypoxia-Induced Pulmonary Hypertension. *M.W. Pauciulo[1], D. Koller[2], P. Hale[1], T.D. Le Cras[3,5], P. Pastura[3], B. Aronow[4,5], C. Tolentino[1,3], D. Li[2], T. Foroud[2], W.C. Nichols[1,5].* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Medical and Molecular Genetics, Indiana University Medical Center, Indianapolis, IN; 3) Division of Pulmonary Biology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 4) Division of Biomedical Informatics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 5) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH.

While mutations primarily in BMPR2 have been identified in patients with both heritable and idiopathic forms of pulmonary arterial hypertension (PAH), data suggest that additional genetic factors contribute to the disease. Short of the necessary large patient cohorts to power genomewide studies that could lead to the identification of additional genetic factors, researchers are left with little alternatives for genetic studies of PAH. To circumvent the paucity of PAH patient cohorts available, we are performing genomewide studies in readily available strains of inbred mice. Mice from 33 different strains were housed under hypoxic conditions (10% O_2) for four weeks with equivalent numbers of age and sex-matched mice maintained under normoxic conditions for all strains. After the hypoxic exposure, all mice underwent right heart catheterization to measure right ventricular systolic pressure (RVSP). Hearts were dissected at necropsy to assess the degree of right ventricular hypertrophy (RVH) as determined by the ratio of the weight of the right ventricle (RV) to the weight of the left ventricle and septum (LV+S). Hematocrit was measured via retro-orbital puncture. Due to the small size of some mice, RVSP was only determined for 31 strains. Haplotype association mapping (HAM) was performed using efficient mixed-model analysis (EMMA) and a set of 132,000 SNPs to identify regions in the genome associated with any of the quantitative traits measured. The HAM included separate analyses for hypoxic and normoxic mice as well as a "response to hypoxia" analysis taking into account the difference in RVSP (or RV/LV+S or hematocrit) after hypoxia as compared to normoxic controls. Associations reaching genomewide significance ($p=1x10^{-5}$) were identified for both RVSP and RV/LV+S. The most significant association for RVSP was identified on chromosome 8 ($p=2.34x10^{-11}$) while that for RV/LV+S was on chromosome 6 ($p=9.37x10^{-11}$). Additional significant associations were identified on other chromosomes. These data suggest that genetic factors contributing to RVH and increases in RVSP can be identified using genomewide methods in inbred mice. Efforts are underway to identify the specific loci involved with the goal of translating these findings to patients with PAH. Identification of additional genetic factors contributing to PAH can ideally reveal novel pathways involved in disease pathogenesis that will lead to the development of novel therapeutics for patient treatment.

To date ~50 loci have been described for fasting glycemic traits in non-diabetic individuals; however these explain only ~5% of phenotypic variance and are represented by common variants with minor allele frequency (MAF)>5%. We aimed to identify potential causal variants at known fasting glucose (FG) and fasting insulin (FI) loci, to uncover novel associated variants and to identify low allele frequency sites influencing glycemic trait variability. To that end, we performed imputation from the largest to date 1000 Genomes reference panel (2188 haplotypes, June 2011 release) within 10 European cohorts with genome-wide association (GWA) data from ENGAGE consortium. Following FG and FI association analysis, we performed a fixed-effects inverse variance meta-analysis for 38,326 and 16,831 individuals, respectively. 14.9M SNPs were present in at least 5 studies and passed quality control. We observed genome-wide significant (p-value$<5x10^{-8}$) associations at 8 known FG loci, but no such associations were seen for FI. Our strategy highlighted several novel characteristics in comparison to previous imputation efforts based on the HapMap2 reference panel: (a) we increased the number of SNPs tested by ~6 fold; (b) for FG we identified a novel signal at common variant within *RMST*gene (rs17331697, MAF=0.10, β=0.05 (se=0.01), $p=2.0x10^{-10}$); (c) a known common missense variant within *GCKR* (rs1260326 [P446L]) on imputation showed more significant association for both, FG and FI, (MAF=0.36, FG $p=7.6x10^{-10}$; FI $p=1.1x10^{-7}$) than its proxy variant previously described as a lead SNP for fasting glycemic traits (rs780094, MAF=0.35 FG $p=5.6x10^{-9}$; FI $p=1.2x10^{-6}$), which could be exampled as a positive control given the strong functional data pointing to P446L as causal variant; (d) in the vicinity of 5 known FG loci we identified novel associations at low MAF variants with larger effect sizes than previously described GWAs signals (e.g. within *G6PC2*, a missense variant rs138726309 [MAF=0.011, β=0.18(se=0.022), $p=9.4x10^{-17}$] 114bp from the known signal at rs560887 [MAF=0.31, $p=1.1x10^{-70}$]), for which conditional analyses will help to verify, whether low frequency variants represent independent associations. Imputation from successively larger and more complete reference panels generated by genome resequencing in existing GWAs underscores the prospective for identification of novel associated variants and for fine-mapping within already known loci.

BRC Allergene study: A TwinsUK GWAS of a metabolite associated with allergic response to nickel. *L. Quaye[1], L. Bevan[1], T. Tsakok[2], C. Menni[1], A. Moayyeri[1], I. Erte[1], T.D. Spector[1], C.J. Hammond[1], F.O. Nestle[2].* 1) Twin Research & Genetic Epidemiology, King's College London, London, United Kingdom; 2) St Johns Institute of Dermatology, King's College London, London, United Kingdom.

Allergic conditions affect 20–30% of the population and are responsible for considerable morbidity. However, little is known about the genetic aetiology of immediate and delayed type immunity underpinning allergic reactions. Allergic response to nickel is common, affecting approximately 15% of women. The identification of associated genes would result in greater understanding of disease mechanisms and potential therapeutic targets. The Biomedical Research Centre allergy project is the first twin study to investigate genetic determinants of type I and IV allergic responses. It encompasses a combination of genetic, expression, methylation and metabolomics data on up to 5,500 individuals from the TwinsUK registry and allergy data using questionnaires, skin and blood. 784 females, comprising 120 monozygotic (MZ) and 270 dizygotic (DZ) twin pairs were tested for 48 hour response to nickel patch testing. A positive reaction was observed in at least 1 individual of 34 MZ and 102 DZ twin pairs. The case-wise concordance was ~50% for MZs and 30% for DZs, which suggests an underlying genetic component to nickel allergy. Associations between nickel response and the abundance of 401 metabolites were evaluated in order to identify a potential biomarker of the allergic response. The strongest association was with isovalerate (P= 1.97E-03), a component of fatty acid metabolism. A genome-wide association study of the abundance of isovalerate was performed to ascertain correlations with common genetic variants. The strongest association was with a SNP of ANO6 (12q12), rs11183014 (P=1.8E-06). We also found suggestive associations with 4 additional SNPs from ANO6 and a variant of CAMK1D (P<9. 5E-06). ANO6 encodes a multi-pass transmembrane protein, which is important for calcium-dependent exposure of phospholipids on the cell surface. CAMK1D encodes a calcium/calmodulin-dependent protein kinase which been proposed to regulate granulocyte function through chemokine signal transduction. The roles of ANO6 and CAMK1D in delayed type hypersensitivity have not previously been described, however loci from ANO6 were identified in Ankylosing Spondylitis and variants of CAMK1D have been implicated in type II diabetes. The results from this study will be replicated with additional samples. To conclude, the combined use of metabolomic and genome-wide genotyping data offer great promise in the discovery of novel genetic variants for nickel allergy.

Experience with Illumina Infinium FFPE DNA Restoration Solution. *J. Romm, S. Pottinger, L. Aker, C. Hilton, C. Ongaco, K. Doheny.* CIDR, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-generation sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. Over the last year, CIDR has gained experience with the Illumina Infinium FFPE DNA Restoration Solution. This solution is intended for formalin-fixed, paraffin embedded (FFPE) samples; however, our current experiences with the kit have been to restore severely compromised, highly-degraded DNA samples. CIDR used the Restoration Solution for severely degraded genomic DNA samples (Project 1–493 samples) as well as for DNA extracted from serum (Project 2–4,126 samples). Without restoration, the predicted overall failure rate for samples and SNPs was 50% and 17% respectively for Project 1 based on the first 3 plates run in the lab and the predicted sample and SNP failure rate was 10% and 15% respectively for Project 2 based on pilot study projections. Project 1 was comprised of both restored and unrestored samples and run using the IlluminaHumanOmniExpress-FFPE BeadChip. Due to the CIDR workflow, all samples were restored in Project 2, including HapMap controls, and run on the Illumina HumanOmni1Quad BeadChip with a reagent substitute from Illumina. Samples for each project were reclustered using GenomeStudio 2011.1, Genotyping module 1.9.4 and Gentrain version 1. Overall quality statistics were very high for the restored samples. Project 1 has an overall missing rate of 1% for the restored samples and a duplicate sample reproducibility rate of 99.97% for the restored samples. Average call rate for the restored samples was 98.8%. Project 2 had an overall missing rate of 0.97%, compared with 0.23% for HapMap samples included with the project. The overall blind duplicate reproducibility rate was 99.91%. The mean call rate of the restored samples was 99.03%. One noticeable observation in the data was the elevated LogRRatio for the restored samples. Average LogRRatio for the restored samples was 0.36 for Project 1 and 0.26 for Project 2, compared with an average LogRRatio of 0.16 for projects with no restored samples.

2140T

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: A genome-wide association analysis of type 2 diabetes. *L.C. Sakoda[1], L. Shen[1], S. Sciortino[1], D.K. Ranatunga[1], R.W. Grant[1], T.J. Hoffmann[2], M.N. Kvale[2], S. Hesselson[2], Y. Banda[2], P. Kwok[2], N. Risch[1,2], C.A. Schaefer[1], A. Ferrara[1].* 1) Division of Research, Kaiser Permanente, Oakland, CA; 2) Institute for Human Genetics, UCSF, San Francisco, CA.

Linking clinical data from electronic medical records (EMRs) to comprehensive genetic data from biological samples offers a highly efficient approach for examining genetic associations with a number of disease-related phenotypes. Conducting such analyses using a large cohort of patients within an integrated health care system has transformative potential to advance clinical care. To assess the utility of this approach, we performed a genome-wide association (GWA) analysis of type 2 diabetes (T2D) in the Kaiser Permanente (KP)/UCSF Genetic Epidemiology Research Study on Adult Health and Aging cohort. Of the ~100,000 participants whose DNA has been genotyped with custom Affymetrix Axiom genome-wide arrays, those with and without diabetes were identified through linkage to the KP Diabetes Registry, which uses algorithms from multiple sources including diagnosis, prescription, and laboratory data. Persons with T2D were distinguished based on self-report, age at diagnosis of ≥30 years, or age at diagnosis of <30 years and no insulin prescriptions. Persons with other or undetermined diabetes type, based on medical diagnosis, prescription records, or self-reported history, were excluded. GWA analyses were limited to non-Hispanic whites: 7,068 with and 62,582 without T2D. Based on additive models adjusted for age (at DNA collection), sex, Ashkenazi/European ancestry, and body mass index (calculated from EMR data), we detected SNP associations in multiple, previously reported T2D susceptibility loci, including *TCF7L2* ($p = 1.4 \times 10^{-83}$), *PPARG* ($p = 1.3 \times 10^{-16}$), *IGF2BP2* ($p = 5.5 \times 10^{-14}$), an intergenic region at 9p21.3 near *CDKN2B-AS1* ($p = 1.3 \times 10^{-13}$), *SLC30A8* ($p = 7.0 \times 10^{-12}$), *JAZF1* ($p = 9.7 \times 10^{-11}$), *SYN2* ($p = 1.9 \times 10^{-8}$), an intergenic region at 10q23.33 near *HHEX* ($p = 2.5 \times 10^{-8}$), and an intergenic region at 2q36 near *IRS1* ($p = 3.6 \times 10^{-8}$). We also found suggestive evidence of novel associations in regions of chromosomes 1 and 5 ($p < 1 \times 10^{-7}$). GWA analyses of T2D in ethnic minorities are ongoing. Using T2D as an example, we demonstrate in this cohort that patient data routinely captured in EMRs are a valid and valuable resource for characterizing phenotypes to discover and replicate gene-disease associations.

2141F

A Genome-wide association study of *Helicobacter pylori* infection susceptibility. *C. Schurmann[1], J. Mayerle[2], L. Stolk[3,4], M.J. Peters[3,4], G. Homuth[1], A.G. Uitterlinden[3,4,5], M.M. Lerch[2], E. Kuipers[3,6].* 1) Department of Functional Genomics, Interfaculty Institute for Genetics and Functional Genomics, University of Greifswald, Greifswald, Germany; 2) Department of Medicine A, University Medicine Greifswald, Greifswald, Germany; 3) Department of Internal Medicine, Erasmus University Medical Center, Rotterdam, The Netherlands; 4) Netherlands Consortium for Healthy Aging, Rotterdam, Leiden, The Netherlands; 5) Department of Epidemiology Erasmus University Medical Center, Rotterdam, The Netherlands; 6) Department of Gastroenterology and Hepatology, Erasmus University Medical Center, Rotterdam, The Netherlands.

Helicobacter pylori (*H. pylori*) is a spiral-shaped, Gram-negative, microaerophilic bacterium that inhabits the stomach. It is the major cause of gastritis, gastroduodenal ulcer disease and the only bacterial pathogen that causes cancer. The infection prevalence rises up to 90% in some developing countries but 10% of subjects are never colonized with *H. pylori* regardless of exposure. Genetic factors are thought to confer *H. pylori* susceptibility. Therefore, the aim of our study was to identify genetic risk factors for *H. pylori* infection susceptibility.

We performed genome-wide association studies (GWAS) in Europeans from three population based cohorts (RS-I, RS-II and SHIP; N=10,485) to identify genetic variants associated with*H. pylori* colonization as defined by the anti-*H. pylori* immunglobulin G (IgG) titer. Furthermore, we analyzed *cis*-eQTL effects of the top GWAS SNPs based on whole-blood gene expression data of two population based cohorts (RS-III and SHIP-TREND; N= 1,753) and investigated the correlation of genome-wide mRNA expression profiles and *H. pylori* colonization (N=961).

Our GWAS meta-analysis identified two loci to be associated with the defined *H. pylori* infection susceptibility phenotype. At the first locus, we identified three genes coding for proteins involved in the innate immune system, of which only one was differentially expressed with respect to the GWAS top SNP genotype. Furthermore, its expression was upregulated in individuals with prominent *H. pylori* colonization measured in stool samples. The relative risk for *H. pylori* infection was reduced by 41% in homozygotes of the protective minor allele. The second locus also contains genes coding for proteins involved in the immune system. For both loci, we identified significant *cis*-eQTL effects.

In summary, we identified two loci to be associated with *H. pylori* susceptibility and propose that variation affecting the corresponding genes might explain why some individuals have a lower risk for *H. pylori* infection.

GWAS needs a good phenotype: clustering tooth surfaces into biologically-informative dental caries outcomes. *J.R. Shaffer[1], E. Feingold[1,2], X. Wang[3], M. Lee[3], K. T.Cuenco[3], D.E. Weeks[1,2], R.J. Weyant[4], R. Crout[5], D.W. McNiel[6], M.L. Marazita[1,3,7].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Center for Craniofacial & Dental Genetics, Department of Oral Biology, School of Dental Medicine, Pittsburgh, PA; 4) Department of Dental Public Health and Information Management, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 5) Department of Periodontics, School of Dentistry, West Virginia University, Morgantown, WV; 6) Dental Practice and Rural Health, West Virginia University, Morgantown, WV; 7) Clinical and Translational Science, School of Medicine, University of Pittsburgh, Pittsburgh, PA.

Dental caries (tooth decay) affects most adults worldwide, and the importance of susceptibility genes in risk of dental caries has been clearly established. While many candidate caries genes have been proposed to date, few of them have been rigorously validated through observational and experimental studies. Moreover, most genetic epidemiological studies have analyzed global caries phenotypes that ignore the possibility that genes may exert differential effects across tooth surfaces of the dentition. However, risk factors for dental caries do not necessarily exert their effects uniformly across all tooth surfaces. Instead, the actions of some risk factors, including genetic factors, may be limited to a subset of teeth/surfaces. Therefore, caries phenotypes that capture the patterns of tooth decay are needed. Toward this end, we used hierarchical clustering on tooth surface-level caries data for 920 Appalachian adults (ages 18–75) to group surfaces based on co-occurrence of caries. Cluster analysis yielded evidence of five distinct groups of tooth surfaces that differ with respect to caries: (1) pit and fissure molar surfaces, (2) mandibular anterior surfaces, (3) posterior non-pit and fissure surfaces, (4) maxillary anterior surfaces, and (5) mid-dentition surfaces. We created new caries outcomes defined as the number of carious tooth surfaces within each cluster. We showed that some cluster-based caries outcomes are heritable (i.e., under genetic regulation; p-value<0.05), and performed genome-wide association studies (GWAS) of each cluster-based phenotype in order to nominate new candidate caries genes. We identified a significant genetic association between dental caries of the anterior mandibular teeth and LYZL2 (p-value=9e-9), a bacteriolytic agent thought to be involved in host defense. We also identified a significant genetic association between caries of the mid-dentition tooth surfaces and AJAP1 (p-value=2e-8), a gene possibly involved in tooth development. Numerous suggestive genetic associations in plausible caries genes were also observed. These results suggest that the permanent dentition can be subdivided into groups of tooth surfaces that are useful for understanding the genetic factors influencing cariogenesis. Funding support was provided by NIH grants U01-DE018903, R01-DE014899, and R03-DE021425.

X Chromosome SNPs Not Strongly Associated with Juvenile Idiopathic Arthritis. *M. Sudman[1], M. Marion[2], T. Howard[2], J. Haas[3], S. Prahalad[4], J. Bohnsack[5], C. Wise[6], M. Punaro[7], C. Rose[8], M. Ryan[1], M. Wagner[9], C. Langefeld[2], D. Glass[1], S. Thompson[1].* 1) Division of Rheumatology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Biostatistical Sciences, Wake Forest University School of Medicine, Winston-Salem, NC; 3) German Centre for Rheumatology in Children and Young People, Garmisch-Partenkirchen, Germany; 4) Division of Rheumatology, Emory Children's Center, Atlanta, GA; 5) Department of Pediatrics, University of Utah Health Sciences Center, Salt Lake City, UT; 6) Sarah M. and Charles E. Seay Research Center, Texas Scottish Rite Hospital for Children, Dallas, TX; 7) Arthritis Clinic, Texas Scottish Rite Hospital for Children, Dallas, TX; 8) Division of Rheumatology, duPont Children's Hospital, Wilmington, DE; 9) Division of Biomedical Informatics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Juvenile Idiopathic Arthritis (JIA) is the most common chronic rheumatic disease in the western world. JIA is a complex genetic disease with an estimated sibling risk ratio of ~15, and is a clinically heterogeneous group of diseases that can be classified into seven subtypes according to the International League of Associations for Rheumatology (ILAR). The two most common subtypes of JIA, oligoarthritis (both persistent and extended) and rheumatoid factor (RF) negative polyarthritis, exhibit a strong female bias with a girl to boy ratio of ~4:1. This gender bias is also common to other rheumatic autoimmune diseases. Given this gender disparity, it is important to investigate whether the X chromosome might hold JIA-predisposing loci. We have completed a meta-analysis of three genome-wide association studies (GWAS) comprising 1902 JIA cases limited to oligoarthritis and RF negative polyarthritis subtypes (1464 female, 438 male) and 12,450 controls (6408 female, 6042 male), all of European descent and genotyped on the Affymetrix Genome-Wide Human SNP Array 6.0. GWAS-1 and GWAS-2 were USA-based cohorts (813 cases/3057 controls, 609 cases/7601 controls, respectively) whereas GWAS-3 was a German-based cohort (480 cases/1792 controls). A total of 21,342 SNPs on the X chromosome passed standard GWAS QC (including principal component analysis), suggesting a Bonferroni adjustment for statistical significance of 2.3x10-6. Analysis was stratified by gender and cohort, and a meta-analysis was computed (weighting by sample size). No SNPs approached chromosome-wide statistical significance. The strongest and most consistent association was on Xq28 for rs6627174 within PASD1 (P=0.00048), a gene whose protein is thought to function as a transcription factor, is expressed in a range of hematopoietic malignancies and stimulates autologous T-cell responses. Although rs6627174 is located within the systemic lupus erythematous (SLE) SLEB15 genetic locus (X:147,100,000–155,270,560), it remains over 2MB from the genes IRAK1 and MECP2, implicated in this region for SLE. A modest association was also observed on Xp21 for rs12008257 (P=0.00065) and rs2404506 (P=0.00097) within the gene DMD. In addition, no SNP had P<0.05 in all three cohorts. Thus, even in these large Affymetrix SNP 6.0 GWAS, we find little evidence that X chromosome SNP variants are associated with JIA, a female-biased disease.

In quest of ageing and longevity associated genetic markers. *R. Tamm[1, 2], M. Alver[2], K. Fischer[1], R. Magi[1], A. Metspalu[1, 2].* 1) Estonian Genome Center, Tartu, Estonia; 2) University of Tartu, Institute of Molecular and Cell Biology, Tartu, Estonia.

Backround Due to longer life expectancy and decline in fertility rates, the proportion of people over 65 years of age is growing faster than any other age group in developed countries. However, healthy life expectancy is not keeping the pace. Age associated chronic diseases account for an overwhelmingly large fraction of mortality and morbidity in the elderly. This has imposed a socio-economic burden on today's societal challenges. Regardless, there are individuals among the elderly endowed with a peculiar capacity to retain basic functions with age, while escaping major age-related diseases and disabilities. The large variation in healthy lifespan together with the importance in providing the well-being of the ageing population has prompted research in understanding the differences between healthy and diseased ageing mechanisms. As these complex phenotypes are influenced by a variety of genes and molecular pathways, environment and stochastic factors, a wider approach is needed to determine the underlying cause. Whole genome SNP analysis using Illumina arrays and a data-driven model in identifying genetic variants is more promising than scrutinizing candidate genes alone.

Methods The aim of the study was to examine allele frequency dependent discrepancies by conducting a genome-wide association study with with >8.9 million HumanOmniExpress genotyped and 1000 Genome Project Imputed and Quality Controlled SNP markers on 4919 Estonians from different age groups (18–39, 40–59, 60–79, 80+). The allele frequencies in all 4 age groups were compared using the Cochran-Armitage test for trend. Genome-wide significance was concluded for p-values less than 5×10^{-8}.

Results and conclusions Results suggest association between allele frequency differences in several loci, including 2p12, 3p24.1, 12q13.2, 14q32.12, of different age groups. These findings indicate the loci, which include the alleles that are increased and/or decreased in the oldest and could putatively represent new ageing related molecular markers. Our results together with other GWAS data would clarify the mechanisms that contribute to healthy and diseased ageing. New insights can provide new targets to prevent, diagnose and treat the disabilities and diseases that occur with increasing age.

2145W

Genome-Wide Association Scan of Osteoporotic Fracture: A Meta-Analysis of 10,012 African-American Women. *K.C. Taylor[1], D. Edwards[2], T. Edwards[2], D.S. Evans[3], G. Li[4], K.E. North[5], N. Franceschini[5], R. Jackson[6], M. Donneyong[1], A.Z. LaCroix[7], J.A. Robbins[8], B. Lewis[9], M.L. Stefanick[10], Y. Liu[11], M. Garcia[12], T.B. Harris[12], J.A. Cauley[13].* 1) Sch Public Health & Information Sci, Univ Louisville, Louisville, KY; 2) Vanderbilt University, Nashville, TN; 3) California Pacific Medical Center Research Institute, San Francisco, CA; 4) University of Washington, Seattle, WA; 5) University of North Carolina at Chapel Hill, Chapel Hill, NC; 6) The Ohio State University, Columbus, OH; 7) Fred Hutchinson Cancer Research Center, Seattle, WA; 8) University of California at Davis Medical Center, Sacramento, CA; 9) University of Alabama, Tuscaloosa, AL; 10) Stanford Prevention Research Center, Stanford University, Stanford, CA; 11) Wake Forest University, Winston-Salem, NC; 12) National Institute on Aging, Bethesda, MD; 13) University of Pittsburgh, Pittsburgh, PA.

Osteoporosis is a major public health problem associated with excess disability and mortality. For postmenopausal women, the lifetime risk of fracture exceeds 40% and it has been estimated that by 2025, 21% of all fractures will occur in non-white women. Osteoporosis and risk for fracture have been shown to be heritable, with 25–85% of the variation in osteoporosis-related traits being attributable to genetic factors. Recently, nine loci have been associated with fracture-related phenotypes in Caucasian populations. The purpose of this study is to leverage GWAS data from several cohorts to identify genetic determinants of fracture among African American (AA) women. Methods: Data on incident fractures, except fingers, toes, face, skull or sternum, were analyzed for unrelated AA female participants in the Women's Health Initiative (N=8155; 313 cases), Cardiovascular Health Study (N= 504; 50 cases), BioVU (N=704; 43 cases), and Health ABC (N= 651; 88 cases). The Affymetrix 6.0 (WHI, CHS, and BioVU) and Illumina 1M (Health ABC) GWAS panels were used for genotyping, and a 1:1 ratio of YRI:CEU HapMap haplotypes was used as an imputation reference panel. We used Cox proportional hazard models to evaluate the effect of ~2.5 million SNPs on incident fracture rate, adjusting for ancestry, age, and region where applicable. Fractures were all adjudicated except in CHS, which used self-reported fractures. SNPs were filtered on minor allele count (N>10) for all studies except BioVU, which filtered data based on minor allele frequency (>15%). We conducted a fixed-effects, inverse variance-weighted meta-analysis. Genome-wide significance was set at P<5x10-8. Results: One SNP, rs12775980 in SVIL on chromosome 10p11.2, reached genome-wide significance (P=3.5x10-8). Although the minor allele frequency is small (0.03), the direction of effect and effect size were consistent across all studies and this SNP had a P-value of 1.2x10-5 in the largest study, WHI. This locus was not reported in any previous osteoporosis-related GWA studies. Conclusions: This large fracture GWAS meta-analysis has identified a novel locus involving supervillin, a platelet-associated factor that has been previously reported to play a role in thrombus formation. As injection of platelets at a fracture site has been reported to aid in fracture healing, this SNP might predict a new pathway involved in fracture. Replication is needed to determine whether the novel finding is robust.

2146T

Genome-wide association analysis of percent body fat in adults from the Fels Longitudinal Study. *B. Towne[1], J. Blangero[2], A.C. Choh[1], J.E. Curran[2], C. Bellis[2], T.D. Dyer[2], E.W. Demerath[3], M. Lee[1], R.M. Siervogel[1], S.A. Czerwinski[1].* 1) Wright State University School of Medicine, Dayton, OH; 2) Texas Biomedical Research Institute, San Antonio, TX; 3) University of Minnesota, Minneapolis, MN.

Elucidating the genetic underpinnings of overweight and obesity continues to be a challenge. Part of the problem has been an over-reliance on crude measures such as weight or BMI. Using more direct and delineated phenotypic measures, however, has provided new insights into the genetics of body composition. We present here results from genome-wide association analysis of percent body fat (PBF) in 916 healthy adults (430 males; 486 females) aged 18 to 96 years (mean 48.9 years) in the Fels Longitudinal Study. PBF data were obtained from total body dual energy x-ray absorptiometry (DXA) scans taken using a Hologic instrument. Mean PBF was 23.1% in males and 34.9% in females. Subjects were all SNP genotyped using the Illumina Human 610-Quad BeadChip. To facilitate comparison of findings with those from other studies, we used these SNP data to impute HapMap2 data set genotypes. Association analyses were conducted on the imputed HapMap2 SNP data using measured genotype analysis implemented in SOLAR (Almasy and Blangero, 1998) accounting for residual non-independence among relatives. SNP rs7170121, on 15q25.3 at 86,794,649bp in the ATP/GTP binding protein-like 1 gene (AGBL1) is significantly associated with PBF (χ^2 = 29.21; p = $6.5x10^{-8}$). The minor (effect) allele (A) has a frequency of 0.0482, is associated with a 0.651 SDU decrease in PBF, and accounts for 3.6% of the phenotypic variation in PBF. Two other SNPs in the same region of AGBL1, rs17595649 and rs8033536, provide corroborative suggestive association with PBF, with similar effect sizes and proportion of phenotypic variance explained. The physiologic functions of AGBL1 are little known, and there have been few linkage or association studies implicating AGBL1. Of particular interest, however, is that Lewis et al. (2005) reported linkage of PBF to 15q25.3 (nearest marker D15S655), ~300kb from the region of our association signals for PBF. Results of that study, and the results presented here, suggest that AGBL1, or an as yet unknown nearby gene, may contribute to variation observed in percent body fat in healthy adults. Thus, further typing of markers in this region and testing their association with percent body fat appear warranted. Supported by NIH grants R01HD012252, R01DK064391, R01DK064870, R01AR052147, and R37MH59490.

It is well-known that body fat distribution differs between men and women, a circumstance that may be due to innate, genetic differences between sexes. Previously, we performed a large-scale meta-analysis of GWAS of waist-to-hip ratio adjusted for BMI (WHR), a measure of body fat distribution independent of overall adiposity and found that of the 14 loci established in men and women combined, seven showed a significant sex-difference. In a subsequent genome-wide analysis that was specifically tailored to detect sex-differential genetic effects for WHR, we identified two additional loci with significant sex-difference. Despite these findings, the genetic basis affecting the sexual dimorphism of WHR as well as the genetic architecture of WHR in general are still poorly understood. We therefore conducted sex-combined and sex-stratified meta-analyses comprising >210,000 individuals (>116,000 women; >94,000 men) of European ancestry from 57 GWAS studies and 28 studies genotyped on the MetaboChip within the GIANT consortium. The sex-combined analysis yielded 39 loci with genome-wide significant association (P<5x10-8), of which 11 loci showed significant sex-difference (Bonferroni-corrected P<0.05/39). Six of these loci influence WHR in women only without any effect in men (near*COBLL1, LYPLAL1, PPARG, PLXND1, MACROD1, FAM13A*); four loci have an effect in women and a less pronounced effect in men (near *VEGFA, ADAMTS9, HOXC13, RSPO3*); and one locus has only an effect in men (near *GDF5*). The sex-stratified analyses identified nine additional female-specific loci that had been missed in the sex-combined analysis due to the lack of effect in men (near *MAP3K1, BCL2, TNFAIP8, CMIP, NKX3-1, NMU, SFXN2, HMGA1, KCNJ2*). No additional loci were identified in the male-specific analysis. We confirmed all previously established sexually dimorphic variants for WHR. Of particular interest is the *PPARG* region that is a well-known target in type 2 diabetes treatments and shows a female-specific association with WHR. The enrichment of female-specific associations, i.e. 19 of the 20 sexually dimorphic loci, is consistent with the heritability of WHR as estimated in the Framingham Heart study; we found that WHR is more heritable in women (h2~46%) compared to men (h2~19%). Our results highlight the importance of sex-stratified analyses and can help to better understand the genetics underpinning the sex-differences of body fat distribution.

1000 Genomes imputation identifies low frequency-large effect circulating biomarker associations undetected by HapMap based imputation. *A.R. Wood[1], J. Tyrrell[1,2], D.G. Hernandez[3,4], M.A. Nalls[3], H. Yaghootkar[1], J.R. Gibbs[3,4], L.W. Harries[5], S. Chong[3], M. Moore[3], J.M. Guralnik[6], S. Bandinelli[7], A. Murray[1], L. Ferrucci[8], A.B. Singleton[3], D. Melzer[5], M.N. Weedon[1], T.M. Frayling[1].* 1) Genetics of Complex Traits, Peninsula College of Medicine and Dentistry, Exeter, United Kingdom; 2) European Centre for Environment and Human Health (ECEHH), Peninsula College of Medicine and Dentistry, Truro, United Kingdom; 3) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD, USA; 4) Department of Molecular Neuroscience and Reta Lila Laboratories, Institute of Neurology, UCL, London, United Kingdom; 5) Institute of Biomedical and Clinical Sciences, Peninsula College of Medicine and Dentistry, Exeter, United Kingdom; 6) Department of Epidemiology and Public Health, University of Maryland School of Medicine, Baltimore, MD, USA; 7) Geriatric Unit, Azienda Sanitaria di Firenze, Florence, Italy; 8) Clinical Research Branch, National Institute on Aging NIA-ASTRA Unit, Harbor Hospital, MD, USA.

Imputation from the sequence-based 1000 Genomes reference panel can potentially identify signals of association not detected by imputation from the genotype-based HapMap reference panel. We tested the hypothesis that imputation of variants identified by the 1000 Genomes Project (including low frequency and rare variants) can enhance previously identified associations and identify novel loci.

We selected 93 traits measured in ~1200 individuals from the InCHIANTI population study, a longitudinal study of aging men and women from Tuscany, Italy. All traits were continuous measures of circulating factors. These phenotypes included circulating lipids, proteins, ions and vitamins and were selected for two reasons. First, strong genetic associations have previously been observed in relatively small sample sizes, and so we potentially had good power to detect novel effects. Second, identifying genetic associations with circulating factors is potentially important to help understand their associations with disease.

We observed 21 signals (3 novel) and 33 signals (8 novel) at $P<5x10^{-8}$ based on HapMap and 1000 Genomes imputation respectively. Of the 13 signals specific to 1000 Genomes imputation, 6 had a HapMap SNP in modest linkage disequilibrium ($r^2 \geq 0.26$) close to GWAS significance ($P<5x10^{-5}$) Of the remaining 7 signals, 6 represented low-frequency (MAF < 2%) large-effect variants with corresponding effect sizes (0.51–2.1 SDs) and were poorly captured by the leading HapMap-imputed SNPs at the loci ($r^2 < 0.034$). One of these associations was between rs28929474 in the *SERPINA1* gene and Alpha-1-antitrypsin deficiency (MAF 0.007) and was previously detected in a candidate gene study, providing validation of our result. Of the 14 signals detected in both HapMap and 1000 Genomes imputation, 10 were marginally stronger in the 1000 Genomes analysis.

We show that 1000 Genomes based imputation can find more putative loci with variants of lower frequency and larger effects compared to HapMap based imputation.

2149T

So fresh or so clean? A genetic variant near olfactory receptor genes associates with cilantro taste preference. *S. Wu, J.Y. Tung, A.B. Chowdry, A.K. Kiefer, J.L. Mountain, N. Eriksson.* 23andMe, Inc., Mountain View, CA.

The leaves of the *Coriandrum sativum* plant, known as cilantro or coriander, are widely used in many cuisines around the world. However, far from being a benign culinary herb, cilantro can be highly polarizing — many people love the taste while others claim that it tastes foul, like soap or dirt. Cilantro aroma is due largely to the presence of several aldehydes; similar aldehydes are found in soaps, lotions, and certain insects. Cilantro taste preference is suspected to have a genetic component, yet to date very little has been discovered about specific mechanisms.

Here we present the results of a genome-wide association study of cilantro preference using genotype and survey response data from customers of 23andMe, Inc., a personal genomics and genetic research company. Across this cohort, we find ethnic differences in cilantro taste preference. South Asians and Latinos were both significantly ($p < 1x10^{-8}$) more likely to enjoy the taste of cilantro (OR=2.32 and 1.75 respectively, controlled for age and sex). Women are less likely to enjoy cilantro (OR=0.84, $p=4x10^{-9}$). In addition, within a European subset, we find that the SNP rs4036310 is significantly associated with both disliking cilantro and detecting a soapy taste ($p<5x10^{-8}$ for each, OR=1.14 and 1.25 respectively). This SNP lies within a cluster of olfactory receptor genes on chromosome 11, notably OR6A2 (also known as OR-I7), which has a high binding specificity for a number of aldehydes that provide the characteristic odor in cilantro, including E-2-dodecenal, E-2-Decenal, decanal, and dodecanal. We propose that OR6A2/OR-I7 contributes to the detection of a soapy taste from cilantro in a subset of people.

2150F

Genome-wide association study for Behçet's disease in an Iranian dataset using a DNA pooling approach. *J. Xavier[1,2], M. Martins[1,2], J. Sobral[1,2], F. Shahram[3], F. Davatchi[3], B.S. Abdollahi[3], A. Nadji[3], N.M. Shafiee[3], F. Ghaderibarim[3], S.A. Oliveira[1,2].* 1) Instituto de Medicina Molecular, Lisbon, Portugal, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Rheumatology Research Center, Tehran University of Medical Sciences, Tehran, Iran.

Behçet's disease (BD) is a complex multifactorial disorder with genetic and environmental risk factors implicated in its etiology, however BD pathology is poorly understood. Genome-wide association studies (GWAS) represent the gold-standard approach to study the genetic basis of complex diseases. Since genotyping individually thousands of polymorphisms in the large datasets required for the study of complex traits is time-consuming, labor-intensive, and cost-prohibitive, we used a recently developed and validated strategy that combines DNA pooling and microarray genotyping.

300 Iranian cases and 300 Iranian controls age and gender-matched were used in the first phase of the GWAS. Two pools of cases and two pools of controls were genotyped in quadruplicate using the Affymetrix Human SNP Array 6.0. Two different statistical approaches were applied to select the SNPs for technical validation: a) the RAS (relative allele score) difference between the average of cases and controls and b) a two sample, equal variance Student's t-test between the 8 arrays of cases and controls. Our results were compared to the results obtained from two previously published GWAS.

We identified 28 autosomal SNPs with RAS difference ≥ 10% and 45 SNPs with a *P*-value ≤5.0E-8. For both strategies, the top SNPs are located in the 6p21.33 locus, confirming the known HLA-B51 association with BD and supporting both strategies. For the RAS difference and t-test approaches there were, respectively, 7 and 5 out of 50 SNPs, previously found associated in the published GWASs. Additionally, we identified significant independent evidence of association with BD at loci 19q13.42 and 1q23.2 using both strategies. These SNPs are currently being individually genotyped in the 600 samples for technical validation. The validated SNPs will be further genotyped in a second independent Iranian sample consisting of 676 BD cases and 539 controls and in a Portuguese replication dataset with 75 cases and 120 controls. We have therefore confirmed well established associations with BD and possibly identified new susceptibility genes.

Sagittal craniosynostosis is a common congenital malformation, affecting approximately one out of 5,000 newborns. We conducted the first genome-wide association study (GWAS) for non-syndromic sagittal craniosynostosis (sNSC) using 130 non-Hispanic white (NHW) case-parent trios. Robust associations were observed in a 120 kb region downstream of *BMP2* on chromosome 20p.12.3, flanked by rs1884302 ($P \leq 1.13 \times 10^{-14}$; odds ratio [OR] = 4.58) and rs6140226 ($P \leq 3.4 \times 10^{-11}$; OR = 0.24) and within a 167 kb region of *BBS9* on chromosome 7p14.3 between rs10262453 ($P \leq 1.61 \times 10^{-10}$; OR=0.19) and rs17724206 ($P \leq 1.50 \times 10^{-8}$; OR = 0.22). We replicated these associations for rs1884302 ($P \leq 4.39 \times 10^{-31}$) and rs10262453 ($P \leq 3.50 \times 10^{-14}$) in an independent NHW population of 172 unrelated sNSC probands and 548 unaffected controls. Both *BMP2* and *BBS9* implicated by these associations are biologically plausible genes with a role in skeletal development warranting functional studies to further understand the etiology of sNSC.

2152T

Finding genome-transcriptome-phenome association with structured association mapping and visualization in GenAMap. *J. Yin[1], R.E. Curtis[2], E.P. Xing[1,3].* 1) Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 2) Joint Carnegie Mellon-University of Pittsburgh PhD Program in Computational Biology, Pittsburgh, PA; 3) Machine Learning Department, Carnegie Mellon University, Pittsburgh, PA.

Despite the success of genome-wide association studies in detecting novel disease variants, we are still far from a complete understanding of the mechanisms through which variants cause disease. Most of previous studies have considered only genome-phenome associations. However, the integration of transcriptome data may help further elucidate the mechanisms through which genetic mutations lead to disease and uncover potential pathways to target for treatment. We present a novel structured association mapping strategy for finding genome-transcriptome-phenome associations when SNP, gene-expression, and phenotype data are available for the same cohort. We do so via a two-step procedure where genome-transcriptome associations are identified by GFlasso, a sparse regression technique presented previously. Transcriptome-phenome associations are then found by a novel proposed method called gGFlasso, which leverages structure inherent in the genes and phenotypic traits. Due to the complex nature of three-way association results, visualization tools can aid in the discovery of causal SNPs and regulatory mechanisms affecting diseases. Using well- grounded visualization techniques, we have designed new visualizations that filter through large three-way association results to detect interesting SNPs and associated genes and traits. The two-step GFlasso-gGFlasso algorithmic approach and new visualizations are integrated into GenAMap, a visual analytics system for structured association mapping. Results on simulated datasets show that our approach has the potential to increase the sensitivity and specificity of association studies, compared to existing procedures that do not exploit the full structural information of the data. We report results from an analysis on a publically available mouse dataset, showing that identified SNP-gene-trait associations are compatible with known biology.

2153F

A genome-wide association study of central corneal thickness in Latinos. *X. Gao[1,2], W.J. Gauderman[2], P. Marjoram[2], M. Torres[1,2], T. Haritunians[3], J.Z. Kuo[3], Y.I. Chen[3], K.D. Taylor[3], J.I. Rotter[3], R. Varma[1,2].* 1) Department of Ophthalmology, Keck School of Medicine, University of Southern California, Los Angeles, CA; 2) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 3) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA.

Central corneal thickness (CCT) is a risk factor for primary open angle glaucoma and keratoconus. Genetic factors controlling CCT in Latinos, the most populous minority population in the US, are unclear. Here we describe the first genome-wide association study (GWAS) report of CCT in Latinos. We performed a population-based GWAS for CCT on 1,779 Latinos recruited in the Los Angeles Latino Eye Study (LALES) using the Illumina HumanOmniExpress Beadchip (~730K markers). To further discover additional associated single nucleotide polymorphisms (SNPs), we imputed SNPs based on the 1,000 Genomes Project reference panels. All subjects were age 40 years and older. We used linear regression with adjustment for age, sex and principal components of genetic ancestry. Statistical analyses were performed using PLINK, R and SAS. We replicated the involvement of several previously reported genes, e.g. COL5A1, FOXO1 and ZNF469, for CCT in Latinos ($P < 0.005$). Moreover, we discovered the involvement of novel SNPs that reached GWAS significance in the uncharacterized LOC100506532 (gene type: miscRNA) for CCT in Latinos ($P = 2.49 \times 10^{-9}$). Genetic analysis in Latinos may lead to the discovery of population-specific loci that regulate CCT, offering insights in the molecular regulatory mechanism of CCT. These results help to further describe the genetic architecture of CCT, demonstrating the utility of using Latinos for GWAS analyses.

PURPOSE: Loci at *CDKN2BAS* modify the risk of primary open-angle glaucoma (POAG). We assessed the association between *CDKN2BAS* single nucleotide polymorphisms (SNPs) and glaucoma features like cup-disc ratio (CDR). **DESIGN**: Observational case series. **METHODS**: We studied associations between ten *CDKN2BAS* SNPs and various glaucoma features among 976 POAG cases from the Glaucoma Genes and Environment (**GLAUGEN**) study and 1971 cases from the NEI Glaucoma Human Genetics Collaboration (**NEIGHBOR**) consortium. For each patient, we chose the feature from the eye with the higher value. We created multivariable models for glaucoma features adjusting for appropriate covariates in each study separately, and then pooled results with meta-analytical techniques. **RESULTS:** Cases with GA or GG genotypes at rs2157719 (associated with reduced POAG risk) had smaller CDR at diagnosis (0.05 units smaller per G allele; 95% CI: -0.08, -0.03; p=6.23E-05) and higher intraocular pressure (IOP) at the time of DNA collection (+0.70 mm Hg per G allele; 95% CI: 0.40, 1.00; p=5.45E-06). The other protective *CDKN2BAS* SNPs showed similar trends with CDR and IOP. Cases with AG or AA genotypes at rs3217992 (associated with increased POAG risk) had larger CDR at diagnosis (0.05 units larger per A allele; 95% CI: 0.02, 0.07; p=4.74E-04) and lower IOP at DNA collection (-0.57 mm Hg per A allele; 95% CI: -0.84, -0.29; p=6.55E-05). There were also other significant relations between *CDKN2BAS* SNPs and some visual field features. **CONCLUSION:** Among POAG subjects, *CDKN2BAS* alleles are associated with CDR and IOP but not with most other glaucoma features.

2155T

Ethnicity and ancestry information from genome-wide association studies: The NHGRI GWAS Catalog. *H.A. Junkins[1], J.A.L. MacArthur[2], P. Hall[1], K.A. Harvey[3], T.A. Manolio[1], L.A. Hindorff[1].* 1) Office of Population Genomics, NHGRI, National Institutes of Health, Bethesda, MD; 2) EMBL-EBI, Wellcome Trust Genome Campus, Hinxton, UK; 3) Centers for Disease Control and Prevention, Atlanta, GA.

The impact of genome-wide association studies (GWAS) on the knowledge base of disease-associated variants has been vast, with over 1,300 publications and 6,400 disease- or trait-associated genetic variants identified to date (http://www.genome.gov/gwastudies). However, much of this knowledge is based upon studies of predominantly European-descent individuals, posing the question of whether these variants will also generalize to non-European populations and, importantly, to populations with disproportionate disease burdens. As part of the curation efforts for the National Human Genome Research Institute GWAS Catalog, we developed a framework for systematically and consistently extracting ethnicity and ancestry information at multiple levels of granularity. Of 443 papers from January, 2011 through April, 2012 (35% of all papers), 56% exclusively report populations of European descent; 11% include both European and non-European populations, and 28% report only non-European populations. On a per-participant level, most participants were also classified as European descent. Of studies that included participants of non-European descent, the most frequently represented countries were China, Japan, Korea, and Singapore. Representation of non-European participants was most pronounced for the following traits: blood pressure, body mass index, HDL cholesterol and type 2 diabetes. Papers including non-European participants were more likely to be published in high impact journals (impact factor >7; OR 1.64, 95% CI 1.04–2.60), adjusted for study year, sample size, and previous GWAS publications. Preliminary data from a small study of 153 papers published from 2005–2008 suggest that a variety of statistical methods were used to account for population stratification in the analysis of GWAS data; an increased number of such methods was associated with use of more than one ethnic group in the discovery set, later publication date and publication in high-impact journals. These data need to be extended to more recent studies, which through meta-analyses of multiple cohorts have increased in complexity. Although these data are limited to GWAS published in 2011–2012, our work suggests that non-European participants are still greatly underrepresented in GWAS and that additional studies are needed to fully evaluate whether potentially functional variants identified in GWAS generalize to populations most impacted by chronic disease.

OFCD syndrome gene BCOR is associated with dental caries. *X. Wang[1], Z. Zeng[2,3], J.R. Shaffer[2], E. Feingold[2,3], D.E. Weeks[2,3], M. Lee[1], K. T.Cuenco[1,2], R.J. Weyant[4], R. Crout[5], D.W. McNeil[6], M.L. Marazita[1,2,7].* 1) Dept Oral Biology, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 3) Dept Oral Biol, Biostatistics, Pittsburgh, PA; 4) Dept Dental Public Health and Information Management, Univ Pittsburgh, Pittsburgh, PA; 5) Dept Periodontics, West Virginia Univ, Morgantown, WV; 6) Dental Practice and Rural Health, West Virginia Univ, Morgantown, WV; 7) Clinical and Translational Science, Univ Pittsburgh, Pittsburgh, PA.

Dental caries (i.e. tooth decay) is one of the most common diseases worldwide. In high-risk populations, the caries prevalence in adults can reach 90%. While treatment of caries costs tremendous amounts each year, untreated caries lesions can lead to pain, tooth loss, and oral infection. Genetic contributions to the etiology of dental caries are well-established. However, few specific caries genes have been successfully discovered and validated. Recent family-based analyses suggested differential genetic factors for primary dentition (i.e., baby teeth) caries and permanent dentition (i.e., adult teeth) caries, as well as for pit and fissure surface and smooth surface caries. Here we sought to find genes preferentially responsible for caries on these two surface types in the permanent dentition. We performed separate genome-wide association studies on caries scores for the above two surface types in the permanent dentition. We used a sample of 1,063 individuals of European ancestry (ages 14 to 56 years), adjusting for the effects of age, sex, presence of Streptococcus mutans (an oral bacteria), and home water fluoride level. More than 1.2 million SNPs were either successfully genotyped or imputed and were tested for association. The BCOR gene, mutations in which are known to cause oculofaciocardiodental syndrome (a condition involving multiple dental anomalies), was suggestively associated with pit and fissure surface caries (p-value = 3.89E-7), while the highly homologous gene, BCORL1, was suggestively associated with smooth surface caries (p-value = 5.54E-6). Associations of other genes with functional plausibility in cariogenesis were also observed for pit and fissure surface caries (INHBA, p-value = 5.14E-6) and for smooth surface caries (CXCR1 and CXCR2, p-value = 1.48E-6). Not only did our study nominate susceptibility genes for dental caries on the two types of surfaces in the permanent dentition but demonstrated that surface-specific phenotypes have potential to increase the power for detecting genes with surface-specific effects despite the presence of a rather high genetic correlation between the two phenotypes. Our findings contribute to a better understanding of genetic pathogenic mechanisms of cariogenesis and eventually, may lead to better prevention and prognosis of dental caries. Supported by NIH/NIDCR U01-DE018903, R01-DE014899, R03-DE021425.

Sickle-cell locus is a major modifier of human susceptibility to invasive bacterial infection - a genome-wide association study of bacteremia susceptibility. *A. Rautanen[1], M. Pirinen[1], C. Spencer[1], T. Mills[1], S. Chapman[1], K. Rockett[1], J.A. Scott[2,3], T.N. Williams[3,4], P. Donnelly[1], A.V. Hill[1].* 1) WTCHG, University of Oxford, Oxford, United Kingdom; 2) KEMRI-Wellcome Trust Programme, Kilifi, Kenya; 3) Nuffield Department of Medicine, University of Oxford, Oxford, United Kingdom; 4) INDEPTH Nettwork, Accra, Ghana.

Bacteremia, a bacterial infection of the bloodstream, is a leading cause of death among children in sub-Saharan Africa. As part of the Wellcome Trust Case Control Consortium 2, we have conducted a genome-wide association study of 1536 microbiologically confirmed bacteremia cases and 2677 controls, recruited from Kilifi, Kenya. This is probably the largest DNA collection from patients with bacteremia world-wide, the first GWAS of bacteremia susceptibility that we know of, and one of the few large-scale GWAS conducted in African populations. None of the genotyped SNPs reached genome-wide significance but imputation against the 1000 Genomes data revealed 4 loci with a $p<5x10^{-8}$. The strongest association was found on chromosome 11 (genotypic $p=4.8x10^{-13}$) in the HBB (beta hemoglobin) gene region and the sickle cell disease causing mutation rs334 was among the most strongly associated SNPs. As the reference panel does not perfectly reflect the Kenyan populations, we confirmed the imputation result by direct genotyping. We replicated the HBB finding in 769 cases and 4337 controls from the same population in Kenya, resulting in a highly significant combined genotypic p-value of $1.1x10^{-21}$. Heterozygotes (sickle-cell trait, HbAS) were protected against bacteremia ($p=8.3x10^{-7}$, OR=0.68, compared to HbAA), whereas minor homozygote individuals (sickle-cell disease, HbSS) were highly predisposed to bacteremia ($p=3.07x10^{-16}$, OR=3.94, compared to HbAA). In addition to bacteremia overall, sub-groups stratified by causative bacteria were analysed: gram-positive, gram-negative, *S. pneumoniae*, *Non-typhoidal salmonella*, *S. aureus*, *H. influenzae*, and *E. coli*being the largest sub-groups. These analyses showed that HbSS most strongly increases the risk of invasive infection caused by encapsulated bacteria whereas protection by HbAS is strongest against E. coli infection. Replication genotyping of the other significantly associated loci is ongoing. This study demonstrates the importance of imputation in African GWAS, even when the reference panel does not perfectly represent the ethnicities under study. HbAS is highly protective against malaria and malaria may predispose to bacteremia in the malaria-endemic region, which could partly explain the heterozygote protection. However, the strong risk of bacteremia conferred by the HbSS genotype is likely independent of malaria as the risk does not change over time, even when the incidence of malaria has dramatically decreased.

Using genomics to decipher causation in severe edematous childhood malnutrition: a pilot GWAS. *N.A. Hanchard[1,2], S. Howell[3], K. Marshall[3], T. Forrester[3], M. Reid[4], X. Wang[1,2], L.M. Franco[1,2,5], J.W. Belmont[1,2], C.A. McKenzie[3].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) USDA/ARS Children's Nutrition Research Center, Baylor College of Medicine, Houston, TX; 3) Tropical Metabolism Research Unit, Tropical Medicine Research Institute, University of the West Indies, Kingston, Jamaica; 4) Sickle Cell Unit, Tropical Medicine Research Institute, University of the West Indies, Kingston, Jamaica; 5) Department of Medicine, Baylor College of Medicine, Houston, TX.

Background: Severe childhood malnutrition (SCM) is an important global health problem that contributes to more than two million deaths worldwide each year. SCM exists in two well-described and clinically distinct forms - edematous SCM (ESCM), which has a higher mortality and is more difficult to treat, and non-edematous SCM (NESCM). The appropriate development of prevention and treatment protocols for SCM requires an understanding of the reasons why some children develop ESCM while others develop NESCM, even though both groups are exposed to the same apparent nutritional stress. The approach to understanding this clinical dichotomy has largely focused on physiological observations of biochemical, inflammatory, and nutritional markers during and after nutritional recovery. We have advocated the application of genome-wide technologies to SCM as a means of circumventing the problem of reverse causation inherent in such physiological studies, and to provide a global integrated view of the physiological response associated with severe nutrient and caloric restriction. Methods and Results: We genotyped ~1.3 million SNPs in 101 ESCM cases and 103 NESCM controls using the Illumina HumanOmni1-Quad BeadChip array. Patterns of linkage disequilibrium, minor allele frequency, and multi-dimensional scaling indicated a close ethnic relationship between the Jamaican samples and the Yoruba of West Africa. After imposition of data quality control filters, 91 ESCM cases and 88 NESCM controls were used for genome-wide association tests under an allelic model. There was no evidence of population stratification (GIF=1.0). No markers met genome-wide significance for association (P<5 x 10-8); however, at a suggestive statistical significance level (P<1 x 10-5) we observed a cluster of SNPs at the Glucan (1,4-alpha-) branching enzyme (GBE1) gene (maximum OR 2.64, 95%CI 1.72–4.05) that were associated with ESCM status. Pathway analysis implicated genes involved in carbohydrate and inositol phosphate metabolism, ErbB signaling, and immune cytotoxicity in ESCM. Conclusions: We have undertaken the first genome-wide association study of SCM. The results from this pilot study illustrate the potential of this approach to further inform the pathophysiology of ESCM and suggest a more prominent role for glycogen and carbohydrate metabolism in ESCM. Larger studies are required to confirm and validate these findings.

Genomewide Association Study of Body Mass Index in Samoans. *R.L. Minster[1], G. Sun[2], S.R. Indugula[2], H. Cheng[2], N.L. Hawley[3], S. Viali[4], R. Deka[2], D.E. Weeks[1], S.T. McGarvey[3].*1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Environmental Health, School of Medicine, University of Cincinnati, Cincinnati, OH; 3) Department of Epidemiology, International Health Institute, Program in Public Health, Brown University, Providence, RI; 4) Ministry of Health, Apia, Samoa.

Compared to most populations worldwide, obesity is considerably more prevalent in Polynesian populations, and it has been speculated that this may be due to greater genetic susceptibility, especially upon exposure to the Western diet and decreased activity. Genomewide association studies (GWAS) of obesity-related traits have been conducted in many populations, including East Asians, but none, to date, have been completed in Polynesian populations. Such studies might highlight obesity-related variants unique to Oceanic populations. Here we report the results of a GWAS of body mass index (BMI) in 3,122 adults from Samoa. A total of 871,188 autosomal single-nucleotide polymorphisms (SNPs) were genotyped and extensive quality control of the genotypes conducted. One region was associated with BMI at genomewide significance ($p < 5 \times 10^{-8}$) on chromosome 5q35.1 (most significant SNP $p = 2.54 \times 10^{-14}$). Thirteen SNPs in this region were associated with BMI at suggestive levels of significance ($p < 10^{-5}$). None of the nearby genes have been described as associated with BMI before. SNPs in five other regions were also suggestively associated with BMI: 10q22, 10q25.2, 13q13.2, 13q14 and 15q26.2. Additional studies of Polynesian populations will be needed to confirm these findings.

2160W

Variants in *RUNX3* contribute to susceptibility to psoriatic arthritis exhibiting further common ground with ankylosing spondylitis. *A. Reis[1], M. Apel[1], S. Uebe[1], J. Bowes[2], E. Psoriatic arthritis (PsA) is a common inflammatory joint disease distinct from other chronic arthritides and frequently accompanied by psoriasis vulgaris (PsV). In a first genome-wide association study (GWAS), we were able to identify several genetic risk factors. However, even combined with previously identified factors, the genetic contribution to disease is not fully explained. Therefore we investigated further 17 loci from our GWAS which did not reach genome-wide significance levels of association in the initial analysis. 19 of 20 single nucleotide polymorphisms (SNPs) were successfully genotyped in independent cohorts of 1,398 PsA cases and 6,389 controls, and a group of 964 German PsV patients. Association to a *RUNX3*variant, rs4649038, was replicated in independent cases and controls and resulted in a combined p-value of 1.40E-08 in a Cochran-Mantel-Haenszel test and an OR of 1.24 (1.15–1.33). Further analyses based on linkage disequilibrium at *RUNX3* refined the most significant association to a linkage disequilibrium (LD) block of ~30kb located in the first intron of one isoform (p=3.40E-08). Weaker evidence for association was detected in German PsV patients (p-value 5.89E-02; OR 1.13 (1.00–1.28)), indicating a possible role in the skin manifestations of psoriasis. Our analyses identified variants in *RUNX3* as susceptibility factors for PsA. *RUNX3* has already been implicated in susceptibility to ankylosing spondylitis, another spondylarthropathy, although its risk allele seems to be independent from that in PsA. RUNX3 is involved in CD8 lymphocyte differentiation and therefore a good candidate for PsA and PsV as T-cell mediated diseases.

2161T

Association analysis between X-chromosome variants and asthma in 50,000 individuals. *C.S. Tang[1], D. Hinds[2], M.A.R. Ferreira[1].* 1) Asthma Genetics, Queensland Institute of Medical Research, Brisbane, QLD, Australia; 2) 23 and Me, Mountain View, California, United States.

Gender differences in asthma development and progression have been widely reported. Recent studies have indicated that more males are affected during early childhood but a gender shift has been observed at puberty, with a higher prevalence of asthma in female than male at adulthood. Factors contributing to such sex difference remain unclear. It has been suggested that hormonal changes together with genetic predisposition might be involved. Despite genes on the sex chromosomes contributing to many sexually dimorphic traits, associations on the X-chromosome were often overlooked in previous genome-wide association scans (GWAS) on asthma. To determine if genetic variants on the X-chromosome contribute to disease risk, we performed a meta-analysis of association studies comprising >50,000 individuals and interrogating >150,000 genotyped or imputed SNPs. Mixed-gender analysis revealed putative novel common variants associated with asthma, mapping to Xq22.3 and Xq27.3. Variants in *IL1RAPL1* were associated with asthma in females only. SNPs from these loci have been selected for replication in independent cohorts. Results from these analyses will presented.

Variations in early growth patterns are associated with obesity, type 2 diabetes and cardiovascular diseases but the genetic basis of this relationship is unknown. We conducted a Genome Wide Association Study (GWAS) of early adiposity parameters (age and body mass index (BMI) at adiposity peak (AP) and at adiposity rebound (AR)) in up to 7,215 children from 4 European birth cohorts with replication in up to 16,017 children from 12 independent studies. Early growth phenotypes were derived using sex-specific mixed effects models fitted on BMI measurements collected longitudinally from 2 weeks to 13 years. These phenotypes were regressed on ~2.5M single nucleotide polymorphisms (SNPs), genotyped/imputed, assuming an additive genetic model and adjusting for gestational age and sex. We identified four loci at p<5x10-8 and two suggestive at p<5x10-6 that associated with BMI at AP, age at AR and/or BMI at AR in overall meta-analyses. Two variants, one near the leptin receptor gene (LEPR; p= 1.23x10-9) and another, suggestive, near proprotein convertase subtilisin/kexin type I (PCSK1; p=1x10-6), associated with BMI at AP, occurring at ~9 months. LEPR encodes the cellular receptor for leptin, a hormone involved in regulating appetite and energy balance. PCSK1encodes an enzyme which is a key in the production of insulin and other hormones involved in regulating energy metabolism, and has been associated with BMI and obesity in adults. Three loci (FTO; p=3.12 x10-30, TFAP2B; p=1.17x10-9, GNPDA2; p= 2.92x10-8) associated with earlier age at AR and/or BMI at AR (~5.5y). Polymorphisms in all of these genes are associated with adult BMI and obesity in large-scale studies, with FTO also involved in BMI regulation in childhood. Another suggestive variant, near discs large homolog 2 (DLG2; p= 5.11x10-6), associated with BMI at AR. Variants in the DLG2 locus are associated with maintenance of glucose homeostasis through insulin sensitivity and β-cell function. We show that the loci identified associated with BMI in an age-dependent manner in childhood. We provide insight into the mechanisms linking early growth measures with later metabolic health and further evidence that the genetic variants associated with adult phenotypes may impact on disease development from early in life. Our methodological novelty is the use of phenotypes from longitudinal growth models. These methods are valuable for understanding bio-mechanisms for preventive purposes.

Multiple human genetic variants associated with Epstein-Barr virus load in the 1000 Genomes and HapMap lymphoblastoid cell lines. *C. Houldcroft[1], A. Gall[1], J.Z. Liu[1], A.L. Palser[1], S.J. Watson[1], C.A. Anderson[1], P. Kellam[1, 2].* 1) Virus Genomics, Wellcome Trust Sanger Institute, Cambridge, Cambs, United Kingdom; 2) Division of Infection & Immunity, University College London, London, United Kingdom.

Epstein-Barr virus (EBV) is a ubiquitous human gammaherpes virus, infecting around 99% of the adult population. It is the aetiological agent of infectious mononucleosis, and associated with a number of cancers such as Burkitt's lymphoma and nasopharyngeal carcinoma. EBV is also an important tool in molecular biology, used to transform white blood cells to derive lymphoblastoid cell lines (LCLs), permanent sources of DNA, RNA and protein. The virus has a two-stage life cycle, a lytic phase where the full repertoire of virus genes are expressed and primary infection of cells occurs; and a latent phase in which very few genes are expressed and virus immunogenicity is low (seen in latent natural infection). It is unclear what role host-genetic variants play in the switch from the latent to the lytic phase in LCLs. Epstein-Barr virus load also varies between LCLs and may be a confounding factor in studies of gene-expression performed on these cell lines. Here we characterise variation in virus load between cell lines and aim to understand the host genetics underlying Epstein-Barr virus load and reactivation from latency. This will allow future studies to take account of this variability and correct for it. Methods: 749 LCLs from 8 populations in the HapMap and 1000 Genomes projects were characterised for intra- and inter-sample EBV load variations. Virus loads were assayed by qPCR using absolute and relative quantification of genome copy numbers. A genome-wide association study was then conducted on 639 individuals genotyped for 500,000 SNPs to identify host genetic variants associated with EBV load using PLINK and EMMAX. Results: Absolute EBV loads varied from 2–350 copies per cell. Cell lines with the highest EBV loads showed evidence of viral lytic reactivation, with mRNA expression of immediate early lytic genes BZLF1 and BRLF1. Mixed-effect modelling using EMMAX showed a number of suggestive associations of host genetic variants with relative EBV loads in the HapMap LCLs. Top SNPs include rs6879787 (p = 4.12x10-8) and a number of associations on chromosome 6. We are currently increasing the sample size to boost our power to detect variants associated with the EBV load trait. Future work will include replication of associations found in this initial screen in an independent sample of LCLs. Microarray data is available for 270 HapMap cell lines and will be used to prioritise candidate genes identified by GWAS for functional validation.

The genetic architecture underlying expressive language (EL) development is largely unknown and so far no common genetic variants have been established. EL is a developmental phenotype that shows a dramatic change in growth, passing from an initial stage with few spoken words (<18 months, mean N of words ≤50) to a stage of rapid word acquisition (>18 months, mean N of words >50), which results in more complex language use thereafter. To identify common variation associated with EL development we focused on an early (ETW: 15–18 months) and a late time window (LTW: 24–30 months), using vocabulary lists of the Communicative Development Inventories and the Language Development Survey. A genome-wide (GW) analysis on EL in European descent children from the general population was conducted using up to 7280 children from ALSPAC or ALSPAC+RAINE cohorts, with variants from 19 (ETW) and 14 (LTW) loci followed up in up to 2038 independent children from the GENR cohort. In each study, we tested the association between the ranktransformed EL score, adjusted for sex, age and age^2, and single SNPs using linear regression. We performed fixed-effects inverse-variance meta-analyses to combine results from all studies. For the ETW, the analyses identified one novel locus on 3p12.3 near the roundabout axon guidance receptor homolog 2 (Drosophila) gene (*ROBO2*), which was associated with EL in ALSPAC (lead SNP: *P*=9.8E-07) and replicated in GENR (*P*=0.0044) reaching GW significance (Total N=8889, meta-*P*=1.3E-08). Variants at two further ETW loci on 11p15.2 and 12q15 were also replicated approaching suggestive levels of GW significance (lead SNPs: meta-*P*=2.0E-07; meta-*P*=7.2E-07). Investigation of the 3 ETW signals in 4772 12-month old infants from the NFBC1966 cohort, i.e. during a time where one-word utterances start, resulted in no such evidence for association. Likewise, a sensitivity analysis of these signals using LTW EL measures markedly attenuated or abolished the association, suggesting that the observed effects might be time-sensitive. We were not able to replicate signals for the LTW part of the GW analysis yet. Estimation of the proportion of additive phenotypic variation in ALSPAC, which is accounted for by all genotyped SNPs together, however supported the assumption that common genetic variation explains a significant proportion of variation in EL development both during early (ETW: h^2(SE)=0.13(0.05), *P*=0.008) and later stages (LTW: h^2(SE)=0.17(0.06), *P*=0.002).

Early menopause affects up to 10% of the female population, reducing reproductive lifespan and thus influencing fertility. The genetic aetiology of early menopause is largely unknown in the majority of cases. We have undertaken a meta-analysis of genome-wide association studies in 3493 early menopause cases and 13598 controls from 10 independent studies. No novel genetic variants were discovered, but 17 variants previously associated with normal menopause age as a quantitative trait were associated with early menopause and POI (Primary Ovarian Insufficiency). Thus early menopause has a genetic aetiology which overlaps normal menopause variation and is at least partly caused by the additive effect of the same polygenic variants. The combined effect of the 17 variants on the risk of early menopause was greater than the best validated non-genetic risk factor, smoking.

Genome wide association study of nocturnal awakening in asthma. *D. Chhabra[1], A. Dahlin[1], Q. Duan[1], B. Himes[1,2], S.T. Weiss[1,2], K.G. Tantisira[1,3].* 1) The Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School., Boston, MA; 2) Partners Center for Personalized Genetic Medicine, Partners Health Care, Boston, MA; 3) Pulmonary Division, Brigham and Women's Hospital, Harvard Medical School., Boston, MA.

Introduction: Nocturnal awakening continues to be a major morbidity affecting quality of life in asthmatic subjects and has been shown to affect school attendance and performance. Genetic variation has been previously associated with nocturnal asthma in candidate gene studies. However, despite numerous reported GWAS in asthmatic subjects, none have focused on nocturnal awakening. We believe that identifying the genetic factors underlying severity of symptoms in asthma patients will improve our ability to personalize treatment and alter management protocols in this population.We hypothesized that a genome wide association study(GWAS) of nocturnal symptoms in asthmatic symptoms will identify novel genetic markers. Methods:For the initial analysis, we used the CAMP (Childhood Asthma Management Program) dataset, which enrolled 1,041 children, initially aged 5–12 years, with mild to moderate persistent asthma. This cohort has information on nocturnal awakening available in the form of interview questionnaires performed at baseline and diary card data. Based on 3 questions from baseline data: night time awakening in the last 6 months, night time awakening in the last month and night time awakening in the last week, we identified 223 cases with at least once weekly nocturnal awakenings and 351 controls. GWAS analysis was then carried out on genotype data obtained on Illumina Human Hap550v3 Bead Chip and Illumina 610 quad chip. Statistical analysis was performed in PLINK using age, sex and height as covariates and was limited to Caucasian subjects. The top 30 SNPs were then carried forward for replication in the Leukotriene Modifier or Corticosteroid or Corticosteroid-Salmeterol Trial (LOCCS). This dataset has nocturnal awakening information in the form of symptom severity in the last week. Results:The SNP (rs13430119) was noted to be the most significant at a p value of 2.09x10-7. This SNP lies in the intronic region of the EML6 gene (Echinoderm microtubule associated protein like 6). Of the top 30 SNPs carried forward for replication rs509237 was found to be significant at a p value of 0.002. Conclusion: Our study has identified novel genetic variants associated with nocturnal awakening in asthma subjects and replication in other populations is currently ongoing. Funding: R01 NR013391,U01 HL065899 and T32 HL007427.

Preliminary Meta-Analysis of Genome-wide Association Studies of Lung Function in Children. *M. Kowgier[1,2], M. Bustamante[3,4,5,6], J. Sunyer[3,4,6], J. Heinrich[11], C. Flexeder[11], G. Koppelman[10], M. Kerkhof[10], E.S. Schultz[7], E. Melen[7], S. Birch[8], R. Granell[9], E. Kreiner-Møller[8], H. Bisgaard[8], J. Henderson[9], L.J. Palmer[1,2].* 1) Ontario Institute for Cancer Research, Toronto, ON; 2) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, ON; 3) Center for Research in Environmental Epidemiology (CREAL) - Hospital del Mar Research Institute (IMIM), Barcelona, Catalonia, Spain; 4) CIBER Epidemiologia y Salud Pública (CIBERESP), Spain; 5) Genes and Disease Program, Center for Genomic Regulation (CRG) and UPF, Barcelona, Catalonia, Spain; 6) Pompeu Fabra University (UPF), Barcelona, Catalonia, Spain; 7) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 8) Copenhagen Prospective Studies on Asthma in Childhood, Health Sciences, University of Copenhagen, Copenhagen University Hospital, Gentofte, Denmark; 9) School of Social and Community Medicine, University of Bristol, UK; 10) Department of Pediatric Pulmonology and Pediatric Allergology, University of Groningen; 11) Institute of Epidemiology I, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany.

Objective/Purpose: Lung function measures, such as forced expiratory volume in one second (FEV1) and forced vital capacity (FVC), are complex traits that are important factors associated with respiratory and other health outcomes (such as asthma). To date, however, there have been no published genome-wide association (GWA) study results for lung function in children. We performed a preliminary meta-analysis of 4 GWAS using two lung function measures: FEV1 and the ratio of FEV1 to FVC. Methods: SNP associations for both lung function measures were computed for ~2.5 million genotyped and imputed single nucleotide polymorphisms (SNPs) in 4 birth cohort studies: ALSPAC, COPSAC, BAMSE and PIAMA. The combined analysis included up to 5,813 children, and stratified analysis in boys and girls included up to 2,838 and 2,788 children, respectively. Each cohort estimated residuals by regressing lung function measures on height, age, sex, passive smoking (if available), and ancestry principal components. The residuals were then used as the primary quantitative trait in the GWA. Regression coefficients for SNP effects were then meta-analyzed across cohorts using the sample-size weighting method, after applying genomic control. Results: Among the 4 cohorts, the age of children ranged from 5 to 10 years. Although no SNPs showed genome-wide significant associations, in the combined analysis of the ratio of FEV1 to FVC a SNP located just upstream of ADAM metallopeptidase with thrombospondin type 1 motif, 9 (ADAMTS9) on chromosome 3 showed near genome-wide level significance with p=1.1x10-7. Three other SNPs in this gene region had p < 1x10-5. Several other SNPs indicated suggestive associations. In girls, for the ratio of FEV1 to FVC, a SNP located in the intronic region of gene KCNMA1 on chromosome 10 showed suggestive association with p=8.96x10-7. Three other SNPs in this region had p < 1x10-5. Conclusions: A novel locus associated with pediatric lung function was identified. This locus belongs to the ADAM gene family whose other members have been previously implicated in the genetics of pulmonary function in adults. This locus, and others, will be further investigated in a larger meta-analysis which will include the addition of two other birth cohorts. The identification of novel genetic determinants of pediatric lung function has the potential to improve our understanding of the biological basis of normal physiology as well as the pathophysiology of asthma.

A genome-wide meta-analysis identifies common variants in *LOC201229* and *NOS2A* associated with fractional exhaled nitric oxide in childhood. *R.J.P. van der Valk[1], L. Duijts[2], M.T. Salam[3], J. Sunyer[4], E. Melen[5], G. Koppelman[6], A. Custovich[7], J. Heinrich[8], H. Bisgaard[9], A.J. Henderson[2], V.W.V. Jaddoe[1], J.C. de Jongste[1] on behalf of GABRIEL and the EArly Genetics and Lifecourse Epidemiology Consortia.* 1) The Generation R Study Group, Erasmus University Medical Center - Sophia Children's Hospital, Rotterdam, the Netherlands; 2) Department of Community Based Medicine, University of Bristol, Bristol, UK; 3) Department of Preventive Medicine, University of Southern California, Los Angeles, California, United States; 4) Center for Research in Environmental Epidemiology, Pompeu Fabra University, Barcelona, Spain; 5) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 6) Department of Pediatric Pulmonology and Pediatric Allergology, Beatrix Children's Hospital, University Medical Center Groningen, GRIAC Research Institute, Groningen, the Netherlands; 7) Respiratory Research Group, University of Manchester, Manchester, UK; 8) Institute of Epidemiology I, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Germany; 9) Copenhagen Prospective Studies on Asthma in Childhood (COPSAC), Health Sciences, University of Copenhagen and Copenhagen University Hospital, Gentofte, Denmark.

Single nucleotide polymorphisms (SNPs) have been associated with childhood asthma. Limited progress has been made in understanding the genetics of specific endotypes of asthma. Fractional exhaled nitric oxide (FeNO) is a non-invasive biomarker of the degree of eosinophilic airway inflammation and is associated with childhood asthma symptoms and exacerbations, doctor diagnosis of asthma and atopy. The genetic factors associated with susceptibility to eosinophilic airway inflammation remain largely unknown. To identify common genetic variants associated with FeNO in childhood, we meta-analyzed 14 genome-wide association (GWA) samples from birth cohorts, including 8,062 subjects. Results showed genome-wide significant signals located at chromosome 17q11.2-q12, in novel locus *LOC201229* and in the candidate locus *NOS2A* (P = 1.28E-09, P = 4.38E-09, respectively). A conditional analysis showed that the signals mapping *LOC201299* and *NOS2A* are independent (P = 1.63E-09, P = 6.93E-08, respectively). In addition we found a further 13 suggestive signals associated with FeNO (P <= 1.00E-05), including an interesting signal at chromosome 4q21 near *SLC4A4* (P = 8.93E-07), best known to be a modifier gene of meconium ileus in cystic fibrosis. We are currently pursuing replication of all fifteen suggestive associated loci in two independent large cohorts with GWA and FeNO data in adults available. The present findings shed light on a novel independent signal in *LOC201229* next to the neighboring candidate *NOS2A* gene, and represents the first multi-site GWA meta-analysis of SNPs and FeNO in children.

2169W

Phenotypic dissection of bone mineral density facilitates the identification of skeletal site specificity on the genetic regulation of bone. *J.P. Kemp[1,2], C. Medina-Gomez C[3,4,5], K. Estrada[3], D.H.M. Heppe[5], M.C. Zillikens[3], N.J. Timpson[1,2], B. St Pourcain[1,2], S.M. Ring[1,2], A. Hofman[3], V.W.V. Jaddoe[5], G. Davey Smith[1,2], A.G. Uitterlinden[3,4,5], J.H. Tobias[6], F. Rivadeneira[3,4,5], D.M. Evans[1,2].* 1) MRC Centre for Causal Analyses in Translational Epidemiology, University of Bristol, Bristol, United Kingdom; 2) School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 3) Department of Internal Medicine, Erasmus Medical Center, Rotterdam, The Netherlands; 4) Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 5) The Generation R Study Group, Erasmus Medical Center, Rotterdam, The Netherlands; 6) School of Clinical Science at North Bristol, University of Bristol, Bristol, UK.

Heritability of bone mineral density (BMD) varies at skeletal sites, ranging from 30% in the extremities to 90% in the skull. These differences may be attributed to varying environmental (i.e. mechanical loading and muscular activity) and genetic (i.e. bone mechanosensing, accrual, modelling and remodelling) components. The skull is least prone to loading and muscular activity, whereas arms experience moderate loading and increased activity. Exposure to both is highest in the legs. To identify genetic variants associated with site specificity and bone mass attainment, we performed a genome-wide association meta-analysis using DXA BMD measures at the skull (S), arms (A), legs (L), and total-body less head (TB). The study (n=9395) combined data from the Avon Longitudinal Study of Parents and their Children (n=5299, mean age=9.9, SD=0.32 years) and the Generation R study (n=4096, mean age=6.2, SD=0.5 years). Association analyses were performed using MACH2QTL, fitting a linear regression model based on expected allelic dosage model for SNPs, whilst adjusting for sex, age, weight or height and population stratification. After controlling for genomic inflation, we combined association data for ~2.5 million imputed SNPs into an inverse variance fixed-effects additive model meta-analysis, using METAL. Variants in 7 loci reached genome wide significance with TB-BMD and several displayed varying degrees of site specificity. SNPs mapping to *WNT4* and *WNT16* were associated with all BMD sites, whereas variants proximal to *TNFRSF11A*, *TNFRSF11B*, *LIN7C*, *LRP5* and *EYA4* were specific to S-BMD. *RSPO3* was associated with unloaded sites (A and S), while *TNFSF11* was associated with A and TB. With the exception of *GALNT3* (solely associated with TB-BMD), the remaining loci (*FUBP3*, *KLHDC5*, *PTHLH* and *RIN3*) were associated with L-BMD. Aside from a variant upstream of the Eyes Absent 4 (*EYA4*) locus (MAF=0.35; B=-0.1267; P=8.3x10-17), all other loci are known to influence BMD in elderly adults. In conclusion: BMD measures of axial and appendicular skeletal sites appear to aid genetic investigations of bone accrual, allowing for the dissection between effects on mechanosensing, muscle bone interactions and mass attainment. Furthermore, loss of function mutations in *EYA4* are associated with sensorineural hearing loss; which has previously been identified in sclerosteosis, where skull base overgrowth occurs in the context of high bone mass, leading to cranial nerve compression.

A multiethnic genome-wide association study of HIV-1 viral load among injection drug users. *D.B. Hancock[1], J.L. Levy[2], G.P. Page[3], S.P. Novak[1], C. Glasheen[1], N.C. Gaddis[2], N.L. Saccone[4], J.P. Rice[5], Q. Wang[6], M. Moreau[6], K. Doheny[7], J. Romm[7], A.I. Brooks[6], L.J. Bierut[5], A.H. Kral[8], E.O. Johnson[1].* 1) Behavioral Health Epidemiology, Research Triangle Institute International, Research Triangle Park, NC; 2) Research Computing Division, Research Triangle Institute International, Research Triangle Park, NC; 3) Genomics, Statistical Genetics, and Environmental Research Program, Research Triangle Institute International, Atlanta, GA; 4) Department of Genetics, Washington University in St. Louis, MO; 5) Department of Psychiatry, Washington University in St. Louis, MO; 6) Rutgers University Cell and DNA Repository (RUCDR), Riscataway, NJ; 7) Center for Inherited Disease Research (CIDR), Johns Hopkins University; 8) Urban Health Program, Research Triangle Institute International, San Francisco, CA.

Among those infected with HIV-1, there is considerable variation in the amount of circulating virus during the asymptomatic phase after acute infection and prior to development of AIDS. Genome-wide association (GWA) studies have discovered genetic risk factors of HIV-1 viral load, most notably single nucleotide polymorphisms (SNPs) in the human leukocyte antigen (HLA) region on chromosome 6. However, much of the population variability in disease progression remains unexplained. The previous GWA studies have generally not focused on viral load among active injection drug users, who may have additional biological challenges controlling the virus due to their drug use. To identify novel genetic risk factors of HIV-1 viral load, we conducted GWA studies in African American and European American HIV-1-positive injection drug users from the Urban Health Study. DNA was extracted from stored serum at RUCDR and treated with Illumina FFPE restoration prior to genotyping at CIDR on the Illumina Omni1-Quad array. Following quality control procedures for genotyped SNPs and participants, the analysis data set included ~700,000 autosomal SNPs in 569 African Americans and 314 European Americans. In the separate ethnic groups, additive SNP genotypes were tested for association with log-transformed viral load using linear regression models adjusted for age, gender, behavioral risk class (based on a latent class analysis of several important behavioral and demographic risk factors), recruitment pre- or post-availability of antiretroviral therapy, and 10 principal component eigenvalues for population stratification. The ethnic-specific GWA results were then combined in a fixed-effects meta-analysis. The lowest meta-analysis P-value ($P=5x10^{-7}$) was observed for an intergenic SNP located between two genes on chromosome 3p14 not previously associated with HIV-1 viral load. However, one of the novel genes has been directly linked to HIV protease inhibitor treatment responsiveness, providing further evidence to support its role in regulation of viral load. Several SNPs on chromosome 6 in the previously implicated HLA region had nominally significant meta-analysis P-values (lowest $P=4x10^{-5}$). Further analyses based on 1000 Genomes-imputed SNPs and genotyping of Hispanic American samples are underway to characterize these and other loci that may offer insights into the control of HIV-1 viral load and clinical progression towards AIDS.

Genetic variants near the *NTRK2* gene are associated with weight at birth in twins. *S.J. Metrustry, T. Spector, A.M. Valdes.* Department of Twin Research and Genetic Epidemiology, King's College London, St Thomas' Hospital, Westminster Bridge Road, London, United Kingdom. SE1 7EH.

Background. The Developmental origins of health and disease hypothesis suggests that pre and peri natal factors have a large impact on adult health. Birth weight has been shown to be associated with an increased risk of developing diseases such as type 2 diabetes, cardiovascular disease, obesity, osteoporosis, thus potentially, osteoarthritis later in life. Studies on the genetics of birth weight, to date, have shown that birth weight has an important genetic component but association studies have, thus far, focused only on singleton births to avoid confounding due to (1) the much lower weight at birth in twins and (2) the large difference in birth weight between twins in a pair which is on average 10% of weight at birth. In this study we investigated the genetic component of birth weight in a large twin cohort from the UK (TwinsUK). **Methods**. Genome-wide association study (GWAS) in 4,775 study participants with birth weight data available. **Findings.** We identified 23 genome wide significant hits in chromosome 9 (top SNP has beta=-0.106, SE=0.0186 and p-value 1.01E-08) close to *NTRK2*, associated with birth weight. *NTRK2*(neurotrophic tyrosine kinase, receptor, type 2) is a membrane-bound receptor. This gene encodes a member of the neurotrophic tyrosine receptor kinase (NTRK) family. This kinase, upon neurotrophin binding, phosphorylates itself and members of the MAPK pathway. Signalling through this kinase leads to cell differentiation and mutations in this gene have been associated with obesity and mood disorders. We ran further association analyses and found that the four top SNPs associated in both the high-weight twin and the lower birth twin although effect sizes were slightly larger in higher birth weight twins. Results were also tested in a cohort of 3000 singleton individuals from the UK. **Conclusions.** Our findings indicate that genetic variation plays an important role in determining birth weight in twins and provides insights into the pathways likely to be involved in affecting birth weight in this group. The *NTRK2* gene has previously been associated with obesity and so these findings reinforce previous work stating that birth weight can be linked to adulthood age-related diseases with an obesity component, such as osteoarthritis.

A Systematic Meta-analysis of Associations of Genetic Variants Influencing Protein Phosphorylation with Bone Mineral Density Phenotypes. *T. Niu[1], L. Zhang[1,2], F.-Y. Deng[1], J. Li[1], Y.-F. Pei[1,2], Y. Liu[1], H. Shen[1], Y.-Z. Liu[1], H.-W. Deng[1*,2,3].* 1) Center for Bioinformatics and Genomics, Department of Biostatistics and Bioinformatics, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA. 70112; 2) Center of System Biomedical Sciences, University of Shanghai for Science and Technology, Shanghai 200093, China; 3) College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, China.

Aim: Protein phosphorylation is a ubiquitous regulatory mechanism and an important type of post-translational modification. Our objective is to identify phosphorylation-related polymorphisms in coding sequences that affect bone mineral density (BMD) phenotypes. **Methods:** We performed a systematic, three-stage meta-analysis of genome-wide association (GWA) studies for lumbar spine, hip, and femoral neck BMD phenotypes. After analyzing 64,035 phosphorylation-related single nucleotide polymorphisms (SNPs) in 11,125 individuals of various ancestries (Stage I), top 60 phosphorylation-related SNPs were selected for in silico replication in 3 GWA studies in Australian, Dutch, and Korean populations respectively (Stage II). Five SNPs, i.e., **rs1827293** (Tyr114Cys; *NBPF3*, 1p36.12), **rs6831280** (Ala361Thr; *IDUA*, 4p16.3), **rs3755955** (Arg105Gln; *IDUA*, 4p16.3), **rs2707466** (Thr253/263Ile; *WNT16*, 4p16.3), and **rs56358776** (Arg1561Gln; *ESPL1*, 12q13.13) were further examined in *de novo* genotyping replication in a cohort comprising a sample of 3,923 unrelated European individuals (CEU3) and a sample of 2,822 unrelated Chinese Han individuals (CHI2) (Stage III). **Results:** In combined meta-analysis across all stages, at $P < 10^{-5}$ level, **rs6831280**, **rs3755955**, and rs2707466 were significantly associated with femoral neck BMD ($P = 3.42x10^{-10}$, $5.18x10^{-10}$, and $5.61x10^{-7}$, respectively) and hip BMD ($P = 1.32x10^{-6}$, $2.18x10^{-6}$, and $1.80x10^{-9}$, respectively) phenotypes, and **rs56358776** was significantly associated with spine BMD ($P = 2.21x10^{-6}$). **Conclusion:** Phosphorylation-related non-synonymous SNPs located in *IDUA*, *WNT16* and *ESPL1* genes could have critical roles in BMD variation, and these results should be corroborated in future studies of osteoporosis. *Corresponding Author: Dr. Hong-Wen Deng (Tulane University).

Genome-wide association studies (GWAS) provide a powerful tool to assess genetic associations between common marker alleles and complex traits in large numbers of individuals. Typically these studies have focused on testing the markers in the 22 autosomal chromosomes while the X-chromosome has been omitted from the analyses. The chromosome X, however, constitutes approximately 5% of genomic DNA encoding for more than 1000 genes, and thus also likely contains genetic variation contributing to common traits and disorders.

We set to test associations between 560,000 genotyped and imputed SNP markers and eight anthropometric (BMI, stature, WHR) and biochemical (CRP, HDL, LDL, TC, TG) traits in 14,710 individuals (7468 males, 7242 females) from five Finnish cohorts.

A region in chromosome Xq21.1 was associated with adult stature (meta-analysis p-value = 3.32×10^{-10}). The lead SNP in the locus explained up to 0.55% of the variance in height in 31-year-old women corresponding to 1.09 cm difference between minor and major allele homozygotes. The associated lead variant (MAF = 0.31) is located upstream of *ITM2A*, a gene encoding for a membrane protein that plays a role in osteo- and chondrogenic differentiation. As this is among the first studies using the X chromosome reference haplotypes from the 1000 Genomes project, we are currently validating the imputation with genotyping methods.

The findings pinpoint the value of including chromosome X in the GWAS of complex traits to identify further relevant gene regions that also account for some of the missing heritability. The study illustrates that the 1000 Genomes reference haplotypes allow for high-resolution investigations of the genetic variants in chromosome X even with a relative modest sample sizes compared to the current-day GWAS meta-analyses. Our finding demonstrates that the same analysis strategy is also likely to be useful in the meta-analyses of the large consortia with complex traits.

Crohn's disease is (CD) an inflammatory bowel disease induced by multiple genetic and environmental factors. Genome-wide association studies (GWAS) have identified many genetic factors for CD in the European population, but information in other ethnic groups is scarce. Though there are no significant differences in the clinical characteristics and natural history, previous studies have showed apparent ethnic differences in the CD susceptibility loci between European and East-Asian populations such as *NOD2*, *IL23R*, and *ATG16L1*. To clarify the genetic factors for CD in Japanese population, we performed a GWAS comprising 372 affected individuals and 3,389 controls. After excluding SNPs located at previously reported loci, we carried out genotyping for the replication study in an independent panel of 1,151 cases and 15,800 controls. After combining the data from the GWAS and the replication study, we confirmed the association in the MHC (rs7765379, P = 2.11 x 10-59), *TNFSF15* (rs6478106, P = 3.87 x 10^{-45}) and *STAT3* (rs9891119, P = 2.24 x 10^{-14}) regions. In addition, we identified two novel susceptibility loci on chromosome 4p14 (rs1487630, P = 2.40 x 10^{-11}, odds ratio = 1.33) and in the *SLC25A15-ELF1-WBP4* region on 13q14 (rs7329174 in *ELF1*, P = 5.12 x 10^{-9}, odds ratio = 1.27). Our analysis suggested that the associated SNPs on 13q14 had eQTL activity. In conclusion, we identified two new susceptibility loci for CD at 4p14 (spanning from 38.32 to 38.37 MB) and 13q14 (spanning from 41.416 to 41.59 MB) in a Japanese population. Further functional studies of these loci will provide a better understanding of the pathogenesis of CD.

Telomeres are the protein bound DNA repeat structures at the ends of chromosomes which have an important role in maintaining genomic stability and in regulating cellular lifespan. Telomere length (TL) is an important determinant of telomere function. Mean leukocyte TL shows considerable inter-individual variability and family-based studies have shown that it is a highly heritable trait with estimates varying between 44-80%. Inter-individual variation in mean leukocyte TL has been associated with cancer and several age-associated diseases. To date, in genome-wide association studies (GWAS), only common variants at one locus on Chr3q26 (*TERC*), explaining <1% of the variance in TL, have shown an association with mean TL in more than one study. Variants at two other loci, Chr10q24.33 (*OBFC1*) and Chr2q21 (*CXCR4*) have shown association at genome-wide significance in a single study. To identify further genetic determinants of TL we conducted a large scale GWAS meta-analysis of 37,684 individuals from 15 European cohorts, followed by replication of selected variants in a further ~11,000 individuals from 6 cohorts. We identified seven loci, including five novel loci, harbouring common variants affecting mean leukocyte telomere length at a genome-wide significant level ($P<5x10^{-8}$). Five of the loci include genes (*TERC*, *TERT*, *NAF1*, *OBCF1*, *RTEL1*) known to be involved in telomere biology, including 3 (*TERC*, *TERT*, *NAF1*) that are involved in the formation and activity of telomerase. The individual impact of the variants on telomere length ranged from ~ 57-117 base pairs per allele. Interrogation of genetic association databases showed that the lead SNPs at two of the loci (*TERC* and *TERT*) are also associated with a several cancers as well as other diseases, including idiopathic pulmonary fibrosis. We report five novel and confirm two previously reported variants associated with TL in humans. Our findings provide a framework for investigating the causal role of telomere length in both telomere- and age-related diseases.

Suggestive loci for osteoporosis: a variance components linkage analysis of extended pedigrees. *S.C. Nguyen, N.D. Nguyen, J.C. Center, J.A. Eisman, T.V. Nguyen.*Osteoporosis and Bone Biology, Garvan Institute of Medical Research, Darlinghurst, NSW, Australia.

Genome-wide association studies to date have been successful at identifying many genes and common variants associated with diseases such as osteoporosis, however they face limitations such as numbers needed to detect, missing heritability, and the prevalance of rare variants. Linkage analysis using large pedigrees represents an attractive alternative as they avoid these issues, potentially identifying genes not detectable in association studies. The primary aim of this study was to identify genetic loci that are linked to bone mineral density (BMD) and quantitative ultrasound parameters (QUS), both measures of osteoporosis.

The Dubbo Osteoporosis Genetics Study is a large multi-generational family study involving 141 pedigrees. Individuals are recruited through probands with high BMD (Z-score greater than +1.28, corresponding to the top 10% of an age- and sex-matched population). BMD (g/cm^2) was measured at the femoral neck, lumbar spine and whole body by DXA (GE-LUNAR), and QUS measurements were obtained using a Sunlight Omnisense. Subjects were genotyped using 530 microsatellite markers. Following adjustment for age, sex and other covariates, variance components linkage analyses were performed using SOLAR.

In this study we analysed 1007 individuals (636 women and 371 men) from 141 pedigrees, with a mean age of 58 ± 19 (range 18-98). We found suggestive linkage for BMD at the whole body on chromosome 6 (LOD score 2.02) and for QUS at the tibia on chromosome 18 (LOD score 2.77), though not for BMD at the femoral neck (highest LOD score 1.50 on chromosome 6) or lumbar spine (highest LOD score 1.38 on chromosome 12). We performed further analysis following stratification in order to identify any age-specific linkage, and found suggestive signals for BMD at both the femoral neck (LOD score 2.88 on chromosome 18) and lumbar spine (LOD score 1.82 on chromosome 18) for individuals aged 50-80 years.

These data suggest the presence of multiple loci regulating bone mineral density and quantitative ultrasound measurements, both in general and age-specific manners. The identification of specific markers or genes may lead to better prediction of disease and fracture risk, and greater individualised osteoporosis treatments.

2177F

Linkage analysis for identification of rare, high-penetrance celiac disease risk variants in the Finnish and Hungarian populations. *E. Einarsdottir[1], K. Kurppa[2], K. Kaukinen[3], I. Korponay-Szabo[4], K. Mustalahti[2], M. Balogh[5], M. Mäki[2], P. Saavalainen[1].* 1) Research Program Unit, Molecular Medicine, University of Helsinki, Helsinki, Finland and Department of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland; 2) Paediatric Research Centre, School of Medicine, University of Tampere, Tampere, Finland and Department of Paediatrics, Tampere University Hospital, University of Tampere, Tampere, Finland; 3) Department of Gastroenterology and Alimentary Tract Surgery, Tampere University Hospital, Tampere, Finland and School of Medicine, University of Tampere, Tampere, Finland; 4) Heim Pal Children's Hospital, Budapest, Hungary and Research Centre for Molecular Medicine, University of Debrecen, Debrecen, Hungary; 5) Markusovsky Teaching Hospital, Szombathely, Hungary.

Background: Celiac disease is an immune disease of the gut, triggered by gluten ingestion in genetically susceptible individuals. GWAS studies have identified a number of risk variants, but a large proportion of the risk is still unexplained and may be due to rare variants of high risk-effect. **Methods:** Our approach to identifying rare celiac disease variants of high risk-effect involved selecting 31 families with Mendelian-like inheritance pattern (minimum of five affected individuals), and performing whole-genome allele-sharing linkage analysis. The custom Illumina Immunochip was used for the analysis, allowing for direct fine-mapping of previously known celiac disease /autoimmune disease loci. **Results:** We obtained non-parametric LOD-scores >2 on chromosomes 6 (the HLA locus), 11, 15, 19 and 21 in the Finnish families (N=28) and in the combined Finnish and Hungarian families (N=31). In the Hungarian families alone (N=3), we had LODs over >2 on chromosomes 2, 9, 17, 19, and 20. A subset of these loci overlap with previously described linkage peaks/association signals. Another subset of loci constitutes novel putative celiac disease loci, some of which have been implicated in other immune disease previously. **Conclusions:** Our preliminary results indicate that using the Immunochip for linkage analysis on large pedigrees can be a viable approach to identifying high-risk variants in complex diseases such as celiac disease. The further follow-up of the most promising loci with whole-locus or exome sequencing will help identify putative high-risk disease variants involved in celiac disease.

2178W

Whole Genome Linkage Analysis to Identify Genes for Childhood Dental Caries. *N. Mukhopadhyay[1], M. Govil[1], Z. Zheng[2,3], E. Feingold[2,3], D.E. Weeks[2,3], J.R. Shaffer[2], X. Wang[1], R.J. Weyant[5,6], R. Crout[5,7], D.W. McNeill[8], M.L. Marazita[1,2,4].* 1) Department of Oral Biology, University of Pittsburgh, School of Dental Medicine, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, Graduate School of Public Health, Pittsburgh, PA; 3) Department of Biostatistics, University of Pittsburgh, Graduate School of Public Health, Pittsburgh, PA; 4) Clinical and Translational Science, School of Medicine, University of Pittsburgh, Pittsburgh, PA; 5) Center for Oral Health Research in Appalachia, University of Pittsburgh, Pittsburgh, PA and West Virginia University, Morgantown, WV; 6) Department of Dental Public Health and Information Management, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 7) Department of Periodontics, West Virginia University School of Dentistry, Morgantown, WV; 8) Department of Dental Practice and Rural Health, West Virginia University School of Dentistry, Morgantown, WV.

Childhood dental caries is one of the most common chronic diseases among children. Approximately 40% of children have a cavity or filling by 5 years of age. Both environmental (including social-economic) and genetic factors play a role in the observed prevalence of the disease, with an increased prevalence of childhood caries in recent years, particularly among children in the 2-11 years age group. Earlier studies have demonstrated the role of multiple genes in the development of caries, although few of the candidate genes proposed to date have been validated. To identify genetic regions with loci that may influence susceptibility to childhood caries, we performed a whole-genome linkage scan for 327 families from the Appalachia region of West Virginia and Pennsylvania. Family sizes ranged from 4-17 individuals. All individuals aged 1 to 43 years with one or more primary teeth having caries were designated as affected. Genotyping for the Illumina HumanHap 550 panel (550,000 evenly spaced SNPs) was conducted by the Center for Inherited Disease Research (CIDR). We carried out a multipoint genome-wide nonparametric linkage analysis as implemented in the software package Merlin. To allow for linkage disequilibrium (LD), the SNPs were clustered based on a 0.1 r2 threshold prior to conducting the linkage analysis. To improve detection of LD clusters among markers, we included an additional 526 genotyped three-member families, although they dropped out of the subsequent analysis. Our preliminary results show a peak LOD score of 3.04 in the 1q24-25 region. A suggestive peak with a LOD score of 2.6 was also obtained for the 3p23-24 region. While we continue to refine the complex childhood caries phenotype as we explore the role of genes implicated in the development of the disease, our linkage results support prior association findings (p-value > 10 E-05) for SNPs on chromosomes 1, 7, 8, 10, 11, 12, 15 and 17 by Shaffer et al. (JDR, 2011). This analysis was supported under NIDCR grants R00-DE018085, U01-DE018903, R01-DE 014899 and 1R03-DE021425.

simQTL: Software for simulation of a complex etiological model under a set of epidemiological model parameters. *J.D. Terwilliger[1, 2, 3, 4, 5], K.M. Weiss[6], J.H. Lee[7, 8, 9], B. Lambert[6].* 1) Genetics and Development, Columbia University, New York, NY; 2) Medical Genetics, New York State Psychiatric Institute, New York, NY; 3) Chronic Disease Prevention, Public Health Genomics Unit, National Institute for Health and Welfare, Helsinki, Finland; 4) Psychiatry, Columbia University, New York, NY; 5) Columbia Genome Center, Columbia University, New York, NY; 6) Anthropology, Pennsylvania State University, State College, PA; 7) Epidemiology, Columbia University, New York, NY; 8) Sergievsky Center, Columbia University, New York, NY; 9) Taub Institute, Columbia University, New York, NY.

Biotechnology has advanced at an absolutely amazing pace over the past two decades, fueled largely by the desire to understand the relationships between genetic variation and the complex common diseases which contribute the largest amount to human morbidity and mortality in Western societies. However, this accomplishment has not brought us significantly closer to the widely promised medical benefits of early diagnosis and treatments, largely because scientists grossly underestimated the complexity of the genotype-phenotype relationships underlying such diseases. We have developed a software package, simQTL, to simulate complex etiological models consistent with user-specified epidemiological and population genetic parameters. The present version of simQTL generates an etiological architecture model involving up to thousands of functional genetic variants, together with environmental exposures (both discrete and continuous, familially shared and unshared) from the infinite number of possible etiological models consistent with a large set of user-defined parameters describing the population distribution and familial correlations seen in a given trait, along with locus-specific effect size estimates from which a complex architecture involving potentially numerous functional and nonfunctional variants per gene is simulated. A population of individuals in families (if desired) is then simulated with a genome-spanning set of marker (and functional variant) data and precise chromosomal segregation patterns, along with environmental exposures and phenotypes (both quantitative and qualitative as requested). Summary statistical analysis is provided as well of both the linkage information (pointwise and multipoint) and the association information (i.e. detectance distributions) in the dataset requested by the user under the requested ascertainment criteria. A whole population is simulated, but a user-described dataset is ascertained and output therefrom. The current version of the software is available freely and runs under various flavors of UNIX with an easy to use GUI guiding the user through the numerous questions which must be answered to define the desired genetic epidemiological characteristics of the resulting etiological model from which the dataset is to be generated. simQTL is freely available from the authors.

2180F

A hybrid likelihood model for sequence-based disease association studies. *Y. Chen[1], H. Carter[1], J. Parla[2], M. Kramer[2], F.S. Goes[3], M. Pirooznia[3], P.P. Zandi[3], W.R. McCombie[2], J.B. Potash[4], R. Karchin[1].* 1) Biomedical Engineering, Johns Hopkins University, Baltimore, MD; 2) Stanley Institute for Cognitive Genomics, Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 3) Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD; 4) Psychiatry, University of Iowa, Iowa City, Iowa.

In the past few years, case-control studies of common diseases have shifted their focus from single genes to whole exomes. New sequencing technologies now routinely detect hundreds of thousands of sequence variants in a single study, many of which are rare or even novel. The limitation of classical single-marker association analysis for rare variants has been a challenge in such studies. A new generation of statistical methods for case-control association studies has been developed to meet this challenge. A common approach to association analysis of rare variants is the burden-style collapsing methods to combine rare variant data within individuals across or within genes. Here, we propose a new hybrid likelihood model that combines a burden test with a test of the positional distribution of variants. In extensive simulations and on empirical data from the Dallas Heart Study, the new model demonstrates consistently good power, in particular when applied to a gene set (e.g., multiple candidate genes with shared biological function or pathway), when rare variants cluster in key functional regions of a gene, and when protective variants are present. The model is potentially useful for detecting causal genes in whole-exome case-control studies with 1000-2000 subjects, when a suitable candidate gene set is known in advance. When applied to data from an ongoing sequencing study of bipolar disorder (191 cases, 107 controls), the model identifies six causal gene sets with nominal p-values < 0.05, of which one “neurological system process” (GO:005087) is significant after multiple testing correction.

2181W

Novel methods for combined linkage and association analyses of complex quantitative traits in very large families sheds light on genetics of musical aptitude. *Y. Huang[1], J. Oikkonen[2,3], L. Ukkola-Vuoti[2], P. Raijas[4], K. Karma[4], P. Onkamo[3], A. Thomas[5], I. Jarvela[2], V.J. Vieland[1,6].* 1) Battelle Ctr Math Med, Res Inst at Nationwide Children's, Columbus, OH; 2) Dept. of Medical Genetics, U. of Helsinki, Helsinki, Finland; 3) Dept. of Biological and Environmental Science, U. of Helsinki, Finland; 4) Sibelius Academy, DocMus Dept., Helsinki, Finland; 5) Dept. of Biomedical Informatics, U. of Utah, Salt Lake City, UT; 6) Dept. of Pediatrics and Statistics, Ohio State U., Columbus, OH.

A previous genome-wide microsatellite linkage scan for musical aptitude in 15 Finnish pedigrees showed evidence for a major locus at 4q22 assuming an additive model under the variance components framework of SOLAR, and targeted haplotype analyses indicated association with AVPR1A using HBAT, which required breaking up the pedigrees. In the current study the original 15 plus 85 new families were genotyped on the IlluminaHumanOMNIExpress 12 1.0v SNP chip. Using the software package Kelvin, which supports combined linkage (posterior probability of linkage, PPL) and linkage disequilibrium (posterior probability of linkage disequilibrium, PPLD) analysis, we were able to keep the very large families intact, conduct full multipoint linkage analyses while utilizing Kelvin's unique approach to integrating over the nuisance parameters of the trait model, and to run genome-wide association analyses on the full pedigrees conditioned on the linkage information. For the linkage portion, exact likelihood calculations were impossible due to inherent limitations of the Elston-Stewart algorithm on the number of markers and of the Lander-Green algorithm on pedigree size. We solved this problem by adapting MCMC sampling of meiosis indicators, as implemented in McLink, to work with Kelvin's direct (non-stochastic) numerical integration routines for handling the trait model, forming a unique “hybrid” approach using MCMC for the marker data and exact likelihood calculations for the trait data. Using two separate quantitative trait musical aptitude phenotyes (Seashore Pitch (SP); Karma Music Test (KMT)) and a combined phenotype (COMB), we obtained evidence of both common and unique loci: with SP peaks at 4p13 (PPL=85%), 16p12.3 (19%), 22q11.21 (36%); KMT peaks at 4q12 (13%), 4q21.21 (24%), and 16p13.11(23%); and COMB peaks at 4q12 (33%), 4q35.1 (12%), 18q22.2 (13%), and 22p16.1(20%). PPLD analyses are currently underway, together with fine-mapping in seven very large (> 30 individuals) individual pedigrees.

Linkage and Genome-wide Association Studies reveal distinct facets of the genetic architecture of Alopecia Areata. *L. Petukhova[1,2], A.M. Christiano[1,3].* 1) Department of Dermatology, Columbia University, New York, NY; 2) Department of Epidemiology, Columbia University, New York, NY; 3) Department of Genetics & Development, Columbia University, New York, NY.

Marker-based methods for genome-wide gene mapping are broadly categorized into two techniques: linkage and association (e.g. GWAS). Both methods utilize genome-wide genotype data to identify genomic regions with distributions of marker alleles that are consistent with the presence of a proximal disease gene. For linkage analysis, families are typed and analyzed to identify genomic regions that cosegregate with disease. Cosegregation will be observed when the disease allele is rare in the population and has strong effects on the phenotype. In contrast, GWAS compare allele frequencies for genetic markers across groups of unrelated cases and controls and is best suited for detecting disease alleles that are common in the population, and which consequently are not likely to have strong phenotypic effects. Thus, because different sets of assumptions underlie each of these two gene-mapping methods, it is expected that each will identify different sets of disease alleles. Therefore, the approaches are complementary to each other. Importantly, emerging empirical evidence, which is well-supported by theoretical arguments, suggests that the genetic architecture of common diseases contains niches for both rare and common alleles. We have previously published the first GWAS for alopecia areata, a prevalent autoimmune disease that targets the hair follicle causing disfiguring hair loss. Here we report for the first time linkage analysis in a cohort of families ascertained in the same population as the GWAS cases and typed with a commercial SNP genotyping array. Linkage analysis combined with pedigree-based association testing (PBAT) identified a set of loci which were not identified in our GWAS. Some of these newly identified loci map to biological processes implicated by the GWAS (e.g. VNN1), while others implicate processes known to be important for hair follicle biology (e.g. FDFT1, COL4A3, COL19A1), but were not identified in pathway analysis of significant GWAS loci. Our data are consistent with emerging evidence in other complex diseases which support the notion that complete enumeration of the genetic architecture may best be achieved by utilizing both linkage and association methods to identify the full spectrum of disease alleles.

Rare and common variants in extracellular matrix gene, FBN2, are associated with Mendelian and multifactorial macular degenerative disease. *R.R. Priya[1], X. Zhan[2], R.N. Fariss[3], C.F. Chakarova[4], K.E. Branham[5], M.M. Campos[4], J.S. Friedman[1], B. Brooks[1], H.K. Rajasimha[1], M.A. Morrison[6], S.G. Jacobson[7], M.L. Klein[8], E.Y. Chew[9], D. Stambolian[10], M.M. DeAngelis[6], S.S. Bhattacharya[4], J.R. Heckenlively[5], G.R. Abecasis[2], A. Swaroop[1].* 1) Neurobiology-Neurodegeneration & Repair Laboratory (NNRL), National Eye Institute, Bethseda, MD; 2) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI, USA; 3) Biological Imaging Core Unit, National Eye Institute, Bethesda, MD, USA; 4) Department of Molecular Genetics, Institute of Ophthalmology, London, EC1 9EL, UK; 5) Department of Ophthalmology, University of Michigan, Ann Arbor, MI, USA; 6) Department of Ophthalmology and Visual Sciences, University of Utah, Salt Lake City, UT, USA; 7) Scheie Eye Institute, Department of Ophthalmology, University of Pennsylvania, Philadelphia, PA, USA; 8) Macular Degeneration Center, Casey Eye Institute, Oregon Health and Science University, Portland, OR, USA; 9) National Eye Institute, National Institutes of Health, Bethesda, MD, USA; 10) Departments of Ophthalmology and Genetics, University of Pennsylvania, Philadelphia, PA, USA.

Macular dystrophies constitute clinically and genetically heterogeneous group of disorders, characterized by progressive loss of visual acuity due to macular dysfunction. Age related macular degeneration (AMD) represents the most common late-onset multifactorial macular disease, associated with at least 19 susceptibility loci and several environmental factors. Stargardt disease, Best macular dystrophy, Sorsby's fundus dystrophy and Doyne honeycomb retinal dystrophy are among the early-onset Mendelian macular diseases that share clinical features with AMD. Using a combination of whole genome linkage analysis and exome sequencing, we have identified a novel heterozygous segregating mutation, p.Glu1144Lys in *FBN2* in a two-generation family with early form of dominant macular dystrophy. *FBN2* encodes a cysteine-rich glycoprotein, which is a principal component of extracellular matrix (ECM). This variant was absent from the 1000 Genomes Project, ESP5400 and dbSNP135 databases. Sequencing of patients with maculopathies and AMD identified additional rare variants. Immunohistological studies in monkey and human fetal eye localized the FBN2 protein in Bruch's membrane, choroid and sclera. Bruch's membrane is multilayered structure located between the choroid and retinal pigment epithelium, and extracellular deposits within or adjacent to Bruch's membrane are often clinically associated with AMD, making *FBN2* an interesting candidate. Genes encoding ECM components have been implicated in both early and late macular degenerative diseases, and recent genomewide association studies have identified variants at or near *TIMP3*, *COL8A1*, and *COL10A1*, conferring susceptibility to AMD patients. This prompted us to explore whether common variants in *FBN2* are associated with AMD. Our analysis revealed the association of a non-synonymous (Val965Ile) SNP, rs154001, with AMD in the analysis of 1988 cases and 2182 population matched controls (p value=1.03×10^{-4}; odds ratio= 0.85). Taken together our findings indicate the importance of *FBN2* in macular degenerative diseases and illustrate a unique scenario where both rare and common variants in a single gene contribute to the clinical phenotype.

Genetic Evidence for an Ethnic Diversity in the Susceptibility to Ménière's Disease. *J. Ohmen[1], C. White[4], J. Wang[1], L. Fisher[2], H. Zhang[5], M. Derebery[3], R. Friedman[1,3].* 1) Molec & Cellular Biol, House Ear Inst, Los Angeles, CA; 2) Department of Clinical Studies, House Ear Institute, Los Angeles CA, 90057; 3) House Clinic, Suite 111, 2100 W. Third St., Los Angeles, CA, 90057; 4) Bioinformatics and Systems Biology Graduate Program, Univ. of California at San Diego, 9500 Gilman Dr., La Jolla, CA, 92093; 5) Cleveland Clinic, Lerner College of Medicine, Case Western Reserve Univ. Cleveland, OH, 44195.

Ménière's disease (MD) is a debilitating disorder of the inner ear characterized by cochlear and vestibular dysfunction. The etiology of this disease is still unknown and epidemiological data for Ménière's disease has not been widely collected, with a small number of groups collecting the bulk of the data in a small number of cohorts. In this paper we characterize a large cohort of definite Ménière's disease patients for gender, age of onset, and use molecular genetic methodologies to characterize their ancestry. We confirm previous observations that there is a sex bias for the disease but note that both sexes have nearly identical age of onset values. Association analysis of genome-wide molecular genetic data for these samples failed to identify any variants associated with early onset of disease. Interrogation of these same data sets with principal component analysis allowed detailed observations about the ethnic ancestry of our patients. Surprisingly, comparison of the ethnicity of MD patients presenting to our tertiary care clinic with the ethnic composition of all patients visiting the clinic revealed a significant ethnic bias, with patients of Caucasian ancestry representing the most susceptible population and individuals with Asian, Hispanic and African ancestry being significantly less susceptible. To the best of our knowledge, this report is the first ethnic characterization of a large Ménière's disease cohort from a large metropolitan region using molecular genetic data. Our data suggest that there is a significant bias in ethnic disease susceptibility.

Genomics of Response to Healing following a Meniscectomy. *D.D. Vance[1], L. Wang[2,3], E. Rampersaud[2,3], T. Guettouche[2,3], W.H. Cade[2,3], R.L. Belton[2,3], B.P. Lesniak[1], J.M. Vance[2,3], M.A. Pericak-Vance[2,3], L.D. Kaplan[1].* 1) Division of Sports Medicine, Department of Orthopaedics, University of Miami, Miami, FL, USA; 2) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 3) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL, USA.

Meniscal tear is a common orthopedic diagnosis that is often treated surgically by an arthroscopic partial meniscectomy, followed by physical therapy. Previous studies examining post-meniscectomy patients have shown that although the procedure is efficacious for some individuals, others retain chronic knee symptoms and functional limitations. While important, age, BMI, location of injury, and quality of physical therapy do not explain all the individual variations. One factor yet to be extensively examined is the contribution of genomic differences between individuals. Molecular analysis of age and sex-related gene expression of tissue collected from meniscal tears has shown significantly elevated expression levels of certain arthritis-related markers. The goal of this project is to better characterize the gene expression profiles in synovial fluid following meniscectomy between individuals from various ethnicities with varying levels of response. By comparing these results to the individual's unaffected knee analytic variability can be reduced. The Genomics of Response to Healing following a Meniscectomy project enrolls individuals through the U of Miami Sports Medicine clinic who have suffered a meniscus tear and are undergoing a partial meniscectomy. Baseline data gathered prior to surgery includes history of present illness (HPI) and applicable knee measurements and knee strength tests. At the time of surgery, intraoperatively, synovial fluid is collected from the affected knee for RNA extraction and gene expression analysis. Following surgery, the study participants undergo a standardized physical therapy regimen along with 2 and 6 month follow-up visits where quantitative assessments of knee function are administered by collecting knee measurements and the results of knee strengthening exercises using the Biodex from both the repaired and control knees of the same individual. Questionnaires are administered to collect information on demographics, medical history, lifestyle modifications as well as self-assessment of post-opt knee function and pain. Results of both the clinical knee assessment and questionnaires are used to compare and contrast gene expression profiles which are currently being assayed. Study design and implementation protocol along with baseline and expression data will be presented.

2186F

GWAS of host-pathogen interactions implicates methionine salvage and microtubules in regulation of inflammatory cell death. *D.C. Ko[1, 2, 3], K.P. Shukla[4], S.I. Miller[4].* 1) Department of Molecular Genetics & Microbiology, Duke University, Durham, NC; 2) Department of Medicine, Duke University, Durham, NC; 3) Center for Human Genome Variation, Duke University, Durham, NC; 4) Department of Microbiology, University of Washington, Seattle, WA.

Recent efforts by many laboratories have made progress in cataloguing human genetic variation and in identifying those variants associated with disease. When genome-wide association studies (GWAS) are combined with approaches that test how variants alter physiology, new biological insights can emerge. Here we used such an approach to reveal unexpected connections between inflammation, metabolism, and the cytoskeleton. We measured phenotypic variation in over 400 HapMap lymphoblastoid cell lines following infection with Salmonellae. Multiple read-outs of infection and host response were measured and genome-wide association of these traits revealed cis-eQTLs associated with pro-inflammatory Salmonella-induced cell death. One of the SNPs was associated with expression of APIP, an enzyme in the methionine salvage pathway. The direction of the association, RNA interference, and overexpression studies indicated that APIP is a previously uncharacterized inhibitor of inflammatory cell death. Furthermore, the precursor to the methionine salvage pathway, methylthioadenosine, was also demonstrated to regulate inflammatory cell death. A second SNP was associated with expression of an isoform of β-tubulin. Experimental studies demonstrated this protein inhibits inflammatory cell death as well, and may provide clues as to the mechanism of the microtubule-depolymerising drug colchicine in treatment of gout and other inflammatory diseases. Our results demonstrate novel insights into basic cell biology with clinical implications that are emerging from the application of GWAS to cellular phenotypes.

An integrative approach to mapping complex, glycemic traits in skeletal muscle tissue. *S. Keildson[1], J. Fadista[2], C. Ladenvall[2], A.K. Hedman[1], H-F. Zheng[3], L. Groop[2], P. Franks[2], O. Hansson[2], C.M. Lindgren[1], the Muther Consortium.* 1) Wellcome Trust Ctr, Roosevelt Drive, Oxford, OX37BN, United Kingdom; 2) Lund University Diabetes Centre CRC, Malmö University Hospital, Jan Waldenströms gata 35, Malmö, Sweden; 3) Department of Medicine, Human Genetics, Epidemiology and Biostatistics, Jewish General Hospital, McGill University, Montreal, Quebec, Canada.

Integrating genome-wide assays of gene expression and genome-wide genotype data may advance our understanding of the biological mechanisms related to diseases and traits, by pinpointing genetic variation in gene expression associated with disease. The MuTHER (Multiple Tissue Human Expression Resource) project lends itself to such analyses, as it includes SNP-genotyping, mRNA and miRNA expression, methylation and metabolite profiling data from a range of tissues collected from well-phenotyped female twins. Since skeletal muscle is an important peripheral tissue in insulin resistance, we examined variation in gene expression, from 9641 genes, associated with various glycemic traits (fasting glucose, fasting insulin, homeostasis model assessment-estimated insulin resistance (HOMA-IR) and HOMA-IR adjusted for BMI (HOMA-IRadjBMI)), as well as metabolic traits (BMI) in 39 skeletal muscle tissue samples, available as a part of MuTHER. We looked for associations between gene transcripts and phenotypes using a linear mixed-effects model adjusted for age, batch and twin structure. At a false discovery rate (FDR) of 5%, we found that 117 transcripts in skeletal muscle were associated with fasting glucose levels (pvalue<8.3E-04), 21 with fasting insulin levels (p-value<1.2E-04), 10 with HOMA-IR (p-value<6.2E-05) and 790 transcripts were associated with HOMA-IR(adjBMI) (pvalue<6.2E-04). Furthermore, 80 transcripts were associated with BMI (p-value<5.3E-04). Using the same mixed-effects model and 1000 Genomes imputed data, we then looked for associations between gene expression levels and genomic variants residing within a 1Mb window of the transcript. In total, 190 (~2%) transcripts were shown to have significant cis-regulatory effects (FDR < 5%, p-value<5.09E-06). When overlapping the results from these two analyses, we found that 1, 3 and 20 significant cis-eQTLs were also significantly associated with HOMA-IR, glucose and HOMA-IR(adjBMI) respectively, highlighting the potential importance of genetic control mechanisms on complex trait variance. To increase sample size and power, we will meta-analyse our data with similar data from the Malmo Men (n=38) and Malmo intervention (n=39) studies. Our study will facilitate mapping the genetic architecture of complex traits related to skeletal muscle.

2188T

cis-eQTL analysis of dysregulated interferon-pathway genes identifies OAS1 as a novel candidate for susceptibility to Sjögren's syndrome. *H. Li[1,2], J.A. Ice[1], J.A. Kelly[1], I. Adrianto[1], S.B. Glenn[1], K.S. Hefner[3], E.S. Vista[4], D.U. Stone[2], R. Gopalakrishnan[2], G.D. Houston[2], D.M. Lewis[2], M.D. Rohrer[5], P. Hughes[5], J.B. Harley[6,7], C.G. Montgomery[1], J. Chodosh[8], J.A. Lessard[9], J-M. Anaya[10], B.M. Segal[11], N.L. Rhodus[5], L. Radfar[2], M.B. Frank[1], R.H. Scofield[1], C.J. Lessard[1,2], K. Moser Sivils[1,2].* 1) Arthritis & Clinical Immunology, OMRF, Oklahoma City, OK; 2) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Hefner Eye Care and Optical Center, Oklahoma City, OK; 4) University of Santo Tomas Hospital, Philippines; 5) University of Minnesota, Minneapolis, MN; 6) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 7) Department of Veterans Affairs Medical Center, Cincinnati OH; 8) Harvard Medical School, Boston, MA; 9) Valley Bone and Joint Clinic, Grand Forks, ND; 10) Universidad del Rosario, Bogotá, Colombia; 11) Hennepin County Medical Center, Minneapolis, MN.

Sjögren's syndrome (SS) is a progressive autoimmune exocrinopathy present in 0.7-1% of Europeans characterized by symptoms of dry eyes and mouth. Dysregulation of interferon-related pathways is well documented in SS and related disorders, like systemic lupus erythematosus. We performed cis-expression quantitative trait loci (c-eQTL) analysis in 132 cases to identify genetic variants regulating proximal IFN-regulated genes through integration of gene expression data with genotypes from a SS genome-wide association study (GWAS). To further characterize the expression of interferon-inducible (IFI) genes in SS, we first performed global gene expression profiling (GEP) in peripheral blood on 48803 probes using the Illumina HumanWG-6 v3.0 Expression BeadChip in 201 SS cases and 76 healthy controls. Analyses were performed in the R Bioconductor suite. After quality control, 20342 probes (in 15607 genes) were quantile normalized and Welch's t-tests, q-values, and fold changes (FC) were calculated. Differentially expressed (DE) genes between cases and controls were selected by: q<0.05 and FC >1.25 or <0.87. Pathway analysis for DE genes was carried out in Genomatix. Thirty-seven IFI genes were among the top 123 DE genes (q<1x10E-10), with interferon alpha-inducible protein 27 (IFI27) demonstrating the greatest fold change (FC=77.25; q=1.88x10E-14). Among pathways in which DE genes were identified, pathways involved in type I interferon-mediated signaling (31/70 genes; p=5.56x10E-14) and viral transcription and genome expression (49/140 genes; p=3.25x10E-16) were highly significant. We selected 19 (q<0.001) DE genes involved in type I interferon-mediated signaling pathways for use as phenotypic traits in eQTL analyses. Single nucleotide polymorphisms (SNPs) from GWAS data spanning 20kb up- and downstream of the target genes were tested for genetic association with expression levels by linear regression. C-eQTL analysis identified significant association of 23 correlated (r2>0.8) SNPs within and flanking the IFI gene 2'-5'-oligoadenylate synthetase 1 (OAS1) with expression levels. Evidence for association of the OAS1 SNP rs10774671, a splice-site polymorphism associated with multiple sclerosis and type 1 diabetes, increased from p=6.99x10E-3 in our SS GWAS (424 cases/2120 controls) to p=5.1x10E-8 in c-eQTL analysis. These results provide a promising novel candidate locus in and around OAS1 for future functional studies to better understand SS pathophysiology.

Integrative Genomic Analysis Identifies Multiple Loci Influencing the Human Immune Response to Influenza Vaccination. *L.M. Franco[1,2], K.L. Bucasas[1], J.M. Wells[3], D. Nino[3], X. Wang[1,4], G.E. Zapata[1,4], N. Arden[5], J.M. Quarles[5], M.S. Bray[4], R.B. Couch[2,3], J.W. Belmont[1,4], C.A. Shaw[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Medicine, Baylor College of Medicine, Houston, TX; 3) Department of Molecular Virology and Microbiology, Baylor College of Medicine, Houston, TX; 4) Children's Nutrition Research Center, Baylor College of Medicine, Houston, TX; 5) Department of Microbial and Molecular Pathogenesis, Texas A&M University, College Station, TX.

Identification of the host genetic factors that contribute to variation in vaccine responsiveness may uncover important mechanisms affecting vaccine efficacy. To identify these, we designed an integrative genomic analysis (IGA) study combining genetic, transcriptional, and antibody response data in humans immunized with a seasonal influenza vaccine. We enrolled a discovery cohort (n = 119) and an independent validation cohort (n = 128) of ethnically homogeneous healthy adults. Genome-wide genotyping was performed. Global gene expression was measured in peripheral blood before and on days 1, 3, and 14 after vaccination. Serum antibody titers were measured before and on days 14 and 28. We show that this study design is powerful in identifying loci that exhibit a transcriptional response to vaccination, genetic regulation of expression (cis eQTL), and correlation between expression and the antibody response. Using mixed-model regression, we identified 945 SNP-transcript pairs, corresponding to 135 genes, with significant genotype-expression association (genotype effect $p < 5 \times 10^{-8}$) and a transcriptional response to the vaccine (day effect $p < 0.05$) in the discovery cohort. Of these, 114 genes were validated in the second cohort (genotype effect $p < 0.05$ and day effect $p < 0.05$), of which 97 would pass equally stringent thresholds in both cohorts (genotype effect $p < 5 \times 10^{-8}$, day effect $p < 0.05$). Twenty-three of these genes also showed significant correlation with the antibody response in both cohorts. Remarkably, a majority of these genes encodes proteins involved in intracellular transport and/or antigen processing. We hypothesized that at some loci the magnitude of the genetic effect could be different before and after the environmental perturbation. This type of effect, which would not be observed in a cross-sectional eQTL or genome-wide association study, could be explicitly examined with our longitudinal data. We found that an increase in the expression variance explained (R_g^2) after vaccination was a general feature of the loci identified. QTL analysis of the antibody response conditioning on expression supports a direct causal role in vaccine immunogenicity for the genes identified. We conclude that variation at these loci significantly influences the human immune response to the vaccine. More broadly, we demonstrate that a longitudinal IGA study design is more efficient in complex-trait gene identification than current cross-sectional methods.

2190W

Barrett's esophagus and esophageal adenocarcinoma show substantial polygenetic variance, with genetic overlap between the diseases. *W.E. Ek[1], D. Whiteman[2], D.M. Levine[3], T.L. Vaughan[4], S. MacGregor[1], in behalf of BEAGESS study investigators.* 1) Statistical Genetics, Queensland Institute of Medical Research, Herston, Queenslans, Australia; 2) Cancer Control Group, Queensland Institute of Medical Research, Herston, Queensland, Australia; 3) Department of Biostatistics, University of Washington, Seattle, Washington, USA; 4) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, Washington, USA.

Most complex diseases are regulated by many causative variants that independently show only a small effect on the trait. These could easily be missed in a standard genome-wide association study (GWAS). However, even though the individual effect of each SNP is low, collectively they might account for a substantial proportion of variation. This implies that, as a complement to GWAS, we can gain information about the genetic architecture by combining effects across SNPs. Our aim was to estimate the variance explained (heritability) for esophageal adenocarcinoma (EA), a rapidly fatal cancer, and its main precursor Barrett's esophagus (BE) when including all genotyped SNPs. We used a new method developed to estimate variance explained for case-control studies of unrelated individuals. We also examined if EA and BE share a similar genetic background by using a large number of SNPs in one trait to predict the risk of developing the other trait. Systematic evaluation of the overlap between the traits is based on “profile” scores, for which we calculated the estimated relative risk for every SNP based on a `discovery' set (BE) and then tested this “profile' in a target set of interest (EA). Our results, based on 1503 EA cases, 2383 BE cases and 3202 controls, show a significant variance explained for both EA (0.28, se= 0.05) and BE (0.39, se=0.05) when including all genotyped SNPs. We also found a substantial polygenetic overlap between EA and BE (p=1e-12). Given this overlap, we expect combining EA and BE as a larger case set versus all controls will improve power to map some loci. Examination of other risk factors showed that the genetic overlap was larger for patients with low BMI and non smokers. These results suggest that the genetic architecture for both diseases consist of many common variants, each of small effect, and the diseases seem to have a shared genetic background.

2191T

Rare germline copy number variants in Hodgkin lymphoma families. *M. Rotunno, M.L. McMaster, L.R. Goldin.* NIH/NCI/DCEG, Rockville, MD.

Hodgkin lymphoma (HL) shows strong familial aggregation but no major susceptibility genes for HL have been identified to date. Studies based on detection of copy number variation (CNV) are promising for identifying disease susceptibility genetic variants. The goal of this study was to identify high-penetrance CNVs in HL-prone families. Using array comparative genomic hybridization (aCGH) from © Oxford Gene Technology, we measured genome-wide germline CNVs in 45 HL cases or obligate carriers from 12 HL-prone families with three or more affected members (5 cases in 3 families, 4 cases in 4 families, and 3 cases in 5 families). The CytoSure Interpret software was used to analyze the CNV data. Each HL case presented with 67 to 150 CNVs (median 101), of average size 1.1Mb (1Kb to 45.3Mb). According to a dominant segregation model, between 10 and 32 (median 13) CNVs were shared by all cases or obligate carriers within each family. Since high-penetrance variants are likely uncommon in the general population, we then filtered out CNVs with frequency larger than 5% based on information from the Toronto Database of Genomic Variants (DGV). We thus identified 3 to 16 (median 8) rare shared CNVs per family, for a total of 56 unique CNVs (29 gains and 27 losses). Thirty-nine of these CNVs included genes, some of which are known to be involved in cancer. Forty-five of the identified CNVs were potentially novel, as they were not annotated in DGV. Thirty-five (33 novel) CNVs occurred in multiple families. In particular, a 24Kb CNV loss (DGV frequency < 3%) on chromosome 3p11 involving EPHA3, a tyrosine-protein kinase receptor gene, was shared by two HL families. CNVs in this gene have been associated with multiple types of hematological malignancies in previous somatic studies. In addition, CNV gains in 10q22.1, 6q16.3, and 3q26.1 were shared by 7, 9, and 11 families, respectively. In conclusion, our results, if validated, indicate that rare germline CNVs may play a role in familial HL risk.

2192F

The proportion of heritability of type 2 diabetes estimated through GWAS that is attributable to functional genetic variation. *J.M. Torres[1], E.R. Gamazon[2], S.K. Das[5], H.M. Highland[4], G.I. Bell[3], C.L. Hanis[4], N.J. Cox[2].* 1) Committee on Molecular Metabolism and Nutrition, University of Chicago, Chicago, IL; 2) Section of Genetic Medicine, University of Chicago, Chicago, IL; 3) Department of Medicine, University of Chicago, Chicago, IL; 4) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX; 5) School of Medicine, Wake Forest University, Winston-Salem, NC.

The growing prevalence of non-insulin dependent diabetes mellitus or type 2 diabetes (T2D) is a major health concern in the United States and disproportionately affects Mexican Americans. For example, Starr County, TX, where 97% of residents identify themselves as Hispanic, reports the highest diabetes-specific morbidity and mortality of any county in Texas despite being only the 53rd largest of Texas' 254 counties. Despite the identification of more than 60 highly significant and reproducibly associated variants for T2D, these variants do not, even collectively, account for much of the narrow sense heritability to T2D. Here, we apply genome-wide complex trait analysis (GCTA) software developed by Visscher et al. to a dataset consisting of 1,273 adult residents from Starr County (837 diabetic cases, 436 normoglycemic controls) genotyped on the Affymetrix Genome-Wide SNP Array 6.0 in order to estimate the phenotypic variance explained by the SNPs interrogated in the GWAS. After performing quality control measures and correcting for sex, BMI, and age at diagnosis, we applied the restricted maximum likelihood analysis (REML) implemented in GCTA and report that ~37% of the phenotypic variance in our dataset is explained by the additive genetic contribution of the interrogated SNPs. This quantity is approximately four times the amount of heritability for T2D often attributed to SNPs implicated through GWAS. We then extracted a subset of SNPs from our dataset that were mapped as expression quantitative trait loci (eQTLs) in either human skeletal muscle or adipose tissue and determined that the proportion of the total phenotypic variation attributable to these SNPs is significant. Furthermore, we applied analyses to validate that these trends are robust to population stratification in this admixed population. These results support the conclusion that a substantial fraction of the heritability of T2D estimated from the variation interrogated in GWAS can be attributed to a subset of genetic variation that impacts the function of metabolic tissues relevant to T2D.

2193W

Proportion of heritability and implications of pleiotropy attributable to GWAS hits for ECG phenotypes in the Erasmus Rucphen Family Study. *A. Isaacs[1,2], C. Silva[1,3], J.A. Kors[4], B.A. Oostra[1,2], C.M. van Duijn[1,2].* 1) Dept. of Epidemiology, Erasmus MC Rotterdam, Rotterdam, the Netherlands; 2) Centre for Medical Systems Biology, Leiden, the Netherlands; 3) Dept. of Biomedical Sciences, Universidad del Rosario, Bogotá, Colombia; 4) Dept. of Medical Informatics Erasmus MC Rotterdam, Rotterdam, the Netherlands.

Electrocardiogram (ECG) parameters are important measures of cardiac electrophysiology and provide crucial information on cardiac function. Genome-wide association studies (GWAS) achieved remarkable success over the past few years in locating genetic loci influencing a broad variety of ECG phenotypes, such as QRS complex duration, PR interval, and QT interval. Despite these advances, however, large portions of the variability of these traits remain unexplained by either genetic or environmental determinants, giving rise to the so-called "missing heritability" problem. The Erasmus Rucphen Family Study (ERF), consisting of more than 3000 individuals descendant from a limited number of founders approximately 250 years ago and connected in a single large pedigree, provided an excellent opportunity to directly estimate the effects of genes on heritability (h^2). Participants were genotyped using Illumina 318/370K single nucleotide polymorphism (SNP) arrays and were extensively phenotyped at baseline, which included 12-lead ECG measurements. Variance component methodology, as implemented in the SOLAR software package, was used to estimate the h^2 of several ECG phenotypes (QRS, QT and PR) and to determine the proportion of h^2 attributable to common genetic variants discovered in GWAS. Differences between models were tested using likelihood ratio tests, with degrees of freedom equivalent to the number of SNPs included in the saturated models. In models adjusted for age, gender, body-mass index, height and heart rate, highly significant ($P < 1.0x10^{-7}$) h^2 (± standard error) were observed for QRS (0.34 ± 0.06), PR (0.38 ± 0.06) and QT (0.34 ± 0.07). Inclusion of SNPs determined from GWAS for each trait decreased the estimated h^2 and increased the proportion of variance attributable to covariates (i.e. SNPs). GWAS SNPs decreased h^2 by 0.05 (15%, $P = 0.001$) for QRS, by 0.01 (1.6%, $P = 1.5x10^{-5}$) for PR, and by 0.09 (27%, $P = 2.2x10^{-15}$) for QT. The inclusion of all ECG SNPs (e.g. including QRS and QT SNPs in the PR model) further increased the explained proportion of h^2 by 0.2% for QRS ($P = 0.05$) and 8% for PR ($P = 5.7x10^{-4}$); for QT this difference (5.7%), although large, was non-significant. These results provide good estimates of the proportion of heritability attributable to common variants discovered thus far via GWAS. The inclusion of additional SNPs found for other ECG traits also increased the explained h^2, suggesting pleiotropic effects yet to be seen in GWAS.

The role of genes and life-course-related processes in onset of common diseases in late life. *A. Kulminski, I. Culminskaya, K. Arbeev, S. Ukraintseva, L. Arbeeva, A. Yashin.* Duke University, Durham, NC.

Complexity of aging-related diseases with post reproductive manifestation tempers progress in genome-wide association studies (GWAS) and contributes to the problem of missing genetic variance. Different strategies to address this problem are extensively discussed (Nat Rev Genet. 2010; 11, 446-450). One issue was that this problem is overblown. This presentation provides evidences supporting this view. We use the Framingham Heart Study original (FHS) and Offspring (FHSO) cohorts to elucidate whether life-course-related processes can substantially impact the role of lipid-related genes, the apolipoprotein E (APOE) e2/3/4 polymorphism and the APOB rs1042034 (C/T) SNP, in onset of cardiovascular disease (CVD). It is shown that the APOE e4 allele and the rs1042034 minor allele homozygote (CC) can play detrimental, neutral, and protective role in etiology of CVD in different ages and environments in sex-specific fashion. The APOE e4 allele is primarily associated with CVD in women. The e4 allele confers risk of CVD in younger-old women ($RR_{\leq 75yrs}$=1.73, p=1.4×10^{-3}) but it can be cardio-protective in older women (RR_{76+yrs}=0.68, p=0.021) in the same FHS cohort. Disregarding the role of aging-related heterogeneity results in insignificant effect (RR=0.84, p=0.143). The role of the e4 allele can change through generations which is a proxy for environment; the e4 allele in the FHSO only confers risks of CVD in older women ($RR_{>64yrs}$=1.57, p=6.6×10^{-3}). Just increasing the sample size by pooling data from the FHS and the FHSO cohorts merely scales the life-course-related heterogeneity in parallel (RR= 1.03; p=0.701). The APOB CC homozygote is associated with CVD in men. It confers highly significant risk of CVD in the FHS (RR=2.18, p=4.5×10^{-5}). In the FHSO, the CC homozygote can be cardio-protective although this association is not significant (RR=0.78, p=0.352). Pooling data from both cohorts makes the estimates to be significantly worse than in the FHS alone (RR=1.30, p=0.088). The observed associations are stable longitudinally ensuring that they are not the result of stochastic realizations at a specific assessment and robust to longitudinal attrition of the samples at CVD risks. The results suggest that life-course-related processes can play a key role in genetic predisposition to healthspan. More detail systemic analyses beyond those offered in standard GWAS will substantially advance the progress in the field.

Ancestry directed sequence analysis for rare variants in admixed populations. *E. Ziv[1,2,3], D. Hu[1,3].* 1) Medicine, UCSF, San Francisco, CA; 2) Helen Diller Family Comprehensive Cancer Center, UCSF, San Francisco, CA; 3) Institute for Human Genetics, UCSF, San Francisco, CA.

Genome wide association studies (GWAS) have only identified a fraction of the heritability of most complex traits. Much of the remaining heritability may be due to rare variants that are not well tagged by arrays commonly used in GWAS. Here we evaluate approaches to identifying rare variants in populations of mixed ancestry. Our approach is motivated by datasets from populations of mixed ancestry that have already undergone GWAS and where a majority of heritability remains unexplained. First, we demonstrate using data from sequencing studies that rare variants in an admixed population are likely to be private to one ancestral population. Then we demonstrate that such private alleles will create deviations in locus specific ancestry in cases. Finally, we consider strategies for leveraging the locus specific ancestry data in sequencing studies. We note that selection of individuals based on their locus specific ancestry can substantially increase the power/efficiency of sequencing analysis. We also examine the case where overall individual ancestry is associated with the trait of interest. We demonstrate that a selection strategy that identifies patients with discordance between local and global ancestry can be more powerful than one which focuses on locus specific ancestry only.

2196W

The Convergence of Functional Genomics, Heritability Estimation and Polygenic Modeling: Emerging Spectrum of Allelic Variation in Bipolar Disorder. *E.R. Gamazon[1], H.K. Im[1], C. Liu[2], D.L. Nicolae[1], N.J. Cox[1].* 1) University of Chicago, Chicago, IL, USA; 2) University of Illinois, Chicago, IL, USA.

It is widely held that a substantial genetic component underlies Bipolar Disorder and other neuropsychiatric disease traits. Recent efforts have been aimed at understanding the genetic basis of disease susceptibility, with genome-wide association studies (GWAS) unveiling some promising associations. Nevertheless, the genetic etiology of Bipolar Disorder remains elusive with a substantial proportion of the heritability - which has been estimated by ourselves and others to be 80% (congruent with previous reports based on twin and family studies) - unaccounted for by the specific genetic variants identified by large-scale GWAS. Furthermore, functional understanding of associated loci generally lags discovery. Studies we report here provide considerable support to the claim that substantially more remains to be gained from GWAS on the genetic mechanisms underlying Bipolar Disorder susceptibility, and that a large proportion of the variation in disease risk may be uncovered through integrative functional genomic approaches. We set out to combine recent analytic advances in heritability estimation and polygenic modeling and leverage recent technological advances in the generation of -omics data to evaluate the nature and scale of the contribution of functional classes of genetic variation to a relatively intractable disorder. We identified 2,375 cis-acting eQTLs in cerebellum that account for 36% (s.e. = 0.024) of the heritability, which represents 65% of the total heritability attributable to SNPs interrogated through GWAS. Our findings show that a much greater resolution may be attained than has been reported thus far on the number of common loci that capture a substantial proportion of the heritability to disease risk and that, importantly, the functional nature of contributory loci may be clarified en masse.

2197T

Contributions of cis and trans eQTLs to the heritability of schizophrenia. *C. Jumper[1], E.R. Gamazon[2], A. Konkashbaev[2], C. Liu[3], D.L. Nicolae[1,2,4,5], N.J. Cox[1,2,4].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Section of Genetic Medicine, University of Chicago, Chicago, IL; 3) Department of Psychiatry, University of Chicago, Chicago, IL; 4) Department of Medicine, University of Chicago, Chicago, IL; 5) Department of Statistics, University of Chicago, Chicago, IL.

We estimated the heritability of variants interrogated in a genome-wide association (GWA) study of schizophrenia (NIMH nonGAIN Schizophrenia) and then determined the proportion of that heritability attributable to cis and trans-regulatory SNPs (eQTLs) in human brain using mixed-effects models. While the heritability estimated for all SNPs is 0.86, the heritability for 311973 cis eQTLs is 0.61, or 71% of the overall heritability. The heritability for 41404 trans eQTLs is 0.20, or 23% of the overall heritability. The total observed heritability of schizophrenia is consistent with other study estimates of approximately 0.8. This study clearly traces the genetic heritability due to identification of cis and trans components, demonstrating how future work would be able to estimate heritability partitioned by gene class. This should enable further insight into the mechanism of schizophrenia through identification of important genetic susceptibility regions and pathways.

The contribution of sequencing based GWAS in explaining the missing heritability of quantitative traits. *E. Porcu[1,2,3], C. Sidore[1,2,3], M. Steri[1], F. Busonero[1,3], A. Mulas[1], M. Dei[1], S. Lai[1], MG. Piras[1], S. Naitza[1], D. Schlessinger[4], G. Abecasis[3], S. Sanna[1], F. Cucca[1,2].* 1) Istituto di Ricerca Genetica e Biomedica (IRGB), CNR, Monserrato, Italy; 2) Dipartimento di Scienze Biomediche, Università di Sassari, SS, Italy; 3) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 4) Laboratory of Genetics, NIA, Baltimore, MD, United States.

Genome-wide association studies (GWAS) have yielded valuable insights into the genetic architecture of complex quantitative traits, but have often left much of the trait heritability unexplained. To assess the hypothesis that a portion of unexplained heritability can be due to variants not included or poorly tagged in common genotyping arrays and in the HapMap dataset, we analyzed 6,145 individuals from the SardiNIA study, for a set of ~8 million variants, directly genotyped or imputed with a reference panel derived from whole-genome low-pass sequencing of 1,146 Sardinian individuals, focusing on four quantitative traits: hsCPR, IL-6, MCP-1 and ESR. When considering only loci previously identified by us in the same cohort, for the first two traits we observed no improvement in the heritability, the top variants resulting from this analysis being in strong linkage disequilibrium (LD) with those already described. By contrast, for MCP-1 and ESR, we observed different leading variants not in LD with those found previously, as well as additional independent signals, which led to an increase in the heritability explained from 9.4% to 11.6%, and from 2.7% to 3.9%, respectively. The imputation of variants detected by sequencing also contributed to the identification of two novel loci for both MCP-1 and hsCRP. The inclusion of these markers further increased the heritability explained to 12.5% for MCP1, and from 5.0% to 6.7% for hsCRP. Our results thus indicate that the forthcoming sequencing based GWAS will contribute to better account for the heritability at previously described loci, and will further help to explain the missing heritability with the identification of novel associations.

2199W

Polygenic analysis shows that low frequency SNPs confer early onset myocardial infarction risk. *E. Stahl[1,2], R. Do[2,3], B. Vilhjamsson[2,4], N. Stitziel[3], S. Sunyaev[2,5], A. Price[2,4], R.M. Plenge[1,2,5], S. Kathiresan[2,3], S. Raychaudhuri[1,2,5].* 1) Dept. Medicine, Div. Rheumatology, Immunology and Allergy, Brigham and Women's Hospital, Boston, Massachusetts, USA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts, USA; 3) Center for Human Genetic Research and Cardiovascular Research Center, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts, USA; 4) Dept. Biostatistics, Harvard School of Public Health, Boston Massachusetts, USA; 5) Dept. Medicine, Div. Genetics, Brigham and Women's Hospital, Boston, Massachusetts, USA.

Myocardial infarction (MI) and coronary artery disease (CAD) is a heritable trait that is caused by many loci. Recent genome-wide association studies have identified common variants associated with MI/CAD in multiple loci (Schunkert et al 2011 Nature Genetics); however, these loci explain only a small proportion of the heritability of MI/CAD, and many more false negative loci have not achieved the stringent statistical evidence required for discovery. Studies have identified a polygenic component of heritability, consisting of thousands of associated SNPs in GWAS data, for several complex diseases including MI (Stahl et al 2012 Nature Genetics). Another component of heritability could be rare variants that are not well captured by GWAS data. If there are enough variants with sufficient allele frequency (e.g. 0.1-5%) and effect size, these could contribute greatly to phenotypic variance in the population. Resequencing studies have identified low frequency SNPs that confer risk for MI, such as the PCSK9 R46L nonsynonymous variant; however, it is currently unknown whether these variants make up a substantial proportion of the missing heritability for complex disease.

We have imputed MIGEN and WTCCC CAD GWAS data into both common and low frequency SNPs using reference panels from whole genome and exome sequencing data (1000G CEU Dec 2010 release, and phased exome sequence+GWAS data) and performed heritability and polygenic risk score analysis for MI and CAD. We show that addition of low-frequency variants increases linear mixed model heritability estimates (MAF>5%, common SNP h2=0.38, P=3e-15; MAF>0.5%, h2=0.44, P=2.5e-15; 0.5%<MAF<5%, h2= 0.085, P=0.04), and quantify the overall contributions of SNPs from HapMap, 1000G and the exome. Furthermore, we find greater polygenic risk score prediction R2 for genic (R2=0.018, P=7e-16) versus intergenic (R2=0.0039, P=2e-4) SNPs, but not of nonsynonymous (R2=0.008, P=7e-8) vs other genic (R2=0.018, P=8e-16) SNPs. These results demonstrate that low-frequency variants make a detectable contribution to MI/CAD heritability, and help to better understand the genomic structure of their contribution.

2200T

Ubiquitous polygenicity of human complex traits: genome-wide analysis of 49 traits in Koreans. *J. Yang[1], T. Lee[2], J. Kim[3], S. Cho[4], P. Visscher[1,5], H. Kim[2,3,4].* 1) University of Queensland Diamantina Institute, University of Queensland, Brisbane, Queensland, Australia; 2) Department of Agricultural Biotechnology, Seoul National University, Seoul, Korea; 3) Interdisciplinary Program in Bioinformatics, Seoul National University, Seoul, Korea; 4) C&K Genomics, Seoul, Korea; 5) The Queensland Brain Institute, The University of Queensland, Brisbane, Queensland 4072, Australia.

Recent studies in population of European ancestry have shown that 30-50% of heritability for human complex traits such as height (Yang et al. 2010) and body mass index (Yang et al. 2011), and common diseases such as schizophrenia (Lee et al. 2012) and rheumatoid arthritis (Stahl et al. 2012) can be captured by common SNPs, and that genetic variation can be attributed to chromosomes, in proportion to their length. Using genome-wide estimation and partitioning approaches, we analyzed 49 human quantitative traits, many of which are relevant to human diseases, in 7,170 unrelated Korean individuals genotyped on 326,591 SNPs. For 43 of the 49 traits, we estimated a significant (P < 0.05) proportion of variance explained by all SNPs (h2G). On average across 47 of the 49 traits for which the estimate of h2G is non-zero, 13.4% (range of 3.4% to 31.6%) of phenotypic variance can be explained by all the SNPs being analysed, or approximately one-third (range of 7.8% to 76.8%) of narrow sense heritability. In contrast, on average across 25 of the 49 traits, the top associated SNPs at genome-wide significance level (P < 5e-8) explain 1.5% (range of 0.5% to 3.8%) of phenotypic variance. The majority (~92%) of explained variation estimated from all SNPs is captured by the SNPs with p-values < 0.031 in single SNP association analyses. Longer genomic segments tend to explain more phenotypic variation, with a correlation of 0.78 between the estimate of variance explained by individual chromosomes and their physical length. This correlation was stronger (0.81) for intergenic regions. Despite the fact that there are a few SNPs with large effects for most traits, these results suggest that polygenicity is ubiquitous for most human complex traits, and that a substantial proportion of heritability is captured by common SNPs.

2201F

Prediction of human height with large panels of SNPs - insights into genetic architecture. *Y.C. Klimentidis[1], A.I. Vazquez[1], G. de los Campos[2].* 1) Energetics, University of Alabama at Birmingham, Birmingham, AL; 2) Biostatistics, University of Alabama at Birmingham, Birmingham, AL.

Prediction of complex traits from genetic information is an area of major clinical and scientific interest. Height is a model trait since it is highly heritable and easily measured. Substantial strides in understanding the genetic basis of height have recently been made through genome-wide association studies (GWAS), and whole-genome prediction (WGP) which fits thousands of SNPs jointly. Here, we attempt to gain insight into the genetic architecture of human height by examining how WGP accuracy is affected by the choice of single-nucleotide polymorphism (SNPs). Specifically, we compare the prediction accuracy of models using: 1) SNPs selected based on the `top hits' of the GIANT consortium meta-analysis for height at different p-value thresholds, and 2) SNPs in genomic regions that surround the most significant `top hits'. We use the Framingham Heart Study and GENEVA datasets, imputed up to 10 million SNPs with 1000 Genomes reference data. The predictive accuracy of each model was evaluated in cross-validation. We find that prediction accuracy increases up to a certain point with the inclusion of more `top hits' from the GIANT study, that including SNPs from the regions surrounding `top hits' contributes minimally to prediction accuracy, and that prediction accuracy increases with the size of the training dataset. Finally, we find that prediction accuracy is greatest for individuals at the phenotypic extremes of height. Our results suggest that improvement of genomic prediction models will require the use of information from a large number of selected SNPs, and that these models may be most useful at the phenotypic extremes.

Height has an extremely polygenic pattern of inheritance. Genome-wide association studies (GWAS) have revealed hundreds of common variants that are associated with human height at genome-wide levels of significance. Each of these common variants has a very modest effect, and only a small fraction of phenotypic variation can be explained by the aggregate of these common variants. In this large study of African-American men and women, we genotyped and analyzed 975,519 autosomal SNPs across the entire genome using a variance components approach, and found that 46.4% of phenotypic variation can be explained by these SNPs in a sample of 9,779 evidently unrelated individuals. We noted that in two samples of close relatives defined by probability of identical-by-descent (IBD) alleles sharing (Pr (IBD=1)>=0.3 and Pr (IBD=1)>=0.4), the proportion of phenotypic variation explained by the same set of SNPs increased to 75.5% (se: 14.8%) and 70.3% (26.9%), respectively. We conclude that the additive component of genetic variation for height may have been overestimated in earlier studies (~80%) and argue that this proportion also includes variation from epistatic effects. Using simulation, we showed that by using common SNPs that are only weakly correlated with causal SNPs, the model could explain a large proportion of heritability. We therefore argue that the heritability estimate from the variance components approach is not necessarily the variation explained by a given set of SNPs, but also possibly reflects distant relatedness between nominally unrelated participants. Finally, we explored the performance of the variance components approach and concluded that the approach fails when a large number of independent variables are included in the model as the structure of the two components becomes similar. Thus some degree of population stratification seems to be required in order for the method to perform well for very large numbers of SNPs; however when modest stratification is present there is a risk of miss-attribution of effects of unmeasured (and untagged) variants to measured variants.

2203T

Optimizing risk stratification to discover novel neuroblastoma genes. *A. Goldenberg[1,2], B. Wang[1], S. Diskin[4], J.M. Maris[4], M. Irwin[3].* 1) Genetics and Genome Biology, SickKids Research Institute, Toronto, ON, Canada; 2) Department of Computer Science, University of Toronto, Toronto, ON, Canada; 3) Cell Biology, SickKids Research Institute, Toronto, ON, Canada; 4) Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA.

Heterogeneity in the clinical definition of complex traits is one of the major obstacles to identifying genetic risk factors. Neuroblastoma (NB), a sympathetic nervous system tumor is the most frequent cause of pediatric cancer-related deaths. The classification for NB into low (LR), intermediate (IR) and high risk (HR) groups is based on age, tumor stage, histology, MYCN status, ploidy, and 11q aberrations. However, each subtype is still very heterogeneous. Importantly, for the HR group the classification provides little guidance for estimating survival and response to therapy. Importantly, we and others hypothesize that there is significant NB germline variation based on 1) early age of onset; 2) fairly quiet somatic landscape of NB. Thus, we have developed a non-parametric, unsupervised method to identify homogeneous clusters of patients (NB subtypes) and the associated genetic variants. We first transform the data into patient similarity (e.g using correlation). We then use a network fusion method to iteratively combine normalized Laplacians of the patient phenotype and genotype networks. We introduce a new feature (SNP) ranking score that is able to identify local contribution for each feature. A feature is identified as important if it is associated with one or more patient clusters. Our simulations show that our method is significantly more powerful than other approaches. Considering IR and HR neuroblastoma patient groups, without assigning these labels to the method, we identified 4 novel clusters - two for HR and two for IR patients. For example, one HR cluster was associated with amplified MYCN status, earlier NB onset and several variants in the T-cell activating gene CD28, while a second HR cluster was associated with MYCN non-amplification and a previously detected variant in BARD1 (Capasso et al, Nat Gen, 2009). The identified candidate SNPs are currently being analyzed for functional significance in vitro and in vivo. Our methodology has several advantages over existing Genome Wide Association methods: 1) it does not require knowledge of disease subtypes; 2) works with a large number of discrete and continuous phenotypes; 3) highly scalable; 4) robust to very large numbers of irrelevant features (SNPs); 5) can be easily applied to any genomic data in a p>>n setting, (p=number of features, n=number of samples), to identify the intrinsic clustering in the data and the small set of features that drive the coherence within those clusters.

2204F

Correlations between associated SNPs cause upward bias in whole-genome based heritability estimation. *C. Li[1], C. Yang[2], J. Ferguson[2], J. Cho[3,4], H. Zhao[2].* 1) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 2) Department of Biostatistics, Yale School of Public Health, New Haven, CT; 3) Department of Genetics, Yale University, New Haven, CT; 4) IBD Center, Division of Gastroenterology, Department of Medicine, Yale University, New Haven, CT.

Although results from initial genome wide association studies (GWAS) suggested that much of the heritability for human complex traits is “missing”, a series of papers published recently argued that common SNPs could explain a significant proportion of heritability. The underlying models behind these developments for `heritability' estimate are linear mixed models (LMM) using whole-genome common SNPs. However, these models make implicit assumptions that may not be satisfied by the underlying genetic model that affects the traits of interest. In this presentation, through both theoretical and empirical studies, we demonstrate that the estimates obtained in the published papers could have upward biases due to correlations among SNPs in real data. In addition, we show that smaller sample sizes lead to larger biases when correlations exist. For instance, when strong correlation exists between the SNPs associated with the phenotype, the heritability estimate can be increased from 0.25 to 0.86 and 0.94 when using 2000 and 1000 samples respectively. The bias can be reduced when ultra-stringent marker pruning is used based on linkage disequilibrium (LD). For example, for a Crohn's disease data set, with LD pruning at r^2 cut-off of 0.5, the heritability estimates based on all 2000 samples and 1000 subsamples are 0.28 and 0.32 respectively. However, as we do more stringent LD pruning, these two estimates get closer, eventually converging at 0.11 when we set r^2 cut-off at 0.01. Therefore, the heritability estimates based on GWAS data using the existing LMM methods should be interpreted with caution.

Enrichment of rare non-synonymous variants in 196 lipid-associated genes in subjects with extreme levels of HDL-C: Evidence for rare allele model in etiology of dyslipidemia. *M.M. Motazacker[1,2], J. Peter[1], M. Treskes[3], J.A. Kuivenhoven[4], G.K. Hovingh[2].* 1) Department of Experimental Vascular Medicine, Academic Medical Center, Amsterdam, Netherlands; 2) Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands; 3) Department of Biochemistry, Tergooi Ziekenhuizen Hilversum, The Netherlands; 4) Department of Pathology and Medical Biology, Molecular Genetics, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands.

Plasma HDL-C levels are inversely correlated with cardiovascular disease but the molecular basis and clinical consequences of extreme HDL-C phenotypes are poorly understood. Meta-analysis of genome-wide association studies has revealed that common variants can only explain a minor fraction of heritability of these phenotypes. This study explores the spectrum of rare non-synonymous variants in lipid-associated genes in individuals with extreme HDL-C phenotypes. Eighty individuals with HDL-C levels below the 1st percentile and above the 99th percentile for age and gender (n=40 in each group) were selected from a clinical chemistry database of a community hospital. Using a custom DNA capture library (SureSelect, Agilent), coding regions and exon-intron boundaries of 196 genes implicated in lipid metabolism (lipid geneset) and 78 genes related to coagulation (control geneset) were captured and sequenced on an Illumina HiSeq2000 platform (average coverage >50x). We identified 124 and 136 rare (frequency < 0.5% in European-Americans) non-synonymous variants in lipid geneset present solely in the low-HDL-C or high-HDL-C groups, respectively. In coagulation geneset, 41 variants were identified. The lipid geneset was enriched for rare non-synonymous variants (OR 1.72; p=0.001) when compared to coagulation geneset after correcting for the number of nucleotides sequenced. This enrichment remained significant after excluding 12 well-established HDL-C genes (OR 1.69; p<0.005). Similar comparison of the two genesets in a Dutch general population cohort (n=500) did not reveal a significant difference. Furthermore, lipid geneset in extreme HDL-C cohort was enriched for rare non-synonymous variants when compared to the Dutch general population cohort (OR 1.36; p<0.05). A similar comparison for control geneset did not show a significant difference. Nine percent of the lipid gene variants in extreme HDL-c cohort were coding-indel, nonsense or splice-site variants while 66% concerned missense variants of conserved nucleotides. Eighty percent of the individuals in extreme HDL-C cohort carried at least two rare non-synonymous variants. Our data suggests that in the majority of cases, multiple rare non-synonymous variants in genes with established or proposed roles in lipid metabolism could be responsible for extreme HDL-C phenotypes. Cataloguing the spectrum of such variants may help in better understanding of complex inheritance patterns of the lipid phenotypes.

Missing heritability and the Use of Genomewide Expression Data as an Indicator of Genetic Variation in Genome Scans. *P. Schliekelman, G. Sun, S. Zhang.* Department of Statistics, University of Georgia, Athens, GA.

It has become clear that HapMap-based Genomewide Association Studies (GWAS) are not adequate to capture all of the genetic variation for complex traits. Thus, there is currently great interest in developing alternative strategies for exploring this variation. In this talk, we advocate for the use of gene expression information as an indicator of genetic variation in genome scans. Using simulations and data analysis, we highlight properties of gene expression variation that may give it advantages as an indicator of genetic variation relative to traditional molecular markers. Consider a genetic polymorphism that is causative for a disease and also for variation in expression in some set of transcripts. First, we show that the test of association between gene expression and disease is equivalent to the test of association between a marker and the disease, with variation in gene expression taking the place of variation due to recombination between marker and locus. As the quality of the expression information increases, the power to detect a disease locus converges to the power of a GWAS to detect a marker in complete disequilibrium with the disease locus. However gene expression has two advantages. First, it is much less sensitive to the number of alleles at the locus than is a GWAS. Second, recent evidence suggests that the influence of multiple causative loci may converge on single transcripts or groups of transcripts. If this is the case, then the expression level is an indicator of a multilocus genotype and then the power to detect the association can be increased substantially higher than that for the GWAS. Transcript groups can be linked to specific sequence polymorphisms using eQTL mapping. Simulations and an application to data show that an expression-based approach can have substantially higher power than a standard GWAS for detecting some disease polymorphisms.

2207F

Estimating the proportion of variation in susceptibility to PTSD captured by common SNPs. *C. Yang[1], J. Gelernter[2], C. Li[3], H. Kranzler[4], L. Farrer[5], H. Zhao[6].* 1) Department of Epidemiology and Public health, Yale University, New Haven, CT, 06, New Haven, CT; 2) Department of Psychiatry, Division of Human Genetics, Yale University School of Medicine, New Haven, Connecticut, 06516, USA; 3) Program in Computational Biology, Yale University, New Haven, CT, 06520. USA; 4) Department of Psychiatry 3900 Chestnut Street Philadelphia, PA 19104, USA; 5) Departments of Medicine, Neurology, Ophthalmology, and Genetics and Genomics, Boston University School of Medicine and Departments of Epidemiology and Biostatistics, Boston University School of Public Health, Boston, MA, USA; 6) Department of Epidemiology and Public health and Department of Genetics, Yale University, New Haven, CT, 06520, USA.

Post-traumatic stress disorder (PTSD) is a complex disorder caused both genetic and environmental factors. In order to understand the genetic architecture of PTSD, the subjects were recruited in the course of genetic studies of alcohol, cocaine, and opioid dependence from 5 US sites: Yale, Univ. CT, UPenn, the Medical University of South Carolina, and McLean Hospital of Harvard Medical School. Originally, the number of European-American (EA) subjects having GWAS data was 1974. Subjects who are related, who were determined to be population group outliers, had abnormal heterozygosity rate, and who were missing PTSD phenotype information were excluded, before estimating the proportion of variation in susceptibility to PTSD captured by common SNPs. After quality control, we have 300 cases, 1278 controls and 695,134 SNPs (SNPs with MAF<0.05, HWE<0.0001 are excluded). We have performed both genome-wide single-SNP analysis and genome-wide interactions analysis. We do not find genome-wide significant association signals for both single-SNP analysis and interaction analysis. However, we estimate that about 18% of variation in liability scale (heritability) is captured by these common SNPs collectively. We also show that the variance explained by each chromosome is linearly related to its length, except chromosome 10. Specifically, the marginal signals of chromosome 10 can are very weak (with smallest p-value 10e-05), but it can contribute to about 10% of heritability. Our result indicates that the genetic architecture of PTSD is polygenic (many genes contribute to the trait but with small effects). It also implies that more individual SNP associations can be identified as the sample size increases.

2208W

Simulation-based study investigating "Missing heritability" — a euphemism for the abject failure of modern genomics to elucidate the etiology of complex traits. *J.H. Lee[1, 2, 3], R. Cheng[1, 2], K.M. Weiss[9], T. Hiekkalinna[8, 10], J.D. Terwilliger[4, 5, 6, 7, 8, 10].* 1) Sergievsky Center, Columbia University, New York, NY; 2) Taub Institute, Columbia University, New York, NY; 3) Epidemiology, Columbia University, New York, NY; 4) Genetics and Development, Columbia University, New York, NY; 5) Psychiatry, Columbia University, New York, NY; 6) Columbia Genome Center, Columbia University, New York, NY; 7) Division of Medical Genetics, New York State Psychiatric Institute, New York, NY; 8) Chronic Disease Prevention, Public Health Genomics Unit, National Institute for Health and Welfare, Helsinki, Finland; 9) Anthropology, Pennsylvania State University, State College, PA; 10) Institute for Molecular Medicine - Finland, Helsinki, Finland.

Human geneticists are forced to deal with "missing heritability" when the findings from their experiments explain a small portion of the genetic component of the etiology of complex traits. Is there anything really "missing"? To address the question systematically, we developed two sophisticated software packages: ForSIM and simQTL. ForSIM simulates a phenogenetic relation over evolutionary time with risk alleles arising by mutation and then subjected to natural selection on phenotypes. simQTL simulates a phenogenetic architecture conditional on a set of epidemiological parameters. Both packages also simulate environmental risk factors as well (both discrete and continuous, familial and random). ForSIM simulation under a wide variety of assumptions consistently lead to genes with a large number of risk variants influencing the phenotype. The signal captured by tagSNPs in those genes explain a small portion of the actual heritability when the effects of all variants in the gene are combined. simQTL simulation allows us to examine the effects of common variants in hundreds of polygenes where those genes have varying effect size and minor allele frequency, and they are randomly scattered throughout the genome. These analyses show weak power even when the functional variants themselves are typed, with methods like GCTA explaining a reasonable portion of the actual polygenic variance. However, when markers in LD with the functional variants are simulated instead, much more of the heritability, as expected, appears to be "missing". We took this a step further, and integrated real sequence and GWAS data in the simulations to incorporate real LD structures, and assigned polygenic function to actual variants. When we repeated the process, the results were even worse because cryptic LD as it exists in the real world further blurs the interpretation. Our simulation experiments clearly show that current models failed to model complexity in a reasonable way. Interestingly GWAS argues strongly against CVCD as a model for common disease.

2209T

A quantitative population genetic framework to constrain the range of genetic architectures underlying complex human traits. *V. Agarwala[1,2,3,5], J. Flannick[1,5], S. Sunyaev[1,2,4], D. Altshuler[1,4,5].* 1) Program in Medical & Population Genetics, Broad Institute, Cambridge, MA; 2) Program in Biophysics, Harvard University, Cambridge, MA; 3) Harvard-MIT Division of Health Sciences and Technology, MIT, Cambridge, MA, USA; 4) Department of Genetics, Harvard Medical School, Boston, MA, USA; 5) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA.

The genetic architecture of complex human traits -the number, frequencies, and effect size distribution of causal alleles- determines both the success of disease gene mapping as well as the likely future of personalized medicine. Despite a vast array of genetic studies, debate continues about the relative contribution of rare and common variants to disease heritability. Given the growing body of data for many complex traits, a critical question is: to what extent can empirical data constrain the space of possible trait architectures?

We present a principled, population genetic framework to evaluate disease models in light of three classes of empirical data: a) observed human genetic variation, b) disease prevalence and heritability, and c) prior genetic mapping results. We forward simulate population-scale, full-sequence variation in hundreds of thousands of individuals. We select a human demographic history which includes recent explosive population growth, and also model natural selection. We show that the resulting simulated data, at both synonymous and non-synonymous sites, is consistent with empirically observed frequency spectra and linkage patterns in over 1,300 European samples.

We find that two disease model parameters - the mutational target size and the strength of coupling between purifying selection and phenotypic effects - are sufficient to produce a wide range of genetic architectures, including the highly debated “common polygenic” and “rare Mendelian” models of complex disease. For type 2 diabetes, we find that both these models were consistent with initial discovery genome-wide association studies (GWAS). Empirical data from larger scale GWAS (over 50K samples) and polygene score analysis, however, can now exclude both models. We rule out models positing either strong or no coupling to selection and demonstrate that the `common-vs-rare' dichotomy is artificial: models with genetic variance largely restricted to one frequency class are in fact inconsistent with T2D empirical data. More generally, as next-generation sequencing studies provide a deluge of empirical data, our framework offers a robust method by which to predict power in these studies, test precise genetic hypotheses, and ultimately further constrain the space of architectures underlying complex traits.

2210F

Multi-ethnic polygenic prediction in CARe and other cohorts contrasts the genetic architectures of height and body mass index. *E.K. Speliotes[1], J. O'Connell[2], R. Do[3,4], B. Stahl[3,22].* 1) University of Michigan, Ann Arbor, MI; 2) University of Maryland, Baltimore, MD; 3) Broad Institute, Cambridge, MA; 4) Massachusetts General Hospital, Boston, MA; 5) Harvard School of Public Health, Boston, MA; 6) University of Florida College of Pharmacy, Gainesville, FL; 7) Jackson Heart Study, Jackson State University, Jackson, MS; 8) Boston University School of Public Health, Boston, MA; 9) University of Texas Health Sciences Center, Houston, TX; 10) Childrens Hospital, Boston, MA; 11) Johns Hopkins School of Public Health, Baltimore, MD; 12) University of North Carolina, Chapel Hill, NC; 13) Montreal Heart Institute, Montreal Quebec, Canada; 14) University of Pennsylvania School of Medicine, Philadelphia, PA; 15) University of Virginia, Charlottesville, VA; 16) University of Mississippi Medical Center, Jackson, MS; 17) National Heart, Lung, and Blood Institute, Bethesda, MD; 18) Cedars-Sinai Medical Center, Los Angeles, CA; 19) University of Washington School of Public Health, Seattle, WA; 20) Case Western Reserve University School of Medicine, Cleveland, OH; 21) University Medical Center Utrecht, The Netherlands; 22) Brigham & Women's Hospital, Harvard Medical School, Boston, MA.

We utilized polygenic prediction analyses to gain insight into the genetic architectures of two human quantitative traits, height and body mass index. Classical heritability methods applied to population GWAS data indicate that common SNPs explain substantial proportions of heritability across complex traits- about 50% for height and 30% for body mass index (BMI). Recent European GWAS meta-analyses for height (N~130,000; Lango Allen Nature 2010) and BMI (N~120,000; Speliotes Nature Genetics 2010) were used as training data. Test data included the PEAR antihypertensive response GWAS (N=450 Europeans [Eur], results shown below), a new GIANT cohort (N=~5,000 Eur) and the CARe cohort (N~8,000 African Americans [AA]). SNP sets were based on a range of P_training thresholds with and without LD-pruning (r2<0.1). Polygenic scores (sums of SNP dosages, weighted by effect sizes assuming a proportion p<=1 of SNPs associated [see Vilhjalmsson Abstract 120121058]) were tested for association to gender-, age- and ancestry-adjusted phenotypes. Polygenic scores based on large-scale European GWAS meta-analysis were highly significant predictors of height and BMI (max R2_height,Eur=0.20, P=3e-10; max R2_BMI,Eur=0.086, P=9e-11), and yielded prediction R2 far greater than genome-wide significant SNPs. Significant SNPs (P_training<0.01, 3,491 SNPs) achieved the best height prediction, whereas including many non-significant SNPs (P_training<0.2, 186K SNPs) improved BMI prediction. LD-pruning yielded better height prediction in Europeans, whereas all SNPs yielded better prediction of BMI in Europeans and of both traits in African Americans. Attenuation of prediction R2 in African Americans (by a factor of 0.18; max R2_height,AA=0.037, P=2e-52, P_training<0.01, 10,592 SNPs; max R2_BMI,AA=0.015, P=7e-25, P_training<1, 363,370 SNPs) is likely due to a combination of population-specific allele frequencies, LD patterns, and causal variants. The results are consistent with a smaller proportion of SNPs genome-wide contributing to variation in height compared with BMI, and with BMI causal variants on average being more poorly tagged and population-specific (and therefore lower-frequency) than height causal variants. Our recent method for inferring common-SNP heritability as well as the allele frequency/effect size distribution from polygenic prediction results (Stahl et al., Nature Genetics, 2012; analysis in progress), promises to directly elucidate these possible explanations.

Can "asthma genes" predict asthma? *J.A. Curtin, D. Belgrave, J. Hankinson, A. Custovic, A. Simpson.* Translational Medicine, The University of manchester, Manchester, United Kingdom.

Background: Large scale genome wide association studies (GWAS) of asthma have yielded many significant associations between single nucleotide polymorphisms (SNPs) and asthma. We investigated whether these genetic factors predict the development of asthma in a population-based birth cohort (Manchester Asthma and Allergy Study). **Methods:** We reviewed all published reports of asthma GWAS and identified 94 SNPs for which information on the risk allele and the odds ratios was available. We genotyped DNA from 880 children using Illumina 610 quad chips and Sequenom. Asthma at age 11 years was defined if all of the following criteria were met: (1) physician-diagnosed asthma; (2) asthma symptoms (wheeze, cough, or both) within the previous 12 months; and (3) current use of anti-asthma medication (n=105); children with none of the above criteria were assigned as controls (n=513). Information on maternal asthma was ascertained during pregnancy. Current wheeze at ages 3 and 11 years was defined as wheezing in the previous 12 months. Atopic sensitisation at age 3 years was defined as a positive skin test to at least one of the common inhalant/food allergens. We generated receiver-operating-characteristic (ROC) curves to determine the ability of genetic factors, atopy, clinical and family history to predict asthma at age 11. **Results:** Using all 94 SNPs, we were able to explain 1% of the variation in asthma with an Area Under the Curve (AUC) of 0.568. When we assessed if the individual SNPs were associated with asthma ($p<=0.05$), we found that 19 SNPs met these criteria. This reduced set of genetic variants explained 4.8% of the variation in phenotype (AUC: 0.642). Maternal asthma explained 0.7% of the variation (AUC: 0.539). In contrast current wheeze at age 3, sensitisation at age 3 and current wheeze at age 11 years each explained 13.6%, 11.2% & 72.0% of the variation respectively, (AUC: 0.697, 0.679 & 0.959 respectively). **Conclusion:** We found that 94 SNPs associated with asthma in published GWAS have limited ability to predict the disease in an unselected birth cohort representative of the general population. Although a subset of these SNPs (for which we confirmed significant association with asthma in our study) improved the predictive ability, these "asthma genes" explained only a small proportion of the variation of asthma (<5%). In contrast, current wheeze and sensitisation at age 3 years were much better predictors of subsequent asthma.

2212T

What is the total SNP-associated heritability for alcohol dependence? *N.G. Martin[1], G. Zhu[1], P.A. Lind[1], A.C. Heath[2], P.A.F. Madden[2], M.L. Pergadia[2], G.W. Montgomery[1], J.B. Whitfield[1].* 1) Genetic Epidemiology, Queensland Institute of Medical Research, Brisbane, Australia; 2) Department of Psychiatry, Washington University School of Medicine, St Louis, MO, USA.

Background. Much has been written about the so-called "missing heritability" for complex traits. Nowhere is this more pertinent than for alcohol and nicotine dependence (AD, ND) for which there are estimates of heritability of up to 65% from twin studies, yet few causal variants have been replicated from GWAS studies, despite large sample sizes, suggesting that individual effect sizes of SNPs must be very small. Recently new statistical genetic techniques have been developed which allow estimation of the total variance associated with all SNPs on a GWAS chip, but this has yet to be applied to AD and ND. Methods. The current analysis is based on AD and ND symptom count data from over 8000 participants in our population-based twin-family studies who have used either alcohol or cigarettes at some stage of their lives. They were individually genotyped with Illumina 370K or 660K chips and 7.034M genotypes were imputed from HapMap 3 and 1000-Genomes data. The GCTA program of Yang, Visscher et al is used first to detect the degree of relatedness between apparently unrelated subjects, based on a set of about 300,000 SNPs pruned for LD. Phenotypic similarity is then regressed on IBS sharing for all possible relative pairs to estimate the total amount of variance due to SNPs on the chip. Results. Based on GCTA analysis for other complex traits we expect to find SNP associated variance accounting for about half the heritability estimated from conventional genetic epidemiology designs. However, these estimates are highly sensitive to population stratification so great care will be taken to remove all traces of population stratification during the analysis. Conclusions. The gap between the SNP-associated variance estimated by GCTA and twin and family estimates of heritability is most likely due to several factors. First, the tag SNPs on the chip are not in perfect LD with the causal SNPs; for other traits, simulation has shown that correcting for imperfect LD raises the SNP "heritability" by about 10%. Another major factor is that commercial chips only interrogate common SNPs so large effects of rare SNPs are simply not captured. Reasonable estimates from simulations suggest that this could account for another 20% of variance. Finally, we recognize that there are large sections of the genome containing highly repetitive DNA which are very poorly tagged by current chips, and where substantial proportions of genetic variance may be hidden.

2213F

A knockout mouse model for canine juvenile epilepsy. *E.M. Nevalainen[1,2], E. Seppala[1,2], H. Lohi[1,2].* 1) Veterinary Biosciences, University of Helsinki, Helsinki, Finland; 2) Folkhalsan Research Unit, Helsinki, Finland.

Epilepsy afflicts more than 1% of the human population. Epilepsies are the most common neurological diseases in two to 10 years old children. Epilepsy is also the most common neurological disorder in dogs. Our group has recently described benign focal juvenile epilepsy in the Lagotto Romagnolo breed (Jokinen et al, J Vet Intern Med 2007). These dogs manifest an epileptic tremor syndrome with similarities to human idiopathic childhood epilepsies. The onset of the epilepsy in lagottos is at the age of five to nine weeks and affected puppies present focal seizures with interictal EEG activities. The disease resolves without treatment by the age of four months. We have identified the genetic cause in the LGI2 gene (Seppälä et al. PLoS Genet 2011). LGI2 is a paralog of the human epilepsy gene, LGI1. We have shown that LGI2, like LGI1, is neuronally secreted and interacts with the members of the ADAM family of neuronal receptors. LGI-ADAM complexes are suggested to function in synaptic remodeling and participate in the development of neuromorphology. Based on the expression pattern, Lgi2 was proposed to have a role in the maintenance of the electric stability of the neural networks in the early phases of the developing brains. We have generated a LGI2-deficient mouse model (using KOMP) to further elucidate the biological roles of LGI2 complexes in the normal and epileptic developing brains. Lgi2-deficient mice develop normally to adulthood, are fertile, and the gross tissue anatomy and morphology is similar to that of wild-type littermates. Different tissues have been collected and the expression of several genes and proteins will be compared in knockout and wild-type mice at varying ages using routine quantitative and immunohistochemical protocols. The homozygous mice have been monitored to follow possible epileptic activities and seizures. We will study the electrophysiological properties of the neuronal cells of the knockout and wild-type mice. Canine epilepsy models are unique in representing naturally-occurring spontaneous models of human epilepsy. The data will shed light on the role of LGI2 in multicellular organisms, and elucidate its role in the development of epilepsy in juvenile dogs and humans.

2214W

ER stress response genes and their natural variation, discovered using the *Drosophila* model system. *C. Y. Chow, M. F. Wolfner, A. G. Clark.* Dept Molec Biol & Gen, Cornell Univ, Ithaca, NY.

The endoplasmic reticulum (ER) is responsible for synthesis and maturation of many proteins essential for cellular function. ER dysfunction can have devastating consequences when misfolded proteins accumulate in the ER, resulting in "ER stress" associated with pathogenesis of diseases from diabetes to neurodegeneration. To understand the contribution of ER stress resistance to disease, it is important to determine the extent of natural variation in ER stress resistance. Drosophila provides an excellent new model for studying variation and for rapid investigation of novel ER stress genes. We characterized variation in ER stress resistance in the Drosophila Genetic Reference Panel (DGRP), a collection of 192 inbred wild-derived lines whose whole-genome sequences are available. We compared their relative survival on food supplemented with the ER stress-inducing drug tunicamycin. Molecular markers of ER stress, such as Xbp1 splicing, indicate that tunicamycin induces ER stress in the fly. Mortality rates, as measured by the Cox proportional hazard ratio, varied by more than 100 fold, indicating extensive genetic variation in ER stress resistance among the DGRP lines. To understand the genetic variation underlying differential survival to ER stress, we used Agilent microarrays to compare gene expression between lines that were either highly sensitive vs. resistant to tunicamycin-induced ER stress. We found that genes involved in cellular responses to ER stress, including genes previously implicated in human disease, varied in response across the genotypes. Some of these canonical ER stress genes showed up to 10-fold difference in ER stress-induced expression. We also discovered additional genes, not previously implicated in ER stress response, that correlated with ER stress and its variation in our lines. Finally, we observed that transcriptome differences observed prior to ER stress induction may be predictive of resistance or sensitivity to ER stress. Our results indicate that natural variation in Drosophila provides a rich new resource for identifying novel ER stress genes and their functions, further elucidating this cellular pathway critical to many human diseases.

Physical and genetic interactions between BBS genes and CEP290. *Y. Zhang[1], K. Bugge[1,2], C.C. Searby[1,2], R.F. Mullins[1], S. Seo[1], V.C. Sheffield[1,2].* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute, USA.

Bardet-Biedl syndrome (BBS) is a heterogenous autosomal recessive inherited disorders with clinical features that include retinal degeneration, obesity and developmental anomalies. At least 17 BBS genes have been reported. Seven BBS proteins form a molecular complex know as the BBSome, and three additional BBS proteins form a second complex known as the BBS chaperone complex based on the homology of these proteins to chaperonins. The chaperone complex is required for BBSome assembly. However, the interaction or function of other BBS proteins remains to be investigated. Recent studies have shown that mutation of a novel centrosomal protein, Cep290, also called NPHP6 and BBS14, results in BBS and other ciliopathies, but the exact mechanism remains unknown. In this study, we examined the BBS-related function of Cep290 and investigated interactions between Cep290 and other BBS proteins. We demonstrate that Cep290 interacts with BBS4 and BBS9, which are components of the BBSome. In addition, we found that the BBSome is required for correct localization of Cep290 in RPE Cells. Furthermore, Cep290 is mislocalized in retina of BBS1M390R/M390R mice, which are homozygous for a methionine to arginine substitution at codon 390 of Bbs1, another component of the BBSome. Moreover, the body weight and leptin level of BBS4 +/- Cep290 +/- (double heterozygous) mice are higher than those of single heterozygous mice. BBS4 +/- Cep290 +/- mice also show leptin resistance compared to single heterozygotes. These data strongly indicate that there is both physical and genetic interactions between Cep290 and the BBSome.

2216F

***Vacuolated lens (vl)*-associated Neural Tube Defects (NTDs) are regulated on a multigenic basis by *Cdx1* and Retinoic Acid (RA) signaling pathway.** *B. Li[1,2], P. Matteson[1], M. Ababon[1], A.Q. Nato[3], T. Matise[3], V. Nanda[1,4], J. Millonig[1,2,3].* 1) Center for Advanced Biotechnology and Medicine, Piscataway, NJ; 2) Department of Neuroscience and Cell Biology, UMDNJ-RWJMS, Piscataway, NJ; 3) Department of Genetics, Rutgers University, Piscataway, NJ; 4) Department of Biochemistry, UMDNJ-RWJMS, Piscataway, NJ.

To understand the molecular genetic basis of neurulation, we are studying the *vacuolated lens* (*vl*) mutation that arose spontaneously on the C3H/HeSnJ background. The mutation affects apposition/fusion of the neural folds, which leads to NTDs, embryonic lethality and abnormal pigmentation. The *vl* phenotypes are caused by a mutation in an orphan G-protein coupled receptor (*Gpr161*), that is expressed in the neural folds. Crossing *vl*^{C3H} mice to the MOLF/EiJ strain rescues the *vl* defects. QTL analysis mapped three modifiers (*Modvl*: **Mod**ifier of ***vl***). One QTL being studied is *Modvl5* (LOD= 5.0; Chr18). A *Modvl5*^{MOLF} congenic strain was generated to study whether this locus is sufficient to rescue the *vl* phenotypes. Analyses on congenic embryos determined that *Modvl5*$^{C/M}$ rescues the embryonic lethality (P= 0.004) and partially rescues the NTDs. Using our bioinformatics pipeline, we determined that the transcription factor,*Cdx1*, is the only gene within the *Modvl5* 95% Confidence Interval (CI) co-expressed with *Gpr161* in the lateral neural folds. Re-sequencing *Cdx1* identified a poly-glutamine polymorphism (5Q-C3H, 7Q-MOLF) predicted to affect secondary and tertiary protein structure. Additional mating to Balb/cJ (5Q allele) does not rescue the *vl* defects, while mating to PWK/PhJ (7Q allele) rescues the phenotypes (p=0.0001). Electrophoretic Mobility Shift Assay (EMSA) demonstrated that 7Q binds better than 5Q allele (p<0.001) to the promoters of Retinoic Acid signaling genes. QRT-PCR indicated that the expression of these genes (*Aldh1a2* and *Cyp26a1*) is down-regulated by *vl* and returns to nearly wild-type levels in *Modvl5*$^{C/M}$. To directly measure RA signaling intensity, E8.5 embryos were cocultured with the RA-responsive reporter cell line F9-RARE-lacZ. Preliminary data suggests that RA signaling is down in *vl* and rescued by *Modvl5*$^{C/M}$(p=0.01). Consistent with this possibility, preliminary analysis indicates that the NTDs phenotype is partially rescued by injecting all-trans RA into E9.5 *vl*^{C3H} embryos. These results establish *vl*as one of the first multigenic mouse mutant models of NTDs and demonstrate that *Cdx1*^{MOLF} bypasses the mutation by up-regulating the downstream RA signaling pathway.

HLA class-I supertypes are associated with specific M. tuberculosis strain infections. *M. Salie[1], L. vd Merwe[2], M. Moller[1], M. Martin[3, 4], X. Gao[3, 4], R. Warren[1], M. Carrington[3, 4], E. Hoal[1].* 1) Biomedical Science, Stellenbosch University, Tygerberg, Western Cape, South Africa; 2) Biostatistics Unit, Medical Research Council, Tygerberg, Western Cape, South Africa; 3) Ragon Institute of MGH, MIT and Harvard, Boston, Massachusetts, USA; 4) Laboratory of Experimental Immunology, Frederick, Maryland, USA.

Tuberculosis (TB) is the second highest cause of mortality due to an infectious disease. Development of active clinical TB is not solely due to the pathogen, Mycobacterium tuberculosis, but environmental and host genetic factors also contribute. The potential role of interactions between the host and bacterial genotype in influencing disease outcome has been proposed and a few studies have indicated the adaptation of M. tuberculosis strains to specific populations. The Human Leukocyte Antigen (HLA) class-I molecules are involved in various immunological processes, including antigen presentation to T cells. The HLA class-I genes; HLA-A, -B and -C were genotyped in 300 TB cases by sequencing using the ABI-3130XL DNA analyzer. M. tuberculosis strain identification was done by means of spoligotyping. Haplotypes were inferred using the EM algorithm. Logistic regression models were used to determine the likelihood of cases having a specific strain, adjusting for age and sex. Significant associations between host genotype and bacterial strain were identified for genotypes, haplotypes and the additive allelic model. For HLA-A, the odds ratio (OR) of having LAM, was 3.89 and 6.33 for the A01/A02 and A03/undefined genotypes, respectively, compared to A01/A01. For HLA-B, the significant ORs of having Beijing were very large and imprecise for B07/B08 (OR=19.6), B01/B44 (OR=10.4) and B08/B62 (OR=25.4) compared to B07/B07. For HLA-C, the ORs of having Beijing were 3.61, 4.39 and 4.46 for C1/C2, C2/C2 and C2/undefined, respectively, compared to C1/C1. Three haplotypes were also found to be significantly associated with infection with a Beijing strain (P=0.0002). Several associations were also identified for HLA alleles and M. tuberculosis strains. We show that HLA alleles could be involved in M. tuberculosis strain susceptibility. Both pathogen and host genetics need to be taken into consideration when studying TB disease development.

2218T

Peripheral blood cell counts are heritable in a large, unselected rhesus macaque pedigree. *A. Vinson[1,2], A.D. Mitchell[1,2], D. Toffey[1].* 1) Oregon National Primate Research Center, Oregon Health & Science University, Beaverton, OR, 97006; 2) Dept. of Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR, 97239.

Circulating blood cell counts are associated with risk for cardiovascular and other complex human disease, and a better understanding of the genes that influence their spontaneous variation will ultimately inform personalized therapies. The goals of this study were to assess heritability of blood cell counts in rhesus macaques, a widely-used non-human primate model for complex human disease. Large, managed populations of rhesus macaques are a powerful resource for genetic analysis of quantitative traits like blood cell counts, offering substantial genetic similarity to humans, available pedigree information, large numbers of informative relative classes, and a controlled environment that will enhance genetic signal over noise. Based on these advantages, we have characterized an unselected pedigree of Indian-origin rhesus macaques for quantitative genetic analysis and gene mapping of complex traits. This pedigree was developed to optimize several criteria: animals must have parentage confirmed by molecular genotyping, belong to a minimum 3-generation lineage, be available for sampling, not have common ancestors outside the pedigree, and form a single, extended pedigree structure. The resulting pedigree contains 1,289 macaques spanning 6 generations, with 800 females and 489 males. Using a maximum likelihood-based variance decomposition approach with clinical data collected on 995 animals, we found significant heritability for white blood cell, red blood cell, and platelet counts, as well as measures of mean cell volume, mean cell hemoglobin, mean cell hemoglobin concentration, hematocrit, and hemoglobin (h^2 range 0.144—0.453, P-value range 1.14×10^{-3} —2.61×10^{-21}). These results indicate that genetic contributions to these important biomedical phenotypes can be detected and measured in this pedigree, and support the need for genome-wide analysis of these and related risk factors for human disease in this population.

A copy number variant at the KIT ligand locus confers risk for canine squamous cell carcinoma of the digit. *E.A. Ostrander[1], B. Decker[1], E. Carlins[1], B. VonHoldt[2], G. Carpintero-Ramirez[1], H.G. Parker[1], R.K. Wayne[2], D.M. Karyadi[1].* 1) Cancer Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Dept of Ecology and Evolutionary Biology, UCLA, Los Angeles CA.

The domestic dog is a robust model for studying the genetics of disease susceptibility as many breeds harbor an elevated risk for certain cancers, despite the simple population structure common to all breeds. One example of breed-specific disease propensity is squamous cell carcinoma of the digit (SCCoD), a locally aggressive cancer that frequently causes lytic bone lesions and multiple toe recurrence. SCCoD is uncommon in most dog breeds, but is prevalent in Standard Poodles. Intriguingly, Poodles with dark coat color are at high risk for SCCoD, whereas Poodles of light coat colors are entirely unaffected, suggesting that interactions between multiple pathways are necessary for oncogenesis. We performed a genome-wide association study on Standard Poodle SCCoD cases compared to unrelated black Poodle controls. Allelic association was calculated with the single-locus chi-squared significance test. The six most strongly associated SNPs (P_{raw}= $5.62x10^{-5}$-$1.20x10^{-7}$) were contiguous markers on canine chromosome 15 and all were statistically significant at the chromosome-wide level ($P_{empirical}$= $0.0299\text{-}7.00x10^{-5}$). Comparison of Poodle cases to other at-risk breeds initially refined the locus to 144.9Kb, a region that harbors 128 variants segregating with risk. The initial risk-associated haplotype is present in 92.9% cases, with 55% of cases are homozygous for the risk allele. While 52.8% of controls are heterozygotes, none are homozygous for the risk haplotype. The region lies upstream from the KIT Ligand (KITLG) gene. Fine mapping and sequencing reduced the locus to a minimal region of 29.7Kb. A dosage dependent effect of a CNV within the region is strongly associated with the disease phenotype in Standard Poodles. Allele-specific expression assays are ongoing to determine the relationship between the CNV and KITLG expression. Additional investigation highlighted a compensatory nonsense mutation in light colored standard poodles that explains their lack of disease, even if they carry the risk allele. The presence of disease is not due to coat color pigments, i.e. light colored Briards lack the compensatory mutation and get the disease if they carry the risk allele, similar to black Briards. This work highlights the utility of the canine system for disentangling the genetics of multigene cancer disorders. Our ongoing studies should highlight other genes contributing in the disease and, by extension, what role these genes play in human cancers.

Large-scale Transcriptional and Epigenetic Changes Bridge Maternal Nutritional Imbalance and Metabolic Syndrome. *X. Yang[1,2], L. Peterson[3], T. Fare[1], J. Zhu[1,4], R. Kleinhanz[1], C. Suver[1,5], A.M. Cumiskey[3], R.L Rosa[3], A. Vosatka[3], M. Skinner[6], E.E Schadt[1,4], P.Y. Lum[1,7].* 1) Merck Research Laboratory, Merck & Co, Inc. Seattle, WA; 2) Integrative Biology and Physiology, UCLA, Los Angeles, CA; 3) Department of Pharmacology, Merck & Co, Inc. Rahway, NJ; 4) Department of Genetics and Genomic Sciences, Institute of Genomics and Multiscale Biology, Mount Sinai School of Medicine, New York, NY; 5) Sage Binetworks, Seattle, WA; 6) Center for Reproductive Biology, School of Biological Sciences, Washington State University, Pullman, WA; 7) Ayasdi Inc, Palo Alto, CA.

Objective: The increasing prevalence of Metabolic Syndrome (MetSyn), a combination of cardiovascular disease risk factors with poorly understood etiology, has resulted in increasing morbidity and mortality worldwide. Among the potential causes for the predisposition to MetSyn is early nutrition during gestation and lactation. The aim of our study is to understand the molecular mechanisms underlying the phenotypic effects of early nutritional perturbation. Research Design and Methods: We characterized the alterations in the transcriptome and epigenome of mouse offspring exposed in utero to a high fat high sucrose diet, a protein-restricted diet, or a standard Chow diet using genome-wide transcriptional and DNA methylation profiling of two key metabolic tissues - hypothalamus and liver - at 15 weeks of age. Results: We found that poorly balanced maternal diets (the high fat high sucrose diet and the low protein diet) induced alterations in the expression of thousands of genes involved in biological processes relevant to MetSyn in the hypothalamus and liver tissues. We also identified significant changes in DNA methylation status of hundreds of genetic loci along with a genome-wide hypomethylation shift in the liver tissue of the mouse offspring. Conclusions: These findings provide molecular insights into the influence of early nutrition on metabolic disease susceptibility and may help direct therapeutic interventions to prevent and treat MetSyn.

Gene Expression Profiling in Mild Traumatic Brain Injury, Post-traumatic Stress Disorder, Sleep Disorders and Depression among Redeployed Military Personnel. *H. Lee[1], D. Wang[1], R. Pierce[2], T. Baxter[2], R. Dionne[1], H. Kim[1], V. Mysliwiec[2], T. Barr[1,3].* 1) National Institute of Nursing Research (NINR), National Institutes of Health (NIH), Bethesda, MD; 2) Madigan Healthcare System, Tocoma, WA; 3) West Virginia University, Morgantown, WV.

Objectives: Post-traumatic Stress Disorder (PTSD) and mild traumatic brain injury (mTBI) remain leading causes of disability among post-deployed military service members and both are frequently comorbid with sleep disorders or depression. Our study aims to identify biomarkers for PTSD, mTBI, sleep disorders and depression through peripheral blood transcriptome profiling in a redeployed military population for developing more sensitive diagnostic criteria. Methods: A total of 106 military service members (>18 years old) within 18 months post-deployment were enrolled (99% male; 68% European American) and were assessed for the 4 clinical factors—PTSD, mTBI, sleep disorders and depression. Total RNA was extracted from blood samples followed by amplification and hybridization to Affymetrix GeneChip Human Gene U133 Plus 2.0 Arrays. In Partek Genomics Suite Beta 6.6, normalized data (log base 2 for each probeset) were subjected to quality control procedures. For gene filtering, probesets with less than 5% of coefficient of variation across the entire sample were filtered out. Differential gene expression was then compared between groups. Considering potential influence of ethnicity and gender on gene expression, analysis was initially limited to 57 European American male subjects.Results: We first performed a separate bivariate analysis for each of the 4 clinical factors, and then compared differentially expressed genes found in the bivariate analyses with ones from multivariate analysis controlling for each other clinical factors. For PTSD, different genes were found from bivariate (*CEACAM8*, *DEFA4*, *CAMP*, and *MMP8*) and from multivariate (*SDHD*,*SLPI*, *RHCE/RHD*, *BEX1*, and *CLCN4*) analyses. However, there were same genes expressed in both bivariate and multivariate analyses, for blast neurotrauma (*MYSM1*, *SLAMF7*, *CBLL1*,*SMAD7*, and *TTC22*), depression (*SLC11A1* and *PI4K2B*), or sleep disturbances (*FAM3B*). Validation study using qPCR follows to confirm these genes. Conclusions: Our interim findings support the use of peripheral blood transcriptome profiling as a potential biomarker which can help diagnose military personnel with these illnesses. Further investigation with a large cohort as well as more objective measurements is necessary to validate the diagnostic accuracy of these biomarkers. Acknowledgements: The study is supported by the Center for Neuroscience and Regenerative Medicine (CNRM) at the Uniformed Services University of the Health Sciences (USUHS).

Genetics of obesity across development in a model system. *C.A. Schmitt[1], S. Service[1], R.M. Cantor[2], A.J. Jasinska[1], M.J. Jorgensen[3], J.R. Kaplan[3], N.B. Freimer[1].* 1) Center for Neurobehavioral Genetics, University of California, Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA; 3) Department of Pathology, Section on Comparative Medicine, Wake Forest School of Medicine, Winston-Salem, NC.

Obesity is a problem of epidemic proportions worldwide, and has severe negative impacts on public health. Obesity arises from a complex interaction of genetic predisposition and environment that can accumulate throughout life, but increasing evidence points to the importance of biological processes occurring early in development in the manifestations of adult disease. In humans, the elucidation of the genetic underpinnings of obesity and concomitant ontogenetic patterns is complicated by the ubiquity of diets extremely high in fats and simple carbohydrates, and the difficulty in assessing what study subjects are actually eating and in what quantities. This research investigates a baseline genetic predisposition to obesity during development in a genetically well-characterized model system under a controlled diet and environment: the African green monkey or vervet (*Chlorocebus aethiops sabaeus*) in the Vervet Research Colony (VRC) at Wake Forest School of Medicine.

We used basic measures taken thrice yearly on body size and composition (such as BMI and waist circumference) in a population of 657 monkeys measured from 2008 through 2012 to search for heritable patterns in obesity. We found that 118 (29% of adults) presented with signs of abdominal obesity at least once, with obesity defined as having an adult waist circumference above 40.5 cm; and 43 (10% of adults) were chronically obese (obese during at least three successive measurements). Loess regressions of mean waist circumference reveal stark differences in growth trajectories between the chronically obese and non-obese colony members: whereas non-obese colony members' waist circumference growth levels off just after attaining full adult size, obese colony members appear to maintain a pubertal growth slope up to a decade after puberty has passed. Analyses of estimated additive genetic heritability using SOLAR show that BMI, waist circumference, and chronic obesity are all highly heritable (BMI: $h^2 = 0.44$, $p < 0.0001$; waist circumference: $h^2 = 0.37$, $p < 0.02$), at levels much higher than those seen in previous studies of NHP populations, with significant covariates represented by age and sex. This preliminary study suggests that a more comprehensive examination of growth trajectories may elucidate previously unknown patterns in the development of obesity. Such novel patterns may be used to assess early obesity risks and promote the discovery of novel biomedical interventions.

Modeling 3D facial shape in relation to sex and genomic ancestry estimated from DNA. *M.D. Shriver[1], P. Claes[2], D.K. Liberton[1], K.M. Rosana[1], E.E. Quillen[1], L.N. Pearson[1], B. McEvoy[3], M. Bauchet[1], H. Tang[4], G. Barsh[4,5], D.M. Absher[5], D.A. Puts[1], J. Rocha[6,7], S. Beleza[4,8], R.W. Pereira[9], J.K. Wagner[10], J. Boster[11].* 1) Dept Anthropolgy, Penn State Univ, University Park, PA; 2) Katholic University of Leuven, KU Leuven, Belgium; 3) Smurfit Institute of Genetics, Dublin, Ireland; 4) Department of Genetics, Stanford University, Palo Alto, CA; 5) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 6) CIBIO: Centro de Investigação em Biodiversidade e Recursos Genéticos, Universidade do Porto, Portugal; 7) Departamento de Biologia, Faculdade de Ciências, Universidade do Porto, Portugal; 8) IPATIMUP: Instituto de Patologia e Imunologia Molecular da Universidade do Porto, Portugal; 9) Programa de Pós-Graduação em Ciências Genômicas e Biotecnologia, Universidade Católica de Brasília, Brasilia, Brasil; 10) Center for the Integration of Genetic Healthcare Technologies, University of Pennsylvania, Philadelphia, PA; 11) Department of Anthropology, University of Connecticut, Storrs, CT.

Human facial diversity is substantial, complex, and largely scientifically unexplained. We use spatially dense quasi-landmarks and partial least squares regression (PLSR) to measure face shapes in population samples with mixed West African and European ancestry from three locations (United States, N=154; Brazil, N=191; and Cape Verde, N=247). We modeled facial variation as shape regressed on ancestry direction (SRAD) and on sex direction (SRSD). We then examined the extent to which distance along these directions (dSRAD and dSRSD) predicted genomic ancestry, sex, and observer judgments of ancestry and sex. We used alternate marker panels and noise injection (NI) experiments to investigate the robustness of facial modeling and find that accurate shape regressions are possible with imprecise estimates of sex and genomic ancestry. The independent variables estimating both sex and ancestry can be reduced in precision by as much as 50% (i.e., r2=0.5 between the original variable and the NI variable) and still show correlation coefficients of about 0.95 between the original and NI dSRAD and dSRSDs. The PLSR approach is remarkably efficient in accessing the information on both genomic ancestry and sex to establish the directions in face space and measurements of the relative positions of individual faces with respect to these directions. Judgments of ancestry and sex shift sharply at certain morphological thresholds, reflecting categorical perception. The strong correlations that we observe between judged sex and judged femininity and dSRSD, and between judged proportional ancestry and judged categorical ancestry dSRAD formally support the idea that we are generating valid and meaningful estimates in the context of human perceptions. Facial models combining the two independent variables - genomic ancestry and sex - allow systematic transformations of individual faces along these directions, establish a framework for mapping genes affecting facial features, and provide the first tool for estimating the appearance of a person's face from genetic markers.

Endogenous DUX4 induces myotube-specific apoptosis in FSHD Muscular Dystrophy and is regulated by Wnt/β-catenin signaling. *G.J. Block, D. Narayanan, A.M. Amell, L.M. Petek, D.G. Miller.* Pediatrics, University of Washington, Seattle, WA.

The gene encoding Double Homeobox Protein 4 (DUX4) is located within each unit of the D4Z4 macrosatellite repeat and is transcriptionally silenced in most cells. In patients with facioscapulohumeral muscular dystrophy (FSHD), D4Z4 loses markers of heterochromatin and DUX4 is transcribed and translated. Previous studies showed that DUX4 protein is rare in muscle cultures from FSHD patients and the cultures do not display defects in differentiation potential or susceptibility to stress. Although over-expression of exogenous DUX4 induces apoptosis in multiple cell and tissue types, there is no evidence that DUX4 induces cell death at physiologic levels, or explanation as to why skeletal muscle is preferentially affected in the disease. Here we describe a novel myotube differentiation protocol to increase the efficiency of myotube formation and detection of DUX4 protein. We show that muscle cultures from FSHD patients only express DUX4 in differentiated myotubes, where the DUX4(+) nuclei then initiate apoptosis. Knockdown of DUX4 by siRNA abolished myotube apoptosis. Finally we demonstrate the utility of our model by modulating DUX4 expression through activation and suppression the Wnt/Beta-catenin signaling pathway. Our data provide the first evidence that DUX4 induces apoptosis of myotubes at physiological levels, and validates a platform that can be used to understand the regulation of DUX4-induced apoptosis in FSHD.

Development of a Novel *Col3a1* Transgenic Mouse Model for Vascular Ehlers-Danlos Syndrome. *F. Malfait[1], Y. Kang[1], S. Symoens[1], P. Coucke[1], M. Renard[1], B. Guillemyn[1], J. De Backer[1], F. Branco-Madeira[2], W. Toussaint[2], L. Vanhoutte[2], S. Janssens[2], B. Descamps[3], C. Vanhove[3], P. Segers[4], B. Lambrecht[2], A. De Paepe[1]*. 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Department of Molecular Biomedical Research, VIB, Ghent, Belgium; 3) Department IBITech-MEDISIP-INFINITY-GROUP-ID Consortium, Ghent University, Ghent, Belgium; 4) IBiTech-bioMMeda, Ghent University, Ghent, Belgium.

Type III collagen (*COL3A1*) mutations cause vascular Ehlers-Danlos syndrome (vEDS), a life-threatening disorder, characterized by thin, translucent skin, abnormal wound healing, easy bruising and increased risk for arterial, intestinal and uterine rupture. The majority of *COL3A1* mutations are glycine-substitutions in the triple-helical domain, resulting in misfolded collagen trimers. In less than 5% of the patients *COL3A1* haploinsufficiency mutations have been reported.

We generated a transgenic mouse model in which mutant mouse *Col3a1* gene with a p.Gly183Ser mutation was introduced into mouse genome by BAC technology. This mutation has been documented in several patients with typical vEDS. This transgenic approach allows near-normal expression of *Col3a1* as the construct contains the endogenous promoter region, regulatory elements and untranslated regions. Currently, five different *Col3a1* transgenic mice lines are available, each harboring different copies of the mutant *Col3a1* transgene. Initial results on the transgenic line harboring the highest transgene copy number show that these mice have decreased pre-weaning survival in comparison with WT-mice (p-value < 0.05). Male transgenic mice are smaller at 12 and 16 weeks of age (12 and 16.2%, respectively) when compared to strain-, age-, and sex-matched WT controls. Moreover, the transgenic males recapitulate the human phenotype and display a fragile, thin skin. At two months they spontaneously develop open wounds starting in the shoulder area and penetrating skin and subdermal tissue. These skin lesions evolve fast and animals need to be euthanized rapidly. Preliminary vascular corrosion-casting experiments on the euthanized mice are complicated by rupture of arterial vessels, suggesting increased vascular fragility. Additionally, post-mortem fluid-induced rupture experiments reveal friable arteries which rupture at a lower pressure, compared to WT mice.

Although further experiments are necessary to fully delineate the phenotype, this mouse model seems to mimic the characteristics of human vEDS.

2226W

An integrative genetic and metabolomic analysis suggests altered phosphatidylcholine metabolism in asthma. *J.S. Ried[1], H. Baurecht[2], F. Stückler[3], J. Krumsiek[3], J. Adamski[4], C. Illig[4, 15], S. Weidinger[2]*. 1) Institute of Genetic Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 2) Department of Dermatology, Allergology, and Venerology, University Hospital Schleswig-Holstein, Campus Kiel, Kiel, Germany; 3) Institute of Bioinformatics and Systems Biology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 4) Institute of Experimental Genetic, Helmholtz Zentrum München - German Research Center for Environmental Health, Germany; 5) Institute of Epidemiology I, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 6) Department of Pediatric Pneumology, Allergy and Neonatology, Hannover Medical School, Hannover, Germany; 7) Institute of Epidemiology II, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 8) Research Unit of Molecular Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 9) Faculty of Biology, Ludwig-Maximilians-Universität, Munich, Germany; 10) Department of Physiology and Biophysics, Weill Cornell Medical College, Doha, Qatar; 11) Institute of Medical Informatics, Biometry and Epidemiology, Chair of Genetic Epidemiology, Ludwig-Maximilians-Universität, Munich, Germany; 12) Institute of Medical Informatics, Biometry and Epidemiology, Chair of Epidemiology, Ludwig-Maximilians-Universität, Munich, Germany; 13) Klinikum Grosshadern, Munich, Germany; 14) Department of Mathematics, Technische Universität München, Munich, Germany; 15) Hannover Unified Biobank, Hannover Medical School, Hannover, Germany.

Background: Genome-wide association studies (GWAS) have identified many risk loci for asthma, but effect sizes are mostly small and in most cases the biological mechanisms are unclear. Targeted metabolomics that is based on the quantitative measurement of a panel of small molecules provide information about a whole range of pathways of intermediary metabolism in a biological sample. Previous studies show that combining genetic and metabolomic information can aid in characterizing genetic association signals with high resolution. Our objective is to investigate the interrelation of current asthma, asthma risk alleles and blood serum metabolites.

Methods: We investigated 151 serum metabolites, quantified by targeted mass spectrometry, in fasting serum of asthmatics and non-asthmatic individuals from the population-based KORA F4 study (n=2,925 participants). For the characterization of differences in metabolomic profile between asthmatics and no asthmatic individuals we performed logistic regression analyses and network reconstruction with Gaussian graphical modeling (GGM). In addition, we analyzed effects of single nucleotide polymorphisms (SNPs) at 40 asthma risk loci on these metabolites.

Results: Two phosphatidylcholines (PC.aa.C42:1 and PC.ae.C42:5) were significantly associated with current asthma (p-value= 8.16×10^{-5}/7.35×10^{-5}, OR= 1.38/1.39). Eight metabolites of different metabolite classes were significantly associated with asthma risk alleles from six loci. Acyl-alkyl-phosphatidylcholines (PC.ae.C42:5 and PC.ae.C44:5) associated with risk alleles in*PSMD3* and *MED24* in turn coincide with asthma risk. The combined effect directions of the SNPs on these two phosphatidylcholines and of phosphatidylcholines on asthma were consistent with known effects of SNPs on asthma risk.

Conclusions: Our study demonstrates the potential of metabolomics to infer asthma-related biomarkers by the identification of deregulated phosphatidylcholines that associate with asthma and asthma risk alleles. This knowledge may be used in the future for better understanding of asthma prediction, diagnosis and treatment.

2227T

Genomic data integration reveals molecular modularity of Parkinson disease. *A. Dumitriu[1, 2], Y. Xia[2], R.H. Myers[1, 2].* 1) Department of Neurology, Boston University School of Medicine, Boston, MA 02118, USA; 2) Bioinformatics Program, Boston University, Boston, MA 02215, USA.

Parkinson disease (PD) is a complex neurodegenerative disorder, with mostly unknown etiology. Several human and model organism genetic studies have been performed for the analysis of PD. While individual studies can provide important knowledge about the biological processes involved in PD, a more complete picture of the disorder can be obtained by combining multiple existing genetic data sources. Complementary to disease-specific data, available functional information can also be considered for the investigation of PD genetics.

We constructed a comprehensive catalogue of PD-relevant genes by integrating data from three different types of genetic studies: whole-genome expression, genome-wide association, and PD animal models. We then showed that PD-relevant gene sets are significantly more interconnected than expected by chance in the network of functional linkages among human genes, and that gene functional information improves the prediction accuracy of PD-relevant genes. Finally, we used the combined genetic data and the functional information to rank a set of canonical pathways for their involvement in PD. Two additional microarray expression studies performed for 1) PD and 2) Hepatitis C Virus (HCV) were used as our positive and negative replication sets, respectively. Only the pathways found to be significant for the combined genetic data set, as well as for the PD microarray, but not for the HCV microarray were considered important. The pathway analysis showed evidence of association with PD for pathways involved in neurotransmission, vesicular transport, signaling, and cell death.

Our results demonstrated the relevance of functional information in the study of PD. We also found that PD candidate genes from expression and association studies are largely different, which suggests that commonly used genetic methods assess distinctive aspects of the disease. Finally, we showed that integrative analyses of PD can benefit from a set of comprehensive and unbiased disease gold-standard genes, which is not currently easily available.

2228F

Pathway analysis of the GENEVA Alcohol Consumption GWAS Meta-Analysis. *O. Harari, A. Goate, GENEVA Alcohol Consumption Working Group.* Psychiatry, Washington University School of Medicine, St. Louis, MO.

The genetic architectures of complex psychiatric traits are likely to be the product of multiple genetic risk factors. Pathway analysis offers a complementary perspective to interpreting GWAS, incorporating repositories of expert knowledge, represented in biological pathways to allow the identification of variants that do not necessarily reach stringent genome-wide significance levels. Our approach to analysis of the GENEVA Alcohol Consumption GWAS meta-analysis, which encompasses 6 studies, included two stages: i) we evaluated each of the studies by itself; and ii) we interrogated the meta-analysis aggregated evidence. We restricted the analysis to subjects with European-American ancestry (EA), including 7,433 females and 7,275 males with harmonized alcohol consumption data (ln-tranformed drinks/week) and genome-wide genotype data (10,329 subjects were genotyped with the Affymetrix 6.0 platform; and 4,379 with different Illumina chips). After verifying that each of the studies included more independently significant SNPs than expected by chance, we performed a pathway analysis employing the ALIGATOR method. We observed that only the analysis of SNPs with p-values < 1.0E-3 identified an excess of Gene Ontology (GO) terms and pathways from the Kyoto Encyclopedia of Genes and Genomes (KEGG). There was not a pathway or term significant (p-value<0.05) for 3 or more studies. When we evaluated the meta-analysis signals, an excess of significantly overrepresented pathways was detected for women but not for men. Variants in alcohol dehydrogenase (ADH) genes modulate drinking levels. Rs1229984 in ADH1B, with a MAF < 5% for EAs, achieves a genome-wide significant level. This SNP is not ascertained in the employed chips and is poorly imputed. Consequently, only SNPs with higher frequency and in high D' could detect this signal in 5 of the GENEVA studies with moderate p-values (between 5.0E-3 and 0.05). We explored if 8 GO terms and 6 KEGG pathways including ADH1B were enriched with SNPs showing this significance level, and found 3 studies with positive results. However the pathways had moderate significance that did not surpass a Bonferroni multiple-correction adjustment. We observed similarly moderate p-values for the GENEVA meta-analysis. Alcohol consumption can be variously measured and it is likely that phenotypic heterogeneity across samples influenced our finding. Larger samples with systematically ascertained alcohol consumption data are necessary.

2229W

Pathway-Based Meta Analysis of Ulcerative Colitis Genome-Wide Association Studies. *C. Kao[1], Z. Wei[2], J. Li[1], W. Wang[2], J. Glessner[1], C. Cardinale[1], J. Bradfield[1], E. Frackelton[1], C. Kim[1], F. Mentch[1], H. Qui[1], S. Grant[1,3], R. Baldassano[1,3], H. Hakonarson[1,3], International IBD Genetics Consortium.* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ; 3) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA.

Inflammatory Bowel Disease (IBD) is a complex inflammatory condition, where the etiology is comprised of various genetic and environmental factors. The major forms of IBD include ulcerative colitis (UC) and Crohn's disease (CD), which are of distinct clinical phenotypes. Genetics studies to date have revealed at least 99 susceptibility loci for IBD, which, however, explain only a small percentage of the overall variance in disease risk, especially for UC. To overcome the power limitation of genome-wide association (GWA) studies, we employed pathway-based approaches to identify gene sets that cooperatively make contribution to the genetic etiology of UC. We compiled 6 UC European cohorts, totaling 5584 UC cases and 11587 controls. Our pathway-based meta-analysis of the 6 cohorts confirmed multiple immune-related pathways that have been implicated in the genetic etiology of IBD, such as “Antigen processing and presentation”, “Type I diabetes mellitus” and “Asthma”, at the genome-wide significance level. We noticed the genes in the major histocompatibility complex (MHC) region made a remarkable contribution to the significance of these pathways. The large GWA signals from MHC-linked genes could potentially mask involvement of other important pathways. To delineate how genes outside of the MHC region contribute to the etiology of UC, we excluded the SNPs in the MHC region and re-surveyed top pathways. As expected, many other immune-related or immunoregulatory pathways remain highly significant, and their association signals replicated in an independent pediatric cohort of European ancestry (CHOP) and in an adult cohort genotyped on the Immunochip. Pathways without obvious immune involvement with significant signals replicating in all three cohorts include those that regulate phosphorylation, such as “Lipid phosphorylation” (p values of 0.00053, 0.034, 0.0099 in discovery, CHOP, and Immunochop cohorts, respectively). Interesting pathways with suggestive signals (i.e. significant in discovery and one replication cohort) include the “Classical complement cascade”, “Parkinson's disease”, “Methionine metabolism”, and “Pantothenate and CoA biosynthesis” pathways. The possible contribution of these pathways to the etiology of UC and insight into the genetic mechanisms of UC are discussed.

2230T

Shared genetic variants between traits and diseases reveal novel disease risk factors. *L. Li[1], D. Ruau[1], C. Patel[1], R. Chen[1,2], A. Butte[1].* 1) Pediatric Department, Stanford University, Stanford, CA; 2) Personalis Inc.

Clinical manifestations of risk factors, or traits, are critical for prognostics and preventive care of complex disease. Currently, these risk factors are identified for disease through large scale epidemiological studies, which are time consuming, costly, and lose power to discover associations for less prevalent diseases. In the last decade, GWAS and candidate gene studies have identified genetic variants for thousands of diseases and traits. We utilized those variants and apply a method to systemically identify common genetic associations between traits and diseases. We hypothesize that traits sharing common genetic variants with diseases could serve as non-invasive means to prognose disease susceptibility. We validated our novel findings using independent patient cohort databases. We used a manually curated database (Varimed) of 8962 GWAS and candidate gene studies, containing 87553 SNPs from 2376 diseases and traits. We obtained 97 diseases and 102 traits by restricting to variants with p<1e-6 and diseases or traits associated with more than 3 genes. Disease-trait similarity was first estimated by the cosine distance between genome-wide binary vectors of associated genes. We then hierarchical clustered using 1000 bootstrap resampling. To assess the clinical relevance of our new predictions, we used summary statistics extracted from Stanford Translational Research Integrated Database Environment (STRIDE) as well as the National Health and Nutrition Examination Survey (NHANES). There were 1986 genes associated in 97 diseases (median=10) and 1718 genes associated in 102 traits (median=9). We identified 42 significant disease-trait pairs. 83% of the pairs were disease and traits from different publications. 28 pairs were known risk factors or predictive markers and 14 pairs were novel findings. We obtained 5 cohorts from STRIDE or NHANES and all were validated: elevated serum pro-brain natriuretic peptide levels and IgA nephropathy (OR:2.4;[1.5-3.7];p<0.001), elevated serum IgE levels and psoriasis (OR:1.7;[1.2-2.6]; p=0.005), elevated erythrocyte sedimentation rate and Alzheimer's disease (OR:1.9;[1.5-2.5]; p<0.0001), higher prostate-specific antigen levels in basal cell carcinoma (p<0.05), and higher bone mineral density in sudden cardiac death (p=0.04). We developed a systemic way to identify novel associations between traits and diseases, suggesting some of these traits can serve as a novel non-invasive means for disease prognosis.

Comparison of pathways implicated in anti-citrillunated peptide antibody positive and negative rheumatoid arthritis patients. *P. Martin[1], S. Viatte[1], A. Brass[2], S. Eyre[1], Rheumatoid Arthritis Consortium for Immunochip (RACI).* 1) Arthritis UK Epidemiolgy Unit, University of Manchester, Manchester, United Kingdom; 2) School of Computer Science, Kilburn Building, Oxford Road, Manchester, United Kingdom.

Introduction: Rheumatoid Arthritis (RA) is a chronic autoimmune disease affecting up to 1% of the adult population. GWAS have been successful in identifying SNPs associated with disease. However, previous studies have been under-powered to detect differences between anti-citrillunated peptide antibody (ACPA) positive and negative patients. Using a custom Illumina array, the RA Immunochip consortium allows comprehensive analysis of disease associations in both ACPA positive and negative patients. Pathway analyses test whether a molecular pathway is associated with disease by testing for enrichment of associated genes. This involves mapping SNPs to genes which can often be problematic or subjective. Here we present a robust workflow based method to assign genes and a comparison of the pathways significantly enriched in ACPA positive and negative patients.

Method: Excluding HLA, 17 confirmed RA SNPs attaining GWAS significance ($p<5x10^{-8}$) in ACPA positive patients were selected from the Immunochip analysis along with the 17 most significant SNPs from known RA associations from the ACPA negative analysis. Genes were assigned to SNPs using a Taverna workflow which defines a region using SNPs in linkage disequilibrium (LD) with the associated SNP. This prevents the bias introduced by assigning SNPs to `biologically plausible' genes and provides a robust, reproducible method for assigning SNP associations to genes. These genes were then tested for enrichment in PANTHER pathways using the Expression Analysis tool.

Results: Overall 4 pathways were significantly ($p<0.05$) enriched in the ACPA positive gene list and 5 in the ACPA negative gene list, with 3 pathways significantly associated in both. The toll receptor signalling pathway was associated in the ACPA positive ($p=0.0072$) group, the interleukin signalling pathway in ACPA negative ($p=0.0014$) patients and the JAK/STAT signalling pathway in both ($ACPA^+$ $p=0.038$; $ACPA^-$ $p=2.05x10^{-5}$). **Discussion:** Although preliminary, this study provides a promising pathway analysis of ACPA positive and negative RA patients. These findings not only suggest shared processes between the two disease sub-groups, but also identify areas where possible differences exist helping to define patient groups and potentially leading to better targeting of therapies.

Patterns of genetic expression in mental retardation associated or not with microcephaly. *T.F. Almeida[1], D.V. Bernardo[2], C.R.D.C. Quaio[1], G.L. Yamamoto[1], E.D.F. Carvalho[1], C.A. Kim[1], D.R. Bertola[1].* 1) Genetic Unity, Children's Institute, HCFMUSP, São Paulo, São Paulo, Brazil; 2) Laboratory of Human Evolutionary Studies, University of São Paulo, São Paulo, Brazil.

Mental retardation (MR) commonly runs with several genetic disorders and may or may not be associated with microcephaly. There is a vast description of single genes in which the disruption of their expression may be involved in these two groups of phenotypes (MR with microcephaly and MR without microcephaly), but fewer studies analyzing a great amount of genes at the same time. The pattern of a gene expression in a specific tissue directly relates with its importance in developing a phenotype. We primarily expected to find a greater expression in the nervous system of genes related to microcephaly than those not related to it. Therefore, we compared the pattern of the expression of genes between these two groups in different areas of the nervous system to determine if some of these regions might have a more important role in the development of microcephaly. Fifty genes for each group were selected in accordance to the order of appearance in OMIM. The level of expression of these genes was obtained by GNF expression atlas 2 data from U133A and GNF1H chips (UCSC site) for different tissues of the nervous system (fetal brain, adult brain, 16 different regions of the CNS and five regions of the peripheral nervous system). The level of expression of each gene was classified as: high expression (if expressed more in the area than the mean for the whole body), average expression and low expression for all of these areas. Frequency tables based on the expression of each gene for each area of the nervous system were compared between the two groups using Chi-squared test and Bonferroni correction for multiple analyses. The expression of genes related to microcephaly was statistically different when compared with genes not related to microcephaly in the fetal brain, the adult brain and four different regions of the CNS: the cerebellum, the cingulate cortex, the subthalamic nucleus and the globus pallidus. There were no major differences in gene expression for the other areas. The expression was comparatively lower in the microcephaly group, contrarily to our first expectation. This may be explained by the fact that 13 genes associated with microcephaly and none determining MR without microcephaly are involved in the cellular cycle and are thought to be equally expressed in the nervous system and the whole body. The regions where the expressivity of the genes was discordant between the two groups may also have an important role in determining microcephaly.

Molecular analysis of *GABRA1* and *EFHC1* genes in patients with juvenile myoclonic epilepsy and other idiopathic generalized epilepsies. *C.V. Soler[1], M.C. Gonsales[1], F.A. Oliveira[1], L.E. Betting[2], F. Cendes[2], I. Lopes-Cendes[1].* 1) Medical Genetics, University of Campinas, Campinas, Brazil; 2) Department of Neurology, Faculty of Medical Sciences, University of Campinas, Campinas, Brazil.

Purpose: Juvenile myoclonic epilepsy (JME) is the most common syndrome among the idiopathic generalized epilepsies (IGEs) with an onset between the ages of 9 and 27 years. It remains unclear whether different forms of IGEs could share a common genetic predisposition. Several genes have been associated with JME and other IGEs but the most relevant are the α1-subunit of the $GABA_A$ receptor gene (*GABRA1*), and the EFHC1 protein gene (*EFHC1*). The first is important to neuronal excitability regulation, while the second is involved in the central nervous system development and in cortical and subcortical architecture alterations. Therefore, the purpose of this study is to search for mutations in *GABRA1* and *EFHC1* in patients with JME other IGEs.

Method: We screened for *GABRA1* and *EFHC1* mutations in 52 patients with JME and 33 with other types of IGEs. In addition, computation algorithms were used for predicting the impact of amino acid exchanges in protein function.

Results: In *GABRA1*, we identified three silent mutations (c.96A> G, c.156 T> C and c.1323G> A) and an intronic (IVS1 +9 A> T), all present in SNPs databases and none were detected as potentially deleterious. In *EFHC1*, we identified two new variants (896A> G and 1766G> A), and six variants already described in SNPs databases (c.475C> T; 545g> A, 685T> C, 1343T> C; 1821A> G and 1855A> C). The predicted pathogenic potential of these variants was not conclusive amongst all analyses.

Conclusion: Since deleterious mutations were not found in *GABRA1*, this gene does not seem to be related to IGE in our cohort. We found eight sequence variants in *EFHC1*, seven of those were predicted as deleterious by at least one algorithm. All of these were present only in patients with JME. However, the deleterious prediction in *EFHC1* function did not reach a consensus. In addition, we did not observe preferential location of the mutations along *EFHC1*. Genome-wide expression analysis of idiopathic scoliosis endophenotypes. *K. Gorman[1], S. Bouhnik[1], Q. Yuan[1], C. Julien[1], A. Franco[1], K. Choquet[1], L. Suvarnan[1], M.-Y. Akoume[1], A. Moreau[1,2].* 1) Viscogliosi Laboratory in Molecular Genetics of Musculoskeletal Diseases, Sainte-Justine University Hospital Research Center, Department of Biochemistry, Faculty of Medicine, Université de Montréal, Canada; 2) Department of Stomatology, Faculty of Dentistry, Université de Montréal.

Idiopathic scoliosis (IS) is a complex pediatric spinal deformity with an unknown etiopathogenesis. Although a genetic basis is supported, phenotypic variability for morphological and developmental (i.e. propensity for curve progression) factors have complicated efforts to understand it. Genetic heterogeneity is presumed from the limited consensus for loci identified. For complex syndromes, the use of well characterized endophenotypes will stratify patients and give studies more power to identify genetic correlates. We previously reported elevated levels of osteopontin (OPN) and a differential Gi protein signalling defect among IS patients. Three distinct Groups are associated with a hypofunctionality of Gi proteins and OPN resistance or sensitivity on a cellular level. The goal of this study is to identify differential gene expression associated with these biochemically distinct Groups. Fifteen age-matched female patients (5 from each Group) with severe curves were selected for genomic expression analysis. Microarrays, on osteoblasts derived from bone samples obtained intraoperatively, were performed at Centre d'Innovation de Génome Québec à Montréal in triplicate using the Affymetrix GeneChip® Human gene 1.0 ST array. Raw data was normalized using Robust Means Analysis, genes were filtered using a Kruskal-Wallis test and a 3-fold threshold for differential expression. Data was corrected using the Benjamini & Hochberg algorithm and genes with a $p \leq 0.05$ FDR were considered. There are 185 genes significantly differentially expressed among the three Groups. Supervised clustering showed that Group 1 is distinct from Groups 2 and 3, and Groups 2 and 3 have similar expression patterns. Unsupervised clustering showed two distinct gene clusters. These are defined by opposing expression patterns between Group 1 and Groups 2 and 3. Importantly, this pattern of gene expression mirrors the cellular activity for OPN previously demonstrated in our lab. Candidate genes from the filtered gene set will relate to a OPN sensitivity and may also explain some of the differential co-morbidities and prognoses among the Groups. Candidate genes are being confirmed on an expanded patient cohort using quantitative PCR. We expect that key genes related to IS endophenotypes will allow for better patient diagnoses and more personalized therapies, and thus better patient prognoses.

Molecular profiling of osteogenic disregulation in non syndromic craniosynostosis: new insights from microarray and morphological studies. *M. Barba[1, 2], W. Lattanzi[1, 2], G. Tamburrini[3], M.C. Geloso[1], L. Massimi[3], M.A. Puglisi[4], M. Caldarelli[3], C. Di Rocco[3], F. Michetti[1, 2], C. Bernardini[1].* 1) Institute of Anatomy and Cell Biology, Università Cattolica del Sacro Cuore, Rome, Italy; 2) Latium Musculoskeletal Tissue Bank, Rome, Italy; 3) Pediatric Neurosurgery Unit, Università Cattolica del Sacro Cuore, Rome, Italy; 4) Institute of Internal Medicine and Gastroenterology, Università Cattolica S. Cuore, Rome, Italy.

Introduction: The genetic basis and the molecular pathogenesis of non syndromic craniosynostosis (NS-CRS) are still largely unknown. This study attempted to clarify the molecular mechanisms underlying the premature ossification of calvarial sutures, using microarray analysis to perform exon-level genome-wide expression on calvarial suture specimens of NS-CRS patients. Methods: Calvarial specimens from both fused and unfused sutures were collected during surgery from patients affected by different craniosynostosis. Matched samples of each patient was used for comparative microarray analysis using GeneChip human exon 1.0 arrays by Affymetrix, which enable two complimentary levels of analysis, gene expression and alternative splicing. The functional relevance of these data was analyzed comparatively in calvarial cells isolated from fused-versus-patent suture specimens using confocal microscopy. Results: Gene-level analysis allowed identifying 28 significantly modulated genes, mainly involved in cell adhesion, cell-matrix interaction, matrix mineralization, osteogenesis, and tissue development. Exon-level analysis produced a list of over 600 genes with significant ($p<0.01$) alternatively spliced variants in fused-versus-patent sutures, indicating the differential somatic expression of different gene isoforms at the dysmorphic site. Interestingly, this list included the CRS-associated genes FGFR1-3 and TWIST1 along with several genes involved in the structure and functions of the centrosome/primary cilium/mitotic spindle constituents. The confocal microscopy analysis showed that cells isolated from fused sutures display a predisposition to produce differently shaped and developed primary cilia during differentiating stages (G0). During cell replicative stages (M), these cells showed more frequent mitotic events with irregularly oriented spindles, compared to patient-matched controls. Conclusions: These data seemed to suggest that a constitutive somatic alteration in the centrosome-primary cilium-mitotic spindle apparatus could underlie the overworking osteogenic process existing at the site of calvarial suture fusion.

Network-based Genomic Mapping highlights the influence of Central-Nervous System Pathways on Obesity. *M. Nikpay[1], P. Lau[1], R. Dent[2], R. McPherson[1].* 1) Atherogenomics Laboratory, University of Ottawa Heart Institute, Ottawa, Ontario, Canada; 2) Weight Management Clinic, The Ottawa Hospital, Ottawa, Ontario, Canada.

Introduction: Given the modular nature of a complex trait, the underlying genetic factors share protein interactions and display coordinated gene expressions; as such, we used these criteria to narrow the list of GWAS loci for obesity and investigate the underlying biological processes in a cohort of 958 obese (BMI ≥ 32 kg/m2) and 869 lean (BMI ≤ 23 kg/m2) subjects (OBLE study) and two other samples selected from controls of OHGS (Ottawa Heart Genomic Study)_B2 (288 obese and 421 lean subjects) and OHGS_A2 (98 obese and 271 lean subjects) to determine the validity of this approach. **Method:** Subjects in OBLE and OHGS_B2 were genotyped using the Affymetrix 6.0 Array, and in OHGS_A2 genotyping was done using 500K Array; moreover, the densities of our SNP Maps were increased by genotype-imputation from the 1000 Genomes dataset. In each cohort, nominally associated loci ($P < 0.001$) were searched in STRINGdb and their protein interactions were extracted by specifying the highest confidence score (Score > 0.9). Next, genes that shared protein interactions were subjected to co-expression analysis using data from COXPRESdb database and those that formed a network of co-expressed (Pearson's $r < 0.5$) genes were selected. We further reduced the number of genes by performing the statistical test of epistasis and retaining those with significant interactions. **Results:** We determined the expression of the resulting genes from OBLE (33 Genes), OHGS_B2 (12 Genes) and OHGS_A2 (12 Genes) across 65 normal human tissues using data from COXPRESdb and found that the identified genes in each study display high and coordinated expression profiles in cluster of brain-related tissues, and more particularly in parietal and frontal brain lobes. To control for possible systematic bias in our approach, we carried out the same set of analyses in OHGS_A2 and OHGS_B2 for the phenotype, Coronary Artery Disease; however, a very dissimilar pattern was obtained. Finally, while the basic model with only sex and age explains for 0.09 of variability of obesity in OHGS_A2, 0.2 in OHGS_B2 and 0.02 in OBLE study; these values increased to 0.45, 0.41 and 0.24, respectively, when SNPs identified by our method were included. **Conclusion:** Our findings support the notion that obesity is in part a central nervous system-mediated trait and show that the network properties of complex trait genes can be utilized to elucidate the genetic nature and the biological processes underlying a complex phenotype.

A comprehensive knowledgebase of autism genetic evidence. *Y. Huang, L. Xu, J. Li, M. Zhao, X. Tang, L. Wei.* Center for Bioinformatics, School of Life Sciences, Peking University, Beijing, P.R.China, Beijing, China.

Autistic spectrum disorder is a complex neurodevelopmental disorder with three cores of behavioral impairment. Twin studies have highlighted its strong genetic etiology, and many previous efforts have been put on identifying the genetic components of autism. To evaluate how many genes contribute to autism and how strong it is, a collection and integration for genetic evidence of autism is called for. Here we compiled a comprehensive autism knowledgebase including 2193 genes, 2806 genetic markers, 158 linkage regions, and 4544 structural variations which are associated with autism by various types of studies. The metadata of each studies and genes including clinical features, experimental procedures, and statistical values were also extracted. By using a ranking system, we identified a total of 434 highly-confident genes, and these genes are located in pathways related to synapse functions. With integrating annotations extracted from more than 30 external resources, we constructed a public online database - autismKB (http://autismkb.cbi.pku.edu.cn) for autism research community.

Mathematical Modeling of the Insulin Signal Transduction Pathway for Prediction of Insulin Sensitivity from Expression Data. *C.K. Ho[1], J.C. Liao[1,2], G. Sriram[2,3], K.M. Dipple[1,4].* 1) Biomedical Engineering Interdepartmental Program, University of California Los Angeles, Los Angeles, CA; 2) Department of Chemical and Biomolecular Engineering, University of California Los Angeles, Los Angeles, CA; 3) Department of Chemical and Biomolecular Engineering, University of Maryland, College Park, MD; 4) Departments of Human Genetics and Pediatrics, University of California Los Angeles, Los Angeles, CA.

Insulin sensitivity is a key component in understanding obesity and type II diabetes mellitus (T2DM). We developed a mathematical model of the insulin signal transduction pathway, which is an extension of a previous model (Sedaghat et al., *Am J Physiol Endocrinol Metab*, 283, E1084, 2002), to quantitatively predict insulin sensitivity in biological systems. Our extended mathematical model incorporates key recently-elucidated mechanisms of action in the insulin signal transduction pathway and predicts the level of glucose transporter (GLUT4) translocation to the plasma membrane in response to a given insulin dose. The model output also provides information regarding glucose clearance, a measurement used routinely in patients with T2DM. We validated this model using published *in-vivo* data that reported differential expression levels of the key genes involved in the insulin signaling pathway. We further evaluated our extended model by applying the model to biological systems, including mice, humans, and rats. Using microarray data of glycerol kinase knockout (Gyk KO) and wild type mice, our simulation showed that the GLUT4 translocation and glucose uptake rate of the Gyk KO is significantly reduced by 3.3% compared to wild type mice. Additionally, we simulated the effect of acute and short term exercising based on insulin sensitivity levels for i) obese non-diabetic or type II diabetic human subjects and (ii) conditioned rat models. Our model predicted that glucose clearance of T2DM patients is improved by 39.1% after performing 7 days of exercise, which is consistent with published data. Our simulations with the rat models also showed the conditioned rats have improved glucose clearance by 11.8%, compared to the sedentary rats. This is also consistent with the literature, indicating that our model is a good predictor of glucose clearance. This extended model is a useful tool for predicting insulin sensitivity in mammalian tissues with altered gene expression in the insulin signal transduction pathway.

Examining genetic risk factors of obesity: Pathway analysis of GWAS data. *M.A Simonson[1], M.C Keller[1,2], M.B McQueen[1,2].* 1) Psychology and Neuroscience, Institute for Behavioral Genetics, Boulder, CO; 2) Integrative Physiology, Institute for Behavioral Genetics, Boulder, CO.

Classic genome-wide association studies are generally limited in their ability explain a large portion of genetic risk for most common diseases. We sought to use both classic GWAS methods, as well as multiple methods of pathway-based analysis applied to single-nucleotide polymorphism (SNP) data to examine the underlying biology of obesity risk. We used data from the NHLBI Multi-Ethnic Study of Atherosclerosis (MESA) SNP Health Association Resource (SHARe), composed of 2343 case-control subjects, as well as the Atherosclerosis Risk in Communities (ARIC) Study, composed of 12771 case-control subjects, and the Coronary Artery Risk Development in Young Adults (CARDIA) Study - Gene Environment Association Studies Initiative (GENEVA), composed of 1808 case-control subjects. A total of 16922 subjects genotyped at ≈1 million SNPs using the Affymetrix Affy 6.0 array. Our investigation performed 3 complimentary forms of pathway analysis examining curated gene sets from online pathway databases, and publications in PubMed. The results of this analysis suggest common SNPs affect biological processes that relate to obesity risk. Work was supported by the National Institute of Child Health and Human Development - National Institutes of Health: Institutional Training Grant (T32 HD 7289-27, John K. Hewitt, Director).

Haines[1].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Ophthalmology, Mass Eye & Ear Infirmary Boston, MA; 3) Department of Medicine, Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 4) Department of Ophthalmology, University of North Carolina, Chapel Hill, NC; 5) Wilmer Eye Institute, Johns Hopkins University Hospital, Baltimore, MD; 6) Eye Doctors of Washington, Chevy Chase, MD; 7) Scripps Genome Center, University of California at San Diego, San Diego, CA; 8) Bascom Palmer Eye Institute and Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 9) Department of Ophthalmology and Visual Sciences, University of Michigan, Ann Arbor, MI; 10) Department of Ophthalmology Duke University Medical Center, Durham, NC; 11) Essentia Institute of Rural Health, Duluth, MN; 12) Department of Ophthalmology, WVU Eye Institute, Morgantown, WV; 13) Department of Ophthalmology, UPMC Eye Center, University of Pittsburgh, Pittsburgh, PA; 14) Department of Ophthalmology, Stanford University, Palo Alto, CA; 15) Department of Genetics, Stanford University, Palo Alto, CA; 16) Department of Ophthalmology and Hamilton, University of California, San Diego, SD, CA; 17) Department of Medicine, Duke University Medical Center, Durham, NC.

Using genome-wide SNP data, we assessed biologic pathways as annotated in the KEGG database for association with risk of primary open-angle glaucoma (POAG). Our pathway analysis includes the entirety of the SNPs in the GWAS to examine associations that do not meet the genome-wide significance threshold. The PARIS (Pathway Analysis by Randomization Incorporating Structure) algorithm used in this study creates random pathways to mimic the size and structure of the actual pathways. The algorithm is also designed to determine whether statistical associations are due to the biologic properties of the pathway or instead its size and structure. We conducted a POAG case-control analysis of 1002 cases and 1183 controls from the GLAUGEN study and 2,517 POAG cases and 2,428 controls from the NEIGHBOR study using the Illumina 660W quad platform. We first analyzed each study individually for single-SNP associations using logistic regression models to test for association. A subsequent meta-analysis of the two studies was performed. After multiple testing correction, we found 14 pathways associated with risk of POAG ($p<0.001$ for all pathways). These pathways are loosely grouped into three categories: metabolism, cellular adhesion and signaling, and autoimmune disorders. Twelve of these pathways contain a substantial amount of genic overlap in the form of the HLA gene family. After removal of the HLA genes from these pathways, 11 were no longer significant, while the HLA gene set was highly significant ($p<0.001$). Furthermore, 2 pathways, butanoate metabolism (hsa00650) and basal transcription factors (hsa03022) contain genes that do not overlap with any other pathway in the database and thus are entirely independent gene sets. We then tested the 14 pathways for association with risk of POAG in the subset of our cases with normal tension glaucoma, the clinical subdivision that our previous GWAS analysis indicated harbors most of the genetic information. Only the butanoate metabolism pathway held statistical significance after correction for multiple testing. A hypothesis-independent approach identified the HLA gene family and the butanoate metabolism pathway as being associated with risk of POAG. These data provide insight into the complex genetic etiology of POAG and provide hypotheses for future functional studies.

Hirschhorn[1,2,4], The Genetic Investigation of Anthropometric Traits (GIANT) Consortium.* 1) Division of Endocrinology, Children's Hospital Boston, Boston, MA; 2) Metabolism Initiative and Program in Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts 02142, USA; 3) Center for Biological Sequence Analysis, Technical University of Denmark, Lyngby, Denmark; 4) Department of Genetics, Harvard Medical School, Boston, Massachusetts 02115, USA; 5) Estonian Genome Center of University of Tartu (EGCUT), Tartu, Estonia; 6) MRC Epidemiology Unit, Institute of metabolic Science, Cambridge, UK; 7) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland 20892, USA; 8) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, 171 77 Stockholm, Sweden; 9) Department of Biostatistics, Center for Statistical Genetics, University of Michigan, Ann Arbor, Michigan 48109, USA; 10) Department of Genetics, University of North Carolina, Chapel Hill, North Carolina 27599, USA; 11) Mount Sinai School of Medicine, New York, NY; 12) Department of Internal Medicine, Division of Gastroenterology, University of Michigan, Ann Arbor, Michigan, USA; 13) Genetics of Complex Traits, Peninsula Medical School, Exeter, UK.

Genome-wide association (GWA) studies have identified thousands of loci where common variants are associated with polygenic diseases or traits. Because of linkage disequilibrium between variants and the possibility of distant regulatory effects, these associated loci typically contain multiple genes. Many loci have no single obviously causal gene, so the challenge for moving from association to novel biological insight is to identify which gene at each locus most likely explains the association. Because follow-up functional studies are often intensive, a key first step is to use computational approaches to prioritize genes within loci as most likely to be biologically relevant. Previous computational approaches have shown some success but often focus on single types of data, limiting their discriminatory power. We have developed a data-driven network-based approach that integrates a diverse panel of data types (including tissue-specific gene expression data, protein-protein interaction data, phenotypic information from mouse knockout studies, and information text-mined from the scientific literature) to systematically identify the most likely causal gene(s) at a given locus. Our method compares each gene within a locus to a set of likely positive and negative genes (which can be derived in unbiased fashion from the GWA data itself, excluding the locus under consideration) and partitions the results for each gene into data type-specific likelihoods. We evaluate our method using the GIANT consortium's GWA meta-analyses for human height and body mass index (BMI). For GWA loci of both human height and BMI, our integrative approach performs consistently better in predicting likely causal genes than approaches based on one or two data types only. As unbiased benchmarks, we tested for enrichment of genes that have associated missense variants or that are closest to the best associated SNPs, both of which are partial indicators of causality. Genes prioritized by our method are enriched for genes with missense variants (height 2.3-fold, P= 0.002; BMI 3.7-fold, P=0.03), and genes nearest to the lead SNPs (height 2.4-fold, P=4.5*10-18; BMI 2.7-fold, P=6.5*10-5); based on these and other benchmarks, this approach outperforms methods using fewer data types. We have developed an unbiased computational approach that integrates a variety of data types and performs well in prioritizing potentially causal genes from GWA data.

A systems biology approach to ionotropic GABAergic networks in epilepsy, a model of complex neurogenetic disease. *M. Jaworski.* Mental Health Services, University of Ottawa Health Services, Ottawa, ON, Canada.

Ionotropic GABAergic neurotransmission requires numerous co-ordinated steps involving multimolecular complexes distributed in spatially and developmentally diverse brain networks. Complex processes whereby GABAergic neurons synthesize and transport GABA into and out of synaptic vesicles, and into the synaptic cleft involve over 300 interacting gene products. Mechanisms which bring presynaptic GABAergic neurons into apposition with their correct post-synaptic neuronal targets are also finely tuned. Regulatory mechanisms modulating the cell surface expression, and post-translational modification of ionotropic GABA receptor subunits are both complex and diverse. Through mammalian neurosciences, particularly proteomics, we now possess a detailed, though incomplete, inventory of the proteins mediating these networks. This current state of knowledge is applied to epilepsy, or perhaps more accurately, the epilepsies, as a model of a common, genetically complex human disease which has the advantage of objective (endo)phenotyping (EEG and increasingly, neuroimaging). The functional effects of epilepsy susceptibiity mutations (including copy number variation) are increasingly understood. For some forms of epilepsy, (Juvenile Myoclonic Epilepsy and Childhood Absence Epilepsy), integrating knowledge from genomics, proteomics, and connectomics is becoming an increasingly achievable goal. Mutated gene products known to be expressed in the GABAergic presynapse (KCNA1 and KCNC3, as well as others), as well as postsynaptic receptor subunits (GABRA1, GABRB3 and GABRG2, amongst others) and their associated scaffolding/trafficking interactants (ARHGEF9, GPHN, SRC, FYN and others) which are also expressed in the GABAergic postsynapse, as well as mutated gene products involved in GABAergic cell proliferation (BRD2) in anatomically defined brain networks, increasingly point to the ionotropic GABAergic system as one of the important contributors to genetic susceptibility to epilepsy. This systems biology (neuroscience) approach, drawing on proteomics and cell circuitry, may suggest one possible mechanism for the extensive locus and alleleic heterogeneity, as well as the pleiotropy of susceptibility genes implicated in neurogenetic and neuropsychiatric diseases.

***P2RX7* SNPs and external apical root resoprtion during orthodontia.** *J. Hartsfield[1,2,4], G. Falcao-Alencar[1], J. Dempsey[1], E. Jacobson[1], G. Kluemper[1], D. Fardo[2], J. Macri[3], L. Morford[1,4].* 1) College Dentistry, Univ Kentucky, Lexington, KY; 2) College Medicine, Univ Kentucky, Lexington, KY; 3) College Public Health, Univ Kentucky, Lexington, KY; 4) Center for Oral Health Research, Univ Kentucky, Lexington, KY.

Objective: Previously, an *IL-1B* genetic marker responsible for decreased IL-1β in cell culture has been associated with external apical root resorption (EARR) during orthodontia. Functional*P2RX7* gene polymorphisms can also influence secretion of IL-1β. We hypothesized that there is an association between functional *P2RX7* polymorphisms and EARR in orthodontic patients. Materials and Methods: Genomic DNA was isolated from 459 Caucasian orthodontic patients (74 EARR, 385 control). Pre/post-treatment radiographs were analyzed by three investigators for maxillary incisor EARR. Variations at rs1718119, rs208294, and rs2230912 were assayed using Taqman®-based SNP genotyping. Hardy-Weinberg Equilibrium (HWE) testing was employed to assess genotyping quality, and Cochrane-Armitage trend analysis was used for association testing. Results: No departures from HWE were detected. Individuals homozygous for the major allele and heterozygous at rs208294 were more likely to have EARR (p=.02) than those homozygous for the minor allele. For rs1718119, people homozygous for the major allele were more likely to experience EARR (p=0.03) than those either heterozygous or homozygous for the minor allele. Individuals homozygous for the major rs2230912 allele were more likely to experience EARR (p=.03) than either the heterozygous or homozygous for the minor allele. Conclusion: Functional SNPs in the *P2RX7* gene are associated with EARR during orthodontia.

Pathway analysis of variation in DNA repair genes indicates involvement of repair of oxidative DNA lesions in human longevity. *M. Soerensen[1, 2], B. Debrabant[1, 3], J. Mengel-From[1, 2], T. Stevnsner[4], V.A. Bohr[4, 5], K. Christensen[1, 2], Q. Tan[1, 2], L. Christiansen[1, 2].* 1) The Danish Aging Research Center, Epidemiology, Institute of Public Health, University of Southern Denmark, Odense C, Denmark; 2) Department of Clinical Genetics and Department of Clinical Biochemistry and Pharmacology, Odense University Hospital, Odense C, Denmark; 3) Biostatistics, Institute of Public Health, University of Southern Denmark, Odense C, Denmark; 4) The Danish Aging Research Center, Institute of Molecular Biology and Genetics, University of Aarhus, Aarhus, Denmark; 5) Laboratory of Molecular Gerontology, National Institute on Aging, National Institute of Health, Baltimore, Maryland, USA.

Approximately 25% of the variation in human life span is thought to be caused by genetic variation, an effect believed to be minimal before age 60 and most profound from age 85 and onwards. An immense number of association studies reporting association of single-variants to human longevity have been published. These single-variants are located in genes taking part in different biological processes including lipoprotein metabolism, oxidative stress and DNA repair.

In the present study we aim to assess the involvement of DNA damage response and DNA repair processes in human longevity by performing case-control pathway analysis of 592 tagging single nucleotide polymorphisms (SNPs) of 77 genes in 1089 oldest-old (92-93) and 736 middle-aged (46-55) Danes. The 77 genes encode proteins participating in nine sub-pathways of key importance for genetic stability and, hence, the aging process: DNA damage response, telomere maintenance, mitochondrial DNA processes, base excision repair, nucleotide excision repair, mismatch repair, non-homologous end-joining, homologous recombinational repair and the RecQ helicases.

For the pathway analysis we applied a method presented by Bucan and co-workers (Wang et al. 2007), which extends gene set enrichment analysis to SNP data. We analyzed the nine different sub-pathways basing the pathway analysis on a best model procedure, i.e. we considered all possible modes of inheritance (an assumption free genotypic model, as well as additive, recessive and dominant genotypic models) for each SNP and combined the highest test statistics for the SNPs in the gene statistics. The pathway statistics showed that of the nine sub-pathways homologous recombinational repair and base excision repair displayed association ($p<0.05$) with case-control status, however, only for base excision repair the p-value (p-value = 0.016) was based on associations of SNPs in more than one gene. Therefore, our data indicate that longevity might be influenced by variation in the genes encoding proteins conducting repair of DNA damage induced by for instance reactive oxygen species.

All participants gave their informed consent prior participation. The project has been approved by the Danish National Committee on Biomedical Research Ethics. Wang K, Li M, and Bucan M, American journal of human genetics, 81(6):1278-1283, 2007.

Constructing Endophenotypes of complex disease using Nonnegative Matrix Factorization and Adjusted Rand index. *H.M. Wang[1,2], C.L Hsiao[2], A.R Hsieh[2], Y.C Lin[2], S.J Fann[2].* 1) Division of Biostatistics, Institute of Public Health, National Yang-Ming University, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Complex diseases are typically caused by combinations of molecular disturbances that vary widely among different patients. Endophenotypes, a combination of genetic factors associated with a disease, offer a simplified approach to dissect complex trait by reducing genetic heterogeneity. Because molecular dissimilarities often exist between patients with indistinguishable disease symptoms, these unique molecular features may reflect pathogenic heterogeneity. To detect molecular dissimilarities among patients and reduce the complexity of high-dimension data, we have explored an endophenotype-identification analytical procedure that combines non-negative matrix factorization (NMF) and adjusted rand index (ARI), a measure of the similarity of two clusters of a data set. To evaluate this procedure, we compared it with a commonly used method, principal component analysis with k-means clustering (PCA-K). A simulation study with gene expression dataset and genotype information was conducted to examine the performance of our procedure and PCA-K. The results showed that NMF mostly outperformed PCA-K. Additionally, we applied our endophenotype-identification analytical procedure to a publicly available dataset containing data derived from patients with late-onset Alzheimer's disease (LOAD). NMF distilled information associated with 1,116 transcripts into three metagenes and three molecular subtypes (MS) for patients in the LOAD dataset: MS1 (n1=80), MS2 (n2=73), and MS3 (n3=23). ARI was then used to determine the most representative transcripts for each metagene; 123, 89, and 71 metagene-specific transcripts were identified for MS1, MS2, and MS3, respectively. These metagene-specific transcripts were identified as the endophenotypes. Our results showed that 14, 38, 0, and 28 candidate susceptibility genes listed in AlzGene database were found by all patients, MS1, MS2, and MS3, respectively. Moreover, we found that MS2 might be a normal-like subtype. Our proposed procedure provides an alternative approach to investigate the pathogenic mechanism of disease and better understand the relationship between phenotype and genotype.

Candidate genes of several complex diseases via an integrated analysis of GWAS and eQTL. *C. Fuller[1], X. He[2], Y. Song[1], H. Li[1].* 1) Integrative Program in Quantitative Biology, 1700 4th Street, University of California, San Francisco, CA 94158; 2) Lane Center of Computational Biology, Carnegie Mellon University, 5000 Forbes Ave, Pittsburgh, PA 15213.

Genome-wide association studies (GWAS) for common disease can yield large numbers of loci, often in non-coding regions, with limited annotation and no obvious functional consequence. Many more loci may fail to reach genome-wide statistical significance but appear in excess relative to expectations under the null distribution. Together, such issues frustrate efforts to understand common disease etiology, since statistically significant, well-annotated loci usually explain only a small fraction of disease heritability. What is needed are straightforward methods to mine weak GWAS associations and place sets of loci in the context of functionally-relevant genes and gene networks. Our method attempts to do this by scoring GWAS results against thousands of genes from expression quantitative trait loci (eQTL) studies. Genes that share associations at multiple loci with GWAS are unexpected by chance and, thus, may play a causal role in the disease. Unlike earlier methods, this approach utilizes all SNPs that associate with a given gene, not just the proximal ones. The method uses a novel Bayesian framework to score the overlap between disease-loci associations from GWAS and gene-loci associations from an eQTL database. Multiple coincident associations boost the likelihood of a causal gene-disease relationship, whereas a penalty is assigned for each mismatched association. This approach is generalizable to any functionally-informative molecular trait for which trait-loci associations are known; it is not inherently limited to gene expression. We demonstrate our approach using GWAS for a number of common diseases: type 1 and type 2 diabetes, Crohn's disease, HIV progression, various cancers, and other conditions. Typically, our gene lists are enriched for highly-plausible genes, as suggested by either recent studies or the underpinnings of related diseases. Importantly, many supporting loci are found in -trans (i.e. distal to the gene itself) and have associations that fall below genome-wide statistical significance. Individually, such loci are uninformative, but collectively, they may yield key functional insights that cannot be extracted from the GWAS results alone.

Association study-based gene-set enrichment analysis identified biological pathways associated with fetal hemoglobin levels in sickle cell disease patients. *G. Galarneau[1,2], S. Coady[3], M. Puggal[3], N. Jeffries[3], D. Paltoo[3], A. Kutlar[4], G.J. Papanicolaou[3], G. Lettre[1,2].* 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Université de Montréal, Montréal, Québec, Canada; 3) National Heart, Lung and Blood Institute, Bethesda, MD, USA; 4) Medical College of Georgia, Augusta, GA, USA.

INTRODUCTION: Fetal hemoglobin (HbF) levels, a highly heritable trait (h2~0.6-0.9), modify disease severity in the β-hemoglobinopathy sickle cell disease (SCD) and β-thalassemia. Single nucleotide polymorphisms (SNPs) at three loci (BCL11A, HBS1L-MYB, β-globin) are associated with HbF levels in anemic and non-anemic populations and clinical complications in SCD (pain crisis) and β-thalassemia (transfusion-dependency). These SNPs only explain 50% of the heritable variation in HbF levels.

METHODS & RESULTS: To identify new HbF regulators, we genotyped 1,213 SCD patients from the Cooperative Study of Sickle Cell Disease (CSSCD) on the IBC array, a gene-centric platform that includes ~50,000 SNPs and covers genetic variation at ~2,100 genes. We confirmed the association with BCL11A and the β-globin locus (the HBS1L-MYB intergenic region is not covered by the IBC array), but did not detect additional array-wide significant association signals. To identify additional HbF loci of smaller effect that might implicate shared biological processes, we performed a pathway analysis using gene-set enrichment methodologies (Wang et al., AJHG, 2009). We used the KEGG database to define biological pathways and phenotype permutations to assess statistical significance. We identified 12 highly redundant pathways that were nominally significant (P<0.05) and replicated seven of these in an independent set of 276 SCD patients. Our analysis suggests a role for acetyl-coA and short fatty acids metabolism as well as amino acid degradation in HbF levels variation.

CONCLUSION: We have identified and replicated biological pathways that are enriched for SNPs that influence HbF levels in SCD patients. Additional genetic validation and functional follow-up of these results will help understand the regulation of HbF production, a strong modifier of severity for two of the most common diseases worldwide.

2248T

Performances of single-SNP and pathway-based analyses of genome-wide data to detect genetic factors shared by eosinophil and basophil counts in asthma-ascertained families. *C. Loucoubar[1,2,3], M. Brossard[1,2,3], PE. Sugier[1,2,3], A. Vaysse[1,2,3], P. Jeannin[1,2,3], MH. Dizier[1,2,3], M. Lathrop[3], E. Bouzigon[1,2,3], F. Demenais[1,2,3], EGEA collaborative group.* 1) INSERM U946, Paris, France; 2) Université Paris Diderot, Paris, France; 3) Fondation Jean Dausset-CEPH, Paris, France.

Eosinophils (EOS) and basophils (BASO) are white blood cells (WBC) that coordinately mediate allergic inflammation. Correlation of their blood counts suggests the existence of shared genetic determinants. Genome-wide association studies of WBC counts in population-based studies have identified a number of loci and loci shared by EOS and BASO were reported in one study. Pathway-based methods have been proposed to facilitate the detection of trait-associated genes and these methods may be useful to identify pleiotropic genes. Our goal was to compare the ability of single-SNP and pathway-based analyses to detect genetic factors shared by EOS and BASO counts in 388 asthma-ascertained families from the French Epidemiological study on the Genetics and Environment of Asthma (EGEA) study. These families included 1,660 subjects who had been genotyped using an Illumina 610K chip. We used linear regression adjusted for family dependence to conduct single-marker association analysis of EOS and BASO counts with 2.5 millions Hapmap2-imputed SNPs. The pathway analysis,implemented in ALIGATOR, searched for overrepresentation of gene ontology(GO)classes containing association signals. The single-SNP analysis showed that the top hits were specific to EOS or BASO counts; the most significant loci, which represented new signals, were on 1p21.3 ($p=2x10^{-7}$)for EOS and on 8q21.11 ($p=4x10^{-6}$)for BASO. However, there were 7 loci(1q41, 2q36.1, 4q28.3, 6p21.3, 13q21.1, 15q14, 18p11.32) that included SNPs showing association signals ($2x10^{-4}\leq p\leq 8x10^{-4}$) with both EOS and BASO and having the same direction of effects. The pathway based-analysis examined association results from 711,681 SNPs that lied within 18,482 genes which were assigned to 7,070 GO categories. We found an overrepresentation of 7 and 10 GO categories for EOS and BASO respectively that achieved a category-specific p-value$\leq 6x10^{-4}$. These GO categories differed between EOS (immune response and lung development pathways) and BASO (calcium and sodium-potassium channel activities) and did not share any gene. This study shows that, in a situation where most trait-associated SNPs belong to genes that are spread across various biological pathways or are intergenic, pathway analysis does not have higher performance than single-SNP analysis to detect shared genetic determinants. Alternative gene-set methods to characterize pleiotropy will be further explored. Funding: ANR-11-BSV1-027-01 grant.

Background: Chronic Obstructive Pulmonary Disease (COPD) is the third leading cause of death in the U.S. Hypoxemia, defined as reduced oxygen levels in arterial blood, is a major complication of COPD and correlates with disease prognosis. Identifying genetic variants associated with hypoxemia may provide clues for deciphering underlying heterogeneity in prognosis among COPD patients. Methods: We performed genome-wide association studies on 2,819 Non-Hispanic White (NHW) and on 820 African American (AA) COPD cases from the COPDGene Study. All cases were genotyped on the Illumina HumanOmniExpress Beadchip for 730,525 markers. After quality control steps, each SNP was tested for its correlation with resting hypoxemia as measured by the linear trait $Sa0_2$, determined by transcutaneous oximetry at rest, under an additive model corrected for sex, current smoking status, lifetime smoking intensity, age and population substructure.The results from the NHW and AA studies were combined in a meta-analysis. Genes with significant SNPs ($P<5x10^{-5}$) were input to Ingenuity Systems Ingenuity Pathway Analysis (IPA) for overrepresentation of genes from known pathways. Results: One variant achieved genome-wide significance in the AA population (rs8025537 on chr 15, $P_{AA}=4.7x10^{-8}$). This variant was excluded from analysis in the NHW due to a low minor allele frequency (MAF=0.001%). This SNP lies 5' to the gene *RHCG*, which codes for Rh blood group CcEe antigens. The SNP rs6736403 on chr 2 was the most highly associated SNP in NHW ($P_{NHW}=2.7x10^{-7}$). IPA revealed that hematological disease genes (*RUNX1*, *COL18A1* and *UROD*) were overrepresented in the most significant meta-analysis results. The cellular development, embryonic development, nervous system development and function network was the most overrepresented network with an IPA score of 47. This network includes the *RUNX1*, *COL18A1* and *UROD* genes. Conclusion and Future Directions: We have identified one SNP in the*RHCG* gene that is associated with hypoxemia in AA COPD cases and several suggestive associations in NHW cases. Future directions include imputation of untyped variants using the 1000 genomes panel and development of new methods that allow for allelelic heterogeneity between NHW and AA populations. Any significant associations in NHW cases will be validated using the ECLIPSE Study. Funding: R01HL094635, R01NR013377, U01HL089856, U01HL089897. ECLIPSE was funded by GlaxoSmithKline (SCO104960; NCT00292552).

ICAM3 expression level integrates the effects of six MS susceptibility alleles: dissecting a molecular cascade relevant to MS susceptibility. *T. Raj[1,2,3,4], M. Kuchroo[1,4], L.B. Chibnik[1,3,4], L. Ottoboni[1,3,4], X. Hu[2,4,5], B.T. Keenan[1,4], S. Raychaudhuri[2,4,5], B.E. Stranger[2,3,4], P.L. De Jager[1,3,4].* 1) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences Department of Neurology, Brigham and Women's Hospital, 77 Avenue Louis Pasteur, Boston, MA 02115, USA; 2) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA 02115, USA; 3) Harvard Medical School, Boston, MA 02115, USA; 4) Medical and Population Genetics Group, Broad Institute, Cambridge, MA 02142, USA; 5) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Harvard Medical School, Boston, MA 02115, USA.

Objectives: There are now 49 confirmed multiple sclerosis (MS) susceptibility loci. We used several RNA expression datasets to: (1) systematically identify the proximal consequences of susceptibility alleles on the expression of nearby genes and (2) uncover functional networks that integrate these individual effects into dysfunctional immune responses. **Methods and results**: First, using a gene expression-based method and an atlas of CNS and immune cell RNA profiles, we identified CD11b+ dendritic cells and CD8+ T cells, in addition to CD4+T cells, as cell types that are preferentially targeted by MS risk alleles. This implicates many different immune but not CNS cell types in MS susceptibility. Second, using transcriptome profiles generated from (1) peripheral blood mononuclear cells of subjects with MS (n=225) and (2) 7 other immune cell types of healthy subjects, we report that 19 of the 49 MS risk-associated alleles alter RNA expression of genes in their vicinity using an additive expression quantitative trait locus (eQTL) analysis ("cis" effect). Further, using the Relative Trait Concordance Method, we show that altered RNA expression is the likely primary functional consequence of 9 of these alleles. Third, we assessed whether the susceptibility loci influenced each other's RNA expression levels ("trans" effect). For example, the MPHOSPH9 SNP influences ICAM3 RNA expression ($p=9.6x10^{-7}$). In fact, in addition to being associated in "cis" with a nearby MS risk allele, ICAM3 expression levels are associated with risk alleles of five other MS loci on different chromosomes: MPHOSPH9, ZNF767, NDFIP1, MPV17L2 and TMEM39A. Furthermore, we formally demonstrate that the effect of the NDFIP1 SNP on ICAM3 RNA expression is significantly mediated by increased NDFIP1 RNA expression. Similar, though not significant, relationships are seen with ZNF767 and TMEM39A RNA expression. **Conclusion:**Our systematic analyses provide compelling evidence for a primary role of altered RNA expression in the function of many MS susceptibility alleles. Some of these effects (1 cis- and 5 trans- eQTL associations), coalesce in increasing ICAM3 RNA expression, and we present evidence for a mechanistic effect for the NDFIP1 locus via increased NDFIP1 RNA expression. Given its role in early activation of T, NK and other immune cell-types, higher ICAM3 expression could lower the threshold for immune responses against self-antigens and therefore be a key node in susceptibility pathways.

Random enrichment of minor alleles of common SNPs affects complex traits and diseases in model organisms and humans. *S. Huang[1], X. Tan[1], J. Liang[1], C. Zeng[1], J. Zhang[2], J. Chen[2], L. Ma[1], A. Dogan[3], G. Brockmann[3], O. Goldmann[4], E. Medina[4], M. Xian[1], K. Yi[1], Y. Li[1], Q. Lu[1], Y. Huang[1], D. Wang[5], J. Yu[5], H. Guo[1], K. Xia[1], Z. Zhu[1], D. Yuan[1].* 1) State Key Laboratory of Medical Genetics, Central South University, Changsha, Hunan, China; 2) High Performance Computing Center, Modern Educational Technology Center, New Campus, Central South University, Changsha, Hunan 410083, China; 3) Department of Crop and Animal Sciences, Faculty of Agriculture and Horticulture, Humboldt-Universität zu Berlin, Invalidenstraβe 42, 10115 Berlin, Germany; 4) Infection Immunology Group, HZI - Helmholtz Centre for Infection Research, Inhoffenstraβe 7, 38124 Braunschweig, Germany; 5) CAS Key Laboratory of Genome Sciences and Information, Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing 100029, China.

The null hypothesis in population genetics posits that most common SNPs are neutral but this has yet to be formally tested by experimental science. We employed two strategies to determine whether the minor alleles (MAs) of common SNPs are minor because of natural selection. First, we analyzed multiple panels of genetic reference populations or recombinant inbred lines (RILs) in model organisms (yeast, worm, fly, mouse, and rat), and identified the MAs of common SNPs in each panel and the fraction of MAs that each strain carries. We measured the brood size of 104 C. elegans RILs and did genotype-phenotype correlation analysis for the brood trait as well as for ~4700 published and unpublished traits for various RIL panels, most of which were archived at GeneNetwork. Although beneficial to immunity as is expected, more MAs correlated significantly with poor measurements in many adaptive traits, including reproductive fitness, life span, tumor susceptibility, anxiety, depression, startle response, and learning and memory. In addition, more MAs were significantly linked with sensitivity to alcohol, methamphetamine, cocaine, pain, and antipsychotic drugs, and levels in glucose, resistin, insulin, IL-17, iron, and dopamine. The majority of the traits examined did not correlate with MAs, including blood pressure and morphine response. Different MA-linked traits may or may not share the same set of MAs with related traits sharing more MAs than non-related traits. Second, we analyzed 21 published GWAS datasets of common diseases and identified the MAs of common SNPs in each control population and the fraction of MAs each control or case carries. In Europeans or European Americans, more MAs were significantly and repeatedly linked with type 2 diabetes, Parkinson's disease, psychiatric disorders, autoimmune diseases, alcohol and cocaine addictions, lung cancer, less life span, and lower education level achieved, but not hypertension and opiate and marijuana addictions. Thus, the effects of excess MAs in humans are remarkably similar to those in model organisms, suggesting that the link between excess MAs and diseases in humans is causal since it can be replicated in model organisms. These data indicate that most SNPs are functional and open a new avenue of inquiry into the genetic basis of complex traits/diseases. They confirm a self-evident intuition that any system can allow some random errors/noises in building blocks but only to a limit.

Functional characterization of DcR3 and NF-κB in EBV transformed cell lines from IBD patients of different allelic background and role in disease pathogenesis. *R. Pandey[1], C. J. Cardinale[1], S. Panossian[1], F. Wang[1], E. Frackelton[1], C. Kim[1], F. Mentch[1], R. Chiavacci[1], K. Kachelries[2], S. Grant[1], R. Baldassano[2], H. Hakonarson[1].* 1) Center For Applied Genomics, Children's Hospital Of Philadelphia, Philadelphia, PA 19104; 2) Division of Gastroenterology, Hepatology and Nutrition, Department of Pediatrics, University of Pennsylvania School of Medicine, PA 19104.

Aim: Decoy receptor3 (DcR3), member of the TNFR superfamily is a soluble receptor for FasL and plays significant role in immune suppression and tumor progression by neutralizing the FasL mediated apoptosis signal. Here we investigate the possible immuno-modulation mediated by DcR3 and NF-κB in EBV transformed control and patient derived cell lines with and without risk variants in the TNF Receptor Superfamily 6B gene, TNFRSF6B captured by the tagging SNP, rs2315008. **Methods:** Expression of DcR3 and its kinetics were examined by immunoblot analysis in whole cell lysates from EBV transformed control and patient derived cell lines of different genotype background for rs2315008 (AA, AT, TT). DcR3 induced rapid activation of nuclear factor κB (NF-κB) monitored by immnunoblot analysis of IkBα. DcR3 knockdown was performed using specific DcR3 siRNA. Cell proliferation and cell death was measured by MMT assay. Caspase8, caspase9, caspase3, and Bcl2 expression were analyzed by western blots. **Results:** EBV transformed cell lines derived from IBD patients harboring risk variants in TNFRSF6B (A allele) exhibit differential pattern of DcR3 expression and NF-κB activation kinetics in comparison with wild type. siRNA mediated knockdown post 24hrs of nucleofection results in decreased DcR3 expression, increased cell death and decreased cell proliferation, effects that were also genotype-dependent. **Conclusion:** EBV cell lines from IBD patients harboring risk variants in the TNFRSF6B gene exhibit differential pattern of DcR3 expression and NF-κB activation. Therefore, therapeutic intervention targeting the NF-κB activation pathways represents a promising opportunity for future therapy of IBD.

Integrative analysis of whole-gene co-expression network and exome sequence data to characterize pathways relevant to rheumatoid arthritis. *H. Nakaoka[1], S. Mitsunaga[2], H. Inoko[2], I. Inoue[1].* 1) Division of Human Genetics, National Institute of Genetics, Mishima, Shizuoka, Japan; 2) Division of Molecular Life Science, School of Medicine, Tokai University, Isehara, Kanagawa, Japan.

New technologies enable to quantify biological measurements on a genome-wide scale (omics data). Systems genomics approach for integrating multiple types of omics data will provide fundamental information to reveal biological pathways associated with disease or phenotype of interest. We propose a systems approach to the integration of whole-gene co-expression networks and exome sequence data to identify susceptibility genes and pathways relevant to rheumatoid arthritis. We constructed multi-tissue gene co-expression networks by using 200 microarrays from synovial tissues with and without rheumatoid arthritis. A clustering algorithm was performed to identify functional modules in these networks. In order to compare the functional modules between normal and diseased networks, a statistical framework was developed. We focused on “aberrant functional modules” that were groups of genes whose expression measurements were tightly correlated in the normal network but the correlations became disrupted in the diseased network. We found some overlaps of genes in the aberrant functional modules with three functional modules identified in our previous work; leukocyte activation and differentiation, pattern-recognition receptor signaling pathway, and chemokines and their receptors. We also found novel pathways such as signal transduction. We performed exome sequencing for 39 patients with rheumatoid arthritis by using Illumina HiSeq2000 and Agilent SureSelect Human All Exon 50Mb Kit. A module-based association study was examined, in which frequencies of rare variants within each aberrant module were compared between 39 affected and 144 unaffected subjects. These results suggest that our integrative approach is useful to identify pathways relevant to disease etiology and to prioritize genes for rare variant association studies at a large scale.

Integrating genetic linkage analysis and computational prioritization in identifying host genetic factors response to influenza A virus infection. *S. Bao[1], X. Zhou[2], X. Zhang[2], P. Tang[3], J. Zhou[4], Y. Li[5], K. To[4], Y. Song[1].* 1) Department of Biochemistry, The University of Hong Kong, Hong Kong, China; 2) Bioinformatics Division, Tsinghua National Laboratory of Information Science and Technology, Tsinghua University, Beijing; 3) Genomics Core Facility, the Institute for Human Genetics, UCSF; 4) Department of Microbiology, The University of Hong Kong, Hong Kong; 5) Chinese Academy of Sciences, QinDao.

The genetic background of the host has a major role on its resistance to pathogens infection. Several independent studies accumulatively added to the evidence that host genetic make-up may be a key factor in the epidemiology of avian influenza A (H5N1) virus infection in humans. Recently, studies based on mouse models, e.g. quantitative trait loci (QTL) analysis on inbred mouse strains, have shed lights on deciphering the molecular basis of host choice behavior. However, few in silico platforms have been developed to systematically identify genetic factors before they were further experimentally verified. Here, we tried to identify the host factors for influenza virus resistance by integrating genetic linkage analysis and gene prioritization algorithms. We collected all genes within mouse QTLs linked to host response to influenza virus by several independent studies as candidate genes. The genetic polymorphism of the two mouse strains (C57BL/6J, DBA/2J), which exhibited different kinetics after they were infected by influenza A virus, help us filter out candidates which were unlikely to be genetic factors. Totally, we identified 20 genes as candidates by integrating the results from three freely available prioritization tools (Endeavour, ToppGene and SUSPECT). After annotated by the Database for Annotation, Visualization and Integrated Discovery (DAVID), most of them functioned as protein binding genes and participated in the biological processes related to stimulus response, immunity and defense. Interestingly, among the genes expressing non-synonymous coding SNPs on DBA genome, Enpp2 and Tnfrsf11b were both mapped to Bhr2 MGI QTL, which is related to influenza infection consequence. The results indicate that genes identified by our model have great potential as genetic factors in causing host specific response to influenza infection and need to be further studied.

Molecular Markers of Severe Cerebral Malaria: Expression of Complement and Toll-Like Receptor Pathway Genes Associates with the Malaria Severity in Mali. *R. Sobota[1, 2], J. Manning[2, 3], A. Dara[2, 4], A. Niangaly[4], A. Djimde[4], O. Doumbo[4], A. Kone[4], M. Thera[4], G. Vernet[5], P. Leissner[6], C. Plowe[7].* 1) Human Genetics, Vanderbilt University, Nashville, TN; 2) Fogarty International Scholars Program, NIH, Bethesda, MD; 3) Brigham and Women's Hospital, Boston, MA; 4) Malaria Research and Training Center, Bamako, Mali; 5) Fondation Merieux, Lyon, France; 6) BioMerieux, Grenoble, France; 7) University of Maryland, Baltimore, MD.

Malaria continues to be a significant cause of mortality in the developing world, with over 3 million deaths and 300 to 500 million cases each year. The host response to infection by Plasmodium falciparum, the parasite most often responsible for severe malaria, ranges from asymptomatic parasitemia to death. There are numerous factors that dictate the clinical trajectory of a given infection, including the patient's age, nutritional status and level of P. falciparum transmitted in a given bite. Our study focused on the evaluation of host gene expression in search of molecular markers of severe malaria. In order to study the differential gene expression between those who develop severe versus uncomplicated malaria symptoms, we enrolled children of both sexes between 6 months and 5 years of age, residing in an endemic region of Bandiagara, Mali. A total of 23 uncomplicated and 24 severe cases were enrolled and followed from an acute episode of malaria through the following low transmission season. Affymetrix microarrays were used to obtain expression data on 10 patients (5 severe, 5 uncomplicated) for the acute disease presentation time point, 6 patients (3 sev, 3 unc) for a convalescence time point one week after presentation and following treatment, and 8 patients (4 sev, 4 unc) in the low transmission dry season following disease. KEGG and Ingenuity Pathway analyses showed that the Complement and Toll-Like Receptor pathways were differentially expressed between the severe and uncomplicated groups, with the severe patients showing higher expression of probes for the C1q, TLR2, TLR4, TLR8 and CR1 genes. All of the other significantly differentiated genes previously associated with malaria pathogenesis, GZMB, FOS, HSPA6, were also higher in the severe malaria group. The longitudinal component of the study revealed that in the severe group, the TLR2, TLR4, TLR8, CR1, GZMB, FOS, HSPA6 genes were all expressed at lower levels during dry season in comparison to their uncomplicated counterparts. Assuming that the post disease dry season data correspond to baseline expression levels for these genes, this finding would make them strong candidates for severe disease molecular markers. Furthermore, this study validates findings from mouse models of cerebral malaria not previously shown in humans (TLR2, TLR4, FOS, GZMB), and demonstrates that genes previously shown to govern human uncomplicated infection also determine the extent of severe symptoms (TLR8, CR1, C1q).

Cross-ethnic gene co-expression network analysis in human adipose reveals novel triglyceride genes. *D. Weissglas[1], BE. Haas[1], S. Horvath[1,2], KH. Pietiläinen[3,4], RM. Cantor[1], E. Nikkola[1], A. Rissanen[5], M. Civelek[6], I. Cruz-Bautista[7], L. Riba[8], J. Kuusisto[9], J. Kaprio[5,10,11], T. Tusie-Luna[8], M. Laakso[9], CA. Aguilar-Salinas[7], P. Pajukanta[1].* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 2) Department of Biostatistics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 3) Department of Medicine, Division of Endocrinology, University of Helsinki, Helsinki, Finland; 4) Institute for Molecular Medicine FIMM, University of Helsinki, Helsinki, Finland; 5) Department of Psychiatry, Helsinki University Central Hospital, Helsinki, Finland; 6) Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, USA; 7) Department of Endocrinology and Metabolism, UNAM, INCMNSZ, Mexico City, Mexico; 8) Department of Molecular Biology and Genomic Medicine, UNAM, INCMNSZ, Mexico City, Mexico; 9) Department of Medicine, University of Eastern Finland, Kuopio, Finland; 10) Department of Mental Health and Substance Abuse Services, National Institute for Health and Welfare, Helsinki, Finland; 11) Department of Public Health, University of Helsinki, Helsinki, Finland.

Background: Unfavorable serum lipid levels, such as elevated serum triglyceride (TG) levels are a well-known risk factor for coronary heart disease (CHD). We hypothesized that searching for TG-correlated gene expression networks in human adipose tissue may reveal novel genes for high TGs, as human adipose tissue is the major storage for fat in the form of TGs. Methods and Results: We measured gene expression in adipose RNAs from two Finnish and one Mexican study sample using either microarrays or RNA sequencing and constructed gene co-expression networks (modules). Significant correlation between serum TG levels and biological modules was observed in each of these study samples. The most correlated TG-modules from each of the three study samples from two distinct populations had a significant overlap of 34 genes ($P<1x10^{-10}$). Eleven of the 34 genes have previous evidence for CHD, type II diabetes, or obesity. Thus, this study provides 23 novel candidate genes for TGs. We also observed more nonsynonymous variants (P=0.034) and overall variants (P=0.018) in these 34 shared genes in subjects with elevated TGs versus subjects with low TGs. Furthermore, two of the 34 genes (ARHGAP9 and LST1) reside in previously reported GWA loci for TG levels, suggesting them as plausible regional candidates underlying the TG GWA signals. Conclusions: This study presents a novel TG biological network with 34 genes shared across three study samples from two distinct populations, Finns and Mexicans. Furthermore, as we utilized two unique methods of measuring gene expression, microarrays and RNA sequencing, these results should be robust to the gene expression measurement method.

2257T

Discovery and replication of nuclear genes influenced by mitochondrial genetic variation. *J. Hall, W. Bush.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

It is well known that most human cells contain nuclear and mitochondrial genomes. We also know that mutations in mitochondrial DNA can lead to disease, but the complex interplay between the two genomes and how variation in both genomes contributes to changes in gene expression is relatively underexplored. Previous research has revealed nuclear-mitochondrial interactions in several species, from Saccharomyces cerevisiae (yeast) to Zea mays (corn) to Drosophila melanogaster (fly). To further explore this topic we hypothesized that gene expression levels for some nuclear-encoded genes are correlated with variation in the mitochondrial genome. We estimated the proportion of variance for gene expression traits that is due to all available nuclear and mitochondrial SNPs simultaneously using a mixed linear model (MLM). Using 1000 Genomes and HapMap genotype data (4,099,887 nuclear SNPs; 1,141 mitochondrial SNPs; 129 samples) and previously published gene expression data for Phase II HapMap samples (10,760 genes), we used MLMs to determine if genetic similarity is related to similarity in gene expression, and to partition the proportion of variance in gene expression due to nuclear and mitochondrial components. All models were adjusted for both nuclear and mitochondrial principal components to control for ethnic ancestry. After false discovery rate correction, we identified 175 nuclear genes (1.62%) that are significantly influenced by mitochondrial genetic variation, and we estimate that roughly 2% to 5% of their variance in gene expression is explained by mitochondrial SNPs. Functions of some significant genes include ATB binding, formation of the mitochondrial matrix, mitochondrial transport, response to oxidative stress, metal ion binding, and electron transport. Using an independent set of 165 additional multiethnic individuals with gene expression data from HapMap phase III, we replicate 8 of these associations ($p < 0.05$), though we expect many effects failed to replicate due to differences in frequency of mitochondrial variants across ethnicities. Genes showing significant replication p-values include PLN, NUCB1, LENG4, FSTL4, and GFRA2. Notably, a mitochondrial anchor protein (AKAP1) shows marginal evidence of replication. The results of this analysis illustrate that cumulative genetic variants in the mitochondria may illicit a response from the cellular environment, either directly or indirectly inducing changes to the expression of these genes.

Polygenic Inheritance of Paclitaxel-Induced Peripheral Neuropathy Driven by Axon Outgrowth Gene Sets. *A. Chhibber[1,2], J. Mefford[3], S.A. Pendergrass[7], R.M. Plenge[4,5,6], M.D. Ritchie[7], E.A. Stahl[4,5,6], J.S. Witte[2,3], D.L. Kroetz[1,2].* 1) Bioeng. & Therapeutic Sci, Univ Cal San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA, USA; 3) Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA, USA; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 5) Division of Genetics, Brigham and Women's Hospital, Boston, MA, USA; 6) Division of Rheumatology Immunology and Allergy, Brigham and Women's Hospital, Boston, MA, USA; 7) Center for Human Genetics Research, Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN, USA.

Peripheral neuropathy (PN) is a common and often dose-limiting toxicity for patients treated with paclitaxel, with grade 2 or greater toxicity affecting up to 25% of patients. While diabetes or previous exposure to other chemotherapeutics with similar toxicity increase susceptibility to paclitaxel-induced neuropathy, for the vast majority of individuals there are no known risk factors that predispose patients to the adverse event. Further, pathogenesis for paclitaxel-induced neuropathy is unknown, though studies in animal and cell models have provided some potential mechanisms. Determining whether there is a heritable component to paclitaxel induced PN would be valuable in guiding clinical decisions and may provide insight into treatment of and mechanisms for the toxicity. Using genotype and patient information for the paclitaxel arm of CALGB 40101, a Phase III clinical trial comparing efficacy of single-agent paclitaxel with the current standard regimen as adjuvant therapy for breast cancer in women, we estimated the variance in maximum grade of PN and dose at first instance of PN explained by all autosomal SNPs as well as SNPs in six gene sets selected based on prior knowledge regarding possible mechanisms of the pathogenesis of paclitaxel-induced PN. DNA was isolated and genotyped using the Illumina 610-Quad platform. Following QC, a total of 859 genetic Europeans and 104 African Americans were included in our analyses. The whole genome and pathway-specific heritability analyses were conducted using the GCTA software tool[1]. For the pathway-specific analysis, we extracted all SNPs 10 kb upstream and downstream of autosomal genes in six specific Gene Ontology (GO) sets. Autosomal SNPs from the whole genome or GO SNP sets were then used to generate a relatedness matrix for Caucasians and African Americans, and subsequently used to estimate variance explained for each trait of interest by linear mixed modeling. While whole genome estimates of heritability were not significant, of the six GO sets selected the Axonogenesis GO Term set had significant estimates of heritability close to 20%. These results suggest that paclitaxel-induced neuropathy does in fact have a significant heritable component, and that this heritability is driven by genes involved in axon outgrowth. Disruption of axon outgrowth may be one of the primary mechanisms by which paclitaxel treatment results in PN in susceptible patients.[1]Yang el al.Nature Genetics(2011)43,519-525.

Association of adrenomedullin gene polymorphisms and lipid levels in Chinese population. *S. Chen, X. Lu, L. Wang, H. Li, J. Huang, D. Gu.* Fuwai Hospital, Beijing, China.

Objective: Dyslipidemia is an important risk factor of cardiovascular disease and is related to morbidity. The high heritability of circulating lipid levels is well established. Whereas the genetic structure of lipid metabolism has not been fully understood. The present study aimed to examine the associations between genetic variants of the adrenomedullin (ADM) gene and lipid levels in Chinese Han population. Methods: A total of 2313 Chinese without history of hypertension, diabetes, cardiovascular disease or cancer were recruited in the present study. Subjects who have current or recent (less than 2 weeks before screening visit) therapy of regulating lipids were excluded. Three tagging single nucleotide polymorphisms (SNPs) based on HapMap CHB data were selected and genotyped. Lipid levels were compared among genotypes of each SNP by general linear model adjusted for multiple covariates including age, gender and body mass index. Results: There were significant associations between the lipid levels and SNPs rs4910118 and rs7944706 after adjusting for covariates of age, gender and body mass index. For SNP rs4910118, total cholesterol level decreased with the number of minor T allele (P=0.03). Total cholesterol level was 192.1±1.0 mg/dl, 188.7±1.3 mg/dl and 185.2±3.4 mg/dl for CC, TC and TT genotypes, respectively. For SNP rs7944706, levels of total cholesterol and low density lipoprotein cholesterol were increased with the number of minor A allele. Total cholesterol level in subjects with GG, GA and AA genotypes was 186.7±1.5 mg/dl, 191.1±1.1 mg/dl and 194.4±1.6 mg/dl (P=0.0019), respectively. Level of low density lipoprotein cholesterol in subjects with GG, GA and AA genotypes was 111.9±1.3 mg/dl, 115.0±1.0 mg/dl and 118.8±1.5 mg/dl (P= 0.0019), respectively. But no association was found between SNP rs4399321 with lipid levels. Conclusion: Genetic variations of the ADM gene were associated with the lipid levels in Chinese population. This finding suggests ADM gene common variations may influence the lipid levels in Chinese. In addition, replications in other populations and further functional studies are required to confirm and interpret the association of ADM with lipids.

A High Throughput Molecular Assay for Detection of Renal Graft Acute Cellular Rejection Using Peripheral Blood. *M. Mikula[1], O. Zhukov[1], F.M. Hantash[1], N. Park[1], K. Zhang[1], J.R. Rion[1], P. Putheti[2], C. Snopkowski[3], A. Buller-Burckle[1], J. Popov[1], W. Sun[1], B. Crossley[1], M.P. Hernandez-Fuentes[4], S. Sacks[4], M. Suthanthiran[3], T.B. Strom[2], C.M. Strom[1], S.J. Naides[1].*1) Dept Molecular Genetics, Quest Diagnostics Nichols Inst, SanJuanCapistrano, CA; 2) Beth Israel Deaconess Medical Center, Boston, MA; 3) New York Presbyterian Hospital-Weill Cornell Medical Center, New York, NY; 4) King's College London, London, United Kingdom.

Purpose: To develop a molecular test for acute cellular rejection (ACR) in renal grafts. Methods: RNA was extracted from peripheral blood in PAXgene RNA tubes from healthy donors and from transplant patients undergoing renal biopsy for cause, then reverse transcribed for real-time PCR. Targeted markers included cytotoxic T lymphocyte markers (granzyme B, GZMB; perforin, PRF1), regulatory T lymphocyte transcription factor foxP3 (FOXP3), and T lymphocyte and monocyte expressed chemokine IP10 (CXCL10). Constitutively expressed T cell marker CD3E and pan-cell marker ABL1 were endogenous normalizers. Cycle threshold (Ct) values were compared to normal pooled control in 4 replicate reactions via the delta-delta-Ct method to give relative quantity (RQ) for each transcript. Multiple replicates confirmed acceptable intra- and interassay precision. Results: 121 healthy adults without renal, autoimmune or inflammatory disease were tested. Normal donor RQ values were Gaussian in distribution; reference ranges were 95th percentile confidence intervals. Of 21 patients undergoing renal graft biopsy for cause, all 3 with ACR, Banff IIb (n=2) or IIb-IIa (n=1), had elevations in at least 2 analytes normalized to CD3E and a moderate to high elevation in CXCL10 normalized to ABL1 (mean, 12.73 ±15.90). Four with acute tubular necrosis had elevations in 3 or 4 analytes normalized to CD3E, but only 2 had a mild elevation in CXCL10 normalized to ABL1 (mean, 1.28 ±1.15). Patients with antibody-mediated rejection (n=4), chronic cellular rejection (n=2), borderline rejection with Banff III histology (n=2), diabetic nephropathy (n=1), transplant nephropathy (n=1), minimal interstitial fibrosis and tubular atrophy (n=1), or normal histology (n=2) did not show elevations in any marker; 1 patient with antibody-mediated rejection had mild elevations in CXCL10, FOXP3, and GZMB when normalized to CD3E but not when normalized to ABL1. Conclusion: A high-throughput test using molecular biomarkers in peripheral blood is able to detect ACR and to differentiate ACR from other diagnoses known to cause renal graft loss.

Protein interaction networks reveal novel Autism risk genes within GWAS statistical noise. *C. Correia[1,2,3], Y. Diekmann[1], G. Oliveira[4,5,6], J.B. Pereira-Leal[1], A.M. Vicente[1,2,3], Autism Genome Project.* 1) Inst Gulbenkian Ciencia,Oeiras, Portugal; 2) Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisboa, Portugal; 3) Center for Biodiversity, Functional & Integrative Genomics, Lisboa, Portugal; 4) Unidade Neurodesenvolvimento e Autismo, Centro de Desenvolvimento, Hospital Pediátrico (HP) do Centro Hospitalar e Universitário de Coimbra (CHUC), Coimbra, Portugal; 5) Centro de Investigação e Formação Clinica do HP-CHUC; 6) Faculdade de Medicina da Universidade de Coimbra.

Autism Spectrum Disorder (ASD) is a highly heritable neurodevelopmental disorder. However, genome-wide association studies (GWAS) thus far met limited success in the identification of common risk variants. This suggests that ASD, like most complex diseases, may result from the interaction of many variants with small individual risk, which cannot be detected in single-SNP analysis. Realizing this limitation, new strategies are needed to increase the power of GWAS analysis and reveal risk variants hidden within the statistical “noise”. One such approach is network-based analysis, which has been successfully applied in the analysis of high-throughput expression and sequencing data. In this study we applied a network-based strategy to the Autism Genome Project (AGP) GWAS, combining family-based association data from 2588 ASD families, genotyped using the Illumina 1M SNP, with Human Protein-Protein interaction (PPI) data compiled from public databases. By evaluating sets of genes selected at different gene-wise *P*-value thresholds for network connectivity, we found that genes associated with ASD at the range of GWAS statistical noise are functionally connected beyond random expectation. This observation was replicated in GWAS for six other complex diseases tested. As a proof of principle, using curated lists of candidate genes for each disorder, we further demonstrated that the selection of functionally connected genes based on the largest connected component (LCC) contains relevant disease biology, outperforming the selection of top GWAS genes. Further analysis of the network obtained using the AGP GWAS revealed enrichment in biological processes such as focal adhesion and Nerve Growth Factor signaling pathways. By overlapping the LCCs obtained from two autism GWAS and six other unrelated disease datasets, we highlighted eighteen genes present in both autism samples but in none of the other datasets. These genes are mostly novel candidates, and point toward processes such as axonogenesis and synaptic plasticity. By showing that relevant disease genes are more functionally related, our results demonstrated that network analysis is an effective strategy to extract biological information from GWAS at much higher significance levels. With this approach, we supported a role of cell-adhesion and NGF signaling in ASD, and highlighted novel susceptibility genes that should be further explored for causal variants and therapeutic targeting.

Systems biology in a non-human primate model: Transcriptomes of normal development in the vervet monkey. *A.J. Jasinska[1], N. Tran[1], C. Blum[1], J. DeYoung[1], O-W. Choi[1], Y. Huang[1], P. Thomas[1], E. Eskin[2,7], K. Dewar[3], J. Wasserscheid[3], G.M. Weinstock[4], W. Warren[4], M. Jorgensen[5], R. Cantor[1,7], R. Woods[6], G. Coppola[1,6], N. Freimer[1].* 1) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience & Human Behavior, University of California, Los Angeles,; 2) Department of Computer Science, The University of California, Los Angeles; 3) Research Institute of the McGill University Health Centre, McGill University and Génome Québec Innovation Centre, and Departments of Human Genetics and Experimental Medicine, 740 Dr-Penfield Avenue, Montreal, PQ, Canada H3A 1A1; 4) The Genome Institute, Washington University School of Medicine, St Louis, MO; 5) Department of Pathology, Section on Comparative Medicine, Wake Forest School of Medicine, Winston-Salem, NC; 6) Dept of Neurology, The University of California, Los Angeles; 7) Department of Human Genetics, The University of California, Los Angeles.

Characterization of transcriptomic variation is emerging as a critical tool for understanding how quantitative trait loci (QTL) contribute to complex phenotypes. Human transcriptomic studies are limited by factors such as the feasibility of invasive tissue collection or variable environmental exposures that can be readily overcome in non-human primate (NHP) models. We characterized transcriptomic variation across multiple tissues and developmental stages and between individuals in 36 vervet monkeys from the Vervet Research Colony extended pedigree. We conducted RNA sequencing across early (7, 90 days, and one year) and later (2.5, 3, and 4+ years old) developmental time points in 6 individuals (3 males, 3 females) at each stage in five tissue types: caudate (brain), two endocrine tissues (pituitary and adrenal) and two peripheral tissues serving as a source of biomarkers (blood and fibroblasts). Comparisons between sexes, across tissue and across developmental stage led to identification of genes and co-expression gene networks showing sex-specific pattern or acting in specific tissues at specific developmental stage. Extending a previous microarray-based approach (Jasinska *et al. Human Molecular Genetics*, 2012) we identified numerous biomarker transcripts, showing high correlations in expression pattern between blood and/or fibroblasts and either adrenal, pituitary or caudate. For example, for 58 transcripts showing highly concordant expression patterns between blood and adrenal we can use blood expression-profiling from large, genotyped vervet population and pedigree samples to obtain insight into the activity of these genes in the adrenal tissue, which is not accessible on a large scale. We are now analyzing whole genome sequencing (WGS) data from all 36 study individuals to identify both cross-tissue and tissue-specific expression QTL (eQTL). Our preliminary data (based on ~8.5 million called variants) indicate that we are able to differentiate the effects on expression of age, tissue, or sex from those due to inter-individual differences. We are now scaling up this study, which ultimately will profile the vervet developmental transcriptome data from birth to adulthood in a larger sample for nearly 100 distinct tissues, providing a unique discovery resource for systems biology.

PURPOSE: Altered estrogen metabolism has been implicated in the pathogenesis of primary open-angle glaucoma (POAG). We assessed the association between estrogen pathway related single nucleotide polymorphisms (SNPs) and specific POAG features. METHODS: We included 3,272 POAG cases and 3,473 controls from the combined Glaucoma Genes and Environment (GLAUGEN) study and NEI Glaucoma Human Genetics Collaboration (NEIGHBOR) consortium in this analysis. We assembled all SNPs from the estrogen metabolism pathway that were available on the Illumina 660W-Quad array platform. We assessed whether this aggregate of SNPs was associated with POAG overall and then by gender using the Pathway Analysis by Randomization Incorporating Structure (PARIS) analysis software package in our combined dataset. In secondary analysis we assessed associations between the estrogen SNP pathway and POAG stratified by intraocular pressure (IOP) $\geq$ 22 mm Hg (HPG) or IOP < 22 mm Hg (NPG) at diagnosis. In addition, we determined which SNPs in the pathway accounted for any significant associations. RESULTS: The estrogen SNP pathway was not associated with POAG, NPG or HPG overall ($p \geq 0.11$). Furthermore the estrogen SNP pathway was not associated with POAG in males (permuted p=1.0) but it was associated with POAG among women (permuted p=0.02). Among women, the estrogen SNP pathway was associated with HPG only (permuted p=0.004). The association between the estrogen SNP pathway and HPG in women was driven by polymorphisms in the following genes: COMT, ESR1, AKR1C4, ESR2, CYP1A2, CYP3A4, SRDSA1 and STS. The COMT SNPs showed the strongest association with POAG across the spectrum of IOP (permuted p<0.001 for HPG and p=0.01 for NPG) among women. CONCLUSIONS: The estrogen SNP pathway was strongly associated with HPG in women and not in men. These data provide insight regarding how common variants in the estrogen SNP pathway contribute to POAG in women.

Possible roles of miRNA to regulate effective signaling network in controlling cell fate. *M. Nomura[1], S. Kondo[1], T. Nagashima[2], Y. Suzuki[3], M. Okada-Hatakeyama[1].* 1) RIKEN RCAI, Yokohama, Kanagawa, Japan; 2) Center for Cancer Research, Tohoku University, Sendai, Miyagi, Japan; 3) Department of Medica Genome Sciences, University of Tokyo, Kashiwa, Chiba, Japan.

MCF-7 breast cancer cell line is a suitable system to study mechanisms of cell fate controlled by growth factors. Through an activation of shared ErbB receptor signaling pathways, the cell is proliferated in response to epidermal growth factor (EGF) stimulation, while it is differentiated in response to heregulin (HRG). In the previous studies, we showed that early responsive mRNA expression is quantitatively regulated by amplitude and duration of upstream signals, and the qualitative difference in mRNA expression induced by these factors were only observed at late time-points. Notably the HRG-mediated differentiation process is associated with delayed expression of transcription factors that positively and negatively regulate upstream cellular events. These coordinated efforts in a signal-transcription network could be seen in time varying changes of molecular functional groups. To elucidate such cliques in the network, we identified about 400 differentially expressed mRNAs in the EGF/HRG-stimulated MCF-7 cells in five time points and made a signal-transcription network using public databases. In addition to mRNA analysis, we measured miRNA time-course expressions and calculated correlation coefficient to consider temporal effects of miRNAs on their target mRNA expressions. Taking together, we will discuss how expression of miRNA is related to reorganization of cliques in the signal-transcription network in time and stimulus dependent manner.

Unraveling the molecular mechanisms underlying the teratogenicity of Topamax(Topiramate). *S.K. Rafi, A.J. Olm-Shipman, I. Saadi.* Department of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS.

Topiramate is a structurally novel anti-epileptic drug (AED) with broad efficacy in epilepsy. It was initially approved by the Federal Drug Administration in 1996 “as an adjunctive therapy for adults with partial onset seizures”, and later, “for prevention of migraine headaches”. Topiramate is also prescribed (off-label) for bipolar disorders, bulimia nervosa, antipsychotic-induced weight gain, and alcohol abuse. Recently, topiramate use during pregnancy has been linked to a significantly increased risk of orofacial clefts (OFC). Approximately 30,000 children are born to epileptic mothers each year. Consequently, in March 2011, the FDA released a warning about the use of topiramate during pregnancy. However, the exact molecular mechanism of the teratogenicity of topiramate is unknown. We want to ascertain these molecular perturbations due to topiramate use to determine whether the beneficial or off-target effects lead to the observed teratogenicity. If the off-target effects are to blame, then future AEDs can be designed to possibly avoid these adverse consequences. The effect of topiramate involves inhibition of several ion channels, including the voltage-gated Na+, Ca+, and K+ ion channels, such as AMPA / GluR5 kainate receptors and ligand-gated non-NMDA glutamate receptors as well as variable modulation of GABA-activated ion channels and intracellular GABA concentration. Although GABA signaling has been implicated in the pathogenesis of OFC, our Ingenuity Pathway analysis of the gene expression microarray data, previously collected by Lamb et al. (Science, 2006), indicates no significant down-regulation of the GABA signaling pathway following topiramate treatment of MCF-7 cells. Instead, the two most significantly up-regulated canonical pathways are TGF-β signaling and retinoic acid receptor activation. Individually, topiramate significantly affects the expression (>1.5 fold) of a large number of other known OFC-related genes (26 up-regulated, 8 down-regulated). We are now looking at the effect of topiramate on actin cytoskeletal remodeling and on phosphorylation changes downstream of several cell-signaling cascades. These studies are likely to unravel critical molecular clues for the increased occurrence of OFC and other teratogenic effects following topiramate use in pregnancy.

The CARTaGENE Genomics Project: Systems Genetics of Cardiometabolic Phenotypes. *Y. Idaghdour, J-P. Goulet, J. Hussin, A. Hodgkinson, E. Gbeha, J-C. Grenier, T. de Malliard, V. Bruat, E. Hip-Ki, C. Boileau, Y. Payette, P. Awadalla.* Sainte-Justine Research Center, University of Montreal, Montreal, QC, Canada.

An area of fundamental biomedical research that merges population and quantitative genomics is the identification of transcriptional and other intermediate biomarkers for disease susceptibility and disease status. These biomarkers are quantitative traits whose architecture is modulated through mechanisms that can incorporate genetic and environmental cues. But what are the relative magnitudes of these effects, and how do gene expression profiles correlate with cardiometabolic phenotypes? To address these questions, we generated whole-genome genotypic data and whole-blood RNA-Seq gene expression profiles from 800 individuals having high and low cardiovascular disease risk scores from an aging cohort of 20,000 participants in Québec, Canada. For each participant, clinical material and medical information spanning a wide range of medically relevant phenotypes, including data from a well characterized and extended pedigree, were collected. We documented latent structure in gene expression profiles and transcriptional signatures that best correlate with cardio-metabolic phenotypes. Furthermore these analyses revealed the spectrum of allelic expression and regulatory variation associated with the clinical traits studied.

Association of insulin-like growth factor-1 gene polymorphism in Kuwaiti Arab patients with rheumatoid arthritis. *M. Haider[1], G. S. Dhaunsi[1], S. S. Uppal[2].* 1) Dept Pediatrics, Fac Med, Kuwait Univ, Safat, Kuwait; 2) Dept Medicine, Fac Med, Kuwait Univ. Safat, Kuwait.

Insulin-like Growth factor-1 (IGF-1) regulates cellular proliferation, differentiation, survival and regeneration, and low plasma levels of IGF-1 have been suggested to contribute towards pathogenesis of rheumatoid arthritis (RA). In view of the biological significance of IGF-1, we investigated a possible association of RA with polymorphism of a 192-bp allele which is cytosine-adenosine repeat located 1kb upstream from the IGF-1 gene transcription site and known to regulate serum IGF-1 levels. Blood samples were collected from 52 healthy controls (HC) and 68 RA patients to measure the levels of IGF-1 and to isolate genomic DNA. Polymorphism of IGF-1 gene was examined using polymerase chain reaction. Severity, duration, and activity of the disease were recorded for all RA patients. We observed that 97% of all the subjects that participated in this study showed the presence of a 192-bp allele of IGF-1 gene. All healthy controls exhibited the presence of 192-bp wild type allele. All non-carriers of the 192-bp allele had RA. Gender correlated significantly with allele frequencies as 14% of the male and only 2% of the female RA patients were non-carriers of 192-bp allele. Plasma IGF-1 levels were significantly lower ($p<0.01$) in RA patients as compared to HC, and all RA patients that were non-carriers of 192-bp allele had a significantly high disease activity score. Our data from Kuwaiti Arabs demonstrates an association of IGF-1 gene polymorphism with risk of developing RA in non-carriers of IGF-192-bp allele.

Variations within ARID5B, CEBPE, and IKZF1 and Risk of Childhood Leukemia. *L. Hsu[1], A. Chokkalingam[1], C. Metayer[1], J. Wiemels[2], P. Buffler[1].* 1) School of Public Health, University of California, Berkeley, Berkeley, CA; 2) Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA.

Leukemia is the most common childhood malignancy, accounting for 31% of all cancers diagnosed in children younger than 15 years old. Two genome-wide association studies found that genes involved in B-lymphocyte development, including IKZF1 (7p12.2), ARID5B (10q21.2), and CEBPE (14q11.2) are associated with ALL predisposition among the Caucasian population. Here, we attempted to validate selected single nucleotide polymorphisms (SNPs) from previous GWAS in both Caucasian and Hispanic populations in the California Childhood Leukemia Study (CCLS). In addition, potential gene and environment interactions between candidate genes and early life infection experiences (early daycare attendance, birth order, and ear infection) were assessed. The study population is comprised of 525 non-Hispanic White and Hispanic ALL cases and 775 controls from the CCLS. We examined the associations between 8 top SNPs identified in previous GWAS and childhood ALL risk and gene environment interactions. Logistic regression assuming a log-additive genetic model of inheritance was used to estimate odds ratios (OR) associated for each SNP, adjusting for age, sex, race and Hispanic status. In the Caucasian population, results for SNPs in ARID5B, CEBPE, and IKZF1 were consistent in terms of both significance and effect direction with previous GWAS findings after accounting for multiple testing. In the Hispanic population, although a similar relationship with disease risk was observed for all 5 ARID5B SNPs, the associations were not consistent for the SNPs in CEBPE and IKZF1. We also examined the associations within ALL subtypes. 5 ARID5B SNPs showed stronger association with ALL when the analysis was confined to B-cell ALL and B-cell hyperdiploidy ALL. CONCLUSIONS: The results from our study confirm that previous GWAS-identified SNPs in B-cell development genes are associated with childhood ALL risk in the Caucasian population. However, only SNPs on ARID5B are associated with ALL risk in the Hispanic population. The findings indicate that susceptibility in the Hispanic population differs from that of the non-Hispanic population, due possibly to differences in genetic structures and/or differences in environmental exposure profiles that modulate the effects of risk variants. Further investigations are needed to both fine-map the gene regions for identification of the causal loci, and to identify environment factors that may modulate the effects of these loci.

2269T

Contribution of common *PCSK1* genetic variants to obesity in a sample of 8,359 subjects from two multi-ethnic American populations. *H. Choquet[1], J. Kasberger[1], A. Hamidovic[2], M. Fornage[3], E. Jorgenson[1].* 1) Ernest Gallo Clinic and Research Center, University of California, San Francisco, Emeryville, CA; 2) Department of Preventive Medicine, Northwestern University, Chicago, IL; 3) Brown Foundation Institute of Molecular Medicine, University of Texas Health Science Center, Houston, TX.

Common *PCSK1* variants (notably rs6232 and rs6235) have been shown to be associated with obesity in European and Asian populations. To determine whether common *PCSK1* variants contribute to obesity in American populations, we conducted association analyses in 8,359 subjects from two multi-ethnic American studies: the Coronary Artery Risk Development in Young Adults (CARDIA) study and the Multi-Ethnic Study of Atherosclerosis (MESA). By exploring the full *PCSK1* locus, we observed that no variant remained significant after correction for multiple testing. Furthermore, we found no significant association for the rs6232 and rs6235 *PCSK1* variants with obesity by combining all subjects in a meta-analysis. However, the rs6232 and rs6235 variants have been shown to be associated with obesity in CARDIA study (OR=1.65 [1.08-2.51], *P*=0.02; OR=1.22 [1.02-1.46], *P*= 0.03 for the rs6232 and rs6235 respectively). In addition, we observed a nominal effect (OR=0.88 [0.78-0.99], *P*=0.03) for rs6235 in MESA study but in a direction inconsistent with the previous study. By evaluating the contribution of the two above-mentioned *PCSK1* variants in each ethnic group, we found that only the rs6232 variant was associated with BMI (*P*=0.006) and obesity (*P*=0.018) in European-American subjects from the CARDIA study. Moreover, the rs6232 variant was found to increase the obesity incidence during the 20 years of follow-up (HR=1.53 [1.07 - 2.19], *P*= 0.019) in European-American subjects from the CARDIA study. Alternatively, only the rs6235 variant was associated with BMI (*P*=0.028) and obesity (*P*= 0.018) in African-American subjects from the CARDIA study. These results indicate that common *PCSK1* variants (notably rs6232 and rs6235) contribute modestly to obesity in multi-ethnic American populations. Further, these results suggest that the association of rs6232 and rs6235 variants with obesity may be ethnicity-specific. However, multiple replication studies in multi-ethnic American populations are needed to confirm our findings.

2270F

Association between IRF6 gene and non-syndromic cleft lip and/or palate in Brazil. *T. Felix[1], L.T. Souza[1], T.W. Kowalski[1], I.L. Monlléo[2], E.M. Ribeiro[3], J. Souza[4], G.F. Leal[5], A.C. Fett-Conte[6], V. Gil-da-Silva-Lopes[7].* 1) Servico de Gen Medica, Hosp Clinicas Porto Alegre, Porto Alegre, RS, Brazil; 2) Medical Genetics Sector, State University of Alagoas, Maceio, AL, Brazil; 3) Medical Genetics Sector, Hospital Infantil Albert Sabin, Fortaleza, CE, Brazil; 4) Medical Genetics Sector, Assistance Center for Cleft Lip and Palate (CAIF), Curitiba, PR, Brazil; 5) Center for Face Defects (CADEFI), Recife, PE, Brazil; 6) Genetics Service, Faculty of Medicine of São José do Rio Preto, São José do Rio Preto, SP, Brazil; 7) Department of Medical Genetics, University of Campinas, Campinas, SP, Brazil.

Oral cleft (OC) is the most common craniofacial birth defect in humans. Cleft lip and palate (CL/P) have a multifactorial inheritance including both genetic and environmental factors. IRF6 gene is strongly expressed in the leading edge ectoderm of the palatal shelves prior to and during formation of the secondary palate. Studies have shown that variants in IRF6 gene are responsible for 12% of OC cases. The rs2235371 (V274I) polymorphism is in linkage disequilibrium with rs642961 polymorphism. This polymorphism was previously suggested to cause disruption of the binding site of transcription factor AP-2α, and to directly influence the risk of CL/P. The aim of this study was to evaluate the association of rs2235371 and rs642961 IRF6 gene polymorphisms in CL/P in Brazil. The SNPs were analyzed using TaqMan assay (Applied Biosystem). Statistical analysis was performed with the transmission disequilibrium test (TDT) using Family Based Association Test (FBAT) software. We analyzed 171 case-parent triads. Minor allele frequency of rs2235371 A allele was 0.080 and 0.178 for rs642961A allele. TDT analysis showed an overtransmission of G allele rs2235371 (p=0. 002) however we did not find association of rs642961 or combined haplotypes. This data confirms previous findings of association of rs2235371 G allele in the clefting population.

2271W

Validation of the *PPP1R12B* as a candidate gene for childhood asthma susceptibility. *M.B. Freidin[1], A.V. Polonikov[2].* 1) Research Institute of Medical Genetics, Tomsk, Russian Federation; 2) Kursk State Medical University, Kursk, Russian Federation.

Genome-wide association studies (GWAS) are a powerful tool for revealing positional candidate genes of complex diseases and traits. A number of such the studies have been performed in childhood and adult bronchial asthma (BA), which allowed disclosing dozens of novel candidate genes. However, given the high genetic heterogeneity of BA, a validation of the GWASs in independent populations is of critical importance. Recently, the *PPP1R12B* gene was revealed as a new candidate gene for childhood asthma in GWAS in Russians of West Siberia using Illumina 610QUAD chip (Mol Biol. 2011;45(3):464-72). We now set out to validate this finding in Russian population of Kursk. One hundred and fourteen patients with childhood BA (age-of-onset up to 16 years) and 279 healthy controls were genotyped using same Illumina chip. After quality assessment, total of 26 markers embracing the *PPP1R12B* gene region were analyzed using linear models approach to measure the associations between the disease and markers. Four markers (rs17438212, rs12734001, rs3767423, and rs3817222) were found to be significantly associated with childhood BA after correction for multiple testing. They represent two relatively distinct linkage disequilibrium (LD) blocks with two markers in each. The odds ratios for the associations varied between 1.78 and 2.04 (Padj = 0.029 - 0.03). The direction of association and the magnitude of the effect for the rs12734001 and rs3817222 markers were in accordance with initial finding in Russians of West Siberia. A haplotype comprised common alleles of four SNPs was protective against asthma, while two haplotypes containing at least one of pair of rare alleles from every LD block increased risk of the disease. Thus, the present data confirmed that the *PPP1R12B* gene is associated with childhood BA in Russians. Further studies are required to provide the functional basis for the association.

2272T

Association of the SNP rs 9939609 of the fat mass and obesity associated gene (FTO)with the risk for obesity in children from Yucatan, Mexico. *L. Gonzalez-Herrera, N. Mendez-Dominguez, F. Herrera-Sanchez, G. Uicab-Pool, V. Hernandez-Escalante, L. Ruiz-Ortiz, G. Storey-Montalvo, J. Zavala-Castro.* Campus de la Salud, Univ Autonoma de Yucatan, Meridal, Yucatan, Yucatan, Mexico.

Obesity in children is the first cause of morbidity in Yucatán, Mexico. Genetic variation plays a major role in determining the susceptibility to the obesogenic environment. Previous studies have identified the common variant rs9939609 in the FTO gene, which represents a T to A change. Significant associations of the SNP rs9939609 with BMI and with the risk for obesity have been suggested in homozygotes, who weigh about 3-4 kg more. Each risk allele A increases the BMI by the equivalent to ~0.40-0.66 kg/m2 in BMI. The central role of FTO might be through an effect on cerebrocortical insulin sensitivity as homozygous have a reduced insulin response in the brain. However, some other studies have reported lack of association of FTO rs9939609 with risk of obesity. In this study we evaluated the association of the rs9939609 of FTO gene with the risk for obesity in children from Yucatan, Mexico. We included 97 obese children with body mass index (BMI) > 25kg/m2 as cases and 73 healthy children with BMI < 25 kg/m2; in order to perform a case-control association study. Total cholesterol, HDL-cholesterol, LDL-cholesterol, and triglycerides were measured in fasting conditions. Genomic DNA was extracted and the SNP rs9939609 was determined by real time PCR with Taqman probes (ID: C_ 30090620_10 Applied Biosystems). Genotype and allele frequencies between cases and controls were compared using SNPstats software. Genotype and allele frequencies were distributed according to Hardy-Weinberg expectations (p>0.05) in cases and controls. The three rs9939609 genotypes were similarly distributed between obese and non-obese children (p>0.05). The homozygous TT wildtype genotype was the most frequent, whereas the homozygous AA genotype was the least frequent in the studied population. Significant differences were not found when comparing genotype and allele frequencies between cases and controls for any allele nor genotype for the rs9939609 (p>0.05), suggesting that this SNP is not associated with the genetic risk for child obesity in the population of Yucatan. Lipid profile was not significant different between obese and non-obese children, except for triglycerides, which was higher in obese children. The mean levels of the measured lipids were not correlated with any rs9939609 genotype (p>0.05) in the studied population. The SNP rs9939609 is not associated with the genetic risk for obesity, nor with the lipid profile in obese children from Yucatan, Mexico.

Shared genetic loci between leprosy and inflammatory bowel disease in Korean patients. *Y. Jung[1], M. Hong[1], J. Baek[1], S. Yang[2], K. Song[1].* 1) Biochem and Molecular Biol, Univ of Ulsan College of Medicine, Seoul, South Korea; 2) Dept Internal Medicine, Univ Ulsan Col Medicine, Seoul, Korea.

Crohn's disease (CD) and ulcerative colitis (UC) are inflammatory bowel diseases of unknown cause. It has been suggested that genetic and environmental factors cause dysregulated mucosal immune responses to the gut flora in susceptible individuals. Mycobacterium avium subspecies paratuberculosis has been implicated in CD. It has shown to cause bowel inflammation in ruminants. It is of interest that significant overlap of susceptibility genes is present between CD and leprosy, an infectious disease caused by Mycobacterium leprae. Recent genome-wide association study of leprosy conducted in the Chinese population identified eight susceptibility loci including CCDC122, LACC1(C13orf31), NOD2, TNFSF15, HLA-DR, IL23R, RAB32, and RIPK2 (Zhang et al. 2009, 2011). Of those, LACC1, NOD2, TNFSF15, HLA-DR, and IL23R were shown to be associated with CD susceptibility in Caucasians, and TNFSF15 and HLA-DR in East Asians, respectively. The goal of this study was to test a potential overlapping of the rest of the leprosy susceptibility genes including CCDC122, LACC1 and RIPK2 with CD or UC in Korean patients. Five single nucleotide polymorphisms from the 3 loci including CCDC122, LACC1, and RIPK2 were genotyped in 631 patients with CD, 636 patients with UC, and 597 healthy controls. Statistically significant association with CD was found at LACC1 (rs3764147, P = 2.4 x 10-4, OR = 1.36 (95% CI = 1.16-1.61) under the allelic model). Rs42490 of RIPK2 showed significant association with UC (rs42490, P = 0.009, OR = 1.62 (95% CI = 1.12-2.33) under the recessive model). Our data suggest that LACC1 and RIPK2 variants might be associated with pathogenesis of CD and UC in Koreans, respectively. Our data may support pathobiological roles of intestinal flora for developing intestinal bowel diseases in genetically susceptible individuals.

2274W

Fatness related allelic variant near insulin receptor substrate 1 (IRS-1) gene is associated with low low-density lipoprotein cholesterol in childhood and a better cardiometabolic profile in their adulthood: The Bogalusa Heart Study. *S. Li[1], W. Chen[1], E.N. Smith[2], S.S. Murray[3], C. Fernandez[1], J. Xu[1], S.R. Srinivasan[1], N.J. Schork[4], G.S. Berenson[1].* 1) Tulane Center for Cardiovascular Health and Department of Epidemiology, Tulane School of Public Health and Tropical Medicine, New Orleans, LA; 2) Department of Pediatrics and Rady's Children's Hospital, School of Medicine, University of California at San Diego, La Jolla, CA; 3) Department of Pathology, School of Medicine, University of California at San Diego, San Diego, CA; 4) The Scripps Research Institute and the Scripps Translational Science Institute, La Jolla, CA.

Recent genome-wide association studies have identified variants near insulin receptor substrate 1 (IRS-1) gene that are associated with body fatness, type 2 diabetes, and various metabolic traits in adults. However, limited information is available in this regard in children. We examined the effects of one variant near IRS-1, rs1399627, which is in perfect linkage disequilibrium with the variant reported to be associated with body fatness, on metabolic profiles in childhood (average age=12.0 years) as well as in adulthood (average age=36.5 years) in a community-based, longitudinal cohort of the Bogalusa Heart Study (n=1,196). The fatness increasing allele (T) of rs1399627 was associated with lower levels of low-density lipoprotein (LDL) cholesterol in children (P<0.001); associated with lower levels of LDL cholesterol (P=0.07), triglycerides (P=0.002), insulin (P=0.06), and glucose (P=0.05), and higher levels of high-density lipoprotein (HDL) cholesterol (P= 0.07) and adiponectin (P=0.007) in adulthood. Further, the T allele was associated with a better metabolic profile, with 20.7% of non-T carriers versus 27.6% of T-carriers having no metabolic abnormalities (according to levels of HDL cholesterol, LDL cholesterol, triglycerides, glucose, systolic and diastolic blood pressures, C-reactive protein, and adiponectin) in adults (P=0.03). In conclusion, fat-increasing allelic variants near IRS-1 gene are associated with lower levels of LDL cholesterol in childhood and a better metabolic profile in adulthood.

2275T

Genetic Variants Associate with Nonalcoholic Fatty Liver Disease (NAFLD) in African and Hispanic Americans. *S.K. Musani[1], N.D. Palmer[2], M.F. Feitosa[3], M.A. Jhun[4], L.M. Yerges-Armstrong[5], R. Hernaez[6], J. Liu[1], B. Kahali[7], J.J. Carr[8], T.B. Harris[9], A.V. Smith[10], L.E. Wagenknecht[11], I.B. Borecki[3], E.K. Speliotes[7], L.F. Bielak[4] for the Genetics of Obesity-Related Liver Disease (GOLD) Consortium.* 1) Jackson Heart Study, University of Mississippi Medical Center, Jackson, MS; 2) Department of Biochemistry, Wake Forest School of Medicine Winston Salem, NC; 3) Department of Genetics, Washington University, Saint Louis, MO; 4) Department of Epidemiology, University of Michigan School of Public Health, Ann Arbor MI; 5) Department of Medicine, Division of Endocrinology, Diabetes and Nutrition - University of Maryland School of Medicine, Baltimore MD; 6) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 7) Department of Internal Medicine, Division of Gastroenterology and Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 8) Departments of Radiologic Sciences, Internal Medicine-Cardiology and Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 9) National Institute on Aging, National Institutes of Health, Bethesda, MD; 10) Icelandic Heart Association, Kopavogur IS-201, Iceland; 11) Division of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC.

NAFLD is an obesity related condition that affects > 50% of individuals in some populations and is expected to become the leading cause of liver disease around the world by 2020. NAFLD is a spectrum of disease that includes hepatic steatosis (fat in liver cells), steatohepatitis (inflammation around the fat), and fibrosis/cirrhosis (scarring of the liver). NAFLD is more prevalent in individuals of Hispanic than European than African ancestries. Association of genetic polymorphisms in or near five genes with NAFLD has been replicated in individuals of European ancestry. Here we investigate whether these polymorphisms are associated with NAFLD in African and Hispanic Americans. As in individuals of European ancestry, hepatic steatosis was quantified using computed tomography and then inverse normally transformed. We used an additive genetic model to examine the association of hepatic steatosis with five single nucleotide polymorphisms (SNPs) in or near *PNPLA3*, *PP1R3B*, *NCAN*, *GCKR* and *LYPLAL1* in five cohorts of African Americans (n=3,124) and one cohort of Hispanic Americans (n=849) controlling for age, age^2, sex, number of alcoholic drinks, principal components for population stratification, and relatedness in the family studies, using regression. We combined results across studies using fixed-effects meta-analysis in METAL. We also estimated heritability of hepatic steatosis in the family studies using SOLAR. Heritability of hepatic steatosis ranged from 0.20 - 0.34 in these cohorts. Variants in or near *PNPLA3* (p=5.1E-18), *NCAN* (p=4.3E-03), *GCKR* (p=5.1E-02), *PPP1R3B* (p=3.3E-06) in African, and *PNPLA3* (p=2.0E-07) and *PPP1R3B* (p=2.5E-02) in Hispanic Americans had statistically significant, directionally consistent effects as those in the European ancestry discovery study. Total variance explained by the five SNPs across these five loci was 5.13% vs. 4.76% vs. 4.24% in individuals of Hispanic, European, and African ancestries. Fine mapping of these loci in African Americans highlights missense variants at *PNPLA3* and *GCKR*and better defines the association region at *LYPLAL1*. Some genetic variants that predispose to NAFLD are shared across ancestries. Missense variants identified in *PNPLA3* and *GCKR*during cross-ancestry analyses are likely functional.

Genetic association to ERAP1 in psoriasis is confined to disease onset after puberty and not dependent on HLA-C*06. *P. Nikamo[1], J. Lysell[1], L. Padyukov[2], I. Kockum[3], M. Ståhle[1].* 1) Department of Medicine, Dermatology Unit, Karolinska Institutet, Stockholm, Sweden; 2) Department of Medicine, Rheumatology Unit, Karolinska Institutet, Stockholm, Sweden; 3) Department of Medicine, Neuroimmunology Unit, Karolinska Institutet, Stockholm, Sweden.

The genetic background of psoriasis is strong and several susceptibility genes have been identified with HLA-Cw*0602 remaining the strongest candidate. Precisely how HLA-C contributes to psoriasis is however unclear. Evidence for an interaction between HLA-C and endoplasmic reticulum aminopeptidase 1, ERAP1, confined to individuals carrying the HLA-C risk allele was recently presented. ERAP1 plays a crucial role in MHC class I peptide processing and is involved in cell surface shedding of proinflammatory cytokine receptors, altogether suggestive of a potential involvement in psoriasis pathogenesis. Psoriasis displays wide clinical variation and genetic heterogeneity likely contributes substantially to clinical diversity. Therefore, stringent stratification for sub-phenotypes may be crucial in genetic analyses. Age of onset is an obvious phenotype and separating psoriasis into type I (onset <40 years of age) and Type II (> 40 years of age) has been useful. To sharpen the age dependent phenotype, we compared genotypes for ERAP1 (rs26653, rs30187, rs27524) and HLA-C*06:02 in healthy controls and cases stratified for onset of psoriasis <10, 10-20, 20-40 and >40 years of age. This approach revealed that association to ERAP1 was confined to cases with onset between 10-20 years (OR 1.59, CI 1.28-1.98, p=0.00008) and no association was detected in cases with onset below 10 years, reflecting genetic heterogeneity within the childhood psoriasis population. In contrast to earlier findings, association to ERAP1 was neither dependent on nor interacting with HLA-C*06:02. ERAP1 SNP rs26653, previously not reported in psoriasis, is non-synonymous, has suggestive functional consequences and herein displays strong association to disease.

2277W

On the association of common polygenic variation with body mass index across adolescent development: A longitudinal twin study. *R.E. Peterson, B.T. Webb, E.C. Prom-Wormley, J.L. Silberg, L.J. Eaves, H.H. Maes.* Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA.

There have been few genetically informative longitudinal studies examining the stability of body composition over time. However, there is some evidence to suggest additive genetic effects associated with BMI are relatively stable across adolescence as indicated by genetic cross-time correlations upwards of 0.80. In contrast, the environmental cross-time correlations have been shown to decrease over time and common environment has been shown to be important in early but not late adolescence or adulthood. Furthermore, genome-wide association studies (GWAS) of BMI using large-scale adult samples have yielded 32 robustly associated variants. Of which 23 were associated with BMI in a cross-sectional analysis of children and adolescents. Further research needs to address when in development these variants become important for predicting BMI. Given the dramatic increase of obesity prevalence in both children and adults in developed countries and the numerous negative consequences associated with elevated body weight, future research is warranted to understand the genetic and environmental contributions to BMI trajectories across adolescence. Therefore, the purpose of this research is to utilize a developmental twin study design to 1) test for changes in the relative contributions of genes and environment, 2) test for shared genetic and environmental liability across time, 3) identify factors driving change versus maintaining stability and 4) evaluate association of validated BMI-SNPs across adolescence. BMI was calculated from weight and height collected on up to four waves and ages ranged from 8 to 18 in 2,794 twin participants from the Virginia Twin Study of Adolescent Behavioral Development (ABD). Preliminary results suggest that SNPs in FTO and TNN13K are associated with BMI from age 11 through development and a SNP in MC4R is associated from age 17. Understanding obesity development will aid in identifying obesogenic vulnerability time-points and facilitate targeted prevention and treatment efforts.

2278T

Absence of the chromosome 16p11.2 duplication in metabolically normal, constitutionally thin individuals with extremely low BMI. *J. Hager[1], N. Germain[2], E. Meugnier[3], B. Galusca[2], H. Vidal[3], B. Estour[2].* 1) Human Genetics, Nestle Institute of Health Sciences, Lausanne, Vaud, Switzerland; 2) Dept. of Endocrinology, Centre Hospitalier Universitaire, Saint Etienne, France; 3) UMR INSERM U-449/INRA-1235, Faculty of Medecine R Laennec, Lyon, France.

We recently described a phenotype termed constitutional thinness (CT), for individuals with extreme low BMI (<17 kg/m2) but normal metabolic profile without any cognitive or psychiatric abnormalities (e.g. anorexia nervosa or other abnormal food-intake behaviors). Constitutionally thin individuals have normal food intake are remarkably resistance to weight gain. Jacquemont et al. recently reported the association of a deletion/duplication variant on chromosome 16p11.2 with extreme high and low BMI's respectively (Nature, 6 October 2011, Vol. 478: 97-102). Given the similarly low BMI in CT individuals it is important to determine if the reported duplication associated with low BMI is also present in the CT phenotype. We used genome-wide genotype data to screen the 16p11.2 area for the reported duplication CNV in constitutionally thin and normal weight individuals. Apart from one normal weight individual, none of the individuals showed evidence for a duplication in the reported chromosomal area. We also evaluated the expression profiles of the genes in the duplication interval in adipose tissue. Again, contrary to reported expression profiles by Jacquemont et al. we did not find any evidence for differential over-expression of genes in the duplication area, substantiating the absence of any duplication in the CT individuals. In summary we did not find evidence that CT individuals carry duplications of the chromosomal region 16p11.2. Constitutionally thin individuals are characterized by a stable very low BMI, comparable to the BMI reported by Jacquemont et al. but are metabolically normal and don't show any of the psychiatric abnormalities that constituted the selection criteria their study. Jacquemont et al. ascertained individuals primarily for a variety of cognitive and psychiatric phenotypes rather than BMI. Indeed this duplication was shown previously to be associated with both autism and schizophrenia. It may be that the association with low BMI of the individuals reported by Jacquemont et al. is secondary to the psychiatric profile and abnormalities in feeding behavior rather than a susceptibility to low BMI per se. In conclusion we believe that our additional findings are important and need to be considered when reporting on associations with BMI. Also it highlights the importance of careful phenotypic description to distinguish extremes in weight distribution due to abnormal food-intake behavior from those due to differences in metabolic state.

Lack of association of genetic variants in *PROX1*, *ADCY5*, *SLC2A2*, *DGKB-TMEM195*, *ADRA2A*, *CRY2*, *FADS1*, *IGF1* and *C2CD4B* with glucose- and insulin-related traits in Chinese adolescents. *R.C.W. Ma, C. Tam, G. Jiang, J. Ho, V. Lam, Y. Wang, H.M. Lee, A. Kong, W.Y. So, J. Chan.* Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, Hong Kong.

Objective - In this study, we aim to examine the associations of previously reported genetic variants for fasting glucose or insulin levels in Chinese adolescents.

Methodology - Nine single nucleotide polymorphisms (SNPs) from *PROX1*, *ADCY5*, *SLC2A2*, *DGKB-TMEM195*, *ADRA2A*, *CRY2*, *FADS1*, *IGF1* and *C2CD4B* were genotyped in 975 adolescents [age mean ± SD = 15.5 ± 1.9 years, % males = 46.6] that participated in a health screening program. Associations of SNPs at additive model with glucose-and insulin-related quantitative traits including fasting plasma glucose and insulin (FPG and FPI), as well homeostasis model assessments of insulin resistance and beta-cell function (HOMA-IR and HOMA-β) were tested by multivariate linear regression adjusted for age, sex and body mass index.

Results - We did not observe any significant association between SNPs and quantitative traits, except that the A-allele of rs11071657 in *C2CD4B* revealed trends of reducing FPI (P = 0.092) and HOMA-IR (P = 0.044). In addition, five and seven SNPs showed similar direction of associations for FPG and HOMA-β to earlier reports, respectively.

Conclusions - Our findings do not support association of the reported loci with glucose- and insulin-related traits in Chinese adolescents. *Acknowledgement* - This work was supported by a CUHK Direct Grant (2041567) and the Innovation and Technology Fund (ITS/487/09FP).

Combined Effects of Genetic Variants identified from Genome-wide Association Studies Increased Risk of Type 2 diabetes in Chinese. *C. Tam, J. Ho, Y. Wang, V. Lam, M. Ng, R. Ma, W. So, J. Chan.* Department of Medicine & Therapeutics, The Chinese University of Hong Kong, Hong Kong, Hong Kong.

Background - Type 2 diabetes (T2D) is a complex disease resulting from the interaction of multiple genetic variants and environmental factors. Recent meta-analysis of genome-wide association studies (GWAS) identified novel loci increasing risk for T2D, which were widely reproduced in European and Asian populations. In the present study, we aim to investigate their univariate and combined genetic effects on T2D in Chinese population.

Methodology - We genotyped 14 single nucleotide polymorphisms (SNPs) from β-cell function-related genes including *NOTCH2*, *ADAMTS9*, *IGF2BP2*, *WFS1*, *CDKAL1*, *JAZF1*, *SLC30A8*,*CDKN2A/B*, *HHEX*, *TCF7L2*, *KCNQ1*, *KCNJ11*, *TSPAN8/LGR5*, *HNF1B* in 6103 T2D patients and 2061 healthy controls with age greater than 16 years. Combined genetic score was calculated by summing the score of risk allele for each SNP under additive genetic model. Associations between T2D and genetic variants were tested by logistic regression adjusted for age, sex and body mass index.

Results - We observed consistent and significant associations of *NOTCH2*, *IGF2BP2*, *WFS1*, *CDKAL1*, *JAZF1*, *SLC30A8*, *CDKN2A/B*, *HHEX*, *TCF7L2*, *KCNQ1* and *KCNJ11* with T2D risk, yielded odds ratios ranged from 1.10 to 2.15 ($1.8x10^{-15} < P < 0.042$). Moreover, the 14 SNPs exhibited joint effect on increasing T2D risk (per-allele OR (95% CI) = 1.15 (1.11 - 1.18); $P = 7.5x10^{-21}$). Subjects carrying 16 or more risk alleles had an OR of 3.45 (95% CI, 2.41 - 4.94) compared to those carrying 11 or less risk alleles.

Conclusion - In summary, our study support common variants in *NOTCH2*, *IGF2BP2*, *WFS1*, *CDKAL1*, *JAZF1*, *SLC30A8*, *CDKN2A/B*, *HHEX*, *TCF7L2*, *KCNQ1* and *KCNJ11* loci independently or jointly increase risk for T2D in Chinese population.

AGRP SNPs and gender effects on obesity in African Americans. *E. Shah[1], A. Patterson[1], U. Al-Alem[2], R.A. Kittles[1,2,3].* 1) Institute of Human Genetics, University of Illinois at Chicago, Chicago, IL; 2) Division of Epidemiology and Biostatistics, School of Public Health, University of Illinois at Chicago, Chicago, IL; 3) Section of Hematology/Oncology, Department of Medicine, University of Illinois at Chicago, Chicago, IL.

Background: Obesity is a complex metabolic disorder that results from a sustained imbalance between food intake and energy expenditure. African Americans (AAs) have the highest prevalence of obesity compared to Hispanics and non-Hispanic Whites. Multiple genetic studies have focused on body mass index (BMI) in diverse populations. Here we aim to identify genetic effects on BMI in candidate genes and/or previous GWAS findings near the *AGRP, FTO, NEGR1, BDNF, JAZF1 and LGR4* gene regions in individuals of west African descent.**Method**: We examined eighteen (18) SNPs previously associated with obesity in whites and West African populations in a total of 1,393 AAs in a two-stage analysis [691 males in our first stage and 702 AAs (278 males and 424 females) in our second stage]. BMI was calculated from weight and height. Regression analyses were used to test for association of SNPs and BMI, controlling for age, gender, and west African genetic ancestry. **Results**: We report that SNP rs11575892, in the Agouti Related Protein gene (*AGRP*), was associated with BMI in our stage one, stage two and pooled analyses (P<0.004). In addition, two other *AGRP* SNPs, rs503891 and rs34123523, were associated with BMI only among females (P=0.02). **Conclusion**: Polymorphisms in the *AGRP* gene have been shown to be involved in the development of body fatness in different populations. Our findings suggest that several *AGRP* SNPs are involved in BMI in AAs. In addition, we detected gender differences in *AGRP* SNP effects on BMI. The gender differences observed in our study may be related to the differences in composition and other measures of adiposity, including serum leptin levels, sex steroids, and body fat patterning, which have been shown to vary between the sexes.

Pleiotropic effects of obesity-susceptibility loci on metabolic traits: a meta-analysis of up to 37,874 individuals. J. van Vliet-Ostaptchouk[1,2,3], M. den Hoed[4], J. Luan[4], J-H. Zhao[4], K.K. Ong[4], P.J. van der Most[2], A. Wong[5], R. Hardy[5], D. Kuh[5], M.M. van der Klauw[1,6], M. Bruinenberg[6], B.H.R. Wolffenbuttel[1,6], N.J. Wareham[4], H. Snieder[2,6], R.J.F. Loos[4,7]. 1) Department of Endocrinology, University Medical Center Groningen, University of Groningen, Groningen, Netherlands; 2) Unit of Genetic Epidemiology and Bioinformatics, Department of Epidemiology, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands; 3) Netherlands Consortium for Healthy Aging, the Netherlands; 4) Medical Research Council Epidemiology Unit, Institute of Metabolic Science, Cambridge, CB2 0QQ UK; 5) MRC Unit for Lifelong Health and Ageing, University College London, WC1B 5JU, UK; 6) LifeLines Cohort Study, University Medical Center Groningen, University of Groningen, The Netherlands; 7) Genetics of Obesity and Related Metabolic Traits Program, Mount Sinai School of Medicine, New York, NY 10029, USA.

Obesity is a key risk factor for a number of metabolic diseases, including type 2 diabetes, dyslipedimia and cardiovascular disease. Although the exact biological mechanisms linking obesity to these co-morbidities are not fully understood, a set of common genetic factors with pleiotropic effects (i.e. affecting multiple traits) might in part explain the observed associations. We aimed to investigate whether the currently established obesity-susceptibility loci identified through genome-wide associations studies for body mass index (BMI) and waist-to-hip-ratio (WHR) influence metabolic traits independently from obesity-related phenotypes. We systematically assessed associations of the 32 BMI and 14 WHR loci, individually and combined in two genetic predisposition scores (GPS-BMI, GPS-WHR), with glycaemic traits, blood lipids, and blood pressure (BP) and examined whether these associations were influenced by the level of obesity by performing meta-analyses of data of up to 37,874 individuals of European ancestry from six population-based studies. The meta-analyses revealed associations of both the individual obesity-susceptibility loci and the genetic predisposition scores with metabolic traits that were not driven by the obesity-related phenotypes. We observed significant associations of the BMI-increasing alleles at five BMI-loci with higher concentrations of LDL and total cholesterol levels (QPTCL), lower 2-hr glucose levels (RBJ, QPTCL), lower levels of HDL- (SLC39A8, MTCH2), LDL- (FLJ35779), and total cholesterol (FLJ35779), and reduced diastolic BP (SLC39A8) (all Ps<2.5x10-4), independent of their effect on BMI. WHR-increasing alleles at two WHR-loci were associated with higher proinsulin levels (GRB14) and lower levels of fasting glucose (CPEB4) (Ps<2.3x10-4), independent of both BMI and WHR. A higher GPS-BMI was associated with increased levels of insulin, pro-insulin and triglycerides and with lower HDL-cholesterol levels (Ps<2.3x10-3), but these associations were abolished after adjusting for BMI. The associations of the GPS-BMI with lower 2-hr glucose and systolic and diastolic BP (P<1.9x10-3) became apparent after adjustment for BMI. The GPS-WHR was associated with lower HDL-cholesterol and higher triglyceride levels independently of WHR and BMI (Ps<2.9x10-3). Conclusions: These results provide evidence that obesity-susceptibility loci are associated with metabolic traits independent of their effect on obesity, suggesting pleiotropic effects.

Investigation of celiac disease susceptibility variants in the Irish population using the immunochip. C. Coleman[1], E. Quinn[1], A.W. Ryan[1], J. Conroy[2], S. Ennis[2], V. Trimble[1], R. McManus[1]. 1) Institute of Molecular Medicine, Trinity College Dublin, Dublin, Ireland; 2) Health Sciences Centre, University College Dublin, Ireland.

Celiac disease (CD) is a common, complex and chronic immune-mediated disease triggered in genetically sensitive individuals by the ingestion of gluten. Susceptibility is prevalent in European populations at a frequency of approximately 1%. HLA-DQA1 and HLA-DQB1 alleles are necessary but not sufficient to cause disease and recent genome wide association studies (GWAS) have identified many associated non-HLA risk loci. A large proportion of the causative susceptibility variants likely remain to be identified due to insufficient capture of genetic variation using existing methodologies. The Immunochip is a custom Illumina Infinium high-density array which addresses these issues, consisting of 196,524 common and rare polymorphisms designed to perform deep replication and fine mapping of established GWAS significant loci for 12 major autoimmune and inflammatory diseases, including celiac disease. Trynka *et al* (Nat Genet, 2011) reported strong association with several existing and new susceptibility loci in a study of celiac disease using the immunochip. In order to replicate these loci in an Irish case control CD study, we genotyped 926 individuals (461 cases and 465 controls) using the immunochip. After QC filters, 101,498 SNPs remained with which to conduct analysis. Association analysis was performed using PLINK and the preliminary results show nominal association in our sample of several of the strongest findings from the Trynka *et al* study, as well as several previously unreported associations. We are currently genotyping the most associated variants in an extended study population. Other non-HLA variants previously reported to be strongly associated with CD show no evidence of association in our study.

Risk alleles associated with ANA production in healthy population or transition to autoimmunity. E. Wakeland[1], P. Raj[1], E. Rai[1], QZ. Li[1], D. Karp[1], P. Doshi[1], N. Olsen[2], KM. Sivils[3], J. James[3], J. Kelly[3], B. Lauwerys[4]. 1) Dept Immunology, Univ Texas SW Med Ctr, Dallas, TX.5323 Harry Hines Blvd, Dallas, Texas 75390-9093, USA; 2) Division of Rheumatology, Penn State Hershey Medical Center, 500 University Drive, Hershey PA 17033; 3) Oklahoma Medical Research Foundation, 825 North East 13th Street, Oklahoma City, Oklahoma 73104, USA; 4) Service de Rhumatologie, SSS/IREC/RUMA, Cliniques Universitaires Saint-Luc & Université catholique de Louvain Avenue Hippocrate 10, bte B2.5390, 1200 BRUXELLES, Belgium.

Susceptibility to SLE is a complex, genetic disease, impacted by more than 30 susceptibility loci and a variety of unknown environmental factors. The production of antinuclear antibody (ANA) is a universal feature of SLE, but is not unique to SLE patients since more than 5% of healthy individuals are also ANA positive. We hypothesize that ANA positive normal individuals have a subset of autoimmune susceptibility alleles and that they have increased risk for development of autoimmunity. We genotyped 1726 ANA negative controls, 318 ANA positive controls and 525 SLE patients using the Immunochip, which contains 196,524 SNPs that provide a dense coverage of susceptibility loci associated with a variety of autoimmune diseases. Genotypes were called on Genome Studio and SNP analysis was done with Golden Helix. Our analysis of this data replicated several GWAS signals in SLE genes and also discovered new genes reaching genome-wide ($p \leq 10^{-8}$) or suggestive association ($p \leq 10^{-5}$). Association test statistics indicated that SLE susceptibility genes could be grouped on the basis of their role in driving the production of ANAs versus driving the transition from ANA positive to SLE. We found that genes of adaptive immune pathway, for example LAMB4, LAMB1, LY9, SLAMF7, LYN, IKZF1, ETS, LRRK2, CCR3, SLC30A7, TNFSF4, BANK1, RTEL1, TNFAIP3, were associated with the transition to ANA positive phenotypes in normal individuals, while variations in IRF5, ITGAM, STAT4, TNFAIP3, XKR6, KIR2DL3, FUT2, HERC2, were associated with the transition, from ANA positive to full SLE phenotype. Additional genes and associations will be discussed during presentation.

Interleukin-18 Genetic Polymorphism and Kawasaki disease in Han Chinese children. H. Chi[1,4], MR. Chen[1,4], NC. Chiu[1,4], FY. Huang[1], HW. Chan[2], SC. Chang[2], CL. Lin[2], YJ. Lee[1,2,3,5]. 1) Department of Pediatrics, Mackay Memorial Hosp, Taipei, Taiwan; 2) Department of Medical Research, Mackay Memorial Hospital, Taipei; 3) Department of Medicine, Institute of Biomedical Sciences, Mackay Medical College, New Taipei City; 4) Mackay Medicine, Nursing and Management College, New Taipei City; 5) Department of Pediatrics, Taipei Medical University, Taipei, Taiwan.

Background: Interleukin 18 (IL18) stimulates interferon-γ production in Th1 cells. Therefore we designed a case-control study to investigate the association between the IL18 gene and KD. Methods: The patients were 190 unrelated children (112 boys) with KD. Their age at the diagnosis was 1.9 ± 1.7 years. The controls were 1211 subjects. dbSNPs rs187238 (-137G>C) and rs1946518 (-607T>G) in the promoter region of the IL18 gene were genotyped. Statistical analysis: We assessed the Hardy-Weinberg equilibrium, estimated the frequencies of haplotypes, and tested pairwise linkage disequilibrium (LD) between the SNPs in both KD and control groups. Statistical differences in genotype, allele, carrier, and haplotype distributions between patients and controls were compared. Odds ratios and 95% confidence intervals were calculated. A Pc value < 0.05 was considered statistically significant. Results: The genotypes of both SNPs were in Hardy-Weinberg equilibrium in controls (rs187238, P = 0.37; rs1946518, P = 0.83). The frequencies of each allele of the SNPs or haplotypes was not significantly different between male and female controls (data not shown). There was no significant difference in the distribution of genotype, allele or carrier of each SNP between the patients and controls. SNP rs187238C was 55 (14.5%) in patients vs. 271 (12.1%) in controls (P = 0.19). rs1946518G was 187 (49.2%) in patients vs. 1095 (48.8%) in controls (P = 0.89). The 2 SNPs were closely linked (D', 0.961; r2, 0.121) and formed 4 haplotypes. Among them, the GG haplotype (rs182738-rs1946518) was the most frequent (48.7%). The distribution of these haplotypes in patients was not significantly different from that in controls (P > 0.05). Conclusion: The IL18 gene was not associated with KD in Han Chinese children.

2286W

Association between IL1A, IL1B and TNFA polymorphisms and glaucoma in a Brazilian population. M.B. Oliveira[1], J.P.C Vasoncellos[2], V.P. Costa[2], M.B. Melo[1]. 1) Center of Molecular Biology and Genetic Engineering, University of Campinas; 2) Department of Ophthalmology, Faculty of Medical Sciences, University of Campinas.

Glaucoma is a progressive atrophy of the optic disc characterized by loss of retinal ganglion cells, which leads to a corresponding visual field defect. It's the major cause of irreversible blindness worldwide. Among several forms of glaucoma, the most prevalent is primary open angle glaucoma (POAG). POAG is a complex disease with several risk factors including intraocular pressure (IOP) increase and positive family history. The treatment of glaucoma is based on IOP reduction, which can be achieved by topical medication and/or surgical procedure in order to avoid disease progression. Linkage analysis, association studies and candidate genes approaches have been performed in order to identify disease-causing genes and variants of susceptibility associated with POAG. Among them there are genes that codify for cytokines (IL1A, IL1B and TNFA), which have been associated in previous studies with higher risk for the development of GPAA in some populations. Besides, these molecules can interfere with the wound healing process that is vital to the success of surgical procedures performed in glaucoma treatment. This case control study involved approximately 100 unrelated POAG patients and 100 healthy controls from Brazil for the determination of polymorphisms in the IL1A, IL1B and TNFA genes. Comprehensive ophthalmic evaluation was performed and genomic DNA was obtained from case and control groups. Five single nucleotide polymorphisms (SNPs): IL1A (-889C/T; rs1800587), IL1B (-511C/T; rs16944), IL1B (3953C/T; rs1143634), TNFA (-238G/A; rs361525) and TNFA (-308G/A; rs1800629) were determined through direct sequencing. The association related above was evaluated using chi-square test. No significant difference was observed in the allele and genotype frequencies for IL1A, IL1B and TNFA SNPs between POAG patients and controls. Among patients with POAG, an analysis comparing genotypes and clinic data as intraocular pressure, vertical cup to disc ratio and number of surgical procedures necessary to IOP control were performed and no statistical differences among the groups were observed. In a Brazilian population sample no association was observed between disease risk alleles in the IL1A, IL1B and TNFA genes and POAG as well as with the severity of glaucoma. A similar study with additional and larger cohorts of patients using also other population groups is necessary to further substantiate the observation.

2287T

Evaluation of new classification criteria for HLA-DRB1 alleles based on three amino acid positions (11, 71 and 74) in Japanese RA patients; disease susceptibility and severity. S. Yoshida[1,2], K. Ikari[1], K. Yano[1], Y. Toyama[2], A. Taniguchi[1], H. Yamanaka[1], S. Momohara[1]. 1) Institute of Rheumatology, Tokyo Women's Medical University, Shinjuku, Tokyo, Japan; 2) Department of Orthopaedic Surgery, Keio University School of Medicine, Shinjuku, Tokyo, Japan.

Background. Rheumatoid arthritis (RA) is a complex polygenic disease of unknown etiology that is characterized by the appearance of progressive joint damage. Though a lot of susceptibility genes to RA have been identified, the human leukocyte antigen (HLA) locus are unequivocally the strongest genetic risk for RA. To date, several studies have suggested that shared epitope (SE, particular sequence of amino acids spanning positions 70-74) are associated with susceptibility to and severity of RA. Recently, however, Raychaudhuri et al. reported that three amino acid positions (11, 71 and 74) can almost completely explain the association between HLA and susceptibility to RA (1). In the present study, we investigated the relevance of this new HLA classification in terms of RA susceptibility and severity in Japanese patients.

Methods. DNA samples from 2068 Japanese RA patients and 752 controls were used for the study. Among them, Sharp/ van der Heijde score (SHS) of hands at 5-year disease duration, which represents joint damage, were measured in 865 patients. Typing of HLA-DRB1 was performed using the AlleleSEQR HLA-Sequencing-Based Typing Kit. Association between RA susceptibility and HLA-DRB1 alleles was examined by the relative predispositional effect method and differences in SHS among copies of the susceptible HLA-DRB1 alleles were analyzed by linear regression analysis.

Results. The result of effect estimates for the three amino acids associated with susceptibility to RA was similar to the results from Raychaudhuri et al. The major difference between SE and susceptible haplotypes in new classification was *0901, which is non-SE allele but one of the strong susceptible alleles in Asian. Though the susceptible haplotypes in new classification were associated with SHS, the single amino acid (Val11 or Leu11) was more explainable for radiographic severity.Conclusion. We confirmed the new classification criteria of HLA-DRB1 in Japanese RA patients. Further studies are needed on the effect of the three amino acid (positions 11, 71 and 74) on radiographic damage.

Reference. 1. Raychaudhuri S. et al. Five amino acids in three HLA proteins explain most of the association between MHC and seropositive rheumatoid arthritis. Nat Genet. 44:291-6. 2012.

Genetic susceptibility to leptospirosis in the Azorean island of São Miguel population. L.M. Esteves[1], S.M. Bulhões[1], M.J. Brilhante[1], C.C. Branco[1,5], F.M. Mota[2], C. Paiva[3], M.L. Vieira[4], L. Mota-Vieira[1,5]. 1) Genetics & Molecular Pathology Unit, Hospital of Divino Espirito Santo of Ponta Delgada (Azores), Portugal; 2) Infectious Diseases Department, Hospital of Divino Espirito Santo of Ponta Delgada (Azores), Portugal; 3) Internal Medicine Department, Hospital of Divino Espirito Santo of Ponta Delgada (Azores), Portugal; 4) Leptospirosis and Lyme Borreliosis Group, Unit of Medical Microbiology, Instituto de Higiene e Medicina Tropical, Centro de Recursos Microbiológicos, Universidade Nova de Lisboa, Portugal; 5) Azores Genetics Research Group, Instituto Gulbenkian de Ciência, Lisbon, Portugal.

In the majority of infectious diseases only a proportion of individuals exposed to the pathogen become infected and develop clinically evident disease. This inter-individual variability is in part determined by the host immune responses to pathogen infection. Here, we investigate how host genetic diversity is involved on the susceptibility/resistance to leptospirosis, a disease well spread in the Azores (Portugal), an archipelago located on the North Atlantic Ocean. The strategy consisted of a population-based case-control study. The cases included 105 individuals diagnosed with leptospirosis by clinical history and laboratory analysis, and the control population consisted of 470 DNA samples of unrelated healthy blood donors from the Azorean São Miguel Island. Twelve genes - *IL10*, *IL1α*, *IL1β*, *IL6*, *IL12RB1*, *CISH*, *TLR2*, *TLR4*, *TLR9*, *CD14*, *LTA* and *TNF* - involved in the innate immune response to pathogens were analyzed by two methods: single (real-time PCR TaqMan® allelic discrimination) and multiplex SNP (SNaPshot minisequencing) genotyping. In a total of 25 SNPs, statistical analysis revealed 3 single risk alleles associated with the disease susceptibility: rs622502 (*CISH*, RR=1.553, 95% CI 1.056-2.250), rs5743836 (*TLR9*, RR=1.182, 95% CI 1.150-1.182) and rs4986790 (*TLR4*, RR=1.068, 95% CI 1.040-1.068). We also observed two SNPs - rs16944 (*IL1β*, RR=0.748, 95% CI 0.578-0.952) and rs2569191 (*CD14*, RR=0.075, 95% CI 0.037-0.143) - that confer resistance to leptospira infection. In order to access if heterozigosity or homozigosity influence this susceptibility, we performed a genotype risk analysis. Results demonstrate that, for rs622502 (*CISH*), carriers of C allele have an increased risk (RR=1.592, 95% CI 1.092-2.254) for the infection. On the other hand, for rs2569191 (*CD14*), carriers of T allele show a resistance effect (RR=0.202, 95% CI 0.099-0.383). Currently, we are studying the association of single and combined SNPs with disease severity and clinical outcome. Overall, these data suggest that, in São Miguel population, at least, *CISH*, *TLR9* and *TLR4* genes play an important role in host susceptibility to leptospirosis. (lmotavieira@hdes.pt, Funding by Fundação Calouste Gulbenkian, ref P-99888: SDH49, and by DRCTC from Government of Azores).

A replication study supports *NOD2* and *CCDC122* as leprosy susceptibility genes. H. Salomão[1], W.L. Silva[2], P. Medeiros[2], V.M. Fava[1], I.M.F. Dias-Baptista[2], M.L.C. Virmond[2], M.O. Moraes[3], M.T. Mira[1,4], A.C. Pereira-Latini[2]. 1) School of Medicine, Pontifícia Universidade Católica do Paraná - PUCPR, Curitiba, Paraná, Brazil; 2) Instituto Lauro de Souza Lima, Bauru, São Paulo, Brazil; 3) Laboratório de Hanseníase, Instituto Oswaldo Cruz, FIOCRUZ, Rio de Janeiro, Brazil; 4) School of Health and Biosciences, Pontifícia Universidade Católica do Paraná, Curitiba, Brazil.

Leprosy is a chronic infectious disease caused by *Mycobacterium leprae* that affects 230.000 new individuals worldwide every year. A previous genome-wide study conducted in a Chinese population sample revealed association between leprosy and five non-HLA genes: *CCDC122, C13orf31, NOD2, TNFSF15* and *RIPK2*. Here, we present the results of an independent, two-step replication study including all five candidate genes. First, we genotyped 36 tag *SNPs* capturing the entire information of all candidate genes in 179 individuals distributed in 51 trios composed by an affected child and both parents. All trios were recruited at the Prata Colony, an isolated, highly endemic former leprosy located at the outskirts of Brazilian Amazon. Positive signals of association were replicated in an independent case-control sample of 402 patients and 413 controls recruited at the city of Rondonópolis, Mato Grosso state, central Brazil. Fluorescence-based TaqMan technology was applied to produce genotypes of all individuals. Family-based association analysis was performed as implemented in the software FBAT. Linkage disequilibrium estimations were carried out using the Haploview software. The statistical software R for Windows, version 2.14.0, was used for case-control analysis. All markers were in Hardy Weinberg equilibrium. The family-based study revealed association between leprosy and susceptibility alleles G of rs8057341 (p=0.01) and T of rs4942254 (p=0.04), located at *NOD2*and *CCDC122*, respectively. Both signals were replicated in the case-control sample (AA genotype of rs8057341: p=0.02; OR=0.56, 95% CI: 0.34-0.94; CC genotype of rs4942254: p=0.03; OR=0.65, 95% CI: 0.44-0.97). The association between leprosy and *NOD2* marker rs8057341 is a perfect replication of the results observed in the original Chinese study. Our results support the hypothesis of a role for variants of *NOD2* and *CCDC122* in the complex molecular mechanism controlling leprosy susceptibility. * HS and WLS authors contributed equally for the study. Funding: DECIT-MS/CNPq. Grant 576051/2008-0.

Positive association of Apolipoprotein E4 polymorphism with Recurrent pregnancy Loss in Iranian patients. M.T. Akbari[1,2], N. Asgari[2]. 1) Department of Medical Genetics, Tarbiat Modares University, Tehran, Iran; 2) Tehran Medical Genetics Laboratory, Taleghani street, No. 251,Tehran, Iran.

Numerous lines of evidence implicate Apolipoprotein E (APOE) in lipid metabolism during pregnancy. Hence, a role for its polymorphism has been envisaged in recurrent pregnancy loss (PRL) considering major structural and functional differences between different genotypes of the three major alleles of E2, E3 and E4. To investigate the role of different APOE genotypes in Iranian patients, we performed a case-control study of 81 women with two or more pregnancy losses who did not have any other known risk factors including anatomic anomalies of the reproductive system, infections, immunologic factors, hormonal imbalances, chromosomal abnormalities and environmental factors; and the control group were 81 women with at least two healthy children and no PRL in their reproductive history. DNA was extracted from the peripheral blood following written consent and APOE genotyping was carried out by amplifying exon 4 of the gene and subjecting it to digestion by HhaI restriction enzyme. Genotyping was concluded by analyzing different fragment sizes produced, which resulted in finding significantly higher frequency of combined E3/E4 & E4/E4 genotypes in the patients (almost 20%) compared to the normal controls (2.4%). The genotypes were confirmed by DNA sequencing. Allelic frequency for E4 was 13.5% in the patients and only 1% in the control group. Our findings is in line with a number of similar studies carried on other populations. Therefore, Apo E4 polymorphism seems to be contributing to the thrombophilic risk factors as a background to RPL.

2291F

Investigation of rs4236601 and rs4977756 SNPs in a Primary Open-Angle Glaucoma Brazilian population. H.F. Nunes[1], M.B. Oliveira[1], .JP.C. Vasconcelos[2], V.P. Costa[2], M.B. de Melo[1]. 1) CBMEG, UNICAMP, campi1-Center of Molecular Biology and Genetic Engineering, University of Campinasnas, Brazil; 2) 2Department of Ophthalmology, Faculty of Medical Sciences, University of Campinas.

Primary open-angle glaucoma (POAG) is a chronic neurodegenerative disease that leads to progressive damage to retinal ganglion cells resulting in visual field loss. Glaucoma is recognized as the main cause of irreversible blindness worldwide. Although the pathophysiology of glaucoma is not well understood, positive family history is one of the most important risk factor for glaucoma development. Two single nucleotide polymorphisms (SNPs) have been widely associated with glaucoma, although their frequencies vary among different populations. The risk allele rs4236601 is located in a LD block at chromosome 7q31 that contains two genes, CAV1 and CAV2 and rs4977756 is located in the CDKN2B-AS1 gene. The goal of this study was to investigate the distribution of these single nucleotide polymorphisms (SNPs) as a glaucoma risk factor in a sample of Brazilian POAG patients. A case control study involving 100 POAG patients and 100 control subjects was genotyped by direct sequencing. The frequency of each of the three possible genotypes of rs4236601 and rs4977756 were compared between POAG patients and controls and a significant difference for the rs42366601 was detected (p=0.00012). The minor allele frequency of rs4236601 in our study group from Brazil was 51.3% in the POAG patients and 31,5% in control subjects. Significant difference was detected in allele frequency between the POAG patients and controls (p=0.002). For the rs4977756 in the CDKN2B-AS1 gene, no significant difference was observed (p=0.9). The minor allele frequency was next to 50% in both groups. The rs4236601 is located between CAV1 and CAV2 genes. However, the mechanism through which alterations in these genes might cause glaucoma is unknown. It has been hypothesized that they might alter nitric oxide or transforming growth factor-β(TGF-β) signal transduction although no glaucoma causing mutations have been identified in either CAV1 or CAV2 genes. Overall, these data and observations imply that a POAG risk allele at the 7q31 locus is possibly strongly associated with glaucoma in a sample of the Brazilian population.

Role of genetic variation at the *FTO* gene in genetic susceptibility to osteoarthritis. K. Panoutsopoulou[1], S. Metrustry[2], S. Doherty[3], L.L. Laslett[4], R.A. Maciewicz[5], D.J. Hart[2], W. Zhang[3], K.R. Muir[6], M. Wheeler[3], arcOGEN. Consortium[7], C. Cooper[8,9], T. Spector[2], F.M Cicuttini[10], G. Jones[5], N.K. Arden[8,9], M. Doherty[3], E. Zeggini[1], A. Valdes[2]. 1) Wellcome Trust Ctr, Wellcome Trust Sanger Institute, Cambridge, CB10 1HH, UK; 2) Dept of Twin Research, King's College London, St Thomas' Hospital, Westminster Bridge Rd, London SE1 7EH, UK; 3) Academic Rheumatology, Clinical Sciences Building, Nottingham City Hospital Hucknall Road, Nottingham, NG5 1PB, UK; 4) Menzies Research Institute, University of Tasmania, Hobart, Australia; 5) Respiratory & Inflammation Research Area, AstraZeneca, Charnwood R&D, Bakewell Road, Loughborough, Leicestershire, LE11 5RH, UK; 6) Health Sciences Research Institute, Warwick Medical School University of Warwick, Gibbett Hill Road, Coventry, CV4 7AL, UK; 7) www.arcogen.org.uk; 8) NIHR Musculoskeletal Biomedical Research Unit, University of Oxford, Oxford, UK; 9) MRC Lifecourse Epidemiology Unit, University of Southampton, Southampton General Hospital, Southampton, SO16 6YD; 10) Department of Epidemiology and Preventive Medicine, School of Public Health and Preventive Medicine, Monash University, Alfred Hospital, Melbourne, VIC 3004, Australia.

Variation in the *FTO* gene is known to play an important role in susceptibility to obesity which is a major risk factor for the development of osteoarthritis (OA). A recent study by the arcOGEN Consortium established an association of rs8044769 at the BMI-associated gene *FTO* and OA reaching almost genome-wide significance. The discovery and replication studies did not match cases and controls for BMI as the discovery dataset employed population-based controls lacking BMI information. A sensitivity analysis in a subset of samples from the discovery set showed attenuation of the signal after BMI adjustment compared to the unadjusted analysis. In this study we have thoroughly investigated the role of the *FTO* polymorphism rs8044769 in risk of knee and hip OA in cases and controls from 7 independent cohorts from the UK and Australia matched for BMI category. We genotyped rs8044769 in 892 normal weight, 2036 overweight (25<=BMI<30) and 2300 obese knee OA patients, 1162 normal weight, 1722 overweight and 1374 obese hip OA patients and 2372 normal weight, 1931 overweight and 890 obese healthy controls. Association analyses were carried out adjusting for gender and the results were meta-analysed. In these samples the *FTO* SNP is strongly associated with overweight status, and overweight status is strongly associated with both knee and hip OA. When samples were stratified by BMI category meta-analysis of the association between the *FTO* SNP and OA resulted in an odds ratio (OR) =0.97 (95%CI 0.82-1.15) for the association between hip OA in normal weight individuals, OR=1.04 (95%CI 0.95-1.14) in overweight (including obese) and OR=1.02 (95%CI 0.76-1.37) for obese individuals showing significant heterogeneity (p<0.01) among cohorts for the latter comparison. For knee OA the results were OR=1.03 (0.87-1.21) in normal weight individuals, OR=1.01 (0.94-1.09) in overweight people and OR=1.05 (0.87-1.26) in obese individuals showing near significant (p<0.06) heterogeneity. No significant associations (p<0.05) were observed at any of the BMI-stratified meta-analyses. Our results indicate that the association between *FTO* and OA is due to its effect on obesity/overweight and that it has no direct effect on OA risk when adjusted for BMI category. This is consistent with what is known of the biology of the *FTO* gene.

2293T

Association of COX-2, IL-1β and IL-1 RN gene polymorphisms with susceptibility to chronic periodontitis in North India population. G. Prakash[1], S. Ajay[2], K.K Gupta[3], J. Dixit[4], D. Bali[5], B. Mittal[1]. 1) Department of Genetics, SGPGIMS, Lucknow, India; 2) Department of Biochemistry, SPPIDMS, Lucknow, India; 3) Department of Periodontics, SPPIDMS, Lucknow, India; 4) Department of Periodontics, Faculty of Dental Sciences, CSMMU, Lucknow, India; 5) Department of Periodontics and Implantology, DAV Dental College & Hospital, Yamuna Nagar, Haryana, India.

Introduction: Periodontitis is a chronic inflammatory disease resulting in the destruction of the tissue and alveolar bone supporting the teeth and leading ultimately to tooth loss. Studies have shown the involvement of inflammatory genes like IL-1, IL-4, IL-6, IL-10, TNF-α, TLR-2, TLR-3 and COX-2 in etiology of chronic periodontitis. Genetic variants in these inflammatory genes are known to affect the respective protein functions, thus may modulate susceptibility of chronic periodontitis. Therefore, in present study we investigated the role of COX-2 (-765 G>C rs20417, +8473 T>C rs5275, -1195 G>A rs689466), IL-1β -511 C>T (rs2853550) and IL-1 RN 86bp VNTR (rs2234663) with risk of chronic periodontitis in North India population. Materials and Methods: The genotyping of COX-2 (-765 G>C, +8473 T>C, -1195 G>A), IL-1β -511 C>T and IL-1 RN 86bp VNTR polymorphisms were carried out in 154 healthy controls and 152 chronic periodontitis patients. Cases were clinically diagnosed by detection of chronic inflammatory changes in the marginal gingiva, presence of periodontal pocket and loss of clinical attachment. All subjects were genotyped by polymerase chain reaction-restriction fragment length polymorphism method (PCR-RFLP). Difference in the allele and genotype frequencies were assessed by Chi-square test (P<0.05). The risk of periodontitis associated with allele and genotype was calculated as Odd ratio (OR) with 95% Confidence Intervals (CI) using SPSS ver.15.0. Results: We did not find significant association of COX-2 (-765 G>C, +8473 T>C, -1195 G>A), IL-1β -511 C>T and IL-1 RN 86bp VNTR with risk of chronic periodontitis at genotypic and allelic level (P value at allelic level for COX-2 -765, 0.254, COX-2 +8473, 0.647, COX-2 -1195 0.374, IL-1β, 0.897and IL-1 RN, 0.561). Even, when subjects were stratified on the basis of gender, no gender-specific risk was observed (P>0.05). In case only analysis, no significant interaction of COX-2 -765 G>C (P=0.502), +8473 T>C (P=0.919), -1195 G>A (P=0.110), IL-1β -511C>T (P=0.193) and IL-1 RN (P=0.771) were observed in patients with tobacco usage habits. Conclusion: The present study shows that COX-2 (-765 G>C, +8473 T>C and -1195 G>A), IL-1β -511 C>T and IL-1 RN 86bp VNTR polymorphism do not play any significant role in genetic susceptibility to chronic periodontitis in North India population. Financial support from ICMR, New Delhi, India.

2294F

A variant of filaggrin (FLG) are associated with susceptibility to food allergy in the Japanese population. T. Hirota[1], M. Ebisawa[2], T. Imai[3], Y. Suzuk[4], N. Shimojo[5], Y. Kohno[5], M. Kubo[1], M. Tamari[1]. 1) CGM, RIKEN Yokohama, Yokohama, Kanagawa, Japan; 2) Clinical Research Center for Allergy and Rheumatology, Sagamihara National Hospital, National Hospital Organization, Kanagawa, Japan; 3) Department of Pediatrics, Showa University School of Medicine, Tokyo, Japan; 4) Departments of Public Health, Chiba University Graduate School of Medicine, Chiba, Japan; 5) Departments of Pediatrics, Graduate School of Medicine, Chiba University, Chiba, Japan.

[Background]: Food allergy (FA) is an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food. FLG encodes an important epidermal protein abundantly expressed in the outer layers of the epidermis. Loss-of-function variants within the FLG gene are associated with atopic dermatitis and other atopic diseases including FA. But genetic influences of FLG on FA in the Japanese population are unclear. **[Objective]**: To investigate the association between filaggrin loss-of-function variants and food allergy and food allergy related phenotypes in the Japanese population. **[Methods]**: Eight variants (R501X, 3321delA, S1695X, Q1701X, S2554X, S2889X, S3296X, K4022X) in FLG gene, which have been already reported in the Japanese populations, were genotyped by Taqman and invader methods. We performed an association study of FA using a total of 532 subjects with FA and 234 controls in the Japanese population. Among the FA case, a total of 60 subjects have food-induced anaphylaxis. We conducted an association analyses by Fisher's exact test.**[Results]**: We found that S2889X variant was associated with FA under an allelic model in the Japanese population (P = .0042; OR, 3.94; 95% CI, 1.39-11.15). In further analyses of patient subgroups, we observed a strong association between S2889X variant and FA patients who had a history of food-induced anaphylaxis (P = .000035; OR, 10.08; 95% CI, 3.15-32.19).**[Conclusion]**: S2889X variant in the FLG gene might be involved in FA in a loss of function manner. It has also been suggested that the variant plays a role in food-induced anaphylaxis. Further studies are needed for better understanding of pathophysiology of food allergy.

2295W

AKT1 fails to replicate as a longevity-associated gene in Danish and German nonagenarians and centenarians. *M. Nygaard[1,2], M. Soerensen[1,2], F. Flachsbart[4], J. Mengel-From[1,2], Q. Tan[1,2], S. Schreiber[4], A. Nebel[4], K. Christensen[1,2,3], L. Christiansen[1,2].* 1) Epidemiology, Institute of Public Health, University of Southern Denmark, Odense, Denmark; 2) Department of Clinical Genetics, Odense University Hospital, Odense, Denmark; 3) Department of Clinical Biochemistry and Pharmacology, Odense University Hospital, Odense, Denmark; 4) Institute of Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany.

Despite the fact that approximately 25% of variation in human lifespan is attributable to genetic factors, polymorphisms in only a few candidate genes have so far been consistently found to be associated with longevity. Recently, *AKT1* has been suggested as a third universal longevity gene, following the well-established apolipoprotein E (*APOE*) and forkhead box O3 (*FOXO3*) genes. To further elucidate this potential role of *AKT1*, case-control studies involving a large and unique sample of 2996 long-lived individuals (nonagenarians and centenarians) and 1840 younger controls of Danish and German ancestry were performed. In addition to the previously described candidate variation, rs3803304, this study was expanded to include a number of additional SNPs to ensure better coverage of the known allelic variance in *AKT1* and to facilitate a more exhaustive exploration of the possible relevance of *AKT1* variations in longevity.

The main finding of this study was a lack of formal replication of the association between rs3803304 and longevity as previously found in three independent populations. However, restricting the analysis to centenarians revealed a trend of supportive evidence in Danish men (p=0.03), with the same direction of effect as identified before (OR=0.49).

Furthermore, six additional SNPs were tested in both the Danish and German study population. Of note, one of these, rs2494731, is in perfect linkage disequilibrium with the *AKT1* SNP rs2498804, which was recently found to be associated with lifespan in a population of Dutch nonagenarians. Nevertheless, we did not replicate an association with longevity, whether applying a cross-sectional approach or taking advantage of the longitudinal data with more than 12 years of follow-up available for the Danish nonagenarian sample.

In conclusion, despite a substantial power, we did not confirm *AKT1* as a longevity-associated gene in populations of Danish and German nonagenarians and centenarians. This finding does not necessarily rule out a potential relevance of *AKT1* in longevity since population genetic differences and incomplete coverage of allelic variation in *AKT1* may explain the lack of replication. However, all in all our results do suggest that *AKT1* is not a universally acting longevity gene.

2296T

Association of _HLA-DRB1_ and _HLA-DQB1_ genes with asthma in the Spanish population. M. Pino-Yanes[1,2,3], A. Corrales[1,2], M. Acosta-Herrera[1,2,10], J. Cumplido[4], F. Sánchez-García[5], R. González[6], J. Figueroa[7], I. Sánchez-Machín[6], O. Acosta[8], A. Sánchez-Palacios[7], J.C. García-Robaina[9], J. Villar[1,10], E.G. Burchard[3], T. Carrillo[4], C. Flores[1,2]. 1) CIBER de Enfermedades Respiratorias, Instituto de Salud Carlos III, Madrid, Santa Cruz de Tenerife, Spain; 2) Research Unit, Hospital Universitario N.S. de Candelaria, Tenerife, Spain; 3) Department of Medicine, University of California San Francisco, San Francisco, CA; 4) Allergy Unit, Hospital Universitario Dr. Negrín, Gran Canaria, Spain; 5) Immunology Unit, Hospital de Gran Canaria Dr. Negrín, Gran Canaria, Spain; 6) Allergy Unit, Hospital del Tórax, Complejo Hospitalario Universitario NS Candelaria, Tenerife, Spain; 7) Allergy Unit, Hospital Universitario Insular de Gran Canaria, Gran Canaria, Spain; 8) Neumology Unit, Hospital Universitario de Canarias, Tenerife, Spain; 9) Allergy Unit, Hospital Universitario N.S. de Candelaria, Tenerife, Spain; 10) Multidisciplinary Organ Dysfunction Evaluation Research Network (MODERN), Research Unit, Hospital Universitario Dr. Negrin, Gran Canaria, Spain.

Before the advent of genome-wide association studies (GWAS), *HLA-DRB1* and *HLA-DQB1* genes were independently associated with asthma in several candidate gene association studies. After years of oblivion, the importance of these genes in the genetic of asthma has been recently corroborated by GWAS studies and one GWAS meta-analysis. In spite of these evidences, the classic alleles underlying these associations have not been determined. Here we aimed to test the reproducibility of *HLA-DRB1* and *HLA-DQB1* associations with asthma in a Spanish sample, and to explore the classic alleles involved in the disease. For this purpose, 22 single nucleotide polymorphism (SNPs) with ability to predict classic alleles from *HLA-DRB1* and*HLA-DQB1* were genotyped using TaqMan®, KASPar® and SNaPshot® in 313 training samples typed for the classic alleles of these genes. After checking the adequate prediction of classic alleles at 2 digit-resolution, these 22 SNPs were genotyped in a case-control sample of 1865 unrelated participants consisting of 606 asthmatics and 1259 controls. Results replicated the association of individual SNPs with asthma after population stratification adjustments ($1.12 \leq OR \leq 1.94$, $2.8 \times 10^{-7} \leq p\text{-value} \leq 0.048$). In addition, the imputation of classic alleles allowed identifying both protective and risk alleles in both genes. Taken together, our results support the important role of these genes in asthma susceptibility.

Supported by FUNCIS 23/07 and grants from the Spanish Ministry of Science and Innovation FIS PI08/1383, FIS PI11/00623 and EMER07/001 to CF. MPY was supported by Fundación Canaria Doctor Manuel Morales (Spain).

Turning the GWAS upside down: A PheWAS approach in studying human disease. S. Hebbring[1,2], S. Schrodi[1], Z. Ye[1], Z. Zhou[1], D. Page[2], M. Brilliant[1]. 1) Marshfield Clinic, Marshfield WI; 2) University of Wisconisin Madison, Madison WI.

In classical genetics, there are two common experimental approaches: “reverse” and “forward” genetics. Forward genetics is the process of going from phenotype to genotype and has been popularized in linkage and genome wide association studies (GWAS). Reverse genetics is the process of going from genotype to phenotype and has been a powerful tool in studying the genetics of animal models. In an attempt to apply a reverse genetics approach to study human disease, we screened 114 putative loss-of-function nonsense polymorphisms in 112 genes, along with four positive control SNPs, with 4841 unique diagnostic codes (ICD9 codes) in 4241 Marshfield Clinic patients as part of the Personalized Medicine Research Project. As anticipated, many of the positive control SNPs were significantly associated with expected ICD9 codes. Previous studies have shown rs2200733 is associated with atrial fibrillation utilizing forward genetic approaches (i.e., GWAS). In this study, ICD9 code for atrial fibrillation (427.31) was one of the top four ICD9 codes associated with rs2200733 (p=0.00024). Interestingly, positive control SNP rs17234657, previously shown to be associated with Crohn's disease, was not associated with Crohn's (43 reported cases with ICD9 555), but the variant allele increased the risk for other inflammatory conditions such as chronic rhinitis (ICD9 472.0, p=0.0012), gastritis (ICD9 535.41, p=0.0040), and sinusitis (ICD9 461, p=0.0091). Aside from the positive control SNPs, novel associations were observed for many of the nonsense SNPs screened. Strong associations were observed for rs28502153, a nonsense SNP within GAB4. Rs28502153 was associated with numerous muscular-skeletal phenotypes affecting the limbs (ICD9 755, p=4.1e-5), fingers (ICD9 736.2, p=0.00083), joints (ICD9 728.3 and 728.5, p=0.0003 and p=0.0031 respectively), and posture (ICD9 781.92, p=0.0093). GAB4 is believed to interact with GRB2, a growth factor receptor binding protein necessary in development. In summary, these results demonstrate that genotype-phenotype relationships previously characterized using forward genetics can be observed when studied in the reverse direction while characterizing other related, yet novel, relationships. Second, with proof-of-principle established, reverse genetics maybe a powerful and complementary approach in studying human genetics. This is the first known attempt to systematically screen nonsense polymorphisms for disease risk.

Assessment of Bias in an EMR-derived Cohort. *W.S. Bush, L.C. Dumitrescu, D.C. Crawford.* Ctr Human Gen, Vanderbilt Univ, Nashville, TN.

Large-scale biological repositories linked to electronic medical records (EMRs) are quickly becoming feasible alternatives to more traditional population-based cohorts for conducting genetic epidemiological studies. The ability to rapidly obtain high-quality DNA from a large number of patients, and then link data from high-throughput genetic assays to patient-specific EMR data, while meeting IRB guidelines for confidentiality, provides the needed infrastructure for research in pharmacogenetics toward individualized medicine. However, extension of a hospital-based approach to etiologic research may be more susceptible to bias if the genetic variant is in some way associated with healthcare utilization, diagnosis, or treatment patterns at that clinic. The most appropriate controls to represent the source population of the cases are not easily defined in this context, and the possible differences in cases and controls may introduce confounding, reduce statistical power, or increase the false positive rate. In this study, we compare the risk estimates for established cancer risk loci from published population-based cohort studies to the risk estimates generated by the EMR-derived cross-sectional study conducted using BioVU, the Vanderbilt DNA Biobank.

2299T

Defining the use of electronic medical records in genetic studies of multiple sclerosis. *M.F. Davis[1], J.L. McCauley[2], J.C. Denny[3], J.R. Oksenberg[4], S.L. Hauser[4], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) John P. Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL; 3) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN; 4) Department of Neurology, School of Medicine, University of California, San Francisco, CA.

Multiple sclerosis (MS) is a neurodegenerative disease with complex genetic underpinnings and clinical heterogeneity. The HLA locus was identified as a critical genetic determinant of the disease in the 1970s, but no other genes or loci were discovered until the recent GWAS era. Over 80 genome-wide significant and confirmed loci exist in the published literature for MS, but these loci account for a small proportion of the genetic contribution of MS. It is possible that these loci affect the expression of MS rather than contributing significantly to the burden of risk for developing the disease. As yet, previous studies have lacked access to long-term clinical information, and few studies have analyzed the genetics of the various clinical aspects of MS. At Vanderbilt University, we have the unique opportunity to access the Synthetic Derivative (SD), a de-identified database of over 2 million electronic medical records (EMR). Records in the SD begin in 1991 and contain all clinic notes, problem lists, letters between physicians, prescribed medications, ICD-9 billing codes, and imaging reports for patients at Vanderbilt. The SD provides us access to the records of 6,022 patients with MS and we are undertaking a study to characterize the clinical information available from the EMR that can be used for genetic studies of MS. We are investigating the range and depth of information that can be extracted, especially age of onset, progression (EDSS, 25-foot timed walk), first neurological symptom, and response to treatments, with the goal of performing genetic analyses using these sub-phenotypes to better understand the genetic heterogeneity of MS. We have developed algorithms to extract this information. Currently, we have been able to extract the subtype of MS for 4,800 individuals, EDSS score for 1,700 individuals, 25-foot timed walk score for 3,500 individuals and age of diagnosis for 3,000 individuals. Through the BioVU resource at Vanderbilt, we have DNA samples for 1,000 individuals with MS and 2,500 control subjects and have genotyped them on the Immunochip for genetic analyses of these traits. The dataset is approximately 90% Caucasian and 10% African-American. Genetic analyses are currently ongoing. Through these efforts we have seen that EMRs provide a rich resource of detailed clinical data, which will be critical to further uncovering the genetic component of MS.

The NINDS Repository: A Public Resource of Biomaterials for Genetic, Mechanistic and Biomarker Discovery for Neurological Disorders. *A. Scutti[1], M. Self[1], K. Reeves[1], J. Santana[1], S. Heil[1], C. Pérez[1], A. Nasuti[1], R. Corriveau[2], C. Tarn[1].* 1) NINDS Repository, Coriell Institute for Medical Research, Camden, NJ; 2) National Institute for Neurological Disorders and Stroke-NIH, Bethesda, MD.

The burden of neurological disorders is a serious health concern and presents a great challenge to healthcare systems globally. In most cases, the causes of neurological disorders are multifactorial, involving interactions of genetic and environmental factors. In neurodegenerative disorders such as Huntington's disease, Parkinson's disease, and Amyotrophic Lateral Sclerosis (ALS), clear mechanisms of disease are not well understood and the lack of reliable biomarkers for early diagnosis hampers timely intervention. Studies aimed at identifying mechanisms of disease onset will likely require large numbers of samples and a variety of biomaterials from affected and unaffected individuals. The National Institute of Neurological Disorders and Stroke (NINDS) Repository is a public resource established to provide a centralized resource of biological samples (DNA, cell lines, fibroblasts, induced pluripotent stem cells [iPSCs], plasma, serum, CSF, and urine) and corresponding clinical and phenotypic data from a diverse population of neurological patients and neurologically normal controls. To date, biomaterials from more than 38,000 individuals with cerebrovascular diseases (>12,000), Parkinson's disease (>7,000), motor neuron diseases (>2,700), epilepsy (>5,000), Tourette syndrome (>3,700), dystonia (>390), Huntington's disease (>30) and neurologically-normal controls (>7,000) have been successfully banked in the NINDS Repository. More than 23,000 samples are currently available through the NINDS Repository web catalog. To aid high-throughput gene discovery, the NINDS Repository offers disease- and neurologically-normal control panels of genomic DNA in 96-well plate formats and custom plate design services. Additionally, genotype data from over 4,000 NINDS Repository samples are available through the NIH's database of Genotypes and Phenotypes (dbGaP). Furthermore, the NINDS Repository establishes and banks fibroblast cell cultures and iPSCs from individuals with neurodegenerative disorders and known genetic mutations. Recently, the NINDS Repository began expanding its collection to include other types of biofluids such as serum, cerebrospinal fluid, and urine, with the goal of facilitating biomarker discovery in neurodegenerative diseases. By establishing a centralized, publicly accessible resource of biospecimens and associated clinical data, the NINDS Repository facilitates discovery of new genetic and molecular signatures related to neurological disorders.

Mutation of *SLC45A3* in familial and sporadic Menière's disease. *C.A. Campbell[1], B.J. Boese[2], C.C. Della Santina[3], C. Li[4], N.C. Meyer[1], L.T. TeGrootenhuis[1], J. Webster[5], D.A. Stephan[6], H. Najmabadi[7], A. Danashi[7], A.P. May[8], K. Fredrickson[2], B.J. Gantz[1], J.P. Carey[3], L.B. Minor[3], M.R. Hansen[1], T.T. Harkins[9, 10], R.J.H. Smith[1].* 1) Otolaryngology - Head and Neck Surgery, University of Iowa, Iowa City, IA; 2) 454 Life Sciences, Branford, CT; 3) Otolaryngology-Head & Neck Surgery, The Johns Hopkins University, Baltimore, MD; 4) Biostatistics, Harvard School of Public Health, Boston, MA; 5) Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ; 6) The Institute For Individualized Health, Palo Alto, CA; 7) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 8) Fluidigm Corporation, South San Francisco, CA; 9) Roche Applied Science, Indianapolis, IN; 10) Present address: Life Technologies, Beverley, MA.

Menière's disease (MD) is a complex idiopathic disorder of the inner ear characterized by the symptom triad of vertigo, sensorineural hearing loss and tinnitus. The incidence of MD varies around the world and it is estimated to affect 1-2 per 1,000 Caucasian individuals. Most cases of MD are sporadic although 5-14% of individuals will report a family history in which MD segregates in an autosomal dominant fashion with incomplete penetrance. To date, a genetic contribution to sporadic and/or familial MD has not been identified reflecting the challenges that complex diseases present to causative gene discovery.

We previously performed a genome-wide linkage scan followed by targeted exon capture and pyrosequencing of the candidate interval (1q32) to identify a deletion in *SLC45A3* which segregated with disease in a Chilean family. We hypothesized a gene identified in the rare familial form of MD would also be involved in the sporadic form of MD.

As a test of the common-disease-rare-variant hypothesis we performed candidate gene sequencing in a large MD cohort (n=250) using a Fluidigm Access Array followed by pyrosequencing as well as Sanger sequencing, and identified the same deletion in two sporadic patients. We subsequently screened 320 sporadic MD patients for the deletion and identified three additional individuals with the identical 36-bp deletion. We found the encoded protein, Prostein to be expressed in the cochlea and endolymphatic sac where it likely plays a role in osmotic regulation.

In summary, through the use of two complementary human genetics approaches - 1) segregation analysis with targeted-sequence capture and massively parallel sequencing; and, 2) candidate gene sequencing in a large MD cohort as a test of the common-disease-rare-variant hypothesis - we identified the first gene causally related to Menière's disease, *SLC45A3*. This study is exciting as we have identified a deletion in *SLC45A3* found in individuals with MD across five populations. The approach is broadly applicable to other complex diseases. (This research was supported in part by a grant from the American Otological Society (RJHS).).

Next generation sequencing identifies genes dysregulated in otosclerotic stapes bone and provides a candidate gene set for filtering of whole exome sequence data in familial cases. *J.L. Ziff[1], J. Lavy[2], H. Powell[2], S. Khalil[2], K.P. Steel[3], S.R. Saeed[1,2], S.J. Dawson[1].* 1) UCL Ear Institute, University College London, United Kingdom; 2) Royal National Throat, Nose and Ear Hospital, London, United Kingdom; 3) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Cambridge, United Kingdom.

Otosclerosis is a common acquired form of conductive hearing loss, characterised by abnormal bone remodeling within the otic capsule, leading to fixation of the stapes bone in the middle ear. Evidence suggests that it is unique to humans and occurs more frequently in females and individuals of Caucasian origin. The aetiology of otosclerosis is unknown; it is considered a complex disorder but also has rare monogenic forms. A number of investigative strategies have been utilised to identify genes involved in the disease process, however, to date no definitive causative genes have been identified. To improve our understanding of the disease pathology, we compared the transcriptomes of 8 otosclerotic and 4 control stapes samples using Illumina HiSeq 2000 paired end RNA sequencing. In subsequent analysis Z ratios were calculated for each gene to distinguish significant changes in gene expression between the diseased and control tissue. In total, 176 genes were found to be significantly differentially expressed in the otosclerotic stapes ($p<0.05$) and to have a fold difference >1.5. Of these 97 were up-regulated and 79 down-regulated. Pathway analysis shows that the dysregulated gene set is enriched for genes involved in TGFβ signalling, collagen fibril formation and calcium binding. Whole exome sequencing has also been performed on 10 individuals across 4 different families, each exhibiting monogenic inheritance of otosclerosis: - two non-immediate family members with otosclerosis from each of two unrelated Caucasian British families; three immediate family members with otosclerosis from a large Caucasian Portuguese family with multiple consanguineous marriages; two affected and one unaffected siblings from a family of Caribbean origin. The candidate gene set obtained from RNA sequencing will be utilised to filter the exome sequencing data with the aim of identifying the pathogenic variant in each of the 4 families.

Dissection of healthy ageing by whole genome and exome sequencing of supercentenarian genomes. *X. Estivill[1], N. Badarinarayan[2], P. Rosenstiel[2], M. Bayés[3], S. Ossowski[1], C. Tornador[1], H. Blanche[4], G. Escaramís[1], M. Gut[3], S. Heath[3], F. Flachsbart[2], A. Nebel[2], M. Lathrop[3], A. Franke[2], M. Gratacòs[1], S. Schreiber[2,5], I. Gut[3], D. Trujillano[1].* 1) Genes & Disease Program, Center Genomic Regulation, Barcelona, Catalonia, Spain; 2) Institute of Clinical Molecular Biology, Christian-Albrechts-University of Kiel, Kiel, Germany; 3) National Center of Genomic Analyses Barcelona, Catalonia, Spain; 4) CEPH, Paris, France; 5) Department of General Internal Medicine, University Hospital S.-H., Kiel, Germany.

Ageing is the major risk factor for the development of chronic disorders, including cancer, cardiovascular, osteoarticular and neurodegenerative diseases. In Europe it is expected that there will be 1.6 million citizens 100+ years old by 2050, a dramatic increase with respect to the nearly 40,000 in 1996. Several individuals have been reported to live over 110 years (supercentenarians). Since the prevalence of supercentenarians is very low, it can be considered a “rare” phenotypic condition, which could provide important insights on key factors of healthy ageing and disease protection. We hypothesize that extraordinary long-lived individuals are gifted with a combination of common and rare protective genetic factors. Thus, in this project we wanted to identify both novel and known genetic variants that influence lifespan in exceptionally old individuals. To reach this goal we carried out whole-genome and whole-exome sequencing of four supercentenarians of European origin (one Spanish, one French and two German). The high depth of sequencing achieved by combining the Illumina and Solid platforms allowed us to confidently mine the data not only for single nucleotide variants (SNV) of interest, but also novel SNV discovery involved in healthy aging. The selected SNVs are being tested for association in a larger cohort of centenarians and controls by means of direct genotyping for common SNVs and targeted resequencing for novel and rare SNVs. In addition the data allowed us a precise detection of indels and structural variants. We identified hundreds of potentially disease-protective variants in our cohort of centenarians. Our analysis pipeline focused on identifying novel, rare, and common SNVs affecting genes involved in pathways associated to age-related diseases. Targeted-resequencing 222 genes enriched in novel and rare SNVs in a validation cohort of 1,000 centenarians and controls from the same geographic regions, and genotyping in the validation cohort a total of 120 common SNVs, that show altered allelic frequencies in our initial sample set when compared to the normal population, allow to draw a network of genes, and variants that show protective effects. Whole-genome and whole-exome sequencing of exceptionally old individuals provides a high level of resolution of SNV discovery to dissect the molecular basis of healthy aging. The results of association studies in centenarian samples should further substantiate these findings.

2304W

Whole Exome Sequencing Cases: Finding and Testing with External Controls. *A. Hendricks on behalf of the UK10K Statistics Group.* Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

It is common for researchers undertaking whole exome sequencing (WES) studies to sequence disease cases and to seek externally available controls. Finding an appropriate control set to use in case-control analysis is an open and important question that is composed of two parts: finding a suitable set of controls and developing appropriate analysis methods and protocols. Here, we explore the ability of various control sets and analysis methods to produce an unbiased distribution of test statistics using a large set of sequenced samples from the UK10K project (www.uk10k.org). Within UK10K we are sequencing 10,000 individuals: 4,000 cohort participants using low depth (6x) whole-genome sequencing (WGS) and 6,000 disease cases using WES (50x). Currently, over 2,400 cohort participants and over 3,000 cases have gone through sequencing, quality control (QC), and variant calling. These data provide a unique opportunity to assess case-control analysis over a variety of samples, traits, possible confounders such as population stratification, sequencing types (WGS and WES), and sequencing attributes such as depth and quality. We started by analyzing single nucleotide variants in WES cases and controls and investigated tests restricted to fairly homogenous samples to assess the impact of simple QC filtering. We first filtered variants for depth and genotype quality on the individual level and then applied sample-wide variant filters. We found that after applying filters on minor allele frequency, call rate, and average quality by depth we produced an observed test statistic distribution similar to the expected distribution. Our particular set of filters controlled for inflation even when case status was assigned so that confounding factors such as batch-specific differences in depth were present. Further, we investigated using WGS cohort samples as population controls for WES cases. Preliminary results suggest that after applying individual level variant filters as well as sample-wide variant filters the observed distribution of test statistics is similar to the expected distribution. Although further research is necessary, this suggests that publicly available WGS cohort samples such as 1000 Genomes or UK10K could possibly be used as controls for WES cases. Finally, while we have focused initially on single variant tests, we will expand our comparisons and development to locus-based analyses.

Whole-exome sequencing study of four families with bipolar disorder. *E. Elhaik[1,2], M. Pirooznia[1], F.S. Goes[1], J. Parla[5], R. Karchin[3], A. Chakravarti[2], P.P. Zandi[1], R.W. McCombie[5], J.B. Potash[4].* 1) Department of Mental Health, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Medical Research Center, University of Iowa, Iowa City, IA; 4) Department of Biomedical Engineering and Institute for Computational Medicine, Johns Hopkins University, Baltimore, MD; 5) Cold Spring Harbor Laboratory, Woodbury, NY.

Background: Bipolar disorder (BP) is a common mental disorder often associated with lifelong disability and premature mortality. We are conducting a whole-exome study of BP using next generation sequencing to examine the whole exomes of up to 100 multiplex BP families (with at least 6 individuals from 2-3 generations of each family), 1,800 BP cases, and 1,800 controls with the goal of identifying rare and common genetic variants associated with the disease. **Methods**: Exome sequencing was performed in a pilot sample of 22 individuals from four multiplex BP families using solution-based capture and paired-end sequencing on the Illumina GA II. Alignment and variant calling were performed with BWA, SAM tools, and GATK. SNVs were annotated with the SIFT and PolyPhen tools. Families were analyzed separately for the segregation of functionally relevant variants with disease. **Results**: We identified a single common (MAF=0.2) deleterious splice site variant (rs8373) in a zinc-finger protein gene (ZFP91) that segregated with all affected relatives and none of the unaffected married-in relatives in all four families. A family-based test indicated the variant was significantly associated with BP in these families (p=0.0026). ZFP91 is involved in the non-canonical nuclear factor kB (NF-kB) signaling pathway, which regulates the canonical NF-kB pathway. The non-canonical pathway is associated with adaptive immunity and protection against inflammation and apoptosis. **Conclusions**: Our initial analysis of four multiplex families with bipolar disorder revealed a common splice-site polymorphism in ZFP91 that segregates with disease in all pedigrees. Mutations inhibiting the non-canonical NF-kB, such as the one identified here, have been shown to induce apoptosis and inflammation due to the continuous activation of the complementary pathway. This variant was imputed in the Psychiatric GWAS Consortium (PGC) mega-analysis of Bipolar Disorder, but it was not significantly associated with illness. However, if the current finding can be replicated in other sequenced families, it may provide evidence of a potential inflammatory etiology in bipolar disorder. Such replication efforts are ongoing.

2306F

Whole exome sequencing of five consanguineous families with juvenile myoclonic Epilepsy. *B. ouled amar bencheikh[1,2], J. Gauthier[1], F. Lahjouji[2], I. Jouan[1], P. La chance touchette[1], K. Khaldi[2], H. Lamghari[2], C. Bourassa[1], D. Spiegelman[1], A. Dionne laporte[1], H. Daoud[1], F. Hamdan[1], H. Belaidi[2], O. Ouazzani[2], P. Dion[1], P. Cossette[1], G. Rouleau[1].* 1) Center of Excellence in Neuroscience of University, Centre de recherche du CHUM, Montréal, Québec, Canada; 2) Service de Neurophysiologie Clinique, Hopital des Spécialites, CHU Ibn Sina, Rabat, Maroc.

Juvenile myoclonic epilepsy (JME) is one of the forms of genetic (Idiopathic) generalized epilepsies (GGEs), which in turn account for 40 to 60% of all epilepsies. GGEs are characterized by a complex genetic mode of transmission most likely due to phenotypic, genetic heterogeneity and incomplete penetrance of the disease. Linkage analyses have had limited success in the identification of genes involved in GGE/JME. The recent development of Next generation sequencing methods is currently facilitating the understanding of Mendelian and complex diseases. We selected 13 patients from five consanguineous families of juvenile myoclonic epilepsy (JME) compatible with an autosomal recessive transmission and performed exome sequencing. Previously identified loci and causative genes for JME have been excluded by linkage analysis. The targeted exome capture was done using the Agilent SureSelect V4 kit and the sequencing was done on an Illumina HiSeq2000 system. The variants were called and annotated using the GATK software and the ANNOVAR program, respectively. Called variants were filtered against dbSNP, 1000 Genomes Project and In-house database (data from in-house exome resequencing projects). We considered all variants homozygous shared between all affected individuals from each family. Only non-synonymous, splice site and coding InDels were included in the analysis. Our best candidate variants were then validated by Sanger sequencing on both strands. The most promising variants segregating with the disease in these consanguineous families will be validated by functional studies. The exome sequencing approach using consanguineous families has great potential to identify new genes of JME which in turn would lead to new insights for GGE and open new avenues for the development of novel therapeutic targets.

GEnetics of Nephropathy - an International Effort (GENIE): CNV Analysis. *Y. Meng[1], R.M. Salem[1,2,3], A.J. McKnight[7], E.P. Brennan[8,9], N. Sandholm[4,5,6], C. Forsblom[4,5], J. Florez[1,3,10], C. Godson[8,9], P-H. Groop[4,5,11], A.P. Maxwell[7,12], J.N. Hirschhorn[1,2,3] for the GENIE Consortium.* 1) Population and Medical Genetics, Broad Inst, Cambridge, MA, USA; 2) Endocrine Research Unit, Department of Endocrinology, Children's Hospital, Boston, MA, USA; 3) Department of Medicine, Harvard Medical School, Boston, MA, USA; 4) Folkhälsan Institute of Genetics, Folkhälsan Research Center, Biomedicum Helsinki, Helsinki, Finland; 5) Division of Nephrology, Department of Medicine, Helsinki University Central Hospital, Helsinki, Finland; 6) Department of Biomedical Engineering and Computational Science, Aalto University, Finland; 7) Nephrology Research, Centre for Public Health, Queen's University of Belfast, UK; 8) Diabetes Research Centre, Conway Institute, School of Medicine and Medical Sciences, University College Dublin, Dublin, Ireland; 9) Mater Misericordiae Hospital, Dublin, Ireland; 10) Center for Human Genetic Research, Massachusetts General Hospital, Boston MA, USA; 11) Baker IDI Heart and Diabetes Institute, Melbourne, Australia; 12) Regional Nephrology Unit, Level 11, Tower Block, Belfast City Hospital, Belfast, UK.

Diabetic nephropathy (DN) is a leading cause of kidney failure. GWA studies of SNPs have been performed for DN, including by our consortium (GENIE), but the role of copy number variation in DN has not been investigated. Copy number variant (CNV) analysis, genotyped on Illumina HumanOmni1-Quad, was performed in 1,726 samples from the UK-ROI cohort within the GENIE consortium. To assess whether CNVs are associated with DN, we estimated copy number at known copy number polymorphisms (CNPs) as well as novel CNVs using Birdsuite and performed association analysis using PLINK. All participants in UK-ROI have type 1 diabetes (T1D), and are classified as normoalbuminuric controls (at least 15 years of T1D duration), end stage renal disease (ESRD), or DN (either macroalbuminuria or ESRD). A total of 1,399 samples passed quality control. Three contrasts were defined for association testing: DN vs. controls, ESRD vs. controls, and ESRD vs. all. We tested association with individual CNPs, association with global CNV burden, and regional associations with rare (≤1%) CNVs, analyzing CNVs occurring within defined genomic or genic regions. No individual CNP showed significant associations after correcting for multiple testing. In the burden analysis, subjects with DN had a greater global burden of CNVs than controls ($p \leq 0.05$), including an excess of lower-frequency (≤5%) and rare (≤1%) duplications, and rare (≤1%) duplications overlapping genes. No significant associations were seen for burden of deletions, and the signal for duplications was not significant after correction for multiple testing. Rare CNVs (≤1%) within 20 kb of each gene in the genome were analyzed, testing for an excess of CNVs in cases. Significance was assessed by 1 million permutations using a 1-sided test. We identified three genic regions on chromosomes 2, 8, and X with an excess of CNVs in DN cases ($p \leq 10^{-4}$, 14-17 CNVs in cases vs. 0 CNVs in controls in each region); one genic region on chromosome 11 with an excess of CNVs in ESRD cases ($p \leq 10^{-4}$, 6 CNVs in cases vs. 0 CNVs in controls). Replication and validation studies, as well as pathway-based analyses, are being initiated. In summary, we performed the first copy number association analyses of DN, and preliminary results have highlighted four gene regions with a possible excess of copy number variation in patients with DN compared with controls.

Whole genome sequencing identifies coding variants influencing canonical lipid species in Mexican American families. *C. Bellis[1], P.J Meikle[2], J.M Weir[2], J.B Jowett[2], T.M Teslovich[3], G. Jun[3], S. Kumar[1], M. Almeida[1], J.M Peralta[1], E.E Quillen[1], C. Fuchsberger[3], A.R Wood[4], T.M Frayling[4], P. Cingolani[5], T.W Blackwell[3], R. Sladek[5], G. Atzmon[6], J. Laramire[7], S. Lincoln[7], D.M Lehman[8], G. Abecasis[3], M.C Mahaney[1], T.D Dyer[1], L. Almasy[1], R. Duggirala[1], J. Blangero[1], J.E Curran[1].* 1) Department of Genetics, Texas Institute for Biomedical Research, San Antonio, TX; 2) Baker IDI Heart and Diabetes Institute, Melbourne, VIC, Australia; 3) University of Michigan, Ann Arbor, Michigan, USA; 4) University of Exeter, Exeter, United Kingdom; 5) McGill University, Montreal, Quebec, Canada; 6) Albert Einstein School of Medicine, Bronx, New York, USA; 7) Complete Genomics Inc., Mountain View, California, USA; 8) University of Texas Health Center at San Antonio, San Antonio, Texas, USA.

The lipidome encompasses the complete universe of fundamental lipid species. It represents a potential gold mine of clinically relevant phenotypes that may be better predictors of disease risk than those that are commonly studied. Additionally, the biologically simpler nature of such lipid species presents the hypothesis that determinants may reside closer to the causal action of genes than more complex integrated lipid measures, such as total cholesterol level, making them valuable phenotypes for finding genes involved in lipid metabolism. Implementation of a targeted capture method involving liquid chromatography electrospray ionization-tandem mass spectrometry provided precise identification and quantification of 356 lipid measures in 1202 Mexican American individuals from large pedigrees in the San Antonio Family Heart Study (SAFHS). Genome-wide association analyses revealed several significant QTL localizations for these canonical lipid phenotypes, however by harnessing the power of whole genome sequence (WGS) data the chance of identifying a functional variant influencing lipid metabolism is significantly increased. We currently have lipidomic profiles and WGS data available for 596 Mexican American individuals, and will be increasing this to 2,000 in the coming months. In this study, we focus on the potential effects of obligately functional protein altering variants. Analysis of the WGS data identified 44,985 such non-synonymous coding variants, of which 11,484 are predicted to be highly deleterious (based on PolyPhen prediction, having a score > 0.7). Preliminary variant-specific and gene-specific burden association results have identified several rare coding variants apparently influencing lipid species including a highly deleterious rare variant in the GPIHBP1 gene previously known to be involved in severe hypertriglyceridemia. In this gene, an S144F mutation is highly associated with multiple forms of lysophosphatidylcholine. These results illustrate the utility of WGS analysis for direct identification of functional targets influencing lipid measures.

2309F

Identifying non-synonymous variants exhibiting pleiotropic effects on preeclampsia and CVD risk traits. *M.P. Johnson[1], S.P. Brennecke[2], J.M. Peralta[1], T.D. Dyer[1], M.A. Almeida[1], J.M. Proffitt[1], C.E. East[2], A.G. Comuzzie[1], M.C. Mahaney[1], L. Almasy[1], J.E. Curran[1], J. Blangero[1], E.K. Moses[1,3].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX, USA; 2) Department of Perinatal Medicine, Royal Women's Hospital & Department of Obstetrics and Gynaecology, University of Melbourne, Parkville, Victoria, Australia; 3) Centre for Genetic Epidemiology and Biostatistics, University of Western Australia, Perth, Western Australia, Australia.

Preeclampsia is a serious pregnancy disorder promoting morbidity and mortality to both mother and child. Delivery of the fetus is the only means to resolve severe symptoms. Women with preeclamptic pregnancies demonstrate increased risk for later life cardiovascular disease (CVD) and good evidence suggests these two syndromes to share several risk factors and pathophysiological mechanisms. We have previously identified preeclampsia susceptibility loci on chromosomes 2q, 5q and 13q using a Caucasian Australian family-based study design. To identify preeclampsia candidate genes at our 2q locus we initially employed an exon-centric Sanger sequencing strategy with follow up genotyping in an extended set of Australian preeclampsia families. Based on our gene-centric multiple testing criteria we identified a significant association (p=2.7E-03) for a missense *LCT* variant (N1639S) with preeclampsia susceptibility. We replicated this association (p=2.0E-02) in an independent Caucasian Australian case-control population. Furthermore, in a large Mexican American familial cohort the N1639S variant exhibited pleiotropic effects with several CVD-related risk traits: AGE products (p=7.3E-03), GR (p=8.9E-03), IL-6 protein (p=8.0E-03), and soluble VCAM1 (p=4.2E-02). More recently, we have employed a next-generation exome sequencing strategy to identify family-specific loci segregating in preeclamptic women only. The exomes of 7 women (3 preeclamptics, 4 controls) from an Australian family contributing to our 5q locus were sequenced using Illumina's TruSeq Exome assay. As a first pass, we prioritized the identification of non-synonymous variants within the 1-LOD localization support interval of the 5q locus. We identified a missense variant (A2803T) in the *GPR98* gene to segregate in the preeclamptic women but not in the unaffected women. Additional next-generation exome sequencing in the Mexican American families identified three *GPR98* missense variants (P1987L, Y2232C, N2345S) to be significantly associated with HDL cholesterol levels (p<1.24E-06). Given that hypertension is a defining feature of preeclampsia it is also of major interest to us that a recent GWAS has reported a significant association with diastolic blood pressure for a SNP at the *GPR98* locus in African Americans. Taken together, these data present for the first time empirical evidence of possible shared genetic mechanisms underlying both preeclampsia and other CVD-related risk traits.

Analysis of Coding Variants Identified from Exome Sequencing in Diabetic and Non-diabetic Nephropathy Genes in African Americans. *J.N. Cooke[1, 3, 4], N.D. Palmer[2, 3, 4], M.C.Y. Ng[3,4], P.J. Hicks[2], J.A. Bonomo[1, 3, 4], J.M. Hester[3, 4, 5], C.D. Langefeld[6], B.I. Freedman[7], D.W. Bowden[2, 3, 4, 8].* 1) Molecular Medicine and Translational Science, Wake Forest School of Medicine, Winston-Salem, NC; 2) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, North Carolina; 3) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, North Carolina; 4) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, North Carolina; 5) Program in Molecular Genetics and Genomics, Wake Forest School of Medicine, Winston-Salem, North Carolina; 6) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, North Carolina; 7) Department of Internal Medicine - Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, North Carolina; 8) Department of Internal Medicine - Section on Endocrinology, Wake Forest School of Medicine, Winston-Salem, North Carolina.

Type 2 diabetes-associated end-stage renal disease (T2D-ESRD) and other non-diabetic forms of nephropathy disproportionately affect African Americans. Prior studies have identified common genetic variants contributing to these diseases; however, novel exome sequencing techniques allow detection of coding variants that may confer additional genetic risk. We identified putative functional coding single nucleotide variants (SNVs) in genes with compelling evidence for association with nephropathy in the NHLBI Exome Sequencing Project database. SNVs were genotyped in 5244 African Americans (n=3438 cases with T2D- or non-T2D ESRD, n=1806 controls) and 1532 European Americans (n=613 T2D-ESRD cases, n=919 controls). Logistic regression analyses were performed to assess the association with T2D-ESRD, non-T2D ESRD, and overall nephropathy; admixture and APOL1 risk status covariates were incorporated in African American analyses. In African American T2D-ESRD analyses, four SNVs were associated (P<0.05; additive model unless specified): rs9481410 in C6orf167 (P= 0.024 [OR=0.89; 95% CI 0.81-0.99]), rs116147257 in APOL3 (P=0.00066 [OR=0.67; 95% CI 0.53-0.84]), rs7285158 in APOL2 (P=0.011 [OR=1.16; 95% CI 1.03-1.29]), rs2239785 in APOL1 (P=0.0012 [OR=0.83; 95% CI 0.74-0.93]). Two SNVs were associated with non-T2D ESRD: rs4925583 in OR2L13/OR2L8 (P=0.0068 [OR 0.84; 95% CI 0.73-0.95]) and rs7285167 in APOL2 (P=0.021 [OR=1.17; 95% CI 1.02-1.34]). Three SNVs replicated association in European American T2D-ESRD: rs4925583 (P=0.047 [OR= 0.73; 95% CI 0.53-1.00]), rs9481410 (P=0.020 [OR=1.22; 95% CI 1.03-1.45]), rs7285167 (P=0.0077 [OR=0.95; 95% CI 0.79-1.15]). Additionally, variants in CNDP1 and OR2L13/ORAK2 were associated with T2D-ESRD in European Americans (rs3747154, P=0.00094, OR=4.95 [95% CI 1.61-15.23]; rs4478844, P=0.0069 [recessive], OR=1.53 [95% CI 1.12-2.08], respectively) but were not associated in African Americans. Importantly, results from this study suggest the presence of newly identified variants in the APOL region as well as variants in other putative nephropathy genes may contribute to diabetic, non-diabetic, and/or all-cause nephropathy in African Americans and/or European Americans. It is therefore apparent that studies of coding variants compliment and extend common variant analyses, contributing insight for some loci, though odds ratios were not striking and recessive models, the likely model for rare variants, are difficult to test.

Assessing the role of low-frequency variants in type 2 diabetes risk using exome sequencing of 2,000 Danish individuals. *K.E. Lohmueller[1], T. Sparso[2], Q.B. Li[3], E. Andersson[2], N. Grarup[2], A. Albrechtsen[4], T. Korneliussen[5], K. Kristiansen[5], T. Hansen[2,6], G. Sanchez[1], I. Hallgrímsdóttir[1], J. Wang[3], R. Nielsen[1,5], O. Pedersen[2,7,8,9].* 1) Integrative Biology, University of California, Berkeley, CA; 2) The Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark; 3) BGI-Shenzhen, Shenzhen, China; 4) Centre of Bioinformatics, University of Copenhagen, Copenhagen, Denmark; 5) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 6) Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark; 7) Faculty of Health Sciences, Aarhus University, Aarhus, Denmark; 8) Hagedorn Research Institute, Gentofte, Denmark; 9) Institute of Biomedical Science, University of Copenhagen, Copenhagen, Denmark.

In an effort to better understand the role that low-frequency variants play in the genetic basis of type 2 diabetes, obesity, and related metabolic phenotypes, we sequenced the exomes of 2,000 Danish individuals. Half the individuals (the cases) suffered from type 2 diabetes, moderate obesity (BMI > 27.5 kg/m^2), and hypertension. The others (the controls) were healthy individuals selected from two Danish population cohorts. Data were generated using Agilent All Exon v.2 capture kits followed by Illumina sequencing. Each individual exome had an average depth of 56x. The high coverage per exome allowed accurate identification of coding region single nucleotide variants (SNVs). After applying stringent quality control filters, we identified >90,000 SNVs with minor allele frequency >0.1% within the exons. Of these, 13% were not present in dbSNP build 134. We applied several gene-based tests to detect genes showing different patterns of genetic variation in cases and controls. However, the results of these tests suggest that there are, at most, a limited number of genes containing low-frequency variants (minor allele frequency between 0.1% and 5%) having a strong effect on diabetes risk. Interestingly, the genes showing the largest effects using the sequence kernel association test (SKAT) also contained SNVs that have nominally significant differences in allele frequency between cases and controls (P<0.05), indicating that, at least in the present study, some of the effects captured by gene-based burden tests may also be observed in marginal (single marker) associations. Overall, our results point to two complementary conclusions for understanding the genetics of type 2 diabetes and for implementing exome sequencing studies for complex traits. First, current exome sequencing studies based on a few thousand individuals may be underpowered to detect associations of moderate effect. Such effect sizes may be typical, even when considering low-frequency variants. Second, genetic heterogeneity may be a considerable impediment of exome sequencing studies if causal variants are located in different genes across different individuals. We will discuss strategies to overcome these challenges.

Whole exome sequencing identifies a novel mutation within the FOXP3 gene in 2-generational family with inflammatory bowel disease (IBD).

D.T. Okou[1], K. Mondal[2], L.J. Kobrynski[3], J.G. Mulle[2], D. Ramachandran[2], V.C. Patel[2], P. Bose[2], J.P. Waters[1], P. Sampath[4], D.J. Cutler[2], M.E. Zwick[2], S. Kugathasan[1, 2, 5]. 1) Dept Pediatric Gastroenterology, Emory Univ School of Medicine, Atlanta, GA; 2) Dept Human genetics, Emory Univ School of Medicine, Atlanta, GA; 3) Dept Pediatric Allergy/Immunology, Emory Univ School of Medicine, Atlanta, GA; 4) Dept Rheumathology, Emory Univ School of Medicine, Atlanta, GA; 5) Children's Health Care of Atlanta, Atlanta, GA.

Early onset Inflammatory Bowel Disease (IBD) has many distinct clinical phenotypes including Crohn's disease and ulcerative colitis. Primary immunodeficiencies can result in chronic bowel inflammations that can mimic IBD with similar clinical, endoscopic and pathological features. We describe an early onset IBD presentation in a 7-year old boy with growth failure, chronic active colitis and severe eczematous dermatitis, who has been resistant to all conventional medications including immunosuppressive and biologics. His two older male siblings have a variety of autoimmune manifestations characterized by diabetes mellitus type 1, psoriasis and severe eczematous dermatitis. His mother has psoriasis and had a colectomy for medically refractory IBD. Because of the variety of immune mediated manifestations within the family, a potential genetic disorder was suspected and the differential diagnosis included X-linked IPEX syndrome. IPEX is a rare disorder caused by mutation in the FOXP3 gene and characterized by the triad of enteropathy, dermatitis and endocrinopathy. Since the presentation was not classical for IPEX, but a strong monogenetic cause was suspected, we performed exome sequencing of the entire family (both parents along with 3 boys). We identified a previously not reported and novel missense variant in exon 6 (c.694A>C, p.C232G) of FOXP3. The affected mother is heterozygous and all male offspring are hemizygous for the same variant. This variation, changes a Cytosine to Guanine at ChrX:49112217(hg19), which is highly conserved among all vertebrates and as well as in placental mammals. The mutation does not affect the FOXP3 protein expression but could interfere with the suppressive function of CD4+CD25+ regulatory T cells (Tregs). No other deleterious variants were identified that could explain the IBD and various other autoimmune disorders in this family. FOXP3 encodes a DNA-binding protein of the forkhead/winged-helix family and is the central controller of the Tregs development. To date, 40 different FOXP3 mutations have been described, and we add a new mutation to the literature. Conclusions: We report a novel mutation within FOXP3 which is associated with a milder form of IPEX syndrome. This may have important implications for IPEX biology as well as IPEX-directed therapeutic development. Our study represents a successful elucidation of a Mendelian disorder using whole exome sequencing.

Identification of rare genetic variants that contribute to diabetic nephropathy in type 2 diabetes through family-based targeted exome sequencing. *M.G. Pezzolesi[1, 2], J. Jeong[1], A.M. Smiles[1], J. Skupien[1,2], J.C. Mychaleckyj[3], S.S. Rich[3], J.H. Warram[1], A.S. Krolewski[1,2].* 1) Section on Genetics and Epidemiology, Joslin Diabetes Center, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA; 3) Center for Public Health Genomics, University of Virginia School of Medicine, Charlottesville, VA.

Genome-wide linkage analysis in extended pedigrees from the Joslin T2DN Family Collection previously identified several chromosomal loci that contribute to variation in urinary albumin excretion and variation in renal function in patients with type 2 diabetes (T2D). To identify susceptibility genes that contribute to these diabetic nephropathy (DN) sub-phenotypes, we recently initiated a family-based resequencing project to identify rare variants that underlie these linkage signals. One-hundred twenty-six DN cases from 42 families with an excess of renal disease (3.0 cases per family) were selected for resequencing of the coding region of all protein-coding genes at four genomic regions with evidence for linkage of urinary albumin excretion levels (chr. 5q, 7q, 21p, and 22q) and two genomic regions linked to variation in renal function (chr. 2q and 7p). Target enrichment of 3,966 exons from 361 genes across these six regions was performed using a custom target enrichment library followed by next-generation sequencing. The resulting data achieved greater than 70X on-target read depth and exceeded 20–fold sequence coverage of greater than 80% across the target regions. Multi-sample variant calling was implemented using GATK. To date we have completed sequencing and analysis of 63 DN cases from 21 of the families selected for sequencing. In this dataset, we identified 2,733 non-reference variants, including 192 novel variants not annotated in dbSNP or present in data from the 1000 Genomes Project. Non-synonymous and/or frameshift variants were identified in 247 genes across the six linkage regions. To prioritize the variants detected across these loci, we restricted our analysis to novel functional variants segregating in the sequenced samples. In doing so, novel candidate DN genes emerged in two distinct loci. Preliminary data from our study highlights the utility of combining evidence from family-based linkage analysis with targeted exome sequencing to uncover rare genetic variants that contribute to DN. Similar analyses in all 126 DN cases are currently underway and will be completed soon; we anticipate that this approach will allow us to discover novel genes that contribute to variation in urinary albumin excretion and renal function in T2D and rare variants that contribute to the linkage signals identified in the Joslin T2DN Family Collection.

2314T

Exome sequencing and functional data identify PRDM1 and NPD52 as susceptibility factors in Crohn's disease. *A. Franke[1], D. Ellinghaus[1], H. Zhang[2], S. Schreiber[1], M. Parkes[2].* 1) Inst Clinical Molec Biol, Kiel, Germany; 2) Addenbrooke's Hospital, University of Cambridge, Gastroenterology Research Unit, Cambridge, UK.

For most of the 71 Crohn's disease genetic susceptibility loci identified to date the causal variants are unknown. Furthermore,more than 70% of the heritability of Crohn's disease is yet to be accounted for. Here, we interrogated 42 exomes from unrelated Crohn's disease cases together with genome-wide association (GWA) data, to directly identify disease-associated causative genetic variants. Rare missense mutations were identified in PRDM1. These increase T cell proliferation and cytokine secretion upon activation and also increase expression levels of adhesion molecules responsible for T cell migration into intestinal tissues. The risk allele of a previously identified common PRDM1 SNP correlated with reduced PRDM1 expression in both ileal biopsies and peripheral blood mononuclear cells. All functional data for PRDM1 are in accordance with previous murine studies, where Prdm1 deletion led to enhanced T cell proliferation and activation and eventually to a Crohn's disease-like phenotype. We identify a new association between Crohn's disease and a common missense variant Val248Ala in NDP52. This impairs NDP52 regulatory function to inhibit proinflammatory NF-κB signalling and affects protein stability in the context of toll-like receptor pathways. NDP52 is an adaptor for selective autophagy of both intracellular bacteria and specific signalling molecules. Our results thus implicate NDP52 as a novel molecular link between selective autophagy and regulation of proinflammatory signalling in Crohn's disease.

Exome sequencing for Crohn's disease pedigrees. *B.-S. Petersen[1], Y. Zeissig[2], M. Kohl[2], S. Schreiber[3], S. Zeissig[3], A. Franke[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University Kiel, Germany; 2) Department of General Pediatrics, University Hospital Schleswig Holstein, Kiel, Germany; 3) Department of Internal Medicine, University Hospital Schleswig Holstein, Kiel, Germany.

Crohn's disease (CD) is a complex, chronic inflammatory bowel disease. A variety of genetic and environmental factors likely play a role in causing CD. Genome-wide association studies and meta-analyses have so far identified 71 susceptibility loci for CD. These, however, explain only 23% of the heritability so far. To identify further sources of heritability, other approaches apart from SNP-based case-control association studies are needed, for example the identification of rare susceptibility variants with high penetrance by systematic resequencing studies. We have therefore carried out exome sequencing for several pedigrees with Crohn's disease for finding rare high penetrance variants and novel candidate genes involved in disease etiology. The project is aimed at the detection of novel mutations shared by several affected individuals of a pedigree as well as *de novo* mutations in sporadically occuring cases. In one trio, we identified a single *de novo* mutation as the cause of early-onset IBD in the male child: a novel hemizygous nonsense SNP in the X-linked inhibitor of apoptosis gene (*XIAP*). Mutations in *XIAP* are known to cause X-linked lymphoproliferative disease type 2 (XLP2) and have once previously been reported to result in early-onset IBD in a male patient. Our preliminary results further indicate that*de novo* mutations indeed seem to play an important role in sporadic early-onset cases and have revealed novel rare mutations shared by the affected individuals of a pedigree which may have an important impact on the development of the disease.

2316W

Whole-exome sequencing of patients with isolated biliary atresia. *E.A. Tsai[1,2], S. Sukhadia[2], C. Grochowski[2], C.-F. Lin[3], O. Valladares[3], L.-S. Wang[3], L. Leonard[2], G.D. Schellenberg[3], K.M. Loomes[4,5], B.A. Haber[6], M. Devoto[4,7], N.B. Spinner[2,3].* 1) Genomics and Computational Biology Graduate Group, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA; 2) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Perelman School of Medicine, Philadelphia PA; 4) Department of Pediatrics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA; 5) Division of Gastroenterology, Hepatology and Nutrition, The Children's Hospital of Philadelphia, Philadelphia, PA; 6) Hepatology, Infectious Diseases Clinical Research Department, Merck Research Laboratories, North Wales, PA; 7) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Biliary atresia (BA) is a severe pediatric liver disease resulting in necroinflammatory obliteration of the extrahepatic biliary tree and presenting within the first few months of life. BA is the most frequent indication for pediatric liver transplantation in the United States. The etiology of BA is unknown, with evidence for infectious, environmental, and genetic factors described. Possible genetic factors include a BA associated locus on 10q24.2 revealed by GWAS, report of *JAG1* missense mutations in a small percentage of patients, and a BA associated deletion within 2q37.3 revealed by chromosomal microarray analysis. Animal models have suggested potential genes, but mutations have not been found in humans. We performed exome-sequencing on 30 Caucasian, non-syndromic BA patients to further investigate the genetic basis of BA. The exomes were captured using the Agilent All Exon V5 71MB capture technology and sequenced on the Illumina HiSeq platform. The 100bp paired end reads were aligned to GrCH37 using BWA and further processed using Picard and SAMtools. The variants were called using GenomeAnalysis ToolKit. There are 4,938 loss of function variants found in these samples including 1,098 nonsense mutations. Preliminary analysis has revealed several variants in candidate regions which are being validated. One patient had a heterozygous, missense mutation in exon 6 of *ADD3*, a gene that maps within 10q24.2 upstream of the BA-associated SNP rs17095355. There were no pathogenic mutations found in either *JAG1* or *GPC1*, the candidate gene in 2q37.3. The polymorphisms in these genes were not enriched in our patient population compared to the 1000 Genomes phase 1 allele frequency in Europeans. Further evaluation of candidate gene and novel gene variants will help delineate the complex genetic architecture of this multifactorial disease.

Identification of low-frequency and common variants associated with circulating levels of vitamin $_{B12}$ and folate. *N. Grarup[1], C.H. Sandholt[1], P. Sulem[2], T.S. Ahluwalia[1], T. Sparsø[1], A. Albrechtsen[3], L. Husemoen[4], D.R. Witte[5], Y. Li[6], A. Linneberg[4], R. Nielsen[3,7,8], T. Jørgensen[4,9,10], J. Wang[1,6,11], T. Hansen[1,12], U. Thorsteinsdottir[2,13], K. Stefánsson[2,13], O. Pedersen[1,14,15,16].* 1) Novo Nordisk Foundation Centre Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark; 2) deCODE Genetics, Reykjavik, Iceland; 3) Centre of Bioinformatics, Faculty of Science, University of Copenhagen, Copenhagen, Denmark; 4) Research Centre for Prevention and Health, Glostrup University Hospital, Glostrup, Denmark; 5) Steno Diabetes Center, Gentofte, Denmark; 6) BGI-Shenzhen, Shenzhen, China; 7) Department of Integrative Biology, University of California, Berkeley, CA, US; 8) Department of Statistics, University of California, Berkeley, CA, US; 9) Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 10) Faculty of Medicine, University of Aalborg, Aalborg, Denmark; 11) Department of Biology, Faculty of Science, University of Copenhagen, Copenhagen, Denmark; 12) Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark; 13) University of Iceland Faculty of Medicine, Reykjavik, Iceland; 14) Faculty of Health Sciences, Aarhus University, Aarhus, Denmark; 15) Hagedorn Research Institute, Gentofte, Denmark; 16) Institute of Biomedical Science, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark.

Background: Vitamin B_{12} (B_{12}) and folate are water-soluble micronutrients. Blood levels are influenced by processes which are dependent on numerous enzymes, cofactors and transporters. B_{12} and folate both play a role in one-carbon metabolism and deficiency results in common clinical features including a wide range of neurological and haematological manifestations. We aimed at elucidating the genetic background determining circulating levels of B_{12} and folate by combining Icelandic and Danish data. *Methods*:In the Icelandic study, 1176 individuals were genome sequenced to a depth of 10× and 22.9 million single-nucleotide variants (SNVs) were identified and imputed into chip-genotyped Icelanders using long-range phasing and the Icelandic genealogical database. The effective Icelandic sample size was 23,493 and 20,542 individuals with measurements of serum B_{12} and serum folate, respectively. In the Danish study, 16,197 coding SNVs, found by exome sequencing to a depth of 8× in 2,000 Danish individuals, were genotyped in ~8,500 individuals. Association analyses were done in the two studies and for overlapping SNVs meta-analyses were performed in total sample sizes of 31,786 and 28,970 for B_{12} and folate, respectively. *Results*: A total of 12 loci associated with circulating serum B_{12} levels at $P < 5 \times 10^{-8}$ were found and six of these were novel loci. The most statistically significant novel locus was for a non-synonymous variant with an allele frequency of 3.1% on chromosome 19p13 ($P = 8.4 \times 10^{-59}$). Other novel loci associated with circulating B_{12} levels at conventional genome-wide significance levels were located at chromosome 2q34, 4q30, 14q24, 11q13 and 22q12. For six loci (chromosome 6p12, 10p13, 11q12, 13q33, 19p13 and 19q13) previously reported to associate with vitamin B_{12} levels we confirmed the association. The combined effect of the associated loci explained 11.5% of the total variation in B_{12} in a sample of the general Danish population. Three novel loci associated with circulating levels of folate located on chromosome 1p36, 11p13 and 11p14 were found in analyses in up to 28,970 individuals. *Conclusion*: Association mapping of circulating B_{12} and folate levels for up to 22.9 million SNVs in up to 31,786 individuals revealed six novel loci for B_{12} and three novel loci for folate levels. Interestingly, eleven of the 12 lead SNVs associated with serum B_{12} are non-synonymous variants in genes coding for proteins known to be involved in B_{12} metabolism.

2318F

Whole-exome sequencing in age-related macular degeneration (AMD) using a highly-discordant phenotype and genotype design: evidence for novel loci underlying bilateral late AMD. *W.K. Scott[1], W.H. Cade[1], M.D. Courtenay[1], P.L. Whitehead[1], I. Konidari[1], W.F. Hulme[1], S.G. Schwartz[2], J.L. Kovach[2], G. Wang[1], A. Agarwal[3], J.L. Haines[4], M.A. Pericak-Vance[1].* 1) Dr. John T. Macdonald Foundation Department of Human Genetics and John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Bascom Palmer Eye Institute, University of Miami, Naples, FL; 3) Vanderbilt Eye Institute, Vanderbilt University, Nashville, TN; 4) Department of Molecular Physiology and Biophysics and Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Age-related macular degeneration (AMD) is the most common cause of irreversible vision loss in older adults in developed countries. Large-scale genome-wide linkage and association studies have identified nineteen genes with variants significantly associated with developing AMD. However, these genes do not explain all of the estimated genetic risk for the disease, as a portion AMD cases carry few of these risk factors, and some unaffected individuals carry many of them. It is believed that this “missing heritability” may comprise gene-gene and gene-environment interactions and rare variant effects not detected by association studies. To identify rare variants that influence the risk of AMD, we first calculated the genetic burden in cases and controls due to the 10 confirmed AMD loci. We then selected for whole exome sequencing (WES) the 20 bilaterally affected choroidal neovascularization cases with the lowest genetic burden and 20 controls with no drusen and the highest genetic burden. Exome capture was performed with the Agilent Sure Select All Exon V4 + UTRs Kit and sequenced on the Illumina HiSeq2000. Sequences were aligned with BWA and variants called with GATK and VQSLOD recalibration. Variants called with adequate depth (6 reads), and quality scores indicating high probability of a true variant call (VQSLOD > -3, PL > 99 for wild type homozygote) were retained for analysis. Gene-based tests of association were conducted in the RVASSOC framework, using a joint test of association by summing individual chi-square tests for all variants in a gene and assessing significance with a permutation test. Preliminary analysis did not detect a gene associated with AMD surpassing a Bonferroni-corrected threshold ($p < 2 \times 10^{-6}$). However, 34 genes met suggestive criteria for association ($p < 0.005$), including two (C3orf17 and PVRL2) with $p < 0.001$. These results indicate that novel biological pathways distinct from complement activation and angiogenesis may contribute to risk of development of bilateral CNV in cases with low burden of known AMD loci.

Rioux[1,2], NIDDK and International IBD Genetics Consortia.* 1) Montreal Heart Inst, Montreal, Canada; 2) Universite de Montreal; 3) Analytic and Translational Genetics Unit (ATGU), Massachusetts General Hospital, Boston, MA, USA; 4) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 5) Division of Gastroenterology, Hepatology and Nutrition, Department of Medicine, School of Medicine, and Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 6) Keck Biotechnology Resource Laboratory and Yale School of Medicine, New Haven, Connecticut, USA; 7) 18Karolinska Institutet, Department of Biosciences and Nutrition, Stockholm, Sweden; 8) 10The Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, California, USA; 9) 13Mount Sinai Hospital Inflammatory Bowel Disease Centre, University of Toronto, Toronto, Ontario, Canada; 10) 7Institute of Clinical Molecular Biology, Schittenhelmstr. 12, D–24105 Kiel, Germany; 11) Division of Gastroenterology, University Hospital Gasthuisberg, Leuven, Belgium.

Genome-wide association studies and follow-up meta-analyses in UC have identified 47 common disease-associated variants that account for only 16% of the expected genetic heritability. It has been suggested that some of the missing heritability may arise from unidentified high effect rare risk variants in known susceptibility regions. To test this, we have used a pooled high-throughput targeted sequencing approach in 200 UC cases and 150 healthy controls (HC), all of French Canadian descent, to study 57 genes in regions associated with UC from our recent meta-analysis of 3 independent genome-wide scans. We performed follow-up genotyping of 42 rare non-synonymous variants in independent case-control cohorts (totaling 12,153 UC cases and 17,575 HC) from the International IBD Genetics Consortium immunochip dataset, and identified significant association ($P<0.0012$) to previously reported rare variants in IL23R and CARD9, as well as novel independent associations with a coding variant in RNF186 ($P=9.11E–04$). Given the challenge inherent in achieving corrected significance thresholds for rare variants, even with large cohorts, we expect that some of the other variants that we identified and found to have nominal significance ($P<0.05$) are truly associated with UC. In fact with our target set of 42 variants included in follow-up genotyping, we would expect <1 SNP to exceed $P < 0.01$ and ~2 SNPs to exceed $P < 0.05$ by chance alone, whereas we observe 3 SNPs with $P < 0.01$ and 9 SNPs with $P < 0.05$, suggesting that there are additional true positives that have not met the more stringent threshold.

Traits of human disease significance segregating in the non-human primate vervet. *W. Warren[1], A.J. Jasinska[2], N. Tran[2], Y. Huang[2], K. Dewar[3], J. Kaplan[4], P. Minx[1], L. Hillier[1], R.K. Wilson[1], M. Nordborg[5], G.M. Weinstock[1], N.B. Freimer[2].* 1) The Genome Institute, Washington University School of Medicine, St Louis, MO; 2) Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, CA; 3) McGill University, Montreal, Canada; 4) Wake Forest University, Wake Forest, NC; 5) Gregor Mendel Institute, Vienna, Austria.

Non-human primates (NHP) are important models for genetic investigations of traits relevant to human pathologies, due to their high conservation of molecular processes and physiology with humans. The vervet monkey (Chlorocebus aethiops sabaeus) is a NHP model with an exceptionally well characterized genetic background: a small number of West African vervets were brought to the Caribbean ~ 80 generations ago, and 57 Caribbean vervets were used to found the Vervet Research Colony (VRC), now a nine-generation deep extended pedigree of ~475 individuals. To investigate the genetic causes of numerous quantitative disease-related phenotypes, some not readily studied in humans, we generated the following tools: 1) Vervet genomic assembly, 2) Whole genome sequencing (WGS) in VRC individuals with deep multi-system phenotypic data, and 3) Population genetic analyses of African, Caribbean and VRC monkeys. We have produced a reference genome (2.8 Gb) from a VRC monkey with an N50 contig and scaffold length of 21kb and 2.87Mb, respectively. Analysis of the reference assembly is focused on comparative studies in relation to other primate genomes. The WGS of the VRC has included 723 past and current animals and is being used to map phenotypes collected on a whole pedigree scale including brain-related expression quantitative traits, brain structural measures, concentrations of neurochemical metabolites in cerebrospinal fluid, and systematic measures of stress responsivity. To elucidate the genetic history of Caribbean vervet populations and to evaluate the feasibility of large-scale association analysis among independent individuals, we performed WGS in 130 wild vervets from three Caribbean islands and five major vervet subspecies drawn from across Sub-Saharan Africa. At least one individual from each geographic group was sequenced at 10x coverage while other individuals representing diverse populations within each subspecies were sequenced at 4x coverage. The population genetic data have already yielded variation data relevant to our understanding of susceptibility to infection with simian immunodeficiency virus (SIV), of which the vervet is the most abundant natural host.

2321F

Association and replication of rare allele windows within cis-regulatory regions to nearby gene expression. *A. Fish, L. Wiley, W. Bush.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Expression Quantitative Trait Loci (eQTLs) have been studied extensively in multiple populations and across multiple tissues, however the vast majority of these analyses have focused on the effect of common alleles. It is unknown how much impact rare alleles have on the regulation of expression for nearby genes. Using 149 individuals from the 1000 Genomes Project and existing gene expression data, we defined cis-regulatory regions surrounding 11,465 genes to perform a rare variant eQTL analysis. Rare alleles (MAF < 0.05) were collapsed into 5KB windows for a sliding window analysis over the cis-regulatory region. Windows were evaluated using a linear regression model. Gene expression values were normalized to adjust for population-level gene expression differences. From the linear regression, we used a Student's t-test to compare population-adjusted mean expression differences between individuals with one or more rare alleles versus individuals carrying no rare alleles. From this screening analysis, we detected 315 windows reaching genome-wide significance, affecting the expression of 65 genes. Using an independent set of 163 additional multiethnic individuals from the 1000 Genomes Project coupled with gene expression data, we replicated 146 significant windows at $p < 0.05$. Of these significant windows, 126 contain known common eQTL signals and represent potential synthetic associations based on surrounding linkage disequilibrium patterns. Significant windows are enriched for lymphoblastoid chromatin immunoprecipitation (ChIP) peaks from the ENCODE project (53/315). 353 Rare alleles within these significant windows are shown to alter transcription factor binding from the HaploREG database. Additionally, 53 significant windows contain a miRNA binding site predicted by either miRanda or TargetScan. The remaining 31 windows with no notable annotations may represent novel regulatory elements. These results illustrate that cis-regulatory regions can harbor rare alleles altering gene expression, and that collections of these alleles can be detected using collapsing methods. Finally, the reported windows represent regions where rare alleles have known functional impact and thus may be excellent candidates for rare-variant analysis of disease phenotypes.

Asthma: An omics view through discordant monozygotic twins. *R. Chen[1], S. Runyon[2], J. Li-Pook-Than[1], K. Nadeau[2], M. Snyder[1]*. 1) Genetics, Stanford University, Stanford, CA; 2) Pediatrics, Stanford University, Stanford, CA.

Asthma, a complex disease that affects 11% of the population in the United States for all ages, or 13% in children under 18 years of age, has a clear hereditary component. However, many of the genetic findings to date are inconsistent, mainly due to the small sample size of available case-control studies, as well as phenotypic heterogeneity of the disease. The low mutation rate in monozygotic twins (estimated 4.6 x 10^{-10} per nucleotide per generation) makes them an extremely valuable population to study complex genetic disorders such as asthma. In our study we determined the whole genomes of 12 pairs of monozygotic twins discordant in allergic asthma (as well as 1 pair discordant in allergy and 2 concordant healthy pairs), and sequenced the whole transcriptome of peripheral blood mononuclear cells (PBMCs) from 20 (including the 12 pairs for whole genome sequencing) discordant monozygotic twins pairs. We observed a spectrum of genomic differences within each pair of monozygotic twin, including single nucleotide variants, insertions/deletions, copy number variants, structural variants, as well as different mobile element insertions. Whole transcriptome sequencing also revealed gene expression differences as well as allele-specific differences within each twin pair and between the asthmatic and normal twin groups. Our study provided a unique perspective to investigate genetic factors associated with this complex, common disease at the omics level.

2323T

Whole-genome deep-coverage sequencing of asthma genomes. *M.A.R. Ferreira, C.S. Tang, G. Chenevix-Trench.* Genetics and Computational Biology, Queensland Institute of Medical Research, Brisbane, Australia.

BACKGROUND. High-impact (nonsense, splice or missense) variants have not been systematically studied for association with asthma risk.

AIM. To screen all high-impact variants detectable in a small number of carefully selected asthmatic individuals (n=13) and prioritize for follow-up the set of uncommon variants most likely to be related to asthma.

METHODS. We sequenced with >30X coverage the genomes of 13 doctor-diagnosed asthmatics, using Illumina GAII or HiSeq. We also sequenced both parents (discordant for asthma) of one asthmatic and an additional 18 unrelated controls. Asthmatics were selected based on seven criteria: (a) never smoker; (b) positive skin prick test; (c) positive bronchial hyperresponsiveness test; (d) childhood-onset asthma; (e) recent asthma treatment; (f) positive family history; and (g) a high ECRHS symptoms score. Sequence reads were analysed using the GATK pipeline, with variants called across the 33 samples jointly and annotated with ANNOVAR.

RESULTS. 8,769,721 SNPs passed QC, of which 92% were known (dbSNP 135) and 8% were novel; the transition to transversion ratio was 2.18 and 2.06, respectively. We identified 31,397 high-impact variants in 11,211 genes. To prioritize variants for follow-up, we selected variants: (a) called in the affected parent and the affected offspring, but not the unaffected mother of the trio (2,567 variants, 1,855 genes); and (b) with a MAF<5% in the NHLBI GO Exome Sequencing and the 1000 Genomes Projects (328 variants, 310 genes); and (c) more common in the 13 asthmatics than in the 18 controls (246 variants, 238 genes); and, finally, (d) located in genes with more high-impact variants in asthmatics than controls (96 variants, 89 genes). One high-impact variant for each of the 89 genes is currently being genotyped in 500 cases and 500 controls. The most promising 30 variants will then be genotyped in a further 1,000 cases and 1,000 controls.

CONCLUSIONS. By sequencing 33 individuals, we identified 89 genes with high-impact uncommon variants that are plausibly related to asthma. These are being genotyped in a larger cohort.

Rare non-coding variant prioritization and burden testing in whole genome sequencing of complex traits. *K.J. Gaulton, M.A. Rivas, M. van de Bunt, C.M. Lindgren, M.I. McCarthy, the GoT2D consortium.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxford, United Kingdom.

Whole genome sequencing studies of complex traits identify millions of non coding variants, however these studies will often be under-powered to detect association in single rare variants of modest effect and require prioritization for follow up or burden testing. A wealth of annotation data exists predictive of functional activity yet optimal strategies of how to use this information to enrich for trait-influencing variants remain unclear. Here we present one of the first systematic approaches to identify rare non-coding variants influencing complex traits, including accumulation and annotation of sequence variants with experimentally and computationally-derived data, identification of annotations relevant to trait biology, separating functional from benign variant effects, and defining units for burden testing. We used this approach to predict and test variants altering transcriptional regulatory elements for contribution to type-2 diabetes (T2D) using whole genome sequence data from the GoT2D project, which is employing a series of genetic techniques to identify variants influencing T2D. A preliminary freeze of 908 samples identified 11.3 million non coding variants, 60% of which are low frequency or rare (MAF<.05). We derived the relevance of experimental regulatory sites across >40 tissues at known T2D-associated variants and identified significant enrichment in several tissues including pancreatic islets (P<1x10–6), chorion (P=7x10–5) and skeletal muscle (P=3x10–4). Of 590k low frequency variants in these cell-type sites, a further 160k were filtered for functional effect by identifying allelic differences in predicted transcription factor (TF) binding for 531 vertebrate factors in JASPAR. We grouped this set of *in silico* regulatory variants in both gene- and TF-centric burden units and tested groups for T2D association using SKAT. Variants in CREB1 binding sites showed significant association to T2D across 531 tested TF groups (P=1.8x10–5). CREB has roles in adipogenesis, brain function and glucose homeostasis and plausibly may contribute to the pathophysiology of T2D. These results highlight the utility of integrating annotation data to identify trait-associated non-coding units harboring rare variants that are individually only nominally significant. More generally, this framework implemented in software CHAOS can be applied to any functional class to identify, group and test annotated sequence variants for contribution to complex traits.

Deep Sequencing of Genomic Regions Associated with Cleft Lip Susceptibility. *C. Harris[1], E. Leslie[2], R. Fulton[1], T. Miner[1], E. Appelbaum[1], C. Fronick[1], M. Mead[1], D. Larson[1], M. Adela Mansilla[3], A. Lidral[4], L. Moreno[5], J. Hecht[6], M. Marazita[7], A. Scott[8], T. Beaty[9], J. Murray[2], R. Wilson[1], G. Weinstock[1].* 1) Washington Univ Sch Medicine, The Genome Institute, Saint Louis, MO; 2) Department of Pediatrics, University of Iowa, Iowa City, Iowa; 3) The Genome Institute, Washington University, St Louis, Missouri, USA; 4) Departments of Pediatrics, Epidemiology, and Biological Sciences, University of Iowa, Iowa City, Iowa; 5) Department of Orthodontics-Dows Institute, University of Iowa, Iowa City, Iowa, USA; 6) Department of Pediatrics and Pediatric Research Center, University of Texas Medical School, Houston, Texas; 7) Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine, Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 8) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, Maryland; 9) Department of Epidemiology, School of Public Health, Johns Hopkins University, Baltimore, Maryland, USA.

Nonsyndromic cleft lip and/or cleft palate (NSCL/P) is a group of common birth defects with complex etiology reflecting the action of multiple genetic and/or environmental factors. Genome wide association studies (GWAS) have been widely used for their unbiased approach to identifying genes controlling complex traits such as NSCL/P. One challenge following GWAS is identifying specific disease-causing etiologic variants at each associated locus tagged by presumably non-causal markers. Here we describe targeted capture and sequencing of thirteen candidate loci from NSCL/P GWAS in 1,800 case-parent triads of European and Asian ancestry. The choice of a case/parent trio design allows use of the TDT to detect the most overtransmitted (and presumably causal) variant(s), identification of rare variants could contribute to missing heritability commonly seen in GWAS studies and the detection of *de novo* variants that could have a high prior probability of being causal. The thirteen regions together make up 6.6 megabases of target space, which we covered at greater than 20X depth across a per-sample average of 83.2% of the targeted regions. To achieve this coverage, the samples were multiplexed with 96 samples per capture of the target region, and two Illumina Hi-Seq lanes were generated per capture-set. Preliminary analysis of 62 trios revealed several potentially interesting missense coding mutations that are homozygous in the children, but not so in any of the parents, and are also previously unknown or reported with very low global minor allele frequency in dbSNP. These occurred in genes such as *ABCA4*, *MAFB*, *NANS*, and *ARHGAP29*. In addition, *de novo* mutation analysis found several potentially regulatory variants outside of coding regions in the affected children. We will present analysis of both inherited and de novo mutations discovered in the target regions for additional families and report their association with the presence of NSCL/P for both specific variants and each targeted gene. Funding Sources: This study was funded in part by NIH R01 DE016148 (MLM), NIH U01 HG–005925 (JCM), NIH R01 DE-014581 (THB) and NIH U54 HG-003079 (RKW).

2326T

Exome sequencing identifies rare variants associated with the common pain disorder fibromyalgia. *H. Hor[1], E. Docampo[1], R. Rabionet[1], M. Gut[2], M. Bayés[2], I. Gut[2], A. Collado[3], S. Ossowski[1], X. Estivill[1].* 1) Genes and Disease Program, Center for Genomic Regulation (CRG) and Pompeu Fabra University, Barcelona, Spain; 2) Centro Nacional de Analisis Genomico, Barcelona, Spain; 3) Department of Rheumatology, Hospital Clínic, Barcelona, Spain.

Fibromyalgia (FM) is a complex and one of the most frequent pain disorders with a prevalence of 2% in the general population, mainly affecting women in their mid-forties. Previous candidate gene approaches, generally performed in a very limited number of samples, identified variants in a small number of genes that were associated with the disease, but these findings lacked replication in independent cohorts. We performed an exome sequencing study on well-characterized sporadic and familial cases of FM of Spanish origin to identify genetic variants that are causally involved or associated with the disease. While aiming at a total sample size of 100 exomes, we already analyzed a subset of 36 exomes of sporadic and familial FM cases by focusing on single nucleotide variants (SNV). Following exome sequencing and SNV calling, we merged the variants of all exomes and performed a prioritization of rare, non-synonymous (and splice-site) SNVs according to their minor allele frequency (MAF) and functional damaging potential. Finally, by focusing only on genes with at least two damaging variants among our samples, we were able to narrow down the list of variants to around 450 candidate genes. To further prioritize these variants, we performed a functional enrichment analysis and we surprisingly found an enrichment of genes related to Medical Subject Headings (MeSH) terms for pain related genes and pathways. Based on this, we selected 26 candidate variants for further validation by genotyping in 1200 FM cases and 1000 control samples of Spanish origin. Two SNVs in candidate genes on chromosome 3 (OR: 1.7) and 19 (OR: 1.5) were significantly associated with FM. We are currently recruiting additional FM samples of European origin to replicate our findings in a second independent cohort of samples. Meanwhile we are also increasing our exome sample size to reach 100 exomes, which will be similarly analyzed to obtain a candidate gene set that can be further analyzed by targeted resequencing in a case-control manner. In conclusion we show that exome sequencing has the power of detecting rare variants for complex disorders and even for a highly heterogeneous disorder such as fibromyalgia. Replication of our findings in other cohorts would convert this study into the identification of the first genetic variants associated with FM.

2327F

Application of whole genome sequencing to identify susceptibility loci for polycystic ovary syndrome. *G. Kosova[1], R.S. Legro[2], A. Dunaif[1], M. Urbanek[1].* 1) Division of Endocrinology, Metabolism and Molecular Medicine, Northwestern Univeristy Feinberg School of Medicine, Chicago, IL, USA; 2) Department of Obstetrics and Gynecology, Pennsylvania State College of Medicine, Hershey, PA, USA.

Polycystic ovary syndrome (PCOS) is a complex polygenic endocrine disorder common among reproductive age women. It is characterized by hyperandrogenemia, chronic anovulation, and menstrual irregularities. In addition, women with PCOS exhibit broad range of metabolic consequences, including increased risk of obesity, type 2 diabetes and insulin resistance. Involvement of inflammatory and TGF-β pathways, as well as ovarian rigidity genes in the etiology of PCOS has been postulated, however to date reproducible associations have been identified with only few variants. In order to survey the complete variation in the genome, 58 women with PCOS, and 12 healthy controls were sequenced for the whole genome at 40x coverage by Complete Genomics, Inc. The first phase of this project focuses on 307 candidate genes, chosen for their roles in ovarian rigidity and follicular structure, inflammation, obesity, type 2 diabetes, and TGF-β and NFκB pathways. We found 116,450 unique variant loci mapping to these genes and 5kb around them; with single nucleotide polymorphisms (SNPs) making up 72.9% of the total observed variation, and coding variants constituting less than 0.5%. Using Fisher's exact test for allele counts at coding SNPs, we identified two missense variants in insulin-like 3 (*INSL3*; min$P$ = 0.0013), and one missense variant in each of cathepsin H (*CTSH*; P=0.014), chordin (*CHRD*; P=0.017) and interleukin 1 receptor associated kinase 1 (*IRAK1*; P= 0.020) genes, whose frequencies were increased in PCOS. Small insertions, deletions and substitutions, approximately one to 100 base pairs in length, will be evaluated in a similar way. These results will help us to prioritize and select variants to be genotyped and tested for associations with PCOS in a larger cohort of ~1000 cases and ~1000 controls. In addition to associations with individual variants, the combined effects of mutations in a gene may pose a risk for developing PCOS. Therefore, we will subsequently test for presence of mutational burden in these candidate genes.

CYP1B1, MYOC and LTBP2 mutations in primary congenital glaucoma patients in the United States. *S. Lim[1], K. Tran-Viet[1], T. Yanovitch[3], S. Freedman[1], T. Klemm[2], W. Call[1], C. Powell[1], A. Ravichandran[1], R. Metlapally[4], E. Nading[1], S. Rozen[2], T. Young[1].* 1) Duke University, Durham, NC; 2) Duke-National University of Singapore Graduate Medical School, Singapore; 3) University of Oklahoma/Dean McGee Eye Institute, Oklahoma, OK; 4) University of California at Berkeley, Berkeley, CA.

Purpose: To screen primary congenital glaucoma (PCG) patient DNA samples for mutations in known PCG genes CYP1B1, LTBP2 and MYOC. Methods: Whole exome sequencing (WES) was performed on affected members of 3 families, and variants were confirmed by Sanger sequencing. Sanger sequencing was performed on additional 44 PCG families. Results: Twelve patients (21.1 %) carried CYP1B1 mutations: 1 nonsense and 6 compound heterozygous mutations. There were no pathogenic LTBP2 and MYOC mutations. Conclusion: This is the largest U.S. PCG cohort study analyzing genetic mutations using WES and Sanger sequencing. Five compound heterozygous CYP1B1 mutations were novel. The low percentage mutation rate in the 3 genes indicates other genes are implicated with PCG. WES may be a powerful tool to identify novel PCG genes.

Enhancing Sequencing Lab Workflows in the SardiNIA Project. *A. Maschio[1,2], F. Busonero[2], C. Sidore[1,2,3], E.A. Ketterer[4], E.B. Pedersen[4], A.M. Chidester[4], A.M. Gurkan[4], M.R. Coon[4], M. Dei[2], S. Lai[2], A. Mulas[2], M.G. Piras[2], M. Lobina[2], B. Tarrier[4], S. Sanna[2], C.A. Brennan[4], G.R. Abecasis[1], F. Cucca[2,3], R.H. Lyons[4].* 1) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 2) Istituto di Ricerca Genetica e Biomedica (IRGB), CNR, Monserrato, Italy; 3) Dipartimento di Scienze Biomediche, Università di Sassari, SS, Italy; 4) DNA Sequencing Core, University of Michigan, Ann Arbor, MI, USA.

Low-pass whole genome sequencing can detect low frequency and non-SNP variants that are not well represented in commercial genotyping arrays. With this purpose we are sequencing 2107 individual genomes from the SardiNIA project each at a depth of 3–4X. Our goal is to use the data to extend our understanding of the genetic factors contributing to many aging related traits. Our sequencing workflow is implemented in the University of Michigan DNA Sequencing Core (UMDSC), which provides expertise and efficient laboratory infrastructure to perform all processing steps (sample QC, library prep, library QC, sequencing, data extraction, data QC and data transfer). A main cause of genotyping errors is related to human factors, that is why to minimize sample tracking errors each sample is genotyped on the Sequenom platform with a set of 36 SNP markers, chosen to be common in the population and previously genotyped with the Affymetrix 6.0 arrays and Illumina MetaboChip. Next, samples proceed to library preparation. With rapidly improving sequencing technology and instrument throughput, we made several improvements to our procedures for preparing paired-end Illumina libraries. We have evaluated multiple automation protocols for library preparation, including the QIAcube (QIAGEN), epMotion 5075 (Eppendorf), and Apollo 324 (IntegenX) protocols, which can facilitate preparation of libraries. Sequencing data generation, which initially used 3 Illumina Genome Analyzers IIx now relies on 7 Illumina HiSeq2000 instruments. Currently runs typically include 24 multiplexed samples per flow cell, resulting in >10GB of sequence data per sample and an average depth of 3–4X after focusing on high-quality mapped bases per each sample. Our results illustrate protocols for lab automation and generation of high quality short read data in a small laboratory.

2330F

Whole-Exome Sequencing Identifies Novel Risk Variants for Thrombotic Storm. *P. Whitehead[1], N.D. Dueker[1], G. Beecham[1], D. Hedges[1], A. Beecham[1], S. Hahn[1], N. Hofmann[1], J.W. Lawson[2], D. Erkan[3], L.R. Brandao[4], A.H. James[5], M.J. Manco-Johnson[6], R. Kulkarni[7], C.S. Kitchens[2], T.L. Ortel[8], J.M. Vance[1], M.A. Pericak-Vance[1].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) University of Florida, Gainesville, FL; 3) Hospital for Special Surgery, Weill Medical Center of Cornell University; 4) Pediatric Hematology/Oncology, The Hospital for Sick Children, Toronto, ON; 5) Department of OB/GYN, Duke University Medical Center, Durham, NC; 6) University of Colorado Denver and The Children's Hospital, Aurora, CO; 7) Pediatrics & Human Development, Michigan State University, East Lansing, MI; 8) Hematology, Duke University Medical Center, Durham, NC.

Thrombotic storm (TS) is a rare disorder defined by ≥ 2 of the following in a short period: 1) more than two acute arterial/venous thromboemboli, or thrombotic microangiopathy, 2) unusual location, 3) progressive/recent unexplained recurrence, or 4) refractory/atypical response to therapy. We hypothesized that prothrombotic genetic risk factor(s) trigger an accelerated form of thrombosis following an initial event. We performed whole-exome sequencing (WES) on two families with TS, each with one case, unaffected parents, and unaffected sibs. Another 25 TS cases were also sequenced. DNA was captured using the Agilent 50mb kit and sequenced using Illumina HiSeq2000. Alignment and genotype calling were performed with Burrows-Wheeler Aligner and Genome Analysis ToolKit. Variants were filtered by function (nonsense, missense, or splice), conservation, damage potential, sequence quality, and rare frequency. We identified variants that met our filtering criteria and were inherited in a de novo or autosomal recessive manner in the two families. Using this approach we identified 2 de novo (SLC26A2; PRMT7) and 7 autosomal recessive (GRIK1, TUBGCP6, ADAMTS9, DPP6, HLA-E, EGFL8, TNFAIP3) variants. We then looked to see if any variants within the 9 identified genes were found in an additional 25 cases. Six of the genes had functional, conserved, potentially damaging, and rare-moderately rare (MAF ≤ 0.05) variants in at least 1 of the other 25 cases; GRIK1, TUBGCP6, ADAMTS9, DPP6, SLC26A2, and TNFAIP3. As a second approach, we identified genes having functional, conserved, damaging, good quality, and rare variants (MAF≤0.01) in ≥ 2 of the 27 cases. A total of 1770 genes met these criteria. Two gene families (ADAMTS/ADAM and DNAH) showed multiple genes within the family meeting these criteria (n=8 ADAMTS/ADAM; n=7 DNAH) and most of these variants have been validated. Further investigation also identified an additional 17 ADAMTS/ADAM genes (all validated) and 5 DNAH genes having a variant in 1 case. Several genes showed variation in more than 10 cases includingZFHX3 and VPS13B. Using whole-exome sequencing we were able to identify several loci that may play a role in the development of thrombotic storm. We are following up functional studies on several TS candidate loci including EGFL8 which has two EGF domains, a common motif in hemostatic and fibrinolytic proteins, and is, thus, potentially involved in coagulation. Further analysis is warranted.

Identification of Genetic Modifiers Associated with Risk of Stroke in Children with Sickle Cell Anemia. *J.M. Flanagan[1], H. Linder[1], V. Sheehan[1], T.A Howard[1], B. Aygun[2], J.S Hankins[2], M. Wang[3], G.A. Neale[3], R.E. Ware[1].* 1) Texas Children's Hematology Center, Baylor College of Medicine, Houston, TX; 2) Department of Hematology, St. Jude Children's Research Hospital, Memphis, TN; 3) Hartwell Center for Bioinformatics and Biotechnology, St. Jude Children's Research Hospital, Memphis, TN.

Introduction: Stroke is one of the most catastrophic acute complications of sickle cell anemia (SCA), occurring in 11% of patients before 20 years of age. A further 20 to 30% of children with SCA will develop less clinically overt cerebrovascular disease events such as transient ischemic attacks (TIA) and silent infarcts. There is a definite need for biomarkers that could determine the cause of these irreversible cerebrovascular events and which might predict which children are at greatest risk. Previous studies of sibling pairs have shown that there is a genetic component to cerebrovascular disease development but few genetic modifiers have been validated as having a substantial effect on risk of stroke. The aim of this study was to perform an unbiased whole genome search for genetic modifiers of stroke risk in SCA. Methods: Pediatric patients with SCA and documented primary stroke (n=177) were compared to a pediatric control non-stroke group with SCA (n=340). All control patients were over 5 years old and without previous clinical stroke prior to beginning any clinical treatment. Genome wide association studies (GWAS) were performed using genotype data obtained from Affymetrix SNP6.0 arrays. A pooled DNA approach was used to perform whole exome sequencing (WES) by Illumina next generation sequencing of pooled control (n=104), and pooled stroke (n=120) groups. Results: From the Affymetrix SNP6.0 GWAS data, 139 single nucleotide polymorphisms (SNPs) were identified with stroke association. From the WES, 294 non-synonymous mutations were found to be significantly associated with stroke. In combination, 22 mutations identified by WES were located within 500kb of a SNP identified by GWAS. These 22 mutations represent key areas of the genome that are targets for further in depth study. To validate the association of these mutations with risk of stroke, 20 mutations were genotyped in an independent cohort of control (n=236) and stroke (n=57) patients with SCA. One mutation in GOLGB1 (Y1212C) was corroborated as having significant association with risk of stroke (p=0.02). This mutation in GOLGB1 is predicted to effect the golgi associated function of the encoded protein and future studies will focus on how this functional mutation may lead to development of cerebrovascular disease in the context of SCA.

2332T

Implication of rare variants from European-derived adiposity loci in African Americans. *J. Hester[1,2,3], P. Mudgal[1,2], J. Li[1,2], J. Xu[1,2], P. Hicks[1,2,4], B. Freedman[5], D. Bowden[1,2,4,5], M. Ng[1,2].* 1) Center for Diabetes Research, Wake Forest University School of Medicine, Winston-Salem, NC 27157; 2) Center for Genomic and Personalized Medicine Research, Wake Forest University School of Medicine, Winston-Salem, NC 27157; 3) Program in Molecular Genetics and Genomics, Wake Forest University School of Medicine, Winston-Salem, NC 27157; 4) Department of Biochemistry, Wake Forest University School of Medicine, Winston-Salem, NC 27157; 5) Department of Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC 27157.

Genome-wide association studies have successfully identified nearly 100 common variants associated with adiposity in multiple populations. However, common variants with relatively small effect can only account for a small proportion of the total variance of BMI. There is potential utility in exploring the impact of rare variants that may have stronger effects in the respective genes. There have been recent efforts focused on sequencing the protein coding regions of the human genome to identify variants that may be potentially functional. 47 exonic variants, predominantly rare ($0.005 < MAF < 0.05$), from seven previously discovered European adiposity loci that replicated association in African Americans ($P < 0.05$) were selected from the Exome Sequence Project (ESP) database and genotyped in 1561 subjects from two African American cohorts. These SNPs were tested for association with BMI after adjustment for age, gender, diabetes status, and admixture in each cohort. Meta-analysis was conducted to combine the results. Meta-analysis of 1561 subjects revealed 3 variants demonstrating significant association at $0.012 < P < 0.045$ with effect sizes between 0.08 and 0.63 SD unit of BMI for each copy of the BMI-increasing allele. The majority of the associations were observed in the *SEC16B* gene. This gene required for organization of transitional endoplasmic reticulum sites and protein export, however, the biological mechanism is largely unknown. Effect sizes for common variants found within the *SEC16B* gene range from 0.03 to 0.05 SD unit of BMI for each copy of the BMI-increasing allele, while the effect sizes observed in rare variants range from 0.08 to 0.43 SD unit of BMI. Our results suggest that rare variants in obesity-associated genes may provide insight into the genetics of obesity in African Americans. A larger sample size will be necessary to confirm or refute the associations.

2333F

Assessing the effect of rare variants on cancer drug-induced cytotoxicity phenotypes using whole genome sequence data. *A. Tikhomirov[1], A. Pluzhnikov[1], C.R. King[2], A. Konkashbaev[1], E. Gamazon[1], M.E. Dolan[3], D.L. Nicolae[1,4,5], N.J. Cox[1].* 1) Section of Genetic Medicine, Department of Medicine, The University of Chicago, Chicago, IL; 2) Department of Health Studies, The University of Chicago, Chicago, IL; 3) Section of Hematology and Oncology, Department of Medicine, The University of Chicago, Chicago, IL; 4) Department of Statistics, The University of Chicago, Chicago, IL; 5) Department of Human Genetics, The University of Chicago, Chicago, IL.

Our goal is to understand the relationship between common and rare variants' contributions to cytotoxicity outcomes, identify genes likely to have rare variants affecting the phenotypes, and characterize network properties of these genes to develop a prediction model. The analyses are performed on 60 unrelated Caucasian (CEU) and 59 unrelated African (YRI) whole genome autosomal sequences obtained from March 2012 release of 1K Genomes data (hg19/b37) comprising over 38M SNPs and structural variants. The lymphoblastoid cell lines (LCL) were phenotyped for cytotoxicity induced by carboplatin, cisplatin, aracin, daunorubicin, and etoposide, as well as for expression of over 14K genes. We use the gene-based method of King et al. (EMMPAT) to obtain a single test statistic per gene combining information from all variants pertinent to the gene, variant allele count and fitness burden, as well as prior information on effect sizes estimated based on MAF. Approximately 16M intragenic SNPs (both rare and common) from over 22K autosomal genes were included in the first round of the analysis supplemented later by over 100K LCL eQTLs (p value < 2e-8). In addition, we use PLINK for single point quantitative trait association tests with cytotoxicity phenotypes. Testing intragenic SNPs alone shows strong effect of rare variants (MAF < 5%) on top association signals for every phenotype regardless of the drug action mechanism and etiology. For the majority of phenotypes, the genes implicated in EMMPAT analyses are congruent with top SNP-based association signals. We extend the gene-based approach to include eQTLs associated with a gene into the model and present the results of comparison between the effects of common vs. rare variants in analyses combining the effects of intragenic SNPs and *cis*-eQTL, as well as both *cis*- and *trans*-eQTLs. We also plan to present results of analyses on at least five additional cytotoxicity phenotypes that have just become available.

Detecting rare variant effects using extreme phenotype sampling in sequencing association studies. *I. Barnett, S. Lee, X. Lin.* Biostatistics Department, Harvard University, Boston, MA.

In the increasing number of sequencing studies aimed at identifying rare variants associated with complex traits, the test power can be improved by guided sampling procedures. We show both analytically and numerically that sampling individuals with extreme phenotypes can enrich the presence of causal rare variants and leads to an increase in power compared to random sampling. While application of traditional rare variant association tests to these extreme phenotype samples requires dichotomizing the continuous phenotypes before analysis, the dichotomization procedure can decrease the power by reducing the information in the phenotypes. To avoid this, we propose a novel statistical method based on optimal SKAT (SKAT-O) that allows us to test for rare variant effects using continuous phenotypes in the analysis of extreme phenotype samples. The increase in power of this method is demonstrated through simulation of a wide range of scenarios as well as in the triglyceride data of the Dallas Heart Study.

Whole Genome Sequencing to Identify Rare Genetic Variation Responsible for Resistance to HIV Infection. *P.R. Shea, K. Pelak, K.V. Shianna, D. Ge, D.B. Goldstein, National Institute of Allergy and Infectious Diseases Center for HIV/AIDS Vaccine Immunology (CHAVI).* Center for Human Genome Variation, Duke University, Durham, NC.

Epidemiologic studies of individuals at a high risk of HIV exposure have found that a small proportion of the human population is resistant to HIV infection. Investigations of these high-risk, seronegative (HRSN) cohorts have identified genetic variants in the CCR5 gene that confer high-level resistance to HIV infection. However, CCR5 variation is only able to explain resistance in a minority of HRSN individuals; therefore the remaining mechanism for HIV resistance is unknown. Interrogation of common genetic variation using genome-wide association has thus far been unable to identify additional genetic variants that have consistently been associated with HIV resistance. Increasingly, we have begun to appreciate that rare genetic variation plays an important role in the etiology of complex diseases. To test the hypothesis that rare genetic variation is responsible for resistance to HIV infection, we performed whole-genome sequencing on more than 225 Caucasian patients with severe hemophilia who were potentially exposed to HIV-contaminated blood products from 1979 to 1984, but remain seronegative. Genome data from these patients was compared to over 200 whole-genome sequenced population controls using single variant association testing. A preliminary gene-based collapsing analysis of rare variants performed with 66 HRSNs and 119 controls identified 12 genes that were enriched for rare genetic variants relative to controls at a statistically significant level (empiric $P < 0.05$). Further investigation of these genes revealed that some, but not all, are artifact caused by genes with high levels of background variation. Additional follow up analyses of individual variants and remaining genes showing enrichment will be needed to determine their role in HIV resistance.

Rare Variants are Strongly Associated with Age of Menarche: First Results from NHLBI-Exome Sequencing Project. *K.L. Bucasas[1], G.T. Wang[1], P.L. Auer[2], M. Kan[1,3], J.M. Murabito[4,5], N. Franceschini[6], E.W. Demerath[7], K.L. Lunetta[8], A. Rodriguez[1], L.A. Lange[6], R.D. Jackson[9], S.M. Leal[1], NHLBI-Exome Sequencing Project.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, 77030; 2) Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle WA, 98109; 3) Institute of Nutritional Sciences, Shanghai Institutes for Biological Sciences, Graduate School of Chinese Academy of Science, Chinese Academy of Sciences, Shanghai, 2000032; 4) Sections of General Internal Medicine, Department of Medicine, Boston University School of Medicine, Boston MA, USA, 02118; 5) NHLBI Framingham Heart Study, Framingham, MA, USA, 02118; 6) Department of Genetics, University of North Carolina, Chapel Hill, NC, 27599; 7) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN 55454; 8) Department of Biostatistics, Boston University School of Public Health, Boston, MA, 02118; 9) Center for Clinical and Translational Science, The Ohio State University, Columbus, OH 43210.

Age of menarche is a highly heritable, common complex trait that is recognized as a significant risk factor for many late onset diseases, including cardiovascular disease and cancer. For most complex traits, the contribution of rare variants is largely unknown since previous surveys of genetic architecture have mainly been limited to evaluating common variation. We took a comprehensive approach in studying both common and rare variants by utilizing next-generation technologies that involve massive parallel sequencing of protein coding sequences across the human genome. We analyzed whole-exome sequence data from 2814 African American and European American women from the NHLBI-ESP (Exome Sequence Project) with age of menarche data. We performed race-stratified, gene-based rare variant association testing (minor allele frequency [MAF]< 0.01) by analyzing nonsynonymous and splice site variants using the Combined Multivariate Collapsing (Li & Leal 2008) method. We also applied the Variable Threshold (Price et al. 2010) test which within a gene region maximizes the test statistic over variant allele frequencies and uses permutation to adjust for multiple testing. Additionally, association tests were performed for all individual variants with a MAF > 0.01. Covariates were included in our regression model to adjust for the effects of population substructure (Multi-Dimensional Scaling Components), cohort membership, generational age effects and body mass index. Our results provide new insights into the genetic etiology of age of menarche. We observed that rare variants within multiple genes including LRRC8B $p=9x10^{-7}$ and several individual variants (e.g. rs62260755 $p=3x10^{-6}$) are associated with age of menarche. Interestingly these findings were limited to European Americans and no significant associations were observed for African Americans, despite similar sample sizes (n= 1332 African Americans and n=1482 European Americans). Differences in the allelic architecture between African Americans and European Americans could partly explain this discrepancy. Finally, this study is among the first to demonstrate evidence for the significant influence exerted by rare variants on a complex trait using a large-scale whole exome sequencing approach.

Waist-to-hip ratio (WHR) is a common anthropometric measure in humans that is used to assess abdominal obesity. Recent genome-wide association studies (GWAS) have identified numerous common genetic loci influencing this trait but the contribution of rare variants is not known. To better understand the underlying genetic architecture of WHR, we performed a large-scale whole-exome sequencing study on 1518 African American (AA) and 2337 European American (EA) participants from seven cohorts in the NHLBI-ESP (Exome Sequence Project) with information on WHR. We stratified our association analyses by race and sex because of the observed differences in WHR distributions between EA and AA (p=1.2x10–8) individuals and males and females (p=2.2x10–16). Due to limited sample sizes for males, we concentrated our analysis on the 1209 AA women and 1551 EA women with WHR data. We performed gene-based rare variant association testing (minor allele frequency [MAF] < 0.01) by analyzing nonsynonymous and splice site variants using the Combined Multivariate Collapsing (Li & Leal 2008) method. We also performed aggregate variant association testing by applying the Variable Threshold (Price et al. 2010) test which within a gene region maximizes the test statistic over variant allele frequencies and uses permutation to account for multiple testing. Additionally, association tests were performed for all individual variants with a MAF $\geq$ 0.01. Covariates were included in our regression models to adjust for the effects of population substructure, cohort membership, age, current smoking status and body mass index. Our strongest association was observed for a burden of rare variants within a gene located on chromosome 8 ($p = 3.1x10–7$) which meets the exome-wide significance level ($p < 2.5 \times 10–6$) within the EA subpopulation. No exome-wide significant associations were detected for AA women, possibly because of a smaller sample size and differences in allelic architecture. This is the first study to demonstrate the significant influence exerted by rare variants within a gene on WHR using large-scale whole exome sequencing.

Identification of Rare Susceptibility Variants for Bipolar Disorder by Exome Sequencing. *C. Cruceanu[1], A. Ambalavanan[2], J.P. Lopez[1], J. Gauthier[2], D. Spiegelman[2], R.G. Lafrenière[2], P. Grof[3], M. Alda[4], G. Turecki[1], G. Rouleau[2,5].* 1) McGill Group for Suicide Studies, Douglas Mental Health University Institute, McGill University, Montreal, Quebec, Canada; 2) Center of Excellence in Neuroscience of the Université de Montréal (CENUM), Montreal, Quebec, Canada; 3) Mood Disorders Centre of Ottawa, Ottawa, Ontario, Canada; 4) Department of Psychiatry, Dalhousie University, Halifax, Nova Scotia, Canada; 5) Centre de Recherche du Centre Hospitalier de l'Université de Montréal (CRCHUM), and Department of Medicine, Université of Montreal, Montréal, Quebec, Canada.

Background: Bipolar disorder (BD) is a complex psychiatric condition characterized by manic and depressive episodes. In spite of the strong support for the role of genetics in BD, molecular studies have by-and-large had minimal success in identifying disease-causing genes. This is likely because of high levels of heterogeneity in the sample sets used, but the problem may be minimized by focusing on a well-defined sub-phenotype of BD. Our group has led efforts to characterize BD patients that respond positively to Lithium (Li) therapy, and shown that Li-response clusters in families. Research in BD genetics to date has consisted of linkage and genome-wide association studies, which presume that common variants in a small subset of genes are the cause for BD. However, the minimal success of this approach suggests that BD is caused by highly penetrant rare variants in a large number of different genes across the population. Methods: Our approach focused on a well-defined clinical subtype of BD (Li-responsive) to minimize clinical heterogeneity, and we used massively-parallel next-generation sequencing to re-sequence the exomes of all affected individuals from multi-generational family units. To identify relevant BD susceptibility genes we prioritized rare variants that segregate with affected status within each family. To validate candidate variants we used Sanger sequencing in all family members. Results: We found that each family shared a only 5–10 potentially highly penetrant (e.g. protein-truncating or missense) or functionally relevant (e.g. 3′UTR, 5′UTR, splicing) variants. After Sanger sequencing validation we were able to narrow in on strong candidates for BD causality or susceptibility within each family, and to further explore the mechanisms by which these variants could lead to pathology using cell line and post-mortem brain samples. Conclusion: By focusing on rare variants, rather than common variants, we hope to have narrowed in on the key genes and biochemical pathways that play an important role in bipolar disorder and can lead directly to clinically relevant diagnostic and therapeutic applications.

Blangero[1].* 1) Texas Biomedical Research Institute, San Antonio, TX, USA; 2) University of Michigan, Ann Arbor, MI, USA; 3) University of Exeter, Exeter, United Kingdom; 4) McGill University, Montreal, Canada; 5) Montreal Diabetes Research Center, Montreal, Canada; 6) Albert Einstein College of Medicine, Bronx, NY, USA; 7) University of Texas Health Science Center at San Antonio, San Antonio, TX, USA; 8) Complete Genomics, Inc., Mountain View, CA, USA.

Thyroid hormones are of paramount importance to human physiology. They are intricately involved in the regulation of many metabolic and physiologic processes, from early development throughout adulthood, including skeletal and neural development, tissue growth and maturation, regulation of metabolism, cardiac function and body temperature, brain maturation, and many more. There are two main circulating thyroid hormones, T3 (triiodothyronine) and T4 (thyroxine), however only the unbound free forms of these hormones are metabolically active, with T3 being the most abundant and also biologically active form. It is well established that there is a correlation between quantitative variation in normal thyroid hormone levels and several disease-related risk factors; however the genetic factors influencing this normal physiological variation remain largely unknown. As part of the San Antonio Family Study (SAFS), we measured free T3 (FT3) in 1,276 Mexican American individuals and found that levels were significantly heritable (h^2= 0.625; p=1.1x10^{-54}). Using a deep whole genome sequencing approach, we concentrated on finding non-synonymous variants influencing FT3 levels in 696 Mexican American individuals from large families, for whom we have both FT3 and sequence variation available (obtained as part of the T2D-GENES Consortium). Initially, we focused on the potential effects of obligately functional protein altering variants that are predicted to be highly deleterious (PolyPhen-2 prediction score > 0.7) of which ~11,000 were observed in our sequencing set. We identified a private variant, Q295H, in the *OR2W5* (olfactory receptor family 2 subfamily W member 5) gene associated with a large increase of 3.4 SDU in FT3 levels (p=8.6×10^{-6}). Although this gene shows some similarities with other olfactory receptors, its function is relatively unknown. Expanding our focus to the remaining non-synonymous variants (~33,000), we identified a second candidate variant influencing FT3 levels. This common variant, V115F, in the *CIDEA* gene is associated with a decrease in FT3 levels of 0.34 SDU (p=3.0×10^{-7}). The V115F variant in *CIDEA* (cell death-inducing DFFA-like effector A) has previously been shown to be associated with metabolic syndrome and obesity, making it an excellent candidate for regulating thyroid hormone levels. Our results highlight the value of focusing on protein-altering variants for the identification of two new QTLs influencing thyroid hormone.

Exome Sequencing to Identify Causal Variants in a Multiplex Anencephaly Family. *D. Krupp, K. LaRocque-Abramson, K. Soldano, M.E. Garrett, A.E. Ashley-Koch, S.G. Gregory.*Center for Human Genetics, Duke University, Durham, NC.

Neural tube defects (NTDs), including anencephaly, are a common class of human birth defects with an estimated worldwide incidence of 1 in 1000 births. Despite widespread prevalence in all ethnic groups, the majority of human NTDs are sporadic cases, suggesting an underlying oligogenic or polygenic mechanism. To further our understanding of genetic variants contributing to human NTDs, we performed exome sequencing of two affected siblings and their parents from a family with three consecutive anencephalic pregnancies. Exonic regions were enriched for the father and both affecteds using the Illumina TruSeq Exome Enrichment kit. The mother's exome was captured using Agilent's Sure Select Human All Exon 50 Mb kit. All enrichments were performed according to the respective manufacturer's protocol, and libraries were sequenced 2x100nt on an Illumina HiSeq instrument. For the exomes of the father and affected offspring, reads were aligned using the Burrows-Wheeler Aligner, duplicates removed using PICARD, and alignment refinement and variant calling performed with the Genome Analysis Toolkit. Variants were filtered by minimum read depth (3), variant quality score (50), mapping quality (45) and quality by depth (7) to reduce false positives. Enrichment of exonic and non-synonymous variants was evaluated in each individual by chi-squared test for 22 NTD-relevant Gene Ontology terms, including neural tube development, the Wnt receptor signaling pathway, SHH signaling, and cilium morphogenesis. In each affected, we observed suggestive to significant overrepresentation of nonsynonymous variants in the cilium cellular compartment (p=0.0279, p=0.0085) and the cilium morphogenesis biological process (p=0.024, p=0.108). No such enrichments were observed in the father, suggesting that defects in cilium formation and/or cilium-dependent processes underlie these anencephaly cases. Such defects have previously been associated with NTDs in mice and humans. Both affecteds were heterozygous for a novel missense variant in IFT172, not present in the father and rated “probably damaging” by Polyphen-2. The affecteds additionally shared three other low-frequency missense SNPs in intraflagellar transport genes. Further analysis, including that of the mother, is ongoing and will be presented at the meeting.

Statistical power and effect size overestimation for combined single point and sequence kernel association tests in case-control studies. *A.M. Valdes, F. Lari.* Twin Research, King's College London, London, United Kingdom.

The cost of generating whole genome sequences data implies that the number of cases that can be assayed is low compared to the sample size in a typical GWAS. New methods have been developed which employ gene or region based approaches. Based on published simulation results a regression method using the Kernel association test (SKAT) appears to give good results under most scenarios. *Objective*: to assess the statistical power and determine optimal strategies for signal selection for replication using as discovery whole genome /exome sequence data from 150–200 cases vs the same number of controls. *Methods*: Computer simulations were carried out using publically available phased sequence data from a portion of chromosome 1 from the 1000 genomes project. Variants in the NFBP3 and NFBP1 genes were annotated. Each missense variant was assumed to contribute to disease risk with an odds ratio (OR) of either 2.0 and 5.0, disease prevalence assumed 5%. All risk variants were assessed for single point analysis and both genes and other 10 genes in chr 1 were tested using SKAT. NFBP3 had 16 missense rare variants with a mean minor allele frequency (MAF) of 2.3% (median MAF =2.2%). NFBP1 had 18 missense variants (mean MAF =1.1% ; median MAF =0.7%). We ran 100 replicates for each model. *Results*: A small case control study does not enough power to detect single point association with rare variants even with very high p-values(p<0.01) and variants with MAF <2% cannot be detected even at very relaxed p-values (p<0.05) unless OR >5.0. ORs are consistently overestimated relative to the true effect size and the magnitude of the overestimation is a function of both MAF and p-value. Power for SKAT is lower for low MAF variants (median MAF= 0.7%) than for higher MAF rare variants (median MAF =2%). SKAT has better statistical power than single point association analysis. Statistical power can be improved and type I error reduced if both single point and kernel association results are combined for signal prioritization *Conclusions*: Small case-control studies (total n<= 400) using whole genome/exome data are underpowered for both gene based and single point analysis unless true individual variant effect sizes can be assumed to be OR>5.0. Very low MAFs (<1%) cannot be detected with either type of method even with nominal significance (p<0.05). A combination of single point and gene-based methods can improve power for signal prioritization and candidate region studies.

Exome sequencing of cluster headache patients with Sardinian ancestry. *L. Jouan[1], H. Daoud[1], B. Oulad Amar Ben Cheikh[1], A. Dionne-Laporte[1], D. Spiegelman[1], O. Diallo[1], E. Henrion[1], A. Szuto[1], J. Gauthier[1], P. A. Dion[1], M. Manchia[2], M. Alda[2], M. Del Zompo[3], G. A. Rouleau[1].* 1) Centre d'Excellence en Neuroscience de l'Université de Montréal, CRCHUM Hôpital Notre-Dame, Montreal, Quebec, Canada; 2) Mood Disorders Program, Department of Psychiatry, Dalhousie University, Halifax, Nova Scotia, Canada; 3) Section of Clinical Pharmacology, Department of Neurosciences, University Hospital Agency of Cagliary, Cagliary, Italy.

Cluster headache (CH) is a devastating disease characterized by recurrent attacks of short-lasting excruciating pain with regular periodicity. Albeit considered for many years a sporadic disease with absence of a heritable component, twin and family studies indicated a role for genetic factors. Complex segregation analyses suggested an autosomal dominant mode of inheritance with low penetrance in some families and a multifactorial inheritance or autosomal recessive in others. To date, only two genes were positively associated with CH, Hypocretin receptor 2 (HCRT2) and Alcohol dehydrogenase (ADH4). To identify novel CH causative genes, we performed exome sequencing of 23 unrelated CH patients from Sardinia, a genetically homogenous population and a valuable resource for fine mapping of susceptibility genes for complex diseases. The exome capture was done using the Agilent SureSelect v4 and the sequencing on Illumina HiSeq2000. Variants were called and annotated using an in-house data pipeline that uses the GATK software. Under the assumption that novel rare variants cause CH, variants were filtered against dbSNP, 1000 Genomes, Complete Genomics data set and >500 in-house exomes to exclude known or common variations. Candidate genes with truncated variants (non-synonymous, splices and Indels) shared by the highest number of CH patients will be prioritized, validated by Sanger sequencing and studied at the functional level. The exome sequencing of CH in patients with Sardinian ancestry has tremendous potential to identify novel CH-causing genes and provide novel insights into our understanding of this disease.

2343W

Whole-genome sequencing analysis of more than 700 members of an extended pedigree. *Y. Huang[1], A. Jasinska[1], V. Ramensky[1], N. Juretic[3], S. Service[1], N. Tran[1], R. Wilson[2], W. Warren[2], G. Weinstock[2], K. Dewar[3], N. Freimer[1].* 1) Center for Neurobehavioral Genetics, UCLA, Los Angeles, CA; 2) The Genome Institute at Washington University in St. Louis, St Louis, MO; 3) McGill University and Genome Quebec Innovation Centre, Montréal, Québec, Canada.

It is hypothesized that much of the genetic risk for complex traits derives from the effects of rare variants. Large-scale population sequencing projects to identify rare trait-related variants have mainly utilized exome-sequencing, and thus have not assayed non-coding variation. Although whole genome sequencing (WGS) is still prohibitively expensive in large population samples, WGS-based studies in extended pedigrees have advantages that make it currently viable to comprehensively capture rare risk alleles: a) There is a good chance in such pedigrees that rare variants are observed in multiple individuals, alleviating the need to conduct sample-wide high depth sequencing; b) The pedigree structure can be leveraged to improve variant calling; c) Due to the limited number of unique haplotypes in a pedigree, a varying-depth sequencing and imputation strategy can be used to obtain nearly comprehensive variants for every pedigree member. We illustrate these points through WGS of the Vervet Research Colony (VRC), which was established in the 1970s from 57 wild monkeys collected from two Caribbean islands, St. Kitts and Nevis. The Caribbean population in turn arose from a small number of vervets brought from West Africa to these islands during the 17–18th centuries. Thanks to the research conducted by a number of research groups during the past four decades, dozens of phenotypes have been measured on a pedigree-wide basis in the VRC. To conduct linkage and association mapping of these traits we sequenced 723 VRC monkeys. We describe a VRC variant discovery pipeline that takes the pedigree structure into account. In particular, we adapted TrioCaller (Chen et al. 2012, submitted), a program that refines genotype-calls from single-locus callers (GATK/SAMtools) and imputes missing genotypes based on haplotype information and trio constraints, to the vervet monkey setting, in which one male monkey could have as many as 25 children with different females. Using this pipeline, we were able to achieve a very low Mendelian inconsistency rate. We also describe a sequencing strategy that prioritizes an individual monkey's sequencing depth based on its position in the pedigree. Results from downsampling showed that we could sequence ~40% of monkeys at 1X with little reduction in the number of variant sites identified (~10 million) and the quality of genotype calls (Mendelian inconsistency rate below 0.5%).

Sequencing Initiative Suomi (SISu): identification of loss of function variants enriched in the Finnish population. *K. Rehnström[1,2], E.T. Lim[3,4,5,6], A. Palotie[1,2] on behalf of the SISu Consortium.* 1) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Institute for Molecular Medicine Finland, FIMM, University of Helsinki, Helsinki, Finland; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts, USA; 5) Departments of Genetics and Medicine, Harvard Medical School, Boston, Massachusetts, USA; 6) Program in Genetics and Genomics, Biological and Biomedical Sciences, Harvard Medical School, Boston, Massachusetts, USA.

Because of a founding bottleneck roughly 100 generations ago, the Finnish population offers substantial advantages in the study of rare and low frequency DNA variation. The Sequencing Initiative Suomi (SISu) aims to bring together all Finnish sequencing projects to make data available as a high density reference set for imputation as well as a control set for medical genetic sequencing studies. Currently, the project includes 3800 whole genomes and >5000 exomes from projects including FINRISK, GoT2D (FUSION, Botnia), H2000, METSIM, NFBC66, and UK10K. Of particular interest, the exome data reveals several key features that distinguish the Finns from other European populations that are of key importance to studying rare variation. We see a strong increase of variants with 1–5% frequency, with 40–50% more loss-of-function variants in this frequency range in Finns than other European samples. Since the founding bottleneck was evolutionarily recent, recessive lethal variants may still persist at or near 1% frequency. Unlike most populations, many recessive Mendelian mutations at this frequency have been documented in Finns. We also observe a strong decrease of singletons and very rare variants. We hypothesize that the enrichment of variants which are rare in other parts of Europe could aid in identification of novel recessive diseases similar to the 36 monogenic disorders of the Finnish Disease Heritage. We have identified functional variants which are enriched in Finland, and will genotype these in large population and patient cohorts to identify association with diseases and possible depletion of homozygous variants suggesting lethality. To identify enriched variants, we compared allele frequencies in a set of equally-sized Finnish and European deep coverage exomes and rigorously selected a set of variants that are at least 2–fold enriched in Finns, with a focus on loss of function variants. We are currently genotyping 145 variants in 2000 individuals from the Young Finns Study to validate allele frequencies and identify disease associations. Later, the most interesting 50–60 variants will be genotyped in over 33 000 individuals from the FINRISK studies, a well phenotyped population cohort to increase power to identify association with disease. The samples are linked to national registers, including the hospital discharge register, prescription drug register and cancer registry enabling detailed phenotype mining of rare variant carriers.

2345F

Diabetes related DNA mutations in Americans of Mexican origin with health disparities disclosed by next-gen sequencing. *H. Q. Qu[1], Q. Li[2], Y. Lu[1], S. P. Fisher-Hoch[1], J. B. McCormick[1].* 1) School of Public Health, Univ of Texas Health Science Center at Houston, Brownsville, TX; 2) Endocrine Genetics Lab, The McGill University Health Center (Montreal Children's Hospital), Montreal, Quebec, Canada.

Diabetes related health disparities are serious health issues in a south Texas Mexican American population with a 30% prevalence of diabetes, as shown by our study of our-randomly selected, community-based Cameron County Hispanic Cohort (CCHC:n=2600) (Fisher-Hoch et al., 2010; 2012). With the majority of the diabetes patients being classified as type 2 diabetes, it is unclear what proportion of the diabetes patients may be rare monogenic forms of diabetes, e.g. Maturity Onset Diabetes of the Young (MODY). MODY diagnosis is of clinical importance, both for determining best choices of therapeutic agents and for genetic counseling. However, MODY diagnosis is complicated and expensive, and in this economically disadvantaged community, diagnosis and screening are unavailable. Advanced genomic technologies have provided new opportunities to address this health disparity issue. We performed a NextGen sequencing study on 75 Mexican Americans from our cohort with diabetes and body mass index (BMI)<25, who were identified by younger ages (range from 18–50) from 1551 random participants of CCHC. Serving as the sequencing controls, 75 obese persons without diabetes selected by older age from the CCHC were also studied. To optimize the cost-benefit, we made 6 DNA pools with 25 individuals in each pool (age-ranked), limiting sequencing to 6 DNA samples. The first 3 DNA pools are 75 age-ranked diabetes patients, i.e. Pool 1 with age 18–33 years old; Pool 2 with age 33–43; and Pool 3 with age 43–50. Three other DNA pools are 75 controls. All 11 MODY genes (MODY1–MODY11) as well as 68 other diabetes genes (type 2 diabetes genes and neonatal diabetes genes) were included. Altogether, 873 exons (0.4 million base-pair genomic regions) of these 79 genes were deep-sequenced at 3000x depth, using NimbleGen Sequence Capture Array and Illumina HiSeq2000. Six MODY mutations were identified from Diabetes Pool 1 and Pool 2 (i.e. 12% of diabetes cases with BMI<25 and age≤43). Among these six, 4 novel MODY mutations (predicted by the SIFT algorithm) were identified. In addition to the MODY mutations, we identified 23 damaging mutations from other diabetes genes. Further validation of these mutations by Sanger Sequencing is in progress. The mutation data in this Mexican American population provide critical health information about the rate of MODY in this population, which will help clinical decision of MODY mutation tests and minimize this diabetes health disparity issue.

Exome Sequencing in Severe COPD Cases and Resistant Smoking Controls from COPDGene. *M.H. Cho[1], M. Emond[2], R.A. Mathias[4], J.E. Hokanson[7], T.H. Beaty[5], N. Laird[6], C. Lange[6], K.C. Barnes[5], M. Bamshad[3], J.D. Crapo[8], E.K. Silverman[1], COPDGene Investigators, NHLBI Exome Sequencing Project.* 1) Channing Laboratory and Pulmonary and Critical Care Medicine, Brigham & Women's Hosp, Boston, MA; 2) Department of Biostatistics, University of Washington; 3) Department of Genome Sciences and Department of Pediatrics, University of Washington; 4) Department of Medicine, Johns Hopkins University; 5) Bloomberg School of Public Health, Johns Hopkins University; 6) Harvard School of Public Health, Harvard University; 7) Colorado School of Public Health, University of Colorado Denver; 8) National Jewish Medical and Research Center.

Background: The burden from chronic obstructive pulmonary disease (COPD) is rising; it now ranks third as a cause of mortality in the United States. Only a minority of cigarette smokers develops disease. Rare protein-coding variants are known to have a role in COPD susceptibility: a small fraction of COPD patients have alpha-1 antitrypsin deficiency (AATD), a well-known Mendelian disorder typically caused by a rare nonsynonymous SNP in SERPINA1 and characterized by severe COPD. COPD is highly heterogeneous; AATD and other monogenic human and smoke-exposed mouse models share the COPD-associated feature of emphysema, or lung destruction. We hypothesize additional rare coding variants, identified by exome sequencing, could also contribute to COPD and emphysema susceptibility. Methods: We selected extremes of COPD susceptibility and emphysema among Non-Hispanic Whites from the COPDGene study, frequency-matched on cigarette smoking. Cases were age < 63.0, severe COPD (GOLD Stage 3–4), and >15% emphysema on CT scan. Resistant smoking controls had age > 65.0, normal lung function, and <5% emphysema. Exome sequencing was performed using the Nimblegen SeqCap EZ V2.0 on Illumina platforms as part of the NHLBI Exome Sequencing Project LungGO. Sequences were aligned using BWA, and variants were called using the Genome Analysis Toolkit. Our primary analysis was a per-gene burden test using a fixed minor allele frequency cutoff (5%) adjusting for exome-based ancestry principal components and P-values calculated by permutation as implemented in Score-Seq. Secondary analyses were performed using SKAT-O. Results: After quality control, a total of 206,546 SNPs, of which 103,809 were nonsynonymous, splice, or stop remained among 205 cases and 196 controls. Quantile-quantile plots demonstrated no evidence of substantial population stratification. Our top genes in our T5 analysis (with P-values from $7.6x10^{-6}$ to $6.0x10^{-4}$) were SHROOM3, SUN2, DMWD, KIF14, PCDHA6, and SLC6A19; however, none of results were exome-wide significant after adjustment for the number of genes tested. Conclusions: Exome sequencing in severe COPD and resistant smoking controls may identify novel genes that contain rare variants that could affect COPD susceptibility. A second phase of association using the Illumina Exome Chip in 2400 subjects is under way.

Meta-analyses of 6391 Danish individuals identify novel genetic loci associated with circulating levels of Interleukin 18, Insulin-like growth factor-binding protein 1, and Heat shock 70kda protein 1b. *T.S. Ahluwalia[1], N. Grarup[1], A. Albrechtsen[1], T. Sparsø[1], C.H. Sandholt[1], T. Lauritzen[2], D.R. Witte[3], T. Jørgensen[4], S. Hamren[5], M. Rowe[5], J.A. Kolberg[5], Y. Li[1,6], R. Nielsen[7,8,9], J. Wang[1,6,8], T. Hansen[1,10,11], O. Pedersen[1,11,12,13].* 1) Novo Nordisk Foundation Centre for Basic Metabolic Research, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 2) School of Public Health, Department of General Practice, University of Aarhus, Aarhus, Denmark; 3) Steno Diabetes Center, Gentofte, Denmark; 4) Research Centre for Prevention and Health, Glostrup University Hospital, Glostrup, Denmark; 5) Tethys Bioscience, Emeryville, California, USA; 6) BGI-Shenzhen, Shenzhen, China; 7) Department of Integrative Biology, University of California Berkeley, Berkeley, California, USA; 8) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 9) Department of Statistics, University of California Berkeley, Berkeley, California, USA; 10) Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark; 11) Hagedorn Research Institute, Gentofte, Denmark; 12) Faculty of Health Science, University of Aarhus, Aarhus, Denmark; 13) Institute of Biomedical Science, University of Copenhagen, Copenhagen, Denmark.

Circulating levels of specific proteins act as signatures for various pathologies. Interleukin 18 (IL18), heat shock 70kd protein 1B (HSPA1B), Insulin like growth factor binding protein 1 (IGFBP1) and 2 (IGFBP2), and Interleukin 2 receptor alpha chain (IL2RA), are biomarkers with established associations with disorders like type 2 diabetes, cardiovascular diseases, insulin resistance, metabolic stress, inflammation and various forms of cancers. Albeit these circulating proteins thus may act as biomarkers for a plethora of disease traits, studies identifying the underlying genetic components for these biomarker levels are lacking. We therefore sought to identify the genetic determinants responsible for fasting serum levels of these five biomarkers from exome-wide genotype data in 6391 middle-aged Danes. In this study 16,192 coding single nucleotide variants (SNVs), discovered by hybrid-capture and 8X whole exome sequencing in 2,000 Danish individuals, were further genotyped in the population-based Inter 99 cohort (N=5483) and the ADDITION cohort (N=908) with measurements of fasting levels of IL18, IGFBP1, IGFBP2, HSPA1B, and IL2RA. After linear regression analyses in the two study samples, meta-analyses were performed for each biomarker trait in a total of 6391 Danish individuals. Two loci associated with IL18 levels, three loci associated with IGFBP1 levels and one locus associated with HSPA1B levels at $P < 5 \times 10^{-8}$. All these genome wide significant loci were novel. Out of the two loci identified for IL18 levels the stronger signal was for a common missense variant with a minor allele frequency (MAF) of 0.38 on chromosome 2p22 ($P = 1.54 \times 10^{-12}$) and the second novel locus (common and non-synonymous) was situated on chromosome 5q13 ($P = 1.17 \times 10^{-10}$). The three novel loci associated with IGFBP1 levels were located on chromosomes 11q12 ($P = 1.99 \times 10^{-16}$), 4q35 ($P = 2.16 \times 10^{-13}$), and 2p23 ($P = 5.64 \times 10^{-10}$), respectively. All these SNVs were common (MAF > 0.05) and non-synonymous. For circulating HSPA1B levels we identified one novel genome-wide significant SNV situated at chromosome 1q32 ($P = 1.18 \times 10^{-15}$). Exome-sequencing driven mapping for fasting circulating levels of IL18, IGFBP1 and HSPA1B demonstrates two novel loci for IL18, three loci for IGFBP1 and one locus for HSPA1B, respectively. All the identified SNVs are non-synonymous variants.

Further analysis of a visual migraine aura locus on chromosome 9q21–q22 using exome sequencing. *M.E. Hiekkala[1], M.A. Kaunisto[1,2], B.S. Winsvold[3,4], E. Hämäläinen[2,3], V. Artto[5], S. Vepsäläinen[5], M. Färkkilä[5], M. Kallela[5], A. Palotie[2,3], M. Wessman[1,2].* 1) Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, Finland; 2) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Finland; 3) Wellcome Trust Sanger Institute, Hinxton, UK; 4) Oslo University Hospital, Ullevål, Norway; 5) Helsinki University Central Hospital, Helsinki, Finland.

Migraine is a common and disabling neurological disorder characterized by recurrent attacks. Migraine aura is the other main phase of a migraine attack, along with typical headache. Most typically (> 90%) aura is visual. We have identified a visual aura locus in Finnish families on 9q21–q22 (Tikka-Kleemola et al. 2010) residing near familial occipitotemporal lobe epilepsy and combined migraine with aura locus (Deprez et al. 2007). Further evidence for a migraine locus on 9q22 was recently reported in the genetic isolate of Norfolk Island (Cox et al. 2012).

In order to further restrict the visual aura locus and identify susceptibility variants we selected 13 migraine families with visual aura and increased frequency of epilepsy linked to the 9q21–q22. We performed Illumina OmniExpress genotyping in 142 individuals and combined this data with whole exome sequencing data (Agilent's 50 Mb capture kit) from 21 migraine with visual aura patients belonging to eight families. Screening the exome sequencing data on a 40 Mb susceptibility region using Exome Variants Analysis (EVA) -program highlighted 27 candidate genes containing potentially functional, low or rare frequency variants. Many of these candidate genes are involved in functions of membrane transport (five of them being ion channels) or neural development. The frequency of 60 potential variants in the Finnish population was checked against already existing control Finnish exome data. The variants having allele frequency less than 3 % in the Finnish population or that were more common in migraine patients than in Finnish control subjects were included in further analysis. After this filtering step 33 variants remained one of which was nonsense and 24 were missense. So far 18 of these variants (two novel) have been validated using Sanger sequencing. Segregation and replication analyses are in progress.

Extensions of Human Variation Database in Japanese Integrated Database Project. *A. Koike[1], N. Nishida[2], M. Yoshida[1], M. Kawashima[2], I. Inoue[3], S. Tsuji[4], K. Tokunaga[2].* 1) Hitachi, Ltd. Cent. Res. Lab., Japan; 2) Dept Human Genetics, Univ. Tokyo, Japan; 3) Dept. of Mol. Life Sci. and Mol. Med., Nat. Inst. of Genet; 4) Dept Neurology, Univ. Tokyo.

Recent advances in microarray-based SNP genotyping technology and next-generation sequencing (NGS) technology drastically changed the nature of disease-related genetic study on a cost-effective genome-wide manner. Since these methods produce valuable but large amount of data, these data management has come to an issue. Our organization has developed `Human Variation Database' as a repository database for genome-wide association studies (GWAS) and novel genetic identified variations detected by NGS (https://gwas.biosciencedbc.jp/) to achieve continuous and intensive management of variation data to prevent them from dissipation and for data-sharing among researchers. Up till now, we have widely called for data submission and offered data-repository and data-redistribution services. In this study, we have extended the Human Variation Database to accumulate variations extracted from scientific literatures by manual curation. Disease names are systemized mainly based on disease ontology and more than 3500 variations are currently registered with their variation kinds and their positions on the reference genome/gene/protein-sequences according to the nomenclature defined by HGVS. Collected variations include short/long insertions/deletions and structural variations detected by various measurements, and they are related to disease susceptibility, virus resistance, and drug response. Their statistical genetic results in each population and corresponding clinical conditions are also incorporated to shed light on locus/variation specific clinical characteristics and deepen our understanding of disease mechanisms. The reference genomes in each population are systematized using healthy public data and population difference in disease-related variation are also displayed on the web browser with other information such as conservation scores. Variations and disease are cross-searchable to clarify their relationships. In this presentation, we provide the overview of database structure, data management policies, and population difference of disease related variations in various diseases.

Multiple sclerosis (MS) is a complex autoimmune disease of the central nervous system. Twin and half-sib studies support the importance of inherited factors in MS predisposition. Close relatives of MS patients have an increased risk of MS, although there are few extended MS families. The prevalence of MS is higher in some population isolates compared to the surrounding areas. The Southern Ostrobothnia (SO) in Finland has a 2–fold prevalence compared to Finland in general and there is familial clustering of MS. Recent genetic burden studies in mixed populations of European descent support the accumulation of common variants in MS families. Our aim was to study the genetic burden caused by common MS associated variants in the Finnish SO isolate and in Finnish multiplex families. We used a weighted log-additive model and 51 SNPs that were reported in a recent international MS GWAS to calculate a genetic burden score. A non-parametric KS-test was used to evaluate the differences between the sample groups in a total of 608 MS cases and 5534 population samples. The genetic burden was significantly increased in the MS patients compared to population samples in all regional and familial comparisons ($p < 0.0001$). However, the analysis of the isolate revealed that the SO cases (n=111, mean=6.64) did not show an increased genetic burden compared to the cases from elsewhere in Finland (n=497, mean=6.77) despite the 2–fold difference in prevalence. Likewise, the SO population samples (n=135, mean=6.31) were not significantly different from the general population (n=5399, mean=6.23). The familial analysis showed similar results: the familial cases (n=63, mean=6.80) were not significantly different from the cases with no reported family background (n=522, mean=6.73). It should be noted, that 44% of the families originate from the isolate. The common variants do not seem to explain the increased prevalence in the isolate or in the Finnish multiplex families. We hypothesize that there are specific variants that contribute to MS predisposition in the isolate region and in the multiplex families.

Assessing association between known PTPN22 and SUMO4 variants and Type 1 diabetes (T1D) in an Indian population. *S.R. Manyam[1], U. Ratnamala[2], K.R.S.S. Rao[1], S.K. Nath[3], U. Radhakrishna[4].* 1) Department of Biotechnology, Acharya Nagarjuna University, Guntur, AP, India; 2) Department of Pharmacology, Creighton University, Omaha, NE, USA; 3) Arthritis and Clinical Immunology, Oklahoma Medical Research Foundation, Oklahoma City, USA; 4) Green Cross Voluntary Blood Bank Pathology and RIA laboratory, Ahmedabad, India.

Type 1 diabetes (T1D), also known as `insulin-dependent diabetes mellitus (IDDM)' and `juvenile-onset diabetes', results from a cellular-mediated autoimmune destruction of the `gb cells of the pancreas. The incidence of T1D is increasing worldwide, especially in younger children. T1D is a genetically heterogeneous disease, multiple genetic predispositions are believed to be responsible for disease etiology in different populations, and however non-genetic factors such as diet, infection or environmental risk factors play an important role in the expression of the disease. T1D can causes many serious health problems including blindness, hearing impairments, nerve damage, heart attack, kidney failure, osteoporosis, infections, pregnancy complications in women. A number of genetic association and linkage studies of different populations have identified twenty four loci with evidence of linkage for T1D on various chromosomes. In addition, an increased incidence of gene polymorphisms such as PTPN22, SUMO4, CTLA4 and IL2RA associated with T1D was reported, however no common gene mutations or pathogenic causative genomic variations have been identified until. We have recruited 350 sporadic cases with T1D patients, and an equal number of age-matched controls from south India. Recently we completed an initial targeted two known and well-associated their polymorphism in its involvement in the pathogenesis of Type-1 diabetes (i.e. PTPN22 and SUMO4) in 100 selected T1D individuals and equal controls using a single nucleotide polymorphism (SNP) array. The data showed PTPN22 polymorphism (SNP rs2476601, 1858C>T) was not associated with in any of the TD1 subjects of Indian origin as the SNP marker rs2476601 was monomorphic (G/G) in both T1D subjects and controls. The data of SUMO4 gene variation (rs237025, 163A > G, M55V) which has been shown to be a susceptibility marker in type-1 diabetes showed a higher frequency of combined AG and GG genotypes (64%) in the affected individuals than in matched controls (56%) of Indian origin. However, the “G” allele frequency between cases and controls are not statistically significant (40% in cases vs. 35% in controls, OR (C.I.) = 1.23 (0.82–1.85), chi2=1.07, p=0.30), probably due to small sample sizes. To the best of our knowledge, this is the first targeted genetic study on the association of genetic loci in Type 1 diabetic patients in India.

2352W

Duffy Interaction with chromosome 4 determine the number of Malaria episodes of individuals from Western Brazilian Amazon. *J. Pescarini[1,2], L.M. Garrido[1,2], L.C. Pereira[1,2], R.G.M. Ferreira[2,3], L.M.A. Camargo[1,2], H. Krieger[1,2].* 1) University of São Paulo, São Paulo, São Paulo, Brazil; 2) Instituto Nacional de Genética Médica Populacional, Brazil; 3) Fundação Oswaldo Cruz, Rondonia, Brazil.

In the 70′s it was observed that Plasmodium vivax and P. knowlesi use Duffy antigen, which is present in the erythrocyte membrane, as a receptor to entry in the target cell. The absence of Duffy antigen in the erythrocyte, commonly known as FY^-, was recognize just a few years ago as caused by a T -46 C mutation, mainly in the FYB allele. FY^- individuals were proved to be less infected by this two species of Plasmodium than FY^+ individuals (FyA, FyB, FyAFyB), being considered a protection factor to malaria. A Cohort of 924 individuals from Monte Negro and of 178 individuals from Portuchelo, both communities located in the Brazilian Western Amazon, revealed that the variable “number of malarial episodes” has a major genetic component related to it, probably located in chromosome 4 (Feitosa, 2002; Ferreira, 2008). In the same study, 850 indivíduals were tested for different erythrocyte antigens (Systems ABO, Rh, MNSs, Kell and Duffy) showing that FY^- was associated with low “number of malarial episodes” in this population. Based on the hypothesis that a genetic mechanism underlying the “number of malarial episodes” in Western Amazon was located in chromosome 4, Pescarini (2011) genotyped a subsample of 96 individuals (48 cases and their controls, who had more and less malaria episodes, respectively) with Affymetrix Genechip Nsp 250K. Analyzing only this chromosome in PLINK (Purcell., data), it was found an association between polymorphism rs17527389 and the “number of malarial episodes” (p = 0.012, with Bonferroni's corretion). In order to analyze if there is any interaction between rs17527389 and the FY system, Independence analysis was performed using FY^- or FY^+ and A or T alleles for both cases and controls. Significant association was verified (X^2_3=21.69; p<0.001). Odds ratios (OR) of Duffy negative (FY^-/FY^+) for allele A and allele T was also analyzed, showing that isolating “risk” (A) and “protection” (T) alleles, FY^- is still inversely related to individuals who showed higher number of malaria episodes (OR(A)= 0.12; OR(T)>6). In spite of small sample sizes, the presence of genetic interaction between Duffy antigen and rs17527389, was verified and may indicate the existence of undescribed physiological pathways.

2353T

Role of genetic variants of inflammatory genes with inflammation, malnutrition and susceptibility to End Stage Renal Disease in north Indian population. *R. Sharma, R.K. Sharma, A. Saxena, S. Agrawal.* Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow U.P.

Background-TNF α, IL6 and IL10 are potent regulators of inflammation and may be causative factor for various co morbidities associated with renal disease. In present study we have investigated association between inflammation, malnutrition and genetic variants of TNF α, IL6 and IL10 with genetic susceptibility to End stage renal disease(ESRD) in north Indian population. Methods-257 patients and 200 controls were registered in study. All baseline biochemical parameters were measured. Genotyping of TNFα-308G<A,TNFα-238G<A,TNFα-850C<T, IL6–174G<C, IL6–572G<C,IL10–1082A<G,IL10–819C<T and IL10–592C<A was done by PCR RFLP. Serum levels of IL6, IL10 and TNF-α were measured using ELISA. Nutritional status was assessed by SGA scores.Statistical analysis was performed by SPSS(Ver.15) Result and Discussion-Significant differences were observed between ESRD patient and control groups in all the biochemical parameters.TNFα-308G<A(O.R.= 3.0,P-value=0.002)TNFα-238G<A(O.R.=2.4,P-value=0.016),TNFα-850C<T(O.R.=3.1,P-value=0.003, IL6–174G<C(O.R.= 3.7,P-value=0.001),IL6–572G<C (O.R.= 2.1,P-value= 0.007)and IL10–1082A<G(O.R.=2.7,P-value=0.003) were significantly different between patient and control groups. The risk haplotypes were IL6 C/C and TNF-α AAC. On comparing inflamed and non inflamed patients diffrences were seen at IL6–174CC (O.R.=2.0 P-value=0.04),IL10–592AA(O.R. = 2.2,P-value=0.02) IL10–1082 GG,GA(O.R.=2.1 P-value=0.04) and IL10–819TT (O.R. =2.2 P-value=0.01)genotypes. These were associated with 2.0 fold higher risk of inflammation. On grouping patients in 2 categories based on nutritional status-normal and malnourished the risk associated genotypes were-TNF-α-238AA (O.R.=4.1 P-value=0.01)and IL6–572GG(O.R.=2.2 P-value=0.05)among malnourished. Levels of IL6,TNF-α and IL10 were significantly different between patient and control group. Malnourished category showed higher levels of IL6 (P-value=0.03)and TNF-α (P-value=0.04). TNF-α-308AA, TNF-α-850TT, IL6–174CC and IL10–592AA were significantly associated with higher TNF-α, IL6 and lower IL10 levels respectively. Conclusion-Our results suggest that inflammatory markers are not only predictors of disease but also important in prediction of malnutrition associated with chronic diseases like ESRD.

2354F

Genetic predisposition to hypertension associates with increased risk of type 2 diabetes. *Q. Qi[1], J. Forman[2], F. Hu[1], L. Qi[1].* 1) Department of Nutrition, Harvard School of Public, Boston, MA; 2) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Hypertension has been associated with increased risk of type 2 diabetes (T2D). Recent genome-wide association studies have identified multiple loci associated with blood pressure and risk of hypertension; however, it is unknown whether these loci are associated with risk of T2D. Such information could help to understand the potentially causal link between hypertension and T2D. We examined the association between genetic predisposition to hypertension and risk of T2D in two nested case-control studies. The present study included 3082 women (1328 T2D cases, 1754 controls) and 2411 men (1113 T2D cases, 1298 controls) of European ancestry from the Nurses' Health Study and Health Professionals Follow-up Study. A genetic predisposition score was calculated by summing up the number of risk alleles of 29 established blood pressure associated genetic variants. The genetic predisposition score showed consistent associations with risk of hypertension and T2D in men and women (all *P* for heterogeneity >0.46), and therefore the results from the 2 cohorts were combined. Each additional hypertension-predisposing allele in the genetic predisposition score was associated with a 6% increased risk of hypertension (odds ratio [OR] 1.06 [95% CI 1.04–1.08], P = 2.0×10^{-8}), and a 3% increased risk of T2D (OR 1.03 [1.01–1.05], *P* = 0.004). Adjustment for hypertension abolished the association with T2D (*P* = 0.13). We also applied Mendelian randomization analysis, and found that the observed effect size of association between the genetic predisposition to hypertension and T2D was not different from the expected effect size (*P* = 0.13). In conclusion, genetic predisposition to hypertension is associated with an increased risk of T2D. Our results support a potential causal role of hypertension in the development of T2D.

A systemic monitoring of cleft lip/palate in Hebei province of China through a birth defect surveillance: a 15–year (1996–2010) report. *J-Z. Zhu[1], N. Zhong[1,2,3].* 1) Medical Genetics and Prenatal Diagnosis, Hebei Provincial Hospital, Shijiazhuan, Hebei, China; 2) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 3) Peking University Center of Medical Genetics, Beijing, China.

Cleft lip with/without palate is the most common visible congenital anomaly, followed by congenital heart diseases, neural tube defects, polydactyly, spina bifida, and hydrocephalus, in Hebei province that is located at northeastern China. Here we present a 15–year systemic monitoring of cleft lip with/without palate in Hebei province through our birth defect surveillance system, which consists of 40 hospitals before year 2000, but expanded to 57 hospitals by year of 2005 and to 60 hospitals by the year of 2006 that is kept to now. Among these monitored hospitals, 16 are in urban and 44 (20 are in mountain area) are in rural areas. The prevalence of total number of people with cleft lip/palate was 664 per 10,000 in 1996, but increased to 1,104 per 10,000 in 2010, which gives an increase of 66%. During this period, the cleft lip/palate was significantly increased by 104.22% in the first 10 years from 1996 to 2005, then decreased from 12.81% in year 2006 to 11.04% in 2010. Looking into the details, we noticed that the decrease was mainly due to a decline of cleft lip without palate from 7.68% to 3.51% but increase of cleft lip with palate from 5.47% in 2006 to 7.35% in 2010. The underlying pathogenic mechanism for this phenomenon is yet unclear. Intensive biological investigation to test if there is any genetic or environmental factors influence the prevalence is recommended.

2356T

De novo and inherited copy number variants are a common cause of short stature. *C.T. Thiel[1], D. Zahnleiter[1], U. Trautmann[1], A.B. Ekici[1], D. Wieczorek[2], E. Kunstmann[3], A. Reis[1], H.-G. Doerr[4], A. Rauch[5].* 1) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany; 2) Institute of Human Genetics, University of Essen, Essen, Germany; 3) Private clinic, Wuerzburg, Germany; 4) Department of Pediatrics and Adolescent Medicine, University of Erlangen-Nuremberg, Erlangen, Germany; 5) Institute of Medical Genetics, University of Zurich, Schwerzenbach-Zurich, Switzerland.

Shortness of stature is one of the most common pediatric concerns and is defined as a body height below -2 SD. The prevalence in the general population is 3%. In the majority of patients with idiopathic growth deficit the etiology remains elusive in the absence of morphological details. Recent GWAS (e.g. GIANT) found significant evidence for both single nucleotide and copy number polymorphisms associated with height variation in the general population. However, these associations explain only a small fraction of the overall variability of human height. To identify novel genetic causes of growth retardation under a “rare variant - frequent disease” hypothesis in 200 indexpatients with idiopathic short stature and their parents we performed molecular karyotyping using Affymetrix SNP 6.0 and CytoScan HD arrays and scored copy number variants (CNVs) with a minimum size of 10 kb. A total of 6,338 aberrations were identified. After exclusion of common polymorphisms using 820 healthy control individuals and comparison with known pathogenic CNVs, we carried out a gene-centric analysis by investigating known gene functions, tissue expression and murine knock-out phenotypes. We considered 20 CNVs (10 %) in 20 patients to be disease causing, including 10 duplications and 10 deletions. All aberrations were larger than 100 kb. 7 were de novo with 1 overlapping the 22q11.1 microdeletion region, and 13 inherited from the also affected parent, including the known microdeletion/duplication loci 1p36, 1q21, 2q33, 22q11.2 und 3q29 in 6 cases. The observed number of de novo CNVs was significantly increased (P value <0.01) compared to the expected level of de novo events. Furthermore, evidence of pathogenicity was strengthened by comparison to a cohort of patients with intellectual deficit and the Decipher database, as well as evaluation of phenotype data from animal models, pathway data and haploinsufficiency scores. 5 CNVs comprise loci of genome wide association (Lango Allen et al. 2010) scored on a level of significance for genome wide CNV association of estimated 2.5E-5. In conclusion, our data indicate that CNVs are one of the main causes of growth retardation in a frequency comparable to other conditions as e.g. intellectual disability. Thus, molecular karyotyping should be considered in idiopathic short stature.

Involvement of sex in differential expression of miRNA in the circulation of subjects with metabolic syndrome: primarily in women. *Y. Wang[1,2], S. Juo[1,3,4].* 1) Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Internal Medicine, National Taiwan University Hospital Yun-Lin Branch, Taiwan; 3) Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 4) Department of Neurology, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Context: The association between circulating miRNAs and metabolic syndrome (MetS) has not been investigated in detail and it is not known whether the change of circulating miRNAs shows a difference between genders. Objective: The study assessed the expression of circulating miRNAs in subjects with and without MetS, and also explored whether there are gender-specific differences in dysregulations of circulating miRNA levels. Design and Patients: The study analyzed serum miRNA levels by RQ-PCR from 104 human subjects, aged 41 to 73 years. The status of MetS was defined by the Adult Treatment Panel III criteria modified for Asians. Subjects who self-reported a history of cardiovascular diseases or on current medication for hyperglycaemia or hyperlipidemia were excluded. Samples which had contamination due to hemolysis were further abandoned. Results: The percentage of MetS participants was 31.4% in men (n=51) and 32.1% in women (n=53). The levels of circulating miRNAs (let7g and mir-221) were higher in MetS subjects (p=0.002 and p=0.008, respectively). The two candidate miRNAs displayed an increase in blood serum when the number of MetS risk components was increased. However, the alterations of let7g and mir-221 in the circulation were prominent in women (both p <0.05 in women but p >0.1 in men). Among women, the serum level of let7g was elevated in individuals with low levels of high-density lipoprotein cholesterol and high blood pressure (p=0.008 and 0.02, respectively). On contrary, circulating mir-221 was upregulated in female subjects with high fasting glucose level (p= 0.025). Conclusions: The circulating levels of let7g and mir-221 were elevated in individuals with metabolic syndrome and these alterations were primarily in women.

Evidence of a Causal Relationship between Adiponectin Levels and Insulin Sensitivity: a Mendelian Randomization Study. *H. Gao[1,2,3], T. Fall[1], R. van Dam[2,3], A. Flyvbjerg[4], B. Zethelius[5], E. Ingelsson[1], S. Hägg[1].* 1) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, SwedenStockholm, Sweden; 2) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 3) NUS Graduate School for Integrative Sciences and Engineering, National University of Singapore, Singapore; 4) The Medical Research Laboratories, Department of Clinical Medicine, Faculty of Health, Aarhus University, Aarhus, Denmark; 5) Department of Public Health and Caring Sciences/Geriatrics, Uppsala University, Uppsala and Medical Products Agency, Uppsala, Sweden.

The adipocyte-secreted protein adiponectin has been associated with insulin sensitivity in observational studies. We aimed to evaluate whether this relationship is causal using a Mendelian randomization approach. In a sample of 71–year-old Swedish men (n=942) from the Uppsala Longitudinal Study of Adult Men (ULSAM), insulin sensitivity was measured by the euglycemic insulin clamp (M/I ratio). We used genetic variants in the *ADIPOQ* gene as instrumental variables to generate causal estimates for the effect of adiponectin on insulin sensitivity. These estimates were compared with those derived by conventional linear regression of insulin sensitivity on adiponectin. The three *ADIPOQ* variants, rs17300539, rs3774261 and rs6444175 were strongly associated with serum adiponectin levels (P<5.4x10^{-9} for all SNPs). Each of the variants were also significantly associated with M/I ratio in the expected direction (P≤0.022 for all SNPs). Instrumental variable analysis confirmed that genetically determined adiponectin increased insulin sensitivity (β=0.470 for rs17300539, β=0.678 for rs3774261 and β=0.805 for rs6444175; P≤1.4x10^{-3} for all SNPs) at similar effect sizes as observational estimates (β=0.498, $P_{difference}$≥0.136 by Durbin-Wu-Hausman test). The genetically determined and observed adiponectin level associations remained similar after adjusting for body mass index (BMI) to address mediation by adiposity. The observed association between higher adiponectin levels and increased insulin sensitivity is likely to represent a causal relationship not mediated by adiposity.

Heritability of daily physical activity as assessed by combined heart rate and movement sensing in 771 same-sex twin pairs. *M. den Hoed[1], S. Brage[1], J.H. Zhao[1], A. Nessa[2], K. Westgate[1], U. Ekelund[1], T.D. Spector[2], N.J. Wareham[1], R.J.F. Loos[1,3].* 1) MRC Epidemiology Unit, Institute of Metabolic Science, Cambridge, UK; 2) Department of Twin Research and Genetic Epidemiology Unit, St Thomas' Campus, King's College London, St Thomas' Hospital, London, UK; 3) The genetics of obesity and related metabolic traits program, Mount Sinai School of Medicine, One Gustave L. Levy Place, Box 1003, New York, NY, 10029–6574, USA.

Background: Despite the health-promoting effects of physical activity (PA) and despite efforts to promote PA in the population, the majority of adults do not adhere to the current PA guidelines. The presence of innate, genetic factors that drive PA behavior may explain this contradiction. However, twin and family studies examining the heritability of daily PA have so far been limited by poor PA measurement quality or small sample size. **Objective**: To examine the heritability of daily PA using combined heart rate and movement sensing in a large population of adult twins. **Methods**: PA was assessed in daily life for 6.8 ± 1.2 days (mean ± SD) in 419 monozygotic and 352 dizygotic same-sex twin pairs using Actiheart (1,542 individuals aged 56.3 ± 10.3 yrs, BMI 26.0 ± 4.8 kg/m^2). Actiheart provided information on trunk acceleration along the longitudinal axis of the body, representing bodily movements produced by skeletal muscles. It also provided information on PA energy expenditure (PAEE) and the time spent on sedentary, light intensity and moderate-to-vigorous intensity activities. We estimated the contribution of genetic (dominant and/or additive) and environmental (common and/or unique) factors to inter-individual variance in daily PA after adjusting for sex, age, age^2 and body size (body mass for PAEE; BMI for the remaining measures) using structural equation modeling. **Results**: Dominant and additive genetic factors together explain between 37% (95% CI 29% - 45%) of the variance in acceleration to 48% (95% CI 41% - 55%) of the variance in PAEE. The remaining variance is explained by unique environmental factors. Common environmental factors play at most a marginal role (0.5% - 6.4%). **Conclusion**: Although environmental factors explain the largest proportion of the variance in daily PA, genetic factors also play a considerable role. Innate biological processes may thus explain inter-individual differences in adherence to the PA guidelines in adults. Such processes may relate to physical fitness, perception of ability, sensitivity to internal/external rewarding cues, physical discomfort following PA and/or triggering of food intake when using PA as a weight loss strategy. Future gene discovery studies are anticipated to increase our understanding of PA behavior.

2360F

Relationship between Hysterectomy and Admixture in African American women. *L. Qi[1], R. Nassir[2,3], R. Kosoy[2,3], L. Garcia[1], L.E. Waetjen[4], H.M. Ochs-Balcom[5], M. Gass[6], J. Robbins[3], M.F. Seldin[2,3].* 1) Department of Public Health Sciences, University of California, Davis, Davis, CA, USA; 2) Department of Biochemistry and Molecular Medicine, University of California, Davis, CA, USA; 3) Department of Internal Medicine, University of California, Davis, CA, USA; 4) Department of Obstetrics and Gynecology, UC Davis Medical Center, Sacramento, CA, USA; 5) Department of Social and Preventive Medicine, University at Buffalo, Buffalo, NY, USA; 6) The North American Menopause Society, Cleveland, OH, USA.

Most studies suggest that hysterectomies are more common in African Americans than in other ethnic groups. To assess this ethnic surgical disparity in a novel way, our main goal was to determine whether admixture (the proportion of sub-Saharan African or European origin in individuals) is associated with hysterectomy frequency in African American women in the Women's Health Initiative (WHI). We used ancestry informative single nucleotide polymorphisms (SNPs) to estimate admixture proportions in >10,000 African American women from the WHI. Logistic regression models were used to investigate the association between admixture and hysterectomy with and without controlling for relevant covariates. We also considered other potential risk factors (adiposity, hypertension, and education) for hysterectomy accounting for admixture. African admixture was a strong risk factor even after adjusting for multiple covariates (OR 1.85, P<.0001). The admixture risk for hysterectomy was highest in the 35–39 age group (OR 3.08, P<.0001) and least evident in the oldest age groups (45 or older, ORs range from 1.14 to 1.35, P>.05). Our analyses also indicated that adiposity, hypertension and education were independent risk factors for hysterectomy in this population group. Higher African admixture is associated with higher frequency of hysterectomy in certain age groups. Although further work is needed to determine whether this is due to genetic or environmental factors, the results provide compelling data that genetic studies specifically targeting African American women and diseases associated with hysterectomy maybe especially useful in understanding the pathogenesis and underlying cause of this disparity in health outcome.

Genetic Loci Associated with C-reactive protein levels and risk of metabolic syndrome, chronic kidney disease, and left ventricular hypertrophy: The Nagahama Study. Y. *Tabara, C. Terao, F. Matsuda.* Kyoto University Graduate School of Medicine, Kyoto, Japan.

Background: Plasma levels of C-reactive protein (CRP) are known to be associated with chronic inflammation and cardiovascular diseases risks. Several genetic variations susceptible for CRP levels have been identified from GWAS in European populations. To clarify unidentified susceptible SNPs, we conducted a GWAS for plasma CRP levels in a Japanese general population. We also investigated association of identified susceptible SNPs with metabolic syndrome (MetS), chronic kidney disease (CKD), and left ventricular hypertrophy (LVH).

Methods: Study subjects were ~3,500 Japanese general population. DNA was extracted from peripheral blood samples. Genome-wide SNP analysis was performed using Illumina 610K quad chips. In the genome-wide association analysis, plasma CRP values were normalized by a rank-based inverse normal translation. Written informed consent was obtained from each participants.

Results: Three known loci, namely rs3091244 in CRP, rs7979473 in HNF1A, and rs769449 in ApoE gene, were reached to genome-wide significance. In addition, a novel suggestive locus (p=6.3*10–7) were identified in the CDKN1A region (rs3176343). Previous reports suggested that a number of genes associated with CRP levels including APOC1, HNF1A, LEPR, GCKR, and HNF4A were directly or indirectly related to metabolic regulatory pathways involved in diabetes mellitus. Suggestive association of the diabetes mellitus associated CDKN1A polymorphism in this study further supports the interpretation. Accumulation of the risk genotype showed step-wise association with CRP levels. However, no direct association was observed between the risk genotypes and MetS, CKD, and LVH, whereas the subjects with MetS (p<0.001), CKD (p<0.001) and LVH (p<0.001) showed significantly higher CRP levels.

Conclusion: Genotypes susceptible for plasma CRP levels were not directly associated with MetS, CKD, and LVH. The lack of association may argue against a causal association of CRP with these diseases.

2362T

Genotype-Phenotype Correlations in Migraine. *A.K. Sullivan, E. Atkinson, F.M. Cutrer.* Neurology, Mayo Clinic, Rochester, MN.

Migraine is a disabling, highly prevalent syndromic disorder which disproportionately afflicts women. Unlike for rare monogenic forms of migraine, approaches to identifying genes for the common forms of migraine have been of limited success. Case control studies have shown modest associations with migraine for several candidate genes, but reported associations have either not been replicated or have only marginal statistical significance. We propose that more clearly defining the clinical phenotype of migraine will help better elucidate the genetic component involved. Approximately 60% of female migraineurs report having migraine attacks around the time of there menstrual period. To investigate genetic factors involved in hormonally modulated migraine, we have selected 24 single nucleotide polymorphisms (SNPs) from a pathway-related group of genes involved in the hypothalamic-pituitary-gonadal-axis (HPGA) that have been implicated in previous studies to confer migraine susceptibility. From our DNA repository of individuals with migraine (the Mayo Migraine Genomic Library which includes age and gender matched controls), we have selected 1750 individuals' ages 18–50, 1132 cases (240 males, 892 females) and 608 controls (258 males, 350 females). We performed logistic regression analyses, and confirmed the association of the SNP rs4680 located within the catechol-O-methyl-transferase gene as well as two other SNPs rs2283265 and rs7131056 that are both located within the Dopamine Receptor D2 gene. When looking at females only, the rs4680 SNP association was still significant. We then compared nonhormonally modulated migraineurs to controls, and we found no associated SNPs. But when hormonally modulated migraineurs were compared to controls, there were 4 SNPs that were found to be significantly associated with migraine: rs4680 SNP, rs22832265 SNP located within the dopamine receptor D2 gene, and 2 SNPs rs2070762 and rs6356 located within the tyrosine hydroxylase gene. These findings could greatly impact clinical management of women with hormonal modulated migraine by suggesting the possible underlying mechanism of their migraine susceptibility leading to development of rational, biologically based therapies.

Association analysis of *Vitamin D receptor* gene polymorphisms and bone mineral density in postmenopausal Mexican-Mestizo women. *A. González-Mercado[1], J.Y. Sánchez-López[1], J.A. Regla-Nava[1], J.I. Gámez-Nava[2], L. González-López[3], E.A. Aguilar-Chávez[2], J. Durán-González[1], J. Rojo-Contreras[2], A. Celis[2], F.J. Perea-Díaz[1], M. Salazar-Páramo[2], B. Ibarra[1].* 1) División de Genética, Centro de Investigación Biomédica de Occidente, IMSS. Doctorado en Genética Humana, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara; 2) Unidad de Investigación Médica en Epidemiología Clínica, UMAE, Hospital de Especialidades, CMNO, IMSS; 3) Servicio de Reumatología del HGR110 IMSS.

Introduction Osteoporosis (OP) is a complex multifactorial genetic disorder with interaction of environmental and genetic factors. It is estimated that 46–62% of Bone Mineral Density (BMD) variation can be attributed to genetic factors, including variations in the expressions of different candidate genes encoding proteins such as calciotropic hormones, cytokines, growth factors, bone matrix proteins and growth factors receptors, which participate in bone metabolism. The Vitamin D receptor (*VDR*) gene has been extensively studied in relation to BMD, with controversial results of association in different populations around the world. ***Purpose*** The aim of this study was to analyze the association between the *Fok*I T>C (rs2228570), *Bsm*I G>A (rs1544410), *Apa*I G>T (rs7975232) and *Taq*I T>C (rs731236) polymorphisms and the haplotypes of the *VDR* gene with BMD in postmenopausal Mexican-Mestizo women from Western Mexico. ***Methods*** We included 320 postmenopausal women from Western Mexico and divided them into three groups, according to WHO criteria: 88 non-osteoporotic women (Non-OP; t-score >-1 SD), 144 osteopenic women (Opn; t-score between -2.5 and -1 SD) and 88 osteoporotic women (OP; t-score <-2.5 SD). The BMD measurements at the lumbar (L1–L4) spine, and the left and right femoral neck were performed by dual-energy X-ray absorptiometry. The four SNPs in the *VDR* gene were genotyped by real-time PCR. Statistical analyses were carried out using SPSS v16.0, and Arlequin v3.01. ***Results*** The genotype and allele frequencies of the four *VDR SNPs* were similar in the Non-OP, the Opn and the OP groups, with the following frequencies for the wild-type alleles: *Fok*I (T) 0.472, 0.510, 0.443; *Bsm*I (G) 0.739, 0.780, 0.773; *Apa*I (G) 0.569, 0.610, 0.563; and *Taq*I (T) 0.727, 0.780, 0.773, in the three groups respectively. We found no association of the SNPs with BMD. A haplotype analysis of the four *VDR SNPs* revealed that the TGGT and CGGT haplotypes were the most common combinations across all the groups with statistically significant differences in the frequencies for CGGT between the groups Non-OP and OP (21.8 vs 31.8%), and for TGGT between the groups Opn and OP (34.7 vs 22.9%), this last also showed a statistically significant result in the association analysis with the recessive model (OR=0.1957, IC 95%=0.06–0.67, p= 0.0047).***Conclusions*** Our results suggest a possible protective effect of the TGGT haplotype on the development of OP in postmenopausal Mexican-Mestizo women.

A novel signal of polygenic inheritance in Genome-Wide Association Studies (GWAS) of diseases and dichotomous traits. *Y. Chan[1,2,3], J.N. Hirschhorn[1,2,3].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Department of Endocrinology, Boston Children's Hospital, Boston, MA.

Genome-wide association studies (GWAS) have been performed for a variety of traits and diseases and their associations with common genetic variants can be detected with sufficiently large sample sizes. The prevailing model for such studies is that variants have modest effects because the genetic contribution to the trait of interest is due to a combination of many loci throughout the genome (polygenic inheritance) as oppose to just one or a few loci. We considered the predicted results from GWAS under a liability threshold model of polygenic inheritance, where many variants contribute additively to an underlying unmeasured quantitative trait and where only individuals with a trait value above a specific threshold are affected with disease. We reasoned that, for a disease with prevalence well under 50%, the statistical power to detect minor alleles that increase disease risk can be substantially higher in a case-control analysis than the power to detect minor alleles that decrease risk, even if the magnitudes of effect on the underlying unmeasured trait are the same. This asymmetry in power raises the possibility that even apparently null GWAS studies may have a signal of polygenic inheritance, reflected in a skew towards nominally significant associations at risk compared with protective alleles. To determine the extent of this power difference, we theoretically evaluated the power to detect variants under varying parameters of threshold, allele frequency, effect size and sample size. We showed that the difference in power, and hence the imbalance between associated risk and protective minor alleles, increases with lower allele frequencies, larger effect sizes and lower disease prevalence until saturation occurs. For example, at a threshold of 1.96 (disease prevalence of 2.5%) with 2000 cases and controls, 1% variants with an effect size of +0.3 and -0.3 standard deviations will have 83.3% and 58.0% power respectively ($\alpha < 0.01$). We also generated sets of simulated data by simulating multiple causal alleles, varying the parameters described above and performed genome-wide case-control association analysis on them. This novel analysis can be performed on GWAS results to gain better insight into the allele frequencies and effect sizes of the causal variants. Furthermore, an imbalance in the associated risk and protective minor alleles can be used to infer the existence of associated variants even if no loci achieve genome-wide significance.

2365T

How allelic variants in INSL3 are associated with not testicular descent? An overview of a group of Mexican patients with idiopathic cryptorchidism. *M. Chávez[1], J. Gutiérrez[1], O. Cuevas[2], J. Rojas[1], O. Gutiérrez[1], D. Landero[1], E. Yokoyama[3], K. Jasso[4], L. Taja[5], R.M. Vigueras[1].* 1) Lab. Biología de la Reproducción, Instituto Nacional de Pediatría, Ciudad de México, Coyoacan, Mexico; 2) Servicio de Urología, Instituto Nacional de Pediatría, Ciudad de México, Coyoacan, Mexico; 3) Departamento de Genética Humana, Instituto Nacional de Pediatría, Ciudad de México, Coyoacan, Mexico; 4) Servicio de Cirugía Colorrectal, Instituto Nacional de Pediatría, Ciudad de México, Coyoacan, Mexico; 5) Lab. de Genética Molecular y Farmacogenética, Instituto Nacional de Cancerología, Ciudad de México, Tlalpan, Mexico.

Cryptorchidism (CO) is a common congenital anormality, affecting at least 2–4% of male births and could present itself like an isolated manifestation (idiopathic). CO is an important factor for male infertility and testicular malignancy on adulthood, its etiology is, in most cases, remain unknown, it is considered a complex disease because in the testicular descent are involved multiple genes like INSL3, RXFP2 and HOXA10. In this study we searched the allelic variants in the gene INSL3 than could contribute as risk factors or susceptibility to idiopathic CO in Mexican patients. 85 patients were included with idiopathic CO and 100 kids on the control group in a first phase, in the INSL3 gene were analyzed four SNPs (p.R102C, p.R102H, p.R105H, c.3334T- C) by allelic discrimination using the Taq-Man method ®. These SNPs weren't detected in our population for this reason we researched for unknown alterations by the method of automatic sequencing of the coding regions of INSL3 gene. The association of SNPs with the phenotype was analyzed with Fisher's exact test, a value of $p \leq 0.05$ was considered significant. The results show us that 100% of patients with CO and the control group were homozygous normal variants and p.R105H p.R102C, while p.R102H variant was detected in just one patient like heterozygous with bilateral CO without family history. The SNP c.3334T-C was the highest allelic heterogeneity in both groups, although there is not significative difference in them was observed the heterozygous genotype predominates in patients with CO. Before, the sequencing of both INSL3′s exons shows two SNP's in exon 1 (p.L42L and p.A60T) and two in exon 2 (p.R105R and p.T86M). There were identified five different alterations or allelic variants and these results represent 5.88% of affected alleles, of which two are for first time reported in the Mexican population. The genotype-phenotype correlation shows us a clear association of the alterations detected and the severe phenotype of our patients with idiopathic cryptorchidism, on the other hand we infer that the genotype TC allelic variant c.3334T-C could be associated with idiopathic cryptorchidism and the CC genotype represents a protective genotype for this disease. Project No. CONACyT 87101/2008, INP-063/2008.

Stature is a classical and highly heritable complex trait, with 80–90% of variation explained by genetic factors. In recent years, genome-wide association studies (GWAS) have successfully identified many common additive variants influencing human height; however, little attention has been given to the potential role of recessive genetic effects. Here, we investigated genome-wide recessive effects by an analysis of inbreeding depression on adult height in over 35,000 people from 21 different population samples. We found a highly significant inverse association between height and genome-wide homozygosity, equivalent to a height reduction of up to 3 cm in the offspring of first cousins compared with the offspring of unrelated individuals, an effect which remained after controlling for the effects of socioeconomic status, an important confounder. There was, however, a high degree of heterogeneity among populations: whereas the direction of the effect was consistent across most population samples, the effect size differed significantly among populations. It is likely that this reflects true biological heterogeneity: whether or not an effect can be observed will depend on both the variance in homozygosity in the population and the chance inheritance of individual recessive genotypes. These results predict that multiple, rare, recessive variants influence human height. Although this exploratory work focuses on height alone, the methodology developed is generally applicable to heritable quantitative traits (QT), paving the way for an investigation into inbreeding effects, and therefore genetic architecture, on a range of QT of biomedical importance.

2367W

Investigation of mitochondrial D-Loop variations in autism. *F. Piryaei[1], M. Houshmand[1], F. Piryaei[2].* 1) National Institute of Genetic engineering and Biotechnology, Tehran, Iran; 2) Department of Biology, Payame Noor University of Tehran, Tehran, Iran.

Autism as one of three recognized condition in the autism spectrum disorders (ASDs) is a neurodevelopmental, multifactorial disorder. In order to investigate if mutations raise within D-loop with respect to high volume of ROS, regarding this region plays an important role in controlling mtDNA transcription and replication, identified D-loop variation frequencies were compared between two patients and control groups. In this study, a cohort of 24 unrelated idiopathic patients and 100 ethnically-matched Persian control individuals were obtained. PCR sequencing of mtDNA fragments was employed to investigate the involvement of mitochondrial variations in autism. According to our data, C16223T showed a significant difference ($P = 0.043$, $P < 0.05$) between two groups with respect to its higher volume in control group. Hence it suggests a lower risk for expressing autism in individuals who carry this SNP. In order to confirm the role of this variation in reducing the autism expression, follow-up studies should be performed with sizeable samples of patients and controls. Haplogroups harbouring this variation also should be determined.

Blood-born diagnostic microRNA biomarkers for inflammatory bowel disease. *G. Hemmrich-Stanisak[1], M. Spehlmann[2], A. El-Sharawy[1], M. Hübenthal[1], A. Keller[3], A. Raedler[4], S. Zeissig[2], S. Nikolaus[2], S. Schreiber[1,2], A. Franke[1].* 1) Institute of Clinical Molecular Biology, University of Kiel, Kiel, Germany; 2) Clinic for Internal Medicine I, University Hospital of Schleswig-Holstein, Kiel, Germany; 3) Department of Human Genetics, Saarland University, Homburg, Germany; 4) Department of Internal Medicine, Asklepios Westklinikum Hamburg, Hamburg, Germany.

Invasive methods, such as endoscopy or colonoscopy are still the gold standard for diagnosis and evaluation of Crohn's disease (CD) and ulcerative colitis (UC). Due to their stability in tissues and body fluids, such as peripheral blood, differential signatures of microRNAs (miRNAs) could serve as new noninvasive biomarkers to predict and discriminate these two major subphenotypes of chronic inflammatory bowel disease (IBD). In this study, we determined the expression profiles of 863 miRNAs by array analysis of 114 blood samples (40 CD, 36 UC, 38 controls) to generate phenotype-specific miRNA signatures. Using a threshold of maximum 100 features per signature resulted in miRNA-signatures of 66 (CD) and 95 (UC) deregulated miRNAs that separated cases from controls with a balanced accuracy of 96% and 93%, respectively. To discriminate both subphenotypes a signature of 68 differentially expressed miRNAs is required (balanced accuracy 88%). The minimal miRNA signature consists of 18 miRNAs for CD and only 3 miRNAs for UC to discriminate between cases and controls with balanced accuracies of 80% and 83% respectively. 14 miRNAs are minimally required to distinguish both CD and UC from one another (balanced accuracy 81%). For validation of our results we plan to replicate the approach using an independent IBD-cohort. In addition an observer-blinded study will prove the predictive potential of the resulting phenotype-specific miRNA signatures.

Influence of emotionally-loaded visual stimuli on experimental jaw-muscle pain and its relation with the tri-allelic polymorphism on the serotonin transporter gene. *E. Horjales-Araujo[1], D. Demontis[2], N.B. Finnerup[1,5], A. Børglum[2], T.S. Jensen[1,3,4], P. Svensson[4,5].* 1) Danish Pain Research Center, Aarhus University Hospital, Aarhus, Norrebrogade 44 Building 1A, 8000; Aarhus C, Denmark; 2) Dept Human Genetics, Institute for biomedicine, Aarhus University, Wilhelm Meters Alle 1240 8000 Århus C; 3) Dept of Neurology, Aarhus University Hospital Norrebrogade 44, 8000 Aarhus C, Denmark; 4) MINDLab, Center of Functionally Integrative Neuroscience, Aarhus University Hospital, Norrebrogade 44, 8000 Aarhus C, Denmark; 5) Department of Clinical Oral Physiology, School of Dentistry; Aarhus University, Vennelyst Boulevard 9 800,0 Aarhus C, Denmark.

Pain is the most common reason patients seek medical attention. However, the symptoms' description and pain perception vary from patient to patient. The perception of pain is determined by a mosaic of genetic, neurobiological, cultural and emotional factors. Recent studies have demonstrated an association between some genotypes and pain perception. In specific, great focus have been given to the tri-allelic polymorphism in the promoter region of the serotonin transporter gene in relation with pain perception. In this study we aim to investigate whether the modulatory effect of the visual stimuli on muscular pain perception observed in our previous study is genotype dependent. This study was approved by the local ethical committee. DNA extracted from saliva (using OC-100; DNA genotek, Ontario, Canada) obtained from 380 Scandinavian healthy volunteers (between 18 and 39 years old). To determine the tri-allelic 5–HTTLPR genotype, PCR- reactions were carried out using the GoTaq® Hot Start Polymerase (Promega) and 80ng of genomic template. Additionally, 10 µl of the PCR product were digested for 2hrs at 37° with 1µl MSP1 (New England Biolabs, Ipswitch, MA, USA). The genotypes were evaluated from running PCR products and digested PCR products on agarose gels. A total of 150 healthy subjects (50 of each genotype for serotonin transporter gene (s/s, s/l and l/l) proceed to the next phase of our study. In this phase, experimental jaw muscle pain was evoked by injection of 0.2 ml hypertonic saline into the masseter muscle. With each injection an emotion (positive, negative or neutral) was generated by visual stimuli (pictures taken from International Affective Picture System). The participants were asked to continuously rate pain intensity (electronic visual analogue scale - VAS) as well as unpleasantness/pleasantness of the conditioning stimuli (pictures). Hypertonic saline evoked moderate levels of pain in all subjects. In participants with high expression of the protein serotonin transporter, conditioning with negatively-loaded pictures increased VAS pain scores compared with neutral and positive emotions. In general, participants with intermediate expression of the protein reported had experienced higher pain intensity than participants with high or low expression of the protein. However there were no significant effects of the pictures on pain perception in participants with neither intermediate nor low expression of the protein.

Genetic Association Analysis between Glycine Cleavage System and Schizophrenia. *A. Yoshikawa[1], F. Nishimura[1], H. Hibino[2], K. Kohda[3], M. Tochigi[1], Y. Kawamura[4], T. Umekage[5], T. Sasaki[6], K. Kasai[1], C. Kakiuchi[1].* 1) Neuropsychiatry, Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Psychiatry, Fukui Memorial Hospital. Kanagawa, Japan; 3) Department of Physiology, The Keio University School of Medicine, Tokyo, Japan; 4) Department of Psychiatry, Sakae Seijinkai Hospital. Kanagawa, Japan; 5) Division for Environment, Health and Safety, The University of Tokyo, Japan; 6) Department of Physical and Health Education, Graduate School of Education, The University of Tokyo, Japan.

Background: Schizophrenia is a devastating psychiatric disease with worldwide lifetime risk of approximately 1%. The pathophysiological mechanisms underlying schizophrenia have not been fully elucidated. Hypofunction of NMDA receptors (NMDAR) has been implicated in the pathophysiology of schizophrenia, but precise mechanisms are not known yet. Glycine is the co-agonist of NMDAR and glycine cleavage system (GCS) is the main pathway which catalyzes glycine. Interestingly, the activity of the GCS is co-localized with NMDAR in neurogenic regions especially in the hippocampus. In addition, several studies suggest that the serum concentration of glycine/D-serine is altered in patients with schizophrenia. Therefore, we hypothesized that the dysfunction of GCS is involved in the pathophysiology of schizophrenia. GCS is a mitochondrial multi-enzyme complex and is composed of GLDC (glycine dehydrogenase (decarboxylating)), AMT (aminomethyltransferase), GCSL (glycine cleavage system protein L) and GCSH (glycine cleavage system protein H). Here we conducted the genetic association study between GLDC and schizophrenia. Aim of the study: To investigate the genetic association of GCS genes with schizophrenia. Methods: We performed a case-control association study between GLDC and schizophrenia in 384 patients with schizophrenia diagnosed by DSM-IV criteria and 384 age and sex matched healthy controls. All the subjects were ethnically Japanese. Written informed consent was obtained from all the subjects. The Human Genome, Gene Analysis Research Ethics Committee of the Faculty of Medicine, University of Tokyo approved the study. We selected the 24 tag SNPs by tag SNPs picker of the Hapmap database (MAF>0.1, r2>0.8). Genotyping was performed by the fluorogenic 5′ nuclease method (Taqman) using ABI7900HT. We analyzed the association by using the Haploview programs. Results: We observed no significant association with any tested SNPs or haplotypes of GLDC. Discussion: No evidence for the association was found between GLDC and schizophrenia in the Japanese population. Assessing the association with larger samples will be needed.

A gene search for a new spinocerebellar ataxia. *K. Ishikawa, N. Sato, Y. Hashimoto, M. Obayashi, H. Matsuo, H. Mizusawa.* Dept Neurology, Tokyo Med & Dental Univ, Tokyo, Japan.

Spinocerebellar ataxia (SCA) is a group of neurodegenerative conditions showing autosomal dominant cerebellar ataxia as a cardinal clinical feature. SCA contains clinically and genetically heterogeneous conditions. Mutations in 22 SCAs (SCA1, 2, 3/Machado-Joseph disease (MJD), SCA5, 6, 7, 8, 10, 11, 12, 13, 14, 15, 17, 18, 23, 27, 28, 31, 35, 36 and dentato-rubral pallidoluysian atrophy (DRPLA)) have been identified, and the gene loci are known in the remaining 9 SCAs (SCA4, 19/22, 20, 21, 25, 26, 29, 30, 32). We have collected 332 index patients with SCAs. After screening common SCA mutations which are SCA1, 2, MJD, SCA6, DRPLA, and SCA31, we found 66 patients (22%) did not harbor any of these 6 mutations. We embarked a positional cloning combined with neurological investigations to identify a new mutation for SCA. Although there was a clinical heterogeneity among these 66 patients, we found that a majority of patients show relatively early age-of-onset (i.e. onset before 35 years of age) and predominantly cerebellar dysfunction. Genotyping was performed on 30 individuals from 6 families using the Affymetrix 6.0 SNP Array. The obtained data were subjected for linakge analysis using a computer software MERLIN. We found supporting data that these families show linkage to a few chromosomal segments not previously assigned for SCAs. We are currently in a process to search mutations in these segments using exome sequencing, copy number variation assay and candidate gene approach. Further study to screen mutations among candidate genes and to collect more families would be needed to identify a new mutation for SCA.

2372F

Combining genotype and gene expression data to unravel the genetics of Major Depressive Disorder. *S. Mostafavi[1], A. Battle[1], X. Zhu[2], S. Montgomery[1,3], JB. Potash[4], MM. Weissman[5], C. Haudenschild[6], C. McCormick[6], KB. Beckman[7], R. Mei[8], A. Urban[2], D. Koller[1,3], DF. Levinson[2].* 1) Department of Computer Science, Stanford University, CA; 2) Department of Psychiatry and Behavioral Sciences, Stanford University, CA; 3) Genetics, Stanford University, Stanford, CA; 4) Department of Psychiatry, University of Iowa, Iowa City, IA; 5) Department of Psychiatry, Columbia University, New York, NY; 6) Illumina, Inc., La Jolla, CA; 7) University of Minnesota, Minneapolis, MN; 8) Centrillion Biosciences, Mountain View, CA.

The goal of this project is to identify and characterize the variability in the transcriptome that is associated with major depressive disorder (MDD), and to link such associated variability with environmental or causal genotypic variations. To this end, we have collected RNA-sequencing data from whole blood (over 60 million reads per subject), SNP genotype data (737,187 common SNPs), and a large number of phenotypic measurements for 949 subjects, including 474 fully eligible MDD cases and 475 controls. All subjects were of self-reported European ancestry, and recruited from a survey panel that was representative of the US population. Panel members were screened with an online CIDI-SF for (a) absence of current substance dependence, and (b) presence of either recurrent MDD or the absence of any two-week period with more than 3 of 9 MDD criteria. These individuals were then interviewed with the SCID (DSM-IV) after giving a blood sample for DNA and RNA (Paxgene collection system). Beyond quantifying gene expression levels, RNA-sequencing allows us to quantify more detailed expression traits such as isoform variability and allele-specific expression (ASE). Using these data, we have developed a statistical model for identifying groups of co-expressed expression traits (modules), including ASE, gene level and isoform variability, that are predictive of case control status, independently of other phenotypic covariates that can confound such associations. In particular, a major challenge in understanding the expression variations that underlie disease status is the abundance of spurious correlations caused by a number of confounding factors, such as age, gender, BMI, and drug intake. To address this issue, our method (1) models these confounding factors and their potential effect on expression variability; and (2) identifies gene modules associated with depression in our dataset, with varying degrees of additional support from genotypic variations. Our preliminary results identify several modules that predict disease status and severity. We are in the process of characterizing these modules for biological meaning, and their link to disease severity. These results provide new insights into genetic factors underlying MDD risk.

2373W

Transcript profile analysis of interleukin-1 beta gene in immature and adult zebrafish brain after seizure. *P.G. Barbalho, F.R. Pinto, R. Mangolin, C.V. Maurer-Morelli.*Department Medical Genetics, University of Campinas, Campinas, Campinas-SP, Brazil.

Introduction: Epilepsy is a common neurological disorder characterized by recurrent spontaneous seizures that afflicts nearly 50 million people worldwide. Proinflammatory cytokines, such as interleukin-1beta (il1b), has shown to be up-regulated in surgical specimens of pharmacoresistent patients and in experimental rodent models of seizure; however the profile of this cytokine in zebrafish model for epilepsy is unknown. In this study we aimed to investigate the il1b transcript profile in adult and immature zebrafish brain after seizure induced by Pentylenetratazole (PTZ). Material and Methods: Zebrafish were maintained according to standard procedures and all experiments were approved by animal ethical committee/UNICAMP. Adult and larvae (7days post fertilization) zebrafish were separated in Seizure (SG) and Control (CG) groups. Animals from SG group were individually exposed to 15mM PTZ (2–3min for adults and 20min for larvae). Animals from CG were exposed to same handling condition, but in normal bath water. A total of n=6 samples were used for each group and age. A single adult sample was composed by pooling two brains and 20 heads were used to compose each larvae sample. At the time 12h, 24h and 48h after seizure insult, animals were anesthetized, the brains were immediately isolated, frozen in N2(L) and total RNA extracted by Trizol (Invitrogen). Reverse transcriptase quantitative-PCR amplifications were carried out in triplicates with efla as endogenous control (TaqMan®, Applied Biosystems). The relative quantification (RQ) was calculated by the equation $RQ=2^{-\Delta\Delta CT}$. Statistical analysis was performed by Kruskall-Wallis test. Results: The mean ± Standard Deviation results obtained were: (i) adult: CG12h 0.95±0.31; SG12h 0.84±0.19; CG24h: 0.75±0.23; SG24h: 0.76±0.27; CG48h 0.85±0.16; SG48h 0.99±0.41; (ii) immature: CG12h 1.84±0.46; SG12h 2.00±0.61; CG24h: 2.18±1.07; SG24h: 1.15±0.51; CG48h 2.5±0.58; SG48h 2.02±0.63. No statistical significance was found between CG and SG ($p \geq 0.05$). Conclusion: This is the first study investigating il1b transcript profile in zebrafish brain after seizure insult. The results indicated that il1b transcript levels have a different pattern in zebrafish as compared to those described in rodent models of epilepsy. In order to better characterize the model for epilepsy studies, further studies are under way to investigate the il1b expression pattern at 0h, 6h and 72h after PTZ induced-seizure.

An integrative analysis pinpoints the pathogenesis of autism in the cerebellar vermis. *D.-A. Clevert, S. Hochreiter.* Institute of Bioinformatics, Johannes Kepler University Linz, Austria.

Motivation: We investigated neurodevelopmental dysfunctions in autism spectrum disorders (ASD) by an integrative analysis including the three largest genome-wide studies on associations between copy number aberrations (CNA) and ASD, the BioGPS tissue atlas, the Allen brain atlas, and in situ hybridization histochemistry data from the developing mouse brain. In contrast to the original association studies, we considered "ASD candidate genes" each of which is the only CNA-impaired gene in an ASD case, therefore, presumably causing ASD. For extracting ASD candidate genes, we developed an analysis pipeline for rare and small CNAs. Rare CNAs are supposed to be more disease-specific, because CNAs that cause ASD with high probability are assumed to be de novo and quickly vanish in the population due to their low reproductive fitness. Small CNAs affect only few genes and, therefore, are very specific concerning the genes they are impairing. **Results:** ASD candidate genes that are indentified independently in all CNA studies include the neurexins *CNTNAP2* and *NRXN1*, the catenin *CTNNA3*, the cadherin *CDH13*, and the contactins *CNTN5* and *CNTN6*. Gene set enrichment analysis of ASD candidate genes showed that significant biological processes are all related to cell and synaptic adhesion the postsynaptic density, membrane and synapse. At data from the BioGPS, the Cancer Genome Anatomy Project, and the Allen brain atlas, ASD candidate genes have significantly different variations in their expression values in cerebellum compared to other genes, where at the Allen brain atlas cerebellar vermis lobes I-II, IV, VI, VII, and VIII where most significant. In situ hybridization histochemistry data indicate that ASD candidate genes are primarily expressed in the developing mouse cerebellum. **Discussion:** Our results, that locate the pathogenesis of ASD in the cerebellar vermis, are consistent with pathological studies of ASD cases, where, in over 90% of the examined brains, well-defined cerebellar abnormalities were found. Also studies on children with vermal lesions showed phenotypes like speech disorders and behavioral disturbances similar to autism. The high percentage, 60–80%, of ASD cases showing motoric deficits again hints at the cerebellum. We explain 4:1 male to female ratio in ASD by the regulatory influence of estrogen on the development of the cerebellum. The human estrogen 17β-estradiol enhances in the cerebellum synaptic connectivity.

Common genetic variants in the GNB3, ARNTL, and NPAS2 loci are associated with objectively measured sleep traits in the elderly. *D.S. Evans[1], N. Parimi[1], C.M. Nievergelt[2], K.L. Stone[1], T. Blackwell[1], S. Redline[3], S. Ancoli-Israel[2], E.S. Orwoll[4], S.R. Cummings[1], G.J. Tranah[1], the Study of Osteoporotic Fractures (SOF) and the Osteoporotic Fractures in Men (MrOS) Study Groups.* 1) Research Institute, California Pacific Medical Center, San Francisco, CA; 2) Department of Psychiatry, University of California, San Diego, La Jolla, CA; 3) Department of Medicine, Brigham and Women's Hospital and Beth Deaconess Medical Center, Harvard Medical School, Boston, MA; 4) School of Medicine, Oregon Health and Science University, Portland, OR.

Aging is associated with changes in sleep quality and an increase in sleep disturbances, which in turn are associated with multiple adverse health outcomes. The internal biological clock controls many aspects of sleep and is regulated by a conserved set of clock genes. We tested the association between common genetic variation in clock genes and objectively measured actigraphic sleep and activity rhythm traits in two large population-based cohorts of elderly participants, the Study of Osteoporotic Fractures (SOF) (n=1407, 100% female, mean age 84 years) and the Osteoporotic Fractures in Men (MrOS) study (n=2527, 100% male, mean age 77 years). Common genetic variation in 30 candidate genes was captured using 529 single nucleotide polymorphisms (SNPs). Meta-analysis revealed that two SNPs in non-coding DNA (rs1047776 and rs2238114) in the GNB3 gene region were significantly associated with wake after sleep onset (rs1047776 $P_{ADD} = 2x10^{-5}$, rs2238114 $P_{ADD} = 5x10^{-5}$). SNP associations in the gene-rich GNB3 region could reflect the effect of variants in at least nine genes due to long-range linkage disequilibrium (LD). Publically available eQTL data from CEU lymphoblastoid cell lines were used to identify genes whose RNA expression might be regulated by rs1047776 and rs2238114. While GNB3 was the candidate gene in this region, neither SNP was associated with GNB3 RNA levels ($P > 0.05$). However, rs2238114 and rs1047776 were significantly associated with LRRC23 RNA levels ($P = 5x10^{-8}$, $P = 0.02$, respectively). LRRC23 is expressed in ocular tissue, and its leucine-rich repeat domain could be involved in protein interactions. In MrOS participants, SNPs within the binding partners ARNTL and NPAS2 were associated with a shift toward a later sleep and wake onset time (sleep onset time: ARNTL rs3816358 $P_{2DF} = 1x10^{-4}$, NPAS2 rs3768984 $P_{2DF} = 5x10^{-5}$; wake onset time: rs3816358 $P_{2DF} = 3x10^{-3}$, rs3768984 $P_{2DF} = 2x10^{-4}$) and the interaction between the two SNPs was significant (sleep onset time $P_{INT} = 0.003$, wake onset time $P_{INT} = 0.001$). In addition, results from a genome-wide association study of objective sleep traits will be discussed. These findings support the importance of clock genes in influencing the regulation of sleep traits in the elderly. The integration of gene expression data with SNP association results led to the serendipitous identification of LRRC23 as a potential candidate gene to regulate sleep fragmentation.

GWAS of alcohol abuse and dependence in the CATIE schizophrenia sample. *V.F. Gonçalves[1], C. Zai[1], A. Paterson[2], L. Sun[3], J.L. Kennedy[1], J. Knight[1].* 1) Neuroscience section, CAMH, Toronto, Canada; 2) Hospital for Sick Children, Toronto, Canada; 3) Statistics Division, Dalla Lana School for Public Health, Toronto, Canada.

Alcohol abuse or dependence (AB/AD) is one of the most frequent comorbidities diagnosed among schizophrenia (SCZ) patients. There is evidence that genetic factors influence AB/AD and the identification of genetic variants related to alcoholism in schizophrenia patients will provide us with better understanding concerning the biological mechanisms of addiction in psychiatric disorders. In this work, it was our objective to identify genetic variants associated with AB/AD in SCZ subjects. Lifetime alcohol abuse or dependence was diagnosed using the SCID research interview and the analyses were conducted considering the presence or absence of symptoms. After initial quality control of both SNPs and samples, data analysis was performed on 421,474 SNPs (Affy500K/Perlegen164K chip) in 391 case-control European-Americans (EA) and 213 case-control African-Americans (AA) from the NIH Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) trial. The association analyses were first performed separately for the EA and AA samples adjusting for the effects of sex, age, site, and the first two principal components. No SNPs achieved genome-wide significance level ($p<5x10(-8)$) in either sample. In the EA sample, the most significant SNP was rs12681165 (chr8) with p=2.6x10(-7). In the AA sample, the most significant SNP was rs7242277 (chr18) with p=2.6x 10(-6). This SNP is located close to the galanin receptor 1 (GALR1) gene, which has been associated with nicotine dependence in humans. Meta-analysis of these two genome-wide association studies was performed. The most interesting SNP was rs1248032 with p-value= 6.2x10(-6). This SNP is located close to the T-box (TBX5) gene. The genomic prioritization method (Sun et al., 2006) was used in both samples considering 1157 SNPs in 57 alcohol-related candidate genes. These SNPs were assigned to a high priority group and all remaining genome-wide SNPs of other genes assigned to a low priority group, and the stratified false discovery rate (SFDR) was applied to the two groups. However, no genome-wide significant association evidence was observed for the AB/AD phenotype in either sample. Genotyping of another schizophrenia sample (N=600) is currently being conducted, and this sample will be used for replication of the SNPs identified in this study. Alternative strategies under consideration include functional SNP analysis to maximize detection of true associations based on biological mechanisms.

Familial Study of Essential Tremor (FASET) at Columbia University. *N. Hernandez[1], D. Tirri[1], L. Clark[2,3], E. Louis[1,3,4,5].* 1) Gertrude H. Sergievsky Center, Columbia University, New York, NY; 2) Department of Patholgoy and Cell Biology, Columbia University, New York, NY; 3) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY; 4) Department of Epidemiology, Mailman Public School of Health, Columbia University, New York, NY; 5) Department of Neurology, Columbia University, New York, NY.

Essential tremor (ET) is one of the most common movement disorders, with prevalence estimated at 4.6% for individuals age 65 years and older. Family studies in addition to twin studies have provided strong evidence for a genetic contribution to ET. To date, linkage studies have identified three susceptibility loci at chromosomes 3q13 (ETM1; OMIM:190300), 2p22–25 (ETM2; OMIM:602134) and 6p23 (ETM3; OMIM:611456) however the genes and causal mutations have yet to be identified. The FASET (Familial study of Essential Tremor) study (NS073872) at Columbia University was initiated to identify and recruit ET families into a genetic study of ET to determine modes of inheritance and identify susceptibility genes. In year 1 of this project, between the period of 10/10/2011 and 4/2/2012 we have conducted a total of 98 in person assessments (home visits and videotape), of which 25 subjects are probands and and 73 are relatives. Total of 90 blood samples and 8 cheek swabs have been sent to the Human Genetics Resource Core at Columbia University for DNA isolation. All subjects recruited into the study were evaluated using the following assessments: 1) a structured clinical questionnaire that collects demographic data and medical data 2) a standardized 35–minute videotaped examination that includes a 20 minute tremor examination (which allows for the detailed assessment of postural, kinetic, intention and rest tremors, the motor portion of the Unified Parkinson's Disease Rating Scale and a detailed dystonia examination 3) Phlebotomy (3 tubes of blood, 8–10ml/tube per subject). All videotaped examinations were reviewed by a neurologist (Dr Louis) while blind to the pedigree structure. Overall, a total of 10 families and 45 family members have completed interviews and assessments. In year 1 of NS073872 we are proceeding with whole genome sequencing in six of the completed families. We have selected the two most distantly related affected subjects to prioritize for sequencing. We will present the pedigree structures of the 10 completed families and preliminary sequencing data. As of May 2012, causal genes for ET have not been identified. The identification of causal genes will lead to an understanding of ET pathogenesis that will allow the development of treatments. Funding: NIH, NINDS #R01 NS073872 (Louis, Clark), the Parkinson's Disease Foundation (Louis, Clark), the Arlene Bronstein Essential Tremor Research Fund, and the Claire O'Neil Essential Tremor Research Fund.

Significant Linkage of Familial Essential Tremor to a novel locus on Chromosome 5. *J.E. Hicks, I. Konidari, J.R. Gilbert, W.K. Scott.* Hussman Institute for Human Genomics, University of Miami, USA.

Essential tremor is a neurological condition characterized by tremor during voluntary movement. To date, three loci causative of familial essential tremor have been identified. We examined the five largest ET families in our 49–family dataset for genetic linkage using a 440,512 SNP Affymetrix Axiom array. 122 individuals (48 with ET; average 9.6 per family) from these five families were studied. Multipoint parametric linkage analysis was performed with a subset of 6,384 SNPs using an affecteds-only dominant model in SIMWALK2. Individuals were considered to be affected with definite ET if they met the consensus criteria developed by the Movement Disorder Society. For one family, linkage analysis identified two regions providing significant evidence of linkage to ET. The strongest of these was on chromosome 5 (MLOD score 3.6, 1–LOD down support interval: 168,502,329–174,594,583, hg19 coordinates). The second was on chromosome 18 (max LOD score 3.2, 1–LOD down support interval: 2,122,401–3,475,401). In order to fully utilize genotype information from all SNPs, identity by descent (IBD) sharing analysis was employed. The BEAGLE and GERMLINE software packages were used to assess IBD sharing in all affected relative pairs in each family. Regions were considered candidate regions if all affected individual pairs were at least IBD=1 for SNPs in the region. This analysis excluded the linkage peak on chromosome 18, as there was not sharing between all individual pairs. Segment sharing under the linkage signal on chromosome 5 reduced the candidate region by 1.3Mb to a 1024 SNP haplotype in the region 169,267,941–174,050,867. This region contains 21 genes, several of which are excellent biological candidate genes. While other families did not achieve significant evidence for linkage, maximum LOD scores corresponded to haplotypes shared IBD by all affected individuals in two more families, one family at 5q14.3, and the other family at 1p34.3 and 20p12.1. This indicates that while linkage may not be able to reach traditional significance thresholds, IBD haplotype sharing may be able to localize disease loci in these families.

Autism and Obesity: Is There Any Mechanistic Connection? *Z. Talebizadeh[1,2], M. Miralles[1].* 1) Pediatrics, Children's Mercy Hosp, Kansas City, MO; 2) University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Autism might be accompanied with other symptoms. These associated symptoms have been used in subject stratification for linkage and association studies resulting in valuable discoveries. Herein, the central point of our model is based on the concept that obesity might be a co-occurring condition in autism. Recently, there have been suggestive reports for a higher rate of obesity in autism. It is not clear if the suggested higher rate of obesity is related to psychotropic medication side effects or to the disorder itself. However, in-depth literatures search suggests that indeed some scientific merit can be found that backs up the potential mechanistic link between autism and obesity. Implications in some metabolic pathways have been independently associated with autism and obesity. To assess the possible relationship between autism and obesity, we evaluated the expression level of genes in a given metabolic pathway in autistic subjects with and without obesity. Subjects were ascertained from the Autism Genetics Resource Exchange (AGRE). Obesity status was determined using Body Mass Index percentiles. PCR arrays were conducted on lymphoblastoid cell line-derived RNA from 16 AGRE subjects. Despite the small sample size in this pilot study, differential expression was detected for several genes in autism-obese group compared with autism-non obese group. Interestingly, two genes with previously reported connections to both autism and fat metabolism were seen among the differentially expressed genes in the obese group. Our pilot study demonstrates that autistic subjects with obesity may represent a more homogeneous subset of this highly heterogeneous population. Applying such a stratification method may provide a way to better understand underlying genetic mechanism in a subset of autistic subjects with a co-occurring obesity. Our study introduces a novel, practical, and effective method to connect different lines of phenotypic and genomic data in unraveling the etiology of this highly heterogeneous neurodevelopmental disorder.

Haplotypes in the expression quantitative trait locus of interleukin-1β gene are associated with schizophrenia. *M. Yoshida[1], K. Shiroiwa[1], K. Mouri[1], T. Sasada[1], H. Ishiguro[2,3], T. Inada[4], T. Arinami[3], O. Shirakawa[5], A. Hishimoto[1].* 1) Department of Psychiatry, Kobe University Graduate School of Medicine, kobe, Hyogo-ken, Japan; 2) Department of Neuropsychiatry and Clinical Ethics, University of Yamanashi School of Medicine, Kofu, Japan; 3) Department of Medical Genetics, Doctoral Program in Social and Environmental Medicine, Graduate School of Comprehensive Human Sciences, University of Tsukuba, Tsukuba, Japan; 4) Department of Psychiatry, Seiwa Hospital, Institute of Neuropsychiatry, Tokyo, Japan; 5) Department of Neuropsychiatry, Kinki University School of Medicine, Osaka, Japan.

Recent genome-wide association studies (GWAS) and gene expression analyses have revealed that single nucleotide polymorphisms (SNPs) associated with complex diseases such as schizophrenia are significantly more likely to be associated with expression quantitative trait loci (eQTL). The interleukin-1β (IL1B) gene has been strongly implicated in the susceptibility to schizophrenia. In order to test this association, we selected five tag SNPs in the eQTL of the IL1B gene and conducted a case-control study using two independent samples. The first sample was comprised of 528 schizophrenic patients and 709 controls and the second sample was comprised of 576 schizophrenic patients and 768 controls. We identified two SNPs and several haplotypes as being significantly associated with schizophrenia. Previous reports indicated that one major haplotype that was protective against schizophrenia reduced IL1B transcription, while two risk haplotypes for schizophrenia enhanced IL1B transcription. Therefore, we measured IL1B mRNA expression in PAXgene-stabilized whole blood from 40 schizophrenic patients and 40 controls to explore the possibility of using five tag SNPs as schizophrenic trait markers. A multiple regression analysis taking confounding factors into account revealed that the T allele of rs4848306 SNP, which is a protective allele for schizophrenia, predicted reduced change in IL1B mRNA expression, regardless of phenotype. Our results appear to support the previous hypothesis that IL1B contributes to the genetic risk of schizophrenia and warrant further research on the association of eQTL SNPs with schizophrenia.

Selection of Candidate Genes from Linkage Regions Identified by the Individual Behavioral Domains of Autism Spectrum Disorders. *A. Hare[1], J. Flax[1], Z. Fermano[1], M. Azaro[1], A. Seto[1], S.Y. Cheong[2], S. Buyske[3], B. Zimmerman-Bier[4], C.W. Bartlett[2], L.M. Brzustowicz[1].* 1) Rutgers University, Department of Genetics, Piscataway, NJ; 2) The Batelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital and Department of Pediatrics, The Ohio State University, Columbus, OH; 3) Rutgers University, Department of Statistics and Biostatistics, Piscataway, NJ; 4) Saint Peter's University Hospital, New Brunswick, NJ.

Autism is a complex disorder defined by symptoms in three domains: 1) Communication Deficits, 2) Social Deficits, and 3) Restricted and Repetitive Behaviors. The New Jersey Language and Autism Genetics Study (NJLAGS) has studied families who have at least one individual with a diagnosis of Autism and at least one individual with Specific Language Impairment (SLI) with the goal of identifying behavioral biomarkers related to language as well as to other conditions associated with autism. Behavioral data assessing language impairment (LI), reading impairment (RI), social impairment (SI), and obsessive-compulsive behaviors (OCB) has been collected for these families, allowing the identification of behavioral phenotypes for use in linkage analyses. Linkage regions have been identified on 13q21.2 (OCB), 14q32.31 (SI), 15q23 (LI), 15q26.2 (SI), and 16p12.3 (RI). With no compelling evidence for association in these regions, we used Ingenuity Pathway Analysis (IPA) to aid in the selection of candidate genes for fine mapping analysis. A list of genes for each linkage region was identified (RefSeq, NCBI Build 37) and biological functions unique to each list were identified using IPA's core analysis. Linkage regions were grouped by domain and were analyzed in IPA separately. Genes playing a role in nervous system development and function were identified and given a score determined by the number of relevant functions. All domains were analyzed and scored together in order to mimic an overall autism model. Scores from the autism model were added to scores obtained in the individual domains analysis. Then candidate genes were prioritized by overall score. The LI domain identified 12 candidate genes of interest, the SI domain identified 3 genes of interest and the OCB domain identified 1 gene of interest. The highest overall scoring candidate gene, AKT1, was identified in the SI domain. AKT1 was identified in IPA's “PTEN Signaling”, “Reeling Signaling in Neurons”, and “Axonal Guidance Signaling” canonical pathways. Other high-scoring candidates in these pathways include NTRK3 (LI), IGF1R (SI), and PPP2R5C (SI). Inclusion of these genes in the overall autism model strengthened their overall score and increased support for roles in “Axonal Guidance Signaling” and “mTOR Signaling.” This method of ranking, in conjunction with other databases such as DAVID and KEGG, has identified strong candidate genes for future fine mapping analyses.

Association of Neuregulin 1 polymorphisms with a north Indian schizophrenia cohort. *P. Kukshal[1,2], T. Bhatia[3], A.M. Bhagwat[2], R.E. Gur[4], R.C. Gur[4], S.N. Despande[3], V.L. Nimgaonkar[5], B.K. Thelma[1].* 1) Department of Genetics, University of Delhi, South Campus, New Delhi, India; 2) C. B. Patel Research Centre, Vile Parle (West), Mumbai, India; 3) Department of Psychiatry, Dr. RML Hospital, New Delhi -110 001, India; 4) The Schizophrenia Research Center, Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA, USA; 5) Departments of Psychiatry and Human Genetics, Western Psychiatric Institute and Clinic, University of Pittsburgh School of Medicine and Graduate School of Public Health, 3811 O'Hara Street, Pittsburgh, PA 15213, USA.

Background: Neuregulin 1 (*NRG1*) plays important roles in the development and plasticity of the brain. *NRG1* polymorphisms have been proposed as risk factors for several common disorders and most strikingly with Schizophrenia. Genetic variation in *NRG1* has been associated with schizophrenia in several studies across ethnic groups and its association with cognition is also well documented. Methods: We tested for association of *NRG1* variants with schizophrenia in a moderately large north Indian cohort (n= 1020 cases and controls each). Cases diagnosed based on DSM IV criteria were age and gender matched to controls from the same geographical region. Informed consent was taken from each participant. On a subset of the cohort (n=116 cases and n=170 controls) a computerized neuropsychological battery was administered and their correlation with neurocognitive measures was evaluated. In the first step, a total of 35 SNPs using iPLEX and three microsatellite markers by fragment analysis were tested for association with Schizophrenia. In the second step, regression analysis for eight neurocognitive parameters was carried out with only SNPs showing allelic association. Results: Five variants rs35753505 (p=0.04; OR=1.147(1.01–1.31)), rs4733263 (p=0.04; OR=1.14(1.01–1.31)), rs4281084 (p=0.05; OR= 0.86(0.75–1.0)), rs6994992 (p=0.026; OR=1.15(1.02–1.3)) and rs10093107 (p=0.05; OR=0.89(0.78–1.0)) and one microsatellite marker 420 M9–1395 (p=0.016) from the 5′ region showed association with the disease but none withstood bonferroni corrections. 5 SNPs namely rs35753505 (p=0.05); rs1354336 (p=0.01); rs10093107 (p=0.03); rs3924999 (p=0.02) and rs11780123 (p=0.006) showed genotypic association. A sliding window haplotype revealed associations in and around rs10093107 in the 3–10 marker haplotypes from the 5′ UTR. On regression analysis of neurocognitive measures associations were observed with emotion and attention. Conclusions: Considering the isoforms and the multiple roles and functions that *NRG1* is involved in, it is believed that regulatory variants in this gene may be responsible in the disease etiology. SNPs from the *NRG1* promoter region are associated with schizophrenia in this large north Indian cohort. Association reported in other populations for rs6994992 and rs35753505 was also replicated. Association with cognitive measures was also observed. These results warrant fine mapping of this gene to identify critical variants for schizophrenia.

2383T

Single nucleotide polymorphism (SNP) fine mapping of the *AVPR1A* and *OXTR* loci reveals an *OXTR* association with a social memory endophenotype in probands with autism and their family members. *A. Lori[1], I. Lee[2], J.F. Cubells[1,3], E.B. Binder[1,4], T. Lehtimäki[5], K. Puura[6], K.N. Conneely[1], L.J. Young[3], D. Skuse[2].* 1) Department of Human Genetics, Emory University School of Medicine; Atlanta Georgia, GA, USA; 2) Behavioral and Brain Sciences Unit, UCL Institute of Child Health; London, UK; 3) Departments of Psychiatry and Behavioral Sciences, Emory University School of Medicine; Atlanta GA, USA; 4) Max-Planck Institute of Psychiatry; Munich Germany; 5) Department of Clinical Chemistry, Tampere University and University Hospital; Tampere, Finland; 6) Department of Child Psychiatry, Tampere University and University Hospital; Tampere, Finland.

Autism spectrum disorders (ASDs) are neurodevelopmental syndromes characterized by deficits in social behaviors and communication, and by idiosyncratic interests and repetitive behaviors (DSM-IVTR). Since the ASD diagnosis encompasses a very heterogeneous set of behavioral phenotypes, endophenotypes related to specific aspects of human social cognition could be potentially superior targets for ASD-related genetic analysis. Vasopressin (AVP), oxytocin (OXT) and their receptors play important roles in evolutionarily conserved social behaviors such as social memory and social attachment. Variants in the genes *AVPR1A* and *OXTR*, encoding respectively the AVP-1a receptor and the OXT receptor, have been reported to associate with ASD. In this study, we evaluated whether single nucleotide polymorphisms (SNPs) at *AVPR1A* and *OXTR* loci were associated with variation in human social cognition by evaluating 4 specific cognitive tasks (face recognition memory, accuracy in detecting direction of eye gaze, recognition of facial emotion of fear, Autism Diagnostic Observation Schedule subscale scores) in 190 families with a single offspring affected by ASD. Criteria for SNP selection included a minor allele frequency of >0.01 and pairwise r2≤ 0.85 among validated SNPs in HAPMAP and SNP Browser. A total of 30 SNPs for *AVPR1A* and 59 SNPs for *OXTR* were successfully genotyped using a Sequenom platform. Genetic associations were tested using QFAM-PLINK for quantitative familial traits (BC-Gene). Correction for multiple testing was performed using p-ACT (Conneely and Boehnke, 2007, AJHG 81:1158–68). One SNP (rs237887) in *OXTR* showed an experiment-wide significant association with face recognition memory (uncorrected p=0.00015, p-ACT= 0.023). This intronic SNP is located in a region predicted to interact with several transcription factors, suggesting a possible functional effect of the SNP on OXTR gene expression. We detected an experiment-wide significant association between a potentially functional SNP in *OXTR* and face recognition memory ability in children with ASD and their family members. The results add to evidence for a role of the OXT system in influencing key components of human social behavior, and suggest for the first time that variation in *OXTR* associates with variation in specific components of social cognition in humans. Support: NIH grant MH056897 to LJY; Wellcome Trust, Nancy Lurie Marks Family Foundation National Alliance for Autism Research to DS.

2384F

The Effects of *ABCB1* Polymorphisms and Expression in Perinatal Depression. *S.E. Parets[1], A. Lori[2], M.N. To[3], D.J. Newport[3], Z.N. Stowe[4], J.F. Cubells[1,2,3], A.K. Smith[1,2].* 1) Genetics and Molecular Biology Program, Emory University, Atlanta, GA; 2) Department of Human Genetics, Emory University, Atlanta, GA; 3) Department of Psychiatry& Behavioral Sciences, Emory University School of Medicine, Atlanta, GA; 4) Psychiatric Research Institute, University of Arkansas for Medical Sciences, Little Rock, AR.

High levels of maternal depressive symptoms have been widely associated with poor infant outcome and provide compelling evidence to continue antidepressant treatment throughout pregnancy. *ABCB1* encodes P-glycoprotein (P-gp), which is integral in controlling the passage of substances, including cortisol and antidepressants, across the blood-brain and placental barriers. Polymorphisms in *ABCB1* account for differences in the rates of substrate transport and associate with depressive symptoms and treatment response. For this study, we recruited 186 women in their 3rd trimester undergoing pharmacotherapy with antidepressants. We then examined the association between maternal polymorphisms in *ABCB1* and the maximum 3rd trimester score on the Hamilton Rating Scale for Depression (HRSD) using linear regression. Associations were observed with 3 exonic SNPs: rs1128503, rs2032582 and rs1045642 ($p<.0001$). Since they are in LD, we examined common haplotypes (≥5%) and observed that the G-G-C haplotype (53.9%) was associated with higher maternal depression ($p=6x10^{-5}$). We next examined the association between neonatal (umbilical cord blood; N=78) genotypes and birth weight using a linear regression model that accounted for the level of antidepressant in the cord blood and its relative affinity for the P-gp transporter. Associations between the neonatal genotypes in 3 SNPs (rs2032582, rs2032583 and rs2235040) and high birth weight were observed ($p<.05$). The G allele of rs2032582 was associated with both higher maternal depression and higher neonatal birth weight, which has been associated with poor infant outcome. This polymorphism alters protein activity/substrate specificity. We next evaluated placental *ABCB1* expression (N=30) and observed association with maximum maternal HRSD score during pregnancy ($p=.02$) and maternal perceived stress during pregnancy ($p=.012$). Interestingly, *ABCB1* expression also increased proportional to gestational age ($t=2.58$; $p=.016$) and APGAR scores ($t=2.48$; $p=.02$) at delivery. Our results suggest that maternal depressive symptoms and stress may be mediated, in part, by genetic variation in *ABCB1*. Expression changes in this gene correlate with developmental outcomes in the offspring and support further investigation of *ABCB1* in perinatal depression.

HMNC1 and COMT gene polymorphism associated with postpartum depression. *M. Romano-Silva, D.M. Miranda, P. Figueira, H. Correa, A. Alvim-Soares.* INCT de Medicina Molecular, Faculdade de Medicina, Universidade Federal de Minas Gerais, Av Alfredo Balena, 190, Belo Horizonte-MG, CEP 30130–100, Brazil.

Postpartum depression is a common disorder affecting women, with consequences for both mother and child. A genetic determinant for PPD is suggested by many genetic epidemiologic studies. One hundred and seventeen women were randomly selected among those who delivered in a maternity and filled in and filled in the Edinburgh Postpartum Depression Scale (EPDS) questionnaire about 8 weeks after delivery. POMC, MC4–R, HMCN-1 and COMT polymorphisms were analysed by PCR. Differences in genotype frequency were calculated by X2 test and the difference between groups was tested with Student's t test. Tests were two-tailed and results significant when $p \leq 0.05$. Those women that scored 13 or greater on EPDS were included in the PPD group [25 (18,97%)], and a total of 94 woman (81,03%), who scored 12 or less, became the Control group. No differences in POMC and MC4R genotype distribution were observed between these groups. We found a significant interaction between the development of depressive symptoms in postpartum and polymorphisms in HMCN-1 ($p=0.03$) and COMT ($p=0,01$). Hemicentin-1 (HMNC-1) gene encodes an extracellular protein that contains four estrogen receptor-binding sites and is involved mainly in the cell migration and protein anchorage. In conclusion, this study supports the notion that PPD is a result of complex interactions between multiple variables, including genetic factors. It is encouraged independent replications in larger samples and further investigation on these gene effects in PPD.

2386T

Disrupted in Schizophrenia 1 gene in autist patients. *P. Sarda[1], J. Puechberty[1], M. Girard[1], A. Schneider[1], S. Taviaux[1], G. Iefort[1], D. Genevieve[1], A. Baghdadli[2].* 1) Department of medical genetics, Arnaud de Villeneuve Hospital, Montpelier, France; 2) Child psychiatry department, Center of resource autism, Montpellier, France.

Disrupted in Schizophrenia 1 (DISC1) is a key susceptibility gene for major mental disorders particularly for psychiatric disorders (schizophrenia, depression, bipolar disorder and schizoaffective disorder) In two previous Finnish and Chinese studies, DISC1 polymorphisms were associated with autism and Asperger syndrome. Two reports have revealed abnormalities of DISC1 in three individuals with autism spectrum disorder. The first report concerns two brothers with autism and mild mental retardation with a large 2.07 Mb duplication on 1q42.2 including the DISC1 gene and inherited through the normal father. The second report concerns a 3–year-old male with developmental delay and autistic behavior who has a large 2Mb interstitial deletion of chromosome 1q42 involving DISC1, DISC2, and TSNAX inherited from his non-affected mother. We report the case of a 4–year-old boy with mild developmental delay and autistic behavior. Molecular karyotyping using SNP 6.0 Affymetrix arrays revealed a 100.7 kb duplication in the first exon of the DISC1 gene. This 100.7 kb duplication was inherited through the father. Anomalies were confirmed by qPCR analysis. The father presented some difficulties in social interaction and communication during childhood. He obtained a secondary degree but had initial difficulties and repeated 2 years during grade school and high school. These observations confirm evidence for a potential role of the DISC1 gene in autism spectrum disorders. This work was funded by the “Programme Hospitalier de Recherche Clinique régional Languedoc-Roussillon”.

2387F

Phenotypic description of a child with a 10q23.1 deletion involving only *NRG3*. *N. Sobreira[1], D. Avramopoulos[2], A. Pulver[2], B. Menten[4], B. Loeys[3], D. Valle[1].* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Center for Medical Genetics, Antwerp University Hospital and University of Antwerp, B-2650 Antwerp, Belgium; 4) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Our group and others have reported deletions in the 10q22q23 region typically ranging from a 4.7 Mb to 7.6 Mb region between 2 low copy repeats. The phenotype of the patients with the deletions is variable and includes developmental delay, macrocephaly, broad forehead, deep-set eyes, upslanting palpebral fissures, smooth philtrum, thin upper lip, cerebellar anomalies, cardiac defects and congenital breast aplasia. Balciuniene et al. (2007) suggested that the 10q22q23 region harbors one or more genes important for cognitive and behavioral development and Chen et al. (2009) showed that *NRG3*, deleted in most of the 10q22q23 deletions, is involved in schizophrenia. Other frequently involved 10q22q23 genes include *BMPR1* associated with juvenile polyposis and *PTEN* associated with Cowden syndrome. We describe a 5 year-old male with short stature, weight < 3rd percentile, microcephaly, brachycephaly, thin upper lip, smooth philtrum, low-set ears, hypospadius, inguinal hernia, sagittal clefts of the thoracic vertebrae, and developmental delay. The patient had a minimum 436 Kb deletion (chr10:83,652,547–84,088,659) by SNP genotyping array limited to the 5′ region of *NRG3*. To determine the precise deletion size and any related chromosomal aberrations we included a 851 Kb region of chr10 (chr10:83,375,977–84,227,714) in a 4.6 Mb targeted capture kit that included other unrelated chromosomal rearrangements and followed with next-generation sequencing. We analyzed the sequencing results using the Integrative Genomics Viewer and by comparing the coverage data between our patient and 5 controls. We found that the breakpoints of the approximately 570 Kb deletion in the telomeric end of the deletion is in a 10 Kb region of LINE repeats belonging to the L1 family (L1PA2) and that the centromeric end of the deletion is in a 6 Kb region of LINE repeats belonging to the family L1 (L1PA2 and L1M5). The detailed characterization of this smaller deletion and of the phenotype of our patient suggests the association of *NRG3* disruption with common features described in patients with larger 10q22q23 deletions including developmental delay, smooth philtrum, and thin upper lip, and with less frequent features like short stature, low weight, microcephaly, brachycephaly, hypospadius, inguinal hernia, and sagittal clefts of the thoracic vertebrae. Our results make *NRG3* a strong candidate gene for the developmental delay and dysmorphic features associated with the 10q22q23 deletions.

2388W

Determination of a rare variant and common variants in COMT for their involvement in the etiology of smoking dependence using Mid-South Tobacco case-control study samples. *J. Yang[1], S. Wang[1], J.Z. Ma[2], T.J. Payne[3], M.D. Li[1].* 1) Psychiatry and Neurobehavioral Sciences, University of Virginia, Charlottesville, VA; 2) Public Health Science, University of Virginia, Charlottesville, VA; 3) Otolaryngology and Communicative Sciences, University of Mississippi Medical Center, Jackson, MS.

Catechol-O-methyltransferase (COMT) is responsible for degrading catecholamines, including the neurotransmitters dopamine, epinephrine, and norepinephrine. Given the role of the dopamine reward pathway in nicotine dependence (ND), in a previous study, we showed that several common variants and haplotypes within the COMT gene are significantly associated with smoking quantity, the Heaviness of Smoking Index, and the Fagerström Test for ND score (FTND) in both European Americans (EA) and African Americans (AA) of the Mid-South Tobacco Family (MSTF) sample. To confirm the involvement of COMT in ND, we performed a case-control-based association analysis in an independent sample, called the Mid-South Tobacco Case-Control study, which consists of 1387 EA subjects and 3161 AA subjects recruited primarily from the state of Mississippi since 2005. The SNPs selected were rs6269, rs4633, rs5031015, rs4818, rs4680, and rs174699, where rs4680 represents a Val/Met missense polymorphism and rs503105 is a rare variant located in exon 4 of the membrane-bound COMT transcript or exon 2 of the soluble COMT transcript that leads a non-synonymous change of G to A (Ala/Thr). Our analysis revealed a significant association of rs4680 (Val/Met) with FTND in the EA (P = 0.00057) and pooled (P = 0.00223) samples and of rs503105 (Ala/Thr) with FTND in all samples (P = 0.00072 for the AA, P = 0.00385 for the EA, and P = 5.2E-08 for the pooled samples). We further found that the A allele of rare variant rs5031015 represents a significant risk effect in the AA (frequency 0.19%, beta = -1.583), EA (frequency 0.4%, beta = -1.945), and pooled (frequency 0.25%, beta = -1.835) samples. In addition, we identified a haplotype, A-T-G-C-A-T, formed by SNPs rs6269, rs4633, rs5031015, rs4818, rs4680, and rs174699, with a significant protective effect against ND in the EA sample (frequency 49.1%, P = 0.00037). In sum, our results not only provide evidence for a significant association of COMT variants with ND in an independent sample but also demonstrate that the rare variant rs5031015 likely plays a significant role in susceptibility to ND. (Supported by NIH grant DA-012844).

2389T

Copy number variations (CNV) and agenesis of the corpus callosum, narrowing the recurrent 8p duplication interval. *S. Esmaeeli Nieh[1], L. Fernandez[1], S. Sajan[2], E. Rider[1], P. Bukshpun[1], M. Wakahiro[1], J.T. Glessner[3], H. Hakonarson[3], S.L. Christian[2], W.B. Dobyns[2], E.H. Sherr[1].* 1) Department of Neurology, University of California, San Francisco, San Francisco, CA; 2) Center for Integrative Brain Research, University of Washington, Seattle, WA;; 3) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Background: Because of low copy repeats (LCRs) and common inversion polymorphisms, the human chromosome 8p is prone to a recurrent cytogenetically visible deletion/duplication rearrangement which is often seen with the brain malformation agenesis of the corpus callosum (AgCC). AgCC is often associated with intellectual disability and autistic features. The genetics of AgCC is complex, however, prior reports from our lab and others have suggested that de novo duplications on 8p may play an important causative role. **Hypotheses:** We hypothesize that individuals with brain malformations have a high rate of de novo copy number variations (CNV) including the 8p22–p11.21 recurrent event and that screening a large cohort might identify smaller CNVs that narrow the critical region. **Methods:** We identified patients with AgCC by a comprehensive radiological and clinical review of our IRB approved AgCC cohort (n>500). Blood samples were obtained from the proband and both biological parents, when available. DNA was extracted and run on an Illumina 610 Quad Chip array. Data were analyzed using PennCNV. CNV's that were selected for analysis contained greater than 9 SNPs, were longer than 30kb, had a PennCNV confidence level above 10 and contained one or more genes. Manual curtain, merging of contiguous large CNVs and PCR confirmation were conducted. **Results:** From a total of 275 AgCC proband arrays, we identified 5 individuals with inverted duplication on 8p22–p11.21, all with similar genomic boundaries. We also identified two individuals who had isolated duplications in this interval. Interestingly, these two patients had complete callosal agenesis and microcephaly, but did not have cardiac defects, a feature common to the larger genomic rearrangement. This finding defines a narrowed critical interval ~10.5Mb on 8p21.2–p12. This region encompasses ~80 genes including several strong candidate genes associated with neurological disorders. Functional interpretation of non-coding regions using Great (version 2.0.1) revealed the highest Binom Rank with a raw P-value=3.1e-6 for central nervous system disease. **Conclusions:** Duplications on 8p constituted the most recurrent genomic regions identified in AgCC patients in our cohort and there is a specific enrichment of neurodevelopmental disorders' genes. These data support a strong etiologic link between AgCC and neurodevelopmental disorders, likely shared molecular and developmental pathways.

2390F

Serotonin Transporter and Receptor Genes Significantly Impact Nicotine Dependence through Genetic Interactions in both European American and African American Smokers. *Z. Yang[1,2], C. Seneviratne[1], S. Wang[1], J.Z. Ma[3], T.J. Payne[4], J. Wang[2], M.D. Li[1].* 1) Psychiatry and Neurobehavioral Sciences, University of Virginia, Charlottesville, VA; 2) Shanxi Key Laboratory of Environmental Veterinary Science, Shanxi Agricultural University, Shanxi, China; 3) Public Health Sciences, University of Virginia, Charlottesville, VA; 4) Otolaryngology and Communicative Sciences, University of Mississippi Medical Center, Jackson, MS.

Pharmacologic studies have demonstrated a modulatory effect of nicotine on serotonergic signaling, primarily through genes encoding the serotonin transporter (SLC6A4) and the 5–HT3AB subunits HTR3A and HTR3B. Thus, the functional state of these genes may alter the susceptibility to nicotine dependence (ND). In this study, we examined the impact of variations in the three genes on ND in 1366 individuals from 402 African American (AA) and 671 individuals from 200 European American (EA) nuclear families. The ND of each smoker was assessed with three commonly used measures: smoking quantity (SQ), Heaviness of Smoking Index (HSI), and Fagerström Test for Nicotine dependence (FTND). Association analysis at the individual SNP level revealed marginal association of rs10160548 in HTR3A with SQ and HSI in AA, 5–HTTLPR in SLC6A4 with FTND in EA, and rs11606194 in HTR3B with FTND in the pooled sample. Additional haplotype-based association analysis revealed a few major haplotypes in HTR3A that were significantly associated with ND in the AA, EA, and pooled samples. However, none of these associations remained significant after correcting for multiple testing except for a haplotype G-C-C-T-A-T formed by SNPs rs1150226, rs1062613, rs33940208, rs1985242, rs2276302, and rs10160548 in HTR3A for the AA sample Finally, we demonstrated significant interactions among variants rs1062613 and rs10160548 in HTR3A, rs1176744 in HTR3B, and 5–HTTLPR and rs1042173 in SLC6A4, affecting all three ND measures in the AA, EA, and pooled samples. Of these significantly interacting variants, rs1062613 in HTR3A and 5–HTTLPR and rs1042173 in SLC6A4 are known to modulate expression of the corresponding gene and rs1176744 in HTR3B to alter serotonin conductance by 5–HT3AB. Serotonergic signaling clearly plays a significant role in ND through interaction among variants in the genes encoding the serotonin transporter and receptors.

2391W

Genetic Association of *FKBP5* and *CRHR1* with Cortisol Response to Acute Psychosocial Stress in Healthy Adults. *P.B. Mahon[1,2], P.P. Zandi[1,2,3], J.B. Potash[4], G. Nestadt[2], G.S. Wand[1,5].* 1) Johns Hopkins Mood Disorder Center, Baltimore, MD; 2) Department of Psychiatry, Johns Hopkins School of Medicine, Baltimore, MD; 3) Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) Department of Psychiatry, University of Iowa, Iowa City, IA; 5) Department of Medicine, Johns Hopkins School of Medicine, Baltimore, MD.

Chronic dysregulation of the hypothalamus-pituitary-adrenal (HPA) axis activity is related to the onset and course of several neuropsychiatric and stress-related disorders. Thus, it is important to identify factors that account for the observed inter-individual variability in HPA axis activity. Studies suggest that cortisol response to stress has a moderate to strong genetic etiology and that FKBP5 and CRHR1 are key proteins regulating the HPA axis response to stress. Polymorphisms in the *FKBP5* and *CRHR1* genes have been associated with mood disorders. The goal of the present study was to examine the relationship between polymorphisms in these genes with HPA axis response to psychological stress in one of the largest Trier Social Stress Test (TSST) cohorts yet examined. Our sample included 368 healthy, young adults who underwent the TSST. Participants were carefully and extensively screened to include only healthy individuals in order to minimize state effects (smoking, alcohol use, medical conditions, etc.) in favor of examining genetic effects on cortisol stress response. Salivary cortisol was measured at multiple time points both before and after the stressor. After quality control, nine SNPs in *FKBP5* and four in *CRHR1* were available for analysis. Single marker and haplotypic analyses were carried out in PLINK and STATA 11.0. Exploratory analyses were also conducted using six stress-related variables as effect modifiers or mediators of the association. The strongest evidence was for an association of rs4713902 and rs7757037 in *FKBP5* with baseline cortisol response to the TSST under a recessive model (p=0.0003 and 0.004, respectively). In addition, we identified a sex-specific effect of three SNPs in *FKBP5* on peak response to the TSST (interaction p=0.02–0.009). The four SNPs in *CRHR1* (rs7209436, rs110402, rs242924, rs242938) were associated with peak cortisol response to the TSST under a recessive model (p=0.04–0.007). We have provided additional evidence for association of variants in *FKBP5* and*CRHR1* with HPA axis response to psychosocial stress. These findings have implications for interindividual variation in HPA axis activity and potentially for the etiology of neuropsychiatric and stress-related disorders.

Associations of Genetic Polymorphisms in *GRIN2B* and *GABRG2* with Epilepsy Susceptibility. *C. Chen[1], C. Hung[1], Y. Kao[1], H. Liou[2].* 1) Department of Pharmacy, College of Pharmacy, China Medical University, Taichung, Taiwan; 2) Pharmacology and Neurology, National Taiwan University Hospital and College of Medicine, National Taiwan University, Taipei, Taiwan, Republic of China.

Purpose: Epilepsy is one of the most common chronic neurological disorders. Alterations of neurotransmitter receptors may be associated with epilepsy susceptibility. GABA and glutamate are the two most widely discussed neurotransmitters which may play a major role in epilepsy. The aim of this study was to investigate the possible role of polymorphisms in GABA and glutamate receptor genes (*GRIN2B*, *GABRG2* and *GABRA1*) in epilepsy susceptibility in Taiwan population. **Method:** Epileptic patients and age, gender matched normal controls were recruited at the department of Neurology of National Taiwan University Hospital (NTUH). 10 ml blood was drawn to extract genomic DNA after signed inform consent. Single nucleotide polymorphisms on *GRIN2B*, *GABRG2* and *GABRA1* (-200G>T and -421C>A for *GRIN2B*; c.588C>T and c.643A>G for *GABRG2*; IVS11+15A>G, c.-142A>G and c.-31C>T for *GABRA1*) were genotyped by real-time PCR SNP analysis. To analyze the associations between SNPs and epilepsy susceptibility, Pearson's $\chi 2$ tests were performed and Bonferroni corrections were used to adjust for multiple comparisons. To further identify the possible gene-gene interaction, logistic regression was performed under adjustment of age, gender and epilepsy syndromes.**Result:** There were 500 epilepsy patients and 200 healthy controls enrolled in this study. Results of statistical analysis showed that the T allele carriers of -200G>T in *GRIN2B* were more likely to be normal subjects, while A allele of c.643A>G in *GABRG2* was over presented in patients with epilepsy (for *GRIN2B* -200G>T, OR:0.464; 95%CI=0.300–0.719; p=0.0006; for*GABRG2* c.643A>G, OR=6.480; 95%CI=3.319–12.652; p<0.0001). There is no significant association between other polymorphisms and epilepsy susceptibility. In the most fitted regression model, under adjusting for confounding factors, *GRIN2B* -200G>T and *GABRG2* c.643A>G influence the occurrence of epilepsy concurrently. **Conclusion:** These results suggested that some polymorphisms in genes encoding for neurotransmitter receptors may be associated with epilepsy susceptibility in Taiwan population. Further studies in different populations are warranted to clarify whether these genetic effects can be observed in different ethnics.

Interpreting the impact of mutations in *SCN1A* in the context of the most severe phenotypes amongst the generalized epilepsies with febrile seizures plus. *M. Gonsales[1], P. Preto[2], M.A. Montenegro[2], M.M. Guerreiro[2], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, University of Campinas, Campinas, Brazil; 2) Department of Neurology, University of Campinas, Campinas, Brazil.

Dravet and Doose syndromes are severe phenotypes within the clinical spectrum of generalized epilepsy with febrile seizures plus. Several mutations in the neuronal voltage-gated sodium channel a1–subunit gene (*SCN1A*) have been identified in patients within this spectrum. However, the prognostic value of these mutations and a possible correlation with the different clinical subtypes remain unclear. Therefore, the aim of this study was to search for *SCN1A* mutations in patients with Dravet and Doose syndromes, thus establishing genotype-phenotype correlations using prediction algorithms to determine potentially deleterious mutations and comparative analysis with mutations previously described. We performed *SCN1A* mutation screening in 15 patients with Dravet and 13 with Doose syndrome. Eight algorithms were used to analyze the possible impact of the mutations in protein function. In addition, MLPA was used to detect copy number variations (CNVs) within *SCN1A*. Mutations previously described in the literature were compiled and analyzed regarding their location in the protein and their potential deleterious effect. Twelve mutations were identified in patients with Dravet: six missense, three splice-site, two frameshift and one in-frame deletion. Patients with Doose syndrome showed no mutations. Moreover, no copy number variants were identified. The compilation of previously described *SCN1A* mutations revealed a total of 518 nucleotide variants and 32 CNVs in Dravet syndrome while only two mutations were found in patients with typical Doose syndrome. Missense mutations are the most frequent type in Dravet (44%), and amino-acid changes are mostly located in the pore-forming and C-and N-terminal regions of the protein, as also observed in our cohort. The high frequency of *SCN1A* mutations in patients with Dravet suggests that molecular testing is useful for individuals with this phenotype, but not clinically relevant in Doose syndrome. Our results, consistent with the analysis of the 518 mutations previously described, show a predominance of missense mutations, initially considered exclusive of mild phenotypes. These substitutions involve conserved amino-acid located in functionally important regions, while other types of mutation are rather distributed along the protein. The analysis using multiple prediction algorithms was effective, especially for predicting the deleterious effect of transmembrane substitutions. Supported by FAPESP/CNPq.

Next-generation sequencing and mutation screening in patients with familial mesial temporal lobe epilepsy: investigating the chromosome 18p11.31 candidate locus. R.*O. Santos[1], M.G. Borges[1], W.T.S.T. Ide[1], C.S. Rocha[1], R. Secolin[1], F.M. Artiguenave[1], C.L. Yasuda[2], A.C. Coan[2], M.E. Morita[2], F. Cendes[2], C.V. Maurer-Morelli[1], I. Lopes-Cendes[1].* 1) Medical Genetics Dept, University of Campinas, Campinas, São Paulo, Brazil; 2) Neurology Dept, University of Campinas, Campinas, São Paulo, Brazil.

Background: The epilepsies form a group of chronic neurological diseases characterized by recurrent seizures. Familial mesial temporal lobe epilepsy (FMTLE) is a clinically well characterized syndrome with an autosomal dominant inheritance. Our previous results pointed to a region on chromosome (ch) 18p11.31 as genetically linked to FMTLE. The identified candidate region spans approximately 6Mb and contains 18 annotated genes. **Objectives:** The present work aims to sequence the entire candidate region previously identified on ch 18p11.31 in patients from a large family segregating FMTLE. **Methodology:** DNA samples were amplified from three patients and one control by long range PCR and sequenced using the SOLiD System® (Applied Biosystems, USA). Sequence data was aligned and analyzed by a logic algorithm developed in our laboratory using Perl language. Results from alignment were compared with databanks in order to verify possible functional relationship with the disease physiopathology. **Results:** We identified 5019 single nucleotide polymorphisms (SNPs) in the sequenced region. Among them, 2474 SNPs were not present in the databases of polymorphisms previously described. After performing a series of pipeline adjustments using the bioinformatics algorithm we found three SNPs present only in the three patients and absent in the control. **Conclusions:** Next-generation sequencing allowed a faster and reliable analysis of the candidate region previously identified by linkage studies in FMTLE. Using an interactive bioinformatics pipeline, we have identified putative functional variants in relevant candidate genes for FMTLE on ch 18p11.31. Among them are those related to cortex development, development of neuronal projections, axons guidance and signal transduction. The next step is to confirm these changes in the others family members with FMTLE and verification of the segregation of these variants in this and other families with similar phenotype. FAPESP, São Paulo Brazil.

Characterization of a GEFS+ locus on 6q16.3q22.31. *P. Szafranski[1], G. Von Allmen[2], B. Graham[1], S. Fogarty[2], A.A. Wilfong[3], S.-H.L. Kang[1], J.A. Fereira[4], W. Bi[1], J.A. Rosenfeld[5], L.G. Shaffer[5], S.W. Cheung[1], P. Stankiewicz[1], S.R. Lalani[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept of Neurology, University of Texas Health Science Center at Houston, TX; 3) Pediatric Neurology, Texas Children's Hospital, Baylor College of Medicine, Houston, TX; 4) Dept of Pediatrics, University of South Florida, Tampa, FL; 5) Signature Genomic Laboratories, PerkinElmer, Inc., Spokane, WA.

Generalized epilepsy with febrile seizures plus (GEFS+) is an autosomal dominant syndrome with variable expressivity and incomplete penetrance. To date mutations causing GEFS+ have been identified in four genes encoding sodium channel subunits, *SCN1A, SCN1B, SCN2A*, and *SCN9A* and two genes encoding GABA receptor subunits, *GABRD* and *GABRG2*. In addition, linkage studies have implicated seven other genomic regions. Using linkage analysis in 15 subjects from a large family with GEFS+, Poduri et al. (2009) obtained a maximum lod score of 4.68 at *D6S1706* (between *NUS1* and *SLC35F1*) and identified an ~ 18.1 Mb shared haplotype on 6q16.3q22.31 in affected family members, defining a novel GEFS+ locus. Of note, this interval does not contain either ion channel or GABA receptor genes; no mutations were found in 16 candidate genes in this interval, including *NUS1* and *SLC35F1*. Rosenfeld et al. (2012) reported five individuals with seizures and deletions involving 6q22 and narrowed the critical epilepsy region to ~5 Mb on 6q22.1q22.31. We present six additional patients with deletions overlapping this region, two of whom manifested seizures, patients 3 and 4. Patient 1 is a 7–year-old boy with autistic spectrum disorder in whom we identified an ~ 1.6 Mb deletion in 6q22.2q22.31. Patient 2 is a 6–year-old boy with developmental delay (DD) with an ~ 5.5 Mb *de novo* deletion in 6q21q22.2. Patient 3 is a 12–year-old girl with moderate DD and epilepsy and an ~ 318 kb *de novo* deletion. Patient 4 is an 11–year-old girl with epilepsy and an ~ 247 kb *de novo* deletion in the overlapping region. Patient 5 is an 8–year-old boy with DD and an ~2.9 Mb *de novo* deletion in 6q22.1q22.31. Patient 6 is a 4–month-old boy with a congenital heart defect and DD who had an ~168 kb deletion entirely within *SLC35F1*; he carried additional, clinically significant copy number changes. We sequenced deletion breakpoints in patients 1–4 and narrowed the critical region to ~ 180 kb between *NUS1* and *SLC35F1* on 6q22.1q22.31. This region includes two ESTs, bearing no similarity to any known gene, and a Piwi-interacting RNA (piRNA) gene, *piR-56963*. piRNAs form complexes with Piwi proteins and have been linked to epigenetic and post-transcriptional gene silencing. Recently, neuronal piRNAs have been implicated in the control of memory-related synaptic plasticity. We hypothesize that loss of piR-56963 or dosage alteration of *SLC35F1* or *NUS1* may contribute to GEFS+ with incomplete penetrance.

Identifying disease genes in a large highly inbred consanguineous kindred from Turkey with idiopathic generalized epilepsy. *F.N. Tuncer[1], S.A. Ugur Iseri[1], M. Calik[2], A. Iscan[3], G. Altiokka Uzun[4], U. Ozbek[1].* 1) Department of Genetics., Istanbul University Institute for Experimental Medicine, Istanbul, Turkey; 2) Department of Pediatric Neurology, Harran University, Faculty of Medicine, Sanliurfa, Turkey; 3) Department of Pediatric Neurology, Bezmialem Vakif University, Faculty of Medicine, Istanbul, Turkey; 4) Neurology Department, Istanbul University, Istanbul Faculty of Medicine, Istanbul, Turkey.

Epilepsy is a complex neurological disorder that affects 1% of the world's population. Among different forms of epilepsies, idiopathic generalized epilepsies (IGEs) are characterized by bilateral and synchronous generalized seizures in the absence of detectable brain lesions or metabolic abnormalities. Thus, the primary etiology for this disorder is believed to be genetic. The proposed study includes a large highly inbred consanguineous kindred with multiple IGE affected individuals. The ultimate aim is identifying a new epilepsy gene to help in delineating the molecular mechanisms of this disease. Physical, neurological and electroencephalography (EEG) examinations were performed on the subjects recruited with information on family history. These examinations revealed 6 affected individuals being 4 siblings and 2 cousins, who exhibit varying types of seizures including generalized tonic-clonic (GTCS), absence and simple febrile seizures. Affected members of this family along with 4 unaffected individuals were genotyped using Illumina Human HumanCytoSNP-12 BeadChip (300K). The genotype data were delineated using easyLinkage Plus software platform, where Mendelian genotyping errors were determined using PedCheck, multipoint lod scores were calculated under the assumption of autosomal recessive inheritance and haplotypes were constructed through GeneHunter. Linkage analysis was performed utilizing 4 affected sibs, their parents and healthy brother. Candidate regions were found on chromosomes 8, 9 and 16 with lod scores of 0.68, 1.20 and 1.08, respectively. Homozygosity mapping was performed on these candidate regions including the genotype of the affected cousin, which revealed partitioned homozygous regions on these chromosomes. Additionally, a 2.79 cM of homozygous region on chromosome 12 was depicted in all affected individuals along with the father and the healthy brother of the affected siblings. These preliminary results support a genetic aspect of epilepsy in this family, but needs to be further delineated using next generation sequencing to depict the gene(s) responsible for the disease. Hence, prospective work includes exome sequencing on the selected family members, as well as consultation with the family members to re-confirm the disease onset and progress.

Haplotype sharing and linkage analyses of multigenerational families with multiple sclerosis identified two chromosomal regions at 12p12.3–q12 and 16q21–q22.3. *N. Matsunami[1], J. Stevens[1], L. Baird[1], B. Otterud[1], T. Varvil[1], T. Leppert[1], J.W. Rose[2], M.F. Leppert[1].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT, USA; 2) Department of Neurology, University of Utah, Salt Lake City, UT, USA.

Multiple Sclerosis (MS) is a complex neuro-inflammatory and autoimmune disorder of the central nervous system. Various family studies have shown that MS has a strong genetic component, particularly at the HLA locus on chromosome 6p21.32. We have carried out Affymetrix Genome-Wide Human SNP array 6.0 experiments on affected and unaffected members of 19 multigenerational Utah families with MS. The number of affected individuals per family ranges from 2 to 7. Phased haplotype sharing analysis and linkage studies identified two regions of interest; 12p12.3–q12 (hLOD= 6.4) and 16q21–q22.3 (hLOD=4.5). The chromosome 12 region overlaps extensively with the previously reported region described by Vitale et al. (Human Molecular Genetics, 2002, Vol.11, No. 3, 295–300) in another multiplex MS family. The size of our shared phased haplotype regions on chr12 and 16 are 21 Mb, containing 95 genes, and 9 Mb, containing 152 genes, respectively. In order to test the hypothesis that rare functional variants in these regions may contribute to MS in these families, we used a custom targeted-enrichment approach to selectively capture exon and promoter regions (Agilent SureSelect) and subsequently sequenced 25 individuals from 11 families that supported chr12 and 16 linkages on an Illumina HiSeq instrument. Reference sequence alignment was carried out using BWA (Li H & Durbin R, 2010) and Novoalign (www.novocraft.com). Variant annotation, classification, and prioritization were carried out using ANNOVAR (Wang K, Li M, & Hakonarson H, 2010), VAAST (Yandell M et al., 2011) and the DNA-Seq Analysis Package of Golden Helix SNP & Variation Suite (SVS, Golden Helix Inc.). We are now in the process of molecular validation of putative functional variants. Following molecular validation, we intend to compare findings with gene functions relevant to the MS pathophysiology.

2398T

Homozygosity Mapping and Exome sequencing Identifies a Gene on 11q24.2 for non-syndromic autosomal recessive intellectual disability (NS-ARID) in a Pakistani family. *MA. Rafiq[1], IA. Balouch[1,2], K. Mittal[1], A. Mikhailov[1], M. Ayub[3], P. John[2], JB. Vincent[1,4].* 1) Molecular Neuropsychiatry, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Atta-ur-Rehman School of Applied Biosciences (ASAB), National University of Sciences and Technology (NUST), H-12 Sector, Islamabad-Pakistan; 3) Tees, Esk and Wear Valleys NHS Foundation Trust United Kingdom; 4) Dept. of Psychiatry, University of Toronto, Toronto, Ontario, Canada.

Intellectual disability (ID), or mental retardation (MR), is a neurodevelopmental disorder that has a huge impact on the health care system. Here we report a study on non-syndromic autosomal recessive intellectual disability (NS-ARID) in a consanguineous Pakistani family. Two affected and one unaffected members of a family were genotyped using Affymetrix 500K single-nucleotide polymorphism (SNP) microarrays. Analysis of microarray data identified three genomic regions (11q24.1–q25, 14q11.2 and 17q24.2–q24.3) that were homozygous-by-descent (HBD) in both affected individuals. All family members (2 affected and 6 unaffected) were genotyped by using highly polymorphic microsatellite markers present in three regions of HBD discovered by microarray analysis. By using this approach we were able to exclude HBD for the 14q11.2 and 17q24.2–q24.3 regions. Using whole exome sequence capture followed by next generation sequencing on the SOLiD 4, we identified a homozygous splice donor site G>A mutation in both affected individuals in a gene on 11q24.2. Sequencing of cDNA from both affected individuals revealed a new splice site 44 nucleotide downstream in the intronic region. Consequently, 15 extra amino acids are added to the protein, and are predicted to disrupt crucial protein function. Studies to measure the effect of mutation on protein activity are being conducted.

2399F

Investigation of inherited copy number variations in extended Asperger syndrome families. *M. Rossi[1,2], K. Rehnström[3], O. Pietiläinen[1,3], V. Leppä[1], T. Hiekkalinna[2], T. Nieminen-von Wendt[4], J. Barrett[3], I. Hovatta[1,5,6], S. Ripatti[1], A. Palotie[1,3].* 1) Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland; 2) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 3) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 4) Unit of Child Neurology, Hospital for Children and Adolescents, Helsinki, Finland; 5) Research Program of Molecular Neurology, University of Helsinki, Helsinki, Finland; 6) Department of Medical Genetics, University of Helsinki, Helsinki, Finland.

Background: Asperger syndrome (AS) belongs to the Autism spectrum disorders (ASDs). AS is characterized by impairments in social interaction and communication, and restricted interests and activities but lacks major cognitive deficiencies. Prevalence estimates for AS vary between 2.5–2.9/1000. Rare copy number variants (CNVs) have emerged as a potential genetic factor for several neurodevelopmental disorders. Low frequency and family specific CNVs have been shown to be involved in ASDs. Our aim was to analyze large multigenerational AS families for inherited CNVs that may have incomplete penetrance and moderate to strong influence on AS predisposition. Materials and methods: We genotyped 177 individuals (naffected= 125) from 24 AS families using Illumina HumanOmni1–Quad BeadChip and Illumina HumanHap550 BeadChip. As controls, we used a set of 6125 population samples genotyped with Illumina 670K BeadChip. First, we analyzed the families for linked loci using a non-parametric multipoint linkage (NPL) analysis (MERLIN). We searched these family specific identical-by-descent (IBD) shared genomic regions for CNVs segregating with AS phenotype. CNVs were called using QuantiSNP and PennCNV. Results: We assumed incomplete penetrance and included CNVs segregating to all except one affected individuals within each family. We identified three intronic deletions in genes XPR1 (4.7kb), MRPL44 (5.5kb) and MIPOL1, and one intergenic 5.5kb duplication on chromosome 6q27. All CNVs were found in separate families except MIPOL1 deletion and intergenic duplication in the same family. Conclusions: We identified four inherited structural variants that may be involved in AS etiology. These CNVs overlap with three genes that have no previously known function related to AS. XPR1 is a retroviral virus receptor and MIPOL1 has been associated with mirror-image polydactyly. MRPL44 encodes for mitochondrial ribosomal proteins and has been linked to mitochondrial cardiomyopathy. Moreover, there are family specific CNVs at several previously identified ASD candidate loci, such as 15q11–13. Unlike previous reports for example in infantile autism, we did not observe a burden of large CNVs in AS. Our findings imply that, together with other genetic factors, rare, heritable CNVs may have a role in AS etiology.

Gene analysis of familial and sporadic amyotrophic lateral sclerosis (ALS) in Kyushu island of Japan. *H. Furuya[1], A. Watanabe[1], H. Arahata[1], Y. Kawano[1], N. Fujii[1], H. Kikuchi[2], T. Fujiwara[3], T. Hokonohara[3], A. Iwaki[3], H. Shibata[3], Y. Fukumaki[3].* 1) Department of Neurology, National Omuta Hospital, Omuta, Fukuoka, Japan; 2) Murakami Karindo Hospital, Fukuoka 812–2161, Japan; 3) Division of Human Molecular Genetics, Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka 812–8582, Japan.

Objective: We analyzed reported causative genes for unrelated familial and sporadic amyotrophic lateral sclerosis (ALS) patients in Kyushu island, a western part of Japan. Background: ALS is a fatal neurodegenerative disease characterized clinically by progressive paralysis leading to death from respiratory failure. The morbidity prevalence rate of ALS is 5–6/100,000 and there are currently no effective therapies. Approximately 5% of cases are familial in nature, whereas the bulk of patients diagnosed with the disease are classified as sporadic. To date, a number of genes have been discovered as causative for classical familial ALS, such as *SOD1, TDP-43, FUS, CHMP2B*, and *OPTN*, and these genes cumulatively account for less than 25% of familial cases. To reveal the hidden familial cases and causative genes of ALS patients, we conducted gene analysis of clinically diagnosed ALS patients. Methods: We screened mutations of four causative genes (*SOD1, TDP-43, FUS, CHMP2B*) in probands of two ALS families and 85 sporadic cases, by the direct sequencing method. Results: We found a known missense mutation (R521C) in *FUS* of one ALS family and a novel *FUS* mutation (H517P) in another ALS family. In sporadic cases, one missense mutation (R521H) in *FUS*, one know missense *SOD1* mutation (C146R) were found. Conclusions: We found two *FUS* missense mutations in familial ALS. Out of 85 sporadic cases, two missense mutations (2.4%) in known ALS related genes were found. These results suggest that there is more heterogeneity of gene mutations in sporadic ALS cases in Kyushu island, than we have expected previously.

2401T

Replication and generalization of genetic risk factors for depression, anxiety and panic attack in a population-based cohort with African, European and Mexican ancestries. *J.N. Vega, K. Brown-Gentry, D.C. Crawford, T.A. Thornton-Wells.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Anxiety and mood disorders are two of the most common psychiatric disorders, with lifetime prevalence estimates above 20% and heritability estimates of 35–50%, despite clear environmental stressors and risk factors. Many functional candidate genes have been implicated in anxiety, stress and mood; however, investigation within non-European populations is incomplete. As part of the Epidemiologic Architecture for Genes Linked to Environment (EAGLE), we conducted an association study of previously-reported genetic risk variants for anxiety or depression in the ethnically diverse population-based cohort, the National Health and Nutrition Examination Survey (NHANES) ascertained and maintained by the Centers for Disease Control and Prevention (CDC). For this study, we accessed NHANES 1999–2002, which includes psychological survey data for 596 non-Hispanic whites (NHWs), 231 non-Hispanic blacks (NHBs), and 354 Mexican Americans (MAs). We selected 35 SNPs in 23 candidate genes previously implicated in anxiety, mood or personality disorders or the hypothalamic-pituitary-adrenal (HPA) axis. We performed genotyping using the Sequenom and Taqman OpenArray platforms and tested for association using logistic regression with an additive allelic model. The G allele of rs6269 in COMT was associated with decreased anxiety in MAs (OR=0.447, CI=[0.262–0.763], p= 0.0031), consistent with previous reports that the G allele is associated with higher COMT activity and lower pain sensitivity. The T allele of rs6999100 in TRIM55, downstream of CRH, was associated with decreased rates of anxiety in non-Hispanic whites (OR=0.633, CI=[0.426–0.941], p=0.0236), consistent with a previous report that the T allele is under-transmitted to individuals with behavioral inhibition to the unfamiliar, with is an intermediate phenotype and risk factor for panic disorder and social phobia. The T allele of rs4570625 in the upstream regulatory region of TPH was associated with decreased rates of depression in non-Hispanic blacks (OR = 0.453, CI = [0.234–0.876], p = 0.0187), in contrast to previous reports in Caucasians that the T allele is associated with amygdala responsivity, panic disorder, anxiety-related disorders and affective disorders. Despite being underpowered, we were able to replicate and characterize genetic associations for anxiety, depression and panic attack. Larger, diverse studies are required to characterize other associations with small genetic effect sizes.

GENOME-WIDE GENETIC STUDIES OF TWO CONSANGUINEOUS PAKISTANI MULTIPLEX PEDIGREES WITH SCHIZOPHRENIA AND BIPOLAR DISORDER. *L. Xiong[1,2,3], S. Zhou[3], M. Christian[3,4], S. Provost[5], G. Asselin[5], M.Q. Brohi[6], M. Denton[7], R. Joober[8], L.E. DeLisi[9], G.A. Rouleau[10].* 1) Dept. of Psychiatry, University of Montreal, Montreal, Quebec, Canada; 2) Centre de recherche Fernand-Seguin, Hôpital Louis H. Lafontaine, Montreal, Quebec, Canada; 3) University of Montreal Hospital Research Centre, Montreal, Quebec, Canada; 4) Department of Zoology, University of Sindh Jamshoro, Sindh, Pakistan; 5) Montreal Heart Institute, University of Montreal, Montreal, Quebec, Canada; 6) Sir Cowasjee Jehangir Institute of Psychiatry, Sindh, Pakistan; 7) Department of Biochemistry, University of Otago, Australia; 8) Montreal Douglas Hospital, Department of Psychiatry, McGill University, Montreal, Quebec, Canada; 9) Department of Psychiatry, Harvard Medical School, Boston, MA, USA; 10) Ste-Justine Hospital Research Center, University of Montreal, Montreal, Quebec, Canada.

Background: Pakistan has the highest rate of endogamous/consanguineous marriage in the world. The potential influence of such a long history of consanguineous unions on overall levels of homozygosity genome-wide and on genetic disease profiles remains largely under-investigated, especially for more common and complex diseases. In the past few years, with the cooperation from local clinicians, we have identified and characterized some large multiplex pedigrees aggregated with schizophrenia (SCZ), schizoaffective disorder (SAF) and bipolar disorder (BPD) from Sindh, Pakistan. **Methods:** Full family studies were carried out in the field and at local clinics by the local geneticist, psychiatrist, and psychologist; and further validated by two independent psychiatrists. Standard clinical instruments, i.e. DIGS/FIGS, were used in each participating individual. A high density SNP array genome scan was performed in two selected SCZ and BPD pedigree, respectively. Parametric and nonparametric linkage analyses were carried out on these two pedigrees separately and jointly using selected SNPs genome-wide. Whole exome sequencing was also performed in all affected individuals from these two selected pedigrees. **Results:** Data analysis has first excluded potential disease-associated common cytogenetic abnormality and copy number variant (CNV) in each pedigree. Joint SIMWALK multipoint linkage analysis under an autosomal dominant model in these two pedigrees identified three regions with LOD scores above 3.0, one region on chromosome 2 (LOD-1 interval 17 cM), and two on chromosome 11 (LOD-1 intervals: 2.6 cM and 5.6 cM); one of the two pedigrees produced maxLOD score of 3.35 at the chromosome 2 locus. Both loci were further supported by NPL statistics. Further haplotype sharing analyses with more informative microsatellite markers from these two candidate regions in these two pedigrees have identified major shared haplotype(s) within each pedigree. These results strongly support high risk genetic variant(s) in these pedigrees. Combined exome sequencing data analyses are underway. **Discussion:** Preliminary linkage analyses strongly suggest major gene effect in these two large consanguineous pedigrees aggregated with SCZ and BPD, with potential candidate regions identified, harbouring high-penetrant risk variants.

2403W

A comprehensive genotype-phenotype study for *CHRNA7* and *CHRFAM7A* in autism and intellectual disability. *J. Ge[1], C.P. Schaaf[1], B. Zhang[1], A.L. Hall[1], M. Ali[1], S. Tinschert[2], U. Moog[3], A. Patel[1], P. Stankiewicz[1], A.L. Beaudet[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) University of Dresden, Germany; 3) University of Heidelberg, Germany.

Deletions and duplications of chromosome 15q13.3 have been associated with autism, schizophrenia, epilepsy, ADHD and intellectual disability. The most likely candidate gene within this region is *CHRNA7*, encoding the α-7 neuronal nicotinic acetylcholine receptor which functions as a ligand gated ion channel at neuronal synapses. Studies of *CHRNA7* are complicated by a chimeric gene *CHRFAM7A*, a fusion of the last 6 exons of *CHRNA7* and exons D through A of *FAM7A*, which is expressed in human brain and elsewhere in the body. A small duplication of*CHRNA7* with uncertain phenotypic effect occurs in about 1 in 185 individuals. *CHRFAM7A* is present as 0, 1, or 2 copies per chromosome and commonly has a 2–bp deletion in exon 6. CHRFAM7A is reported to have a dominant negative effect on CHRNA7. Complete genotyping for the *CHRNA7* cluster requires detailed copy number analysis for all segments, determination of the 2–bp deletion, and sequencing of all coding regions distinguishing *CHRNA7* and *CHRFAM7A* by analysis of cDNA or genomic DNA with long-range PCR. BP4 BP5 inversions occur and may affect CHRNA7 function. We have performed extensive genotyping and are expanding the analysis for 50 Bp4 Bp5 deletion, 25 duplication, 8 *CHRNA7* deletion and 177 *CHRNA7* duplication families with penetrant and nonpenetrant members detected in the CLIA lab, for three families with homozygous deletion of *CHRNA7*, one family with *CHRNA7*triplication, and for ~500 Simons Simplex autism trios, ~200 NIMH schizophrenia plus epilepsy cases, and ~600 NIMH normal controls.

Genetic variant of AKT1 and AKTIP associated with risk for late-onset depression in a Brazilian population. *P. Pereira[1], M. Romano-Silva[1], M. Bicalho[1,2], E. Moraes[2], L. Malloy-Diniz[1,2], R. Nicolato[1], G. Pimenta[1], M. Mello[1], I. Bozzi[1], D. Miranda[1].* 1) UFMG, Belo Horizonte, Minas Gerais, Brazil; 2) Centro Jenny Faria de Assistência à Saúde do Idoso e da Mulher, Hospital das Clínicas, Universidade Federal de Minas Gerais (UFMG), Brazil.

Major depressive disorder (MDD) is one of the most prevalent and costly neuropsychiatric diseases. DSM-IV defines late-onset depression (LOD) as a disorder that starts after or at the age of 65 years old. Several lines of evidence have suggested that gene-gene interactions may confer susceptibility to MDD. The serine/threonine protein kinase protein B (PKB), also known as Akt1, is a downstream enzyme that has been implicated in the pathogenesis of neurotransmitter-related disorders, such as depression. The PI3K/AKT/GSK3b pathway is involved in neuronal survival, plasticity and also neurogenesis. The identification of a novel AKT1– binding protein (AKTIP) was pointed to as an important new target for investigation. AKTIP binds directly to AKT1, enhancing the phosphorylation of regulatory sites and this modulation are affected by Akt1 activation. The association of AKT1 and AKTIP polymorphisms with depressive symptoms was not investigated in late-onset depression (LOD). The aim of the present study was to examine the association between polymorphisms in the AKT1 and AKTIP genes and late-onset depression (LOD) in the Brazilian population. We genotyped nine tagSNPs in the AKT1/AKTIP genes in 188 outpatients with LOD and 79 healthy individuals from the control group. The participants were evaluated using DSM-IV criteria, MINI-PLUS and the Geriatric Depression Scale (GDS). Our findings suggested an association between the tagSNP rs3730358 homozygous A/A (p= 0.006) and risk for LOD. A strong association of allele A and increased risk for LOD was demonstrated for the tagSNP rs3730358 (p-value= 0.003). Our study is the first one to establish the association of the AKT1/AKTIP gene and late onset depression and further studies are necessary to clarify the functional role of these proteins.

Whole genome gene expression analysis of patients with 22q11 Deletion Syndrome and controls. *K.K Mantripragada, S. Chawner, M.B van den Bree, R.G Thomas, L. Bates, M.J Owen, N.M Wiliams.* Institute of Psychological Medicine and Clinical Neurosciences, School of Medicine, Cardiff University, Cardiff, United Kingdom CF14 4XN.

The 22q11 Deletion Syndrome (22q11DS), also known as Velo-Cardio-Facial Syndrome(VCFS), has a variable constellation of phenotypes including cardiac malformations, dysmorphology and high prevalence of psychiatric diseases, including schizophrenia. Genes located within the 22q11 deleted region have been suggested to alter the expression of several genes involved in maturation and development of neurons and neurotransmission. Using Illumina HumanHT-12 v4 Expression BeadChip system, we investigated genome-wide gene expression of lymphoblastoid cell lines (LCLs) from 17 individuals including 7 VCFS patients with schizophrenia, 7 VCFS patients without schizophrenia and 3 non-affected parents of VCFS individuals. We analysed gene expression across the genome with special attention to 22q11 genes to examine whether haploinsufficiency of 22q11 genes influenced functional genetic networks relevant to schizophrenia. Our preliminary data from VCFS individuals shows that 17% of the genes display altered expression (p value <0.05) between the schizophrenia and non-schizophrenia patients. Pathway analysis suggests that these genes are significantly enriched in 20 pathways. These pathways fall into three themes: embryonic brain development, immune response signalling and protection and recovery to brain damage. This pilot study substantiates previous reports which support 22q11 deletion syndrome as a research model for schizophrenia. This indicates that deletion of 22q11 region in conjunction with other genetic factors is relevant in schizophrenia. These are preliminary findings and are limited by small sample numbers. Further analysis using extensive sample numbers is required to implicate specific pathways in schizophrenia.

2406W

Fine-mapping of a region of interest in an extended family with multiple cases of autism. *N.H. Chapman[1], K. Ankeman[1], R. Bernier[1], A. Estes[1], J. Munson[1], Z. Brkanac[1], W. Raskind[1], H. Coon[2], E.M. Wijsman[1].* 1) University of Washington, Seattle, WA; 2) University of Utah, Salt Lake City, UT.

We describe a genome scan and follow-up of autism in a single large family, made up of 47 people in 4 generations, with 11 affected people and 10 unaffected siblings of affected people. STR genotypes are available on 45 individuals, and dense SNP genotypes are available on 42.

An initial single-marker genome scan using STR-based parametric linkage analysis identified several regions with suggestive lod scores(>1.0). One of these was consistently larger than the others, and was robust to details of the parametric model. We focused on this region to explore the use of dense SNP data to refine the region of interest. Multipoint linkage analyses were done in three stages: Stage 1: using STR markers alone; Stage 2: using STRs and evenly spaced supplemental SNPs with maximum heterozygosity; and Stage 3: using STRs and carefully selected SNPs.

Due to the size of the pedigree, a Markov chain Monte Carlo (MCMC) approach was used to calculate likelihoods and lod scores. The program gl_auto, available in MORGANv3.0, was used to sample patterns of inheritance consistent with the observed marker genotypes, conditional on the pedigree structure, marker map, and marker allele frequencies. At each marker of interest, we used the program IBDgraph to sort samples into classes with equivalent inheritance patterns. Finally, at each marker we calculated likelihoods for each class, and used a weighted sum over classes as the estimated likelihood to obtain lod scores for each marker.

The results of Stage 1 identified a region of 7.2 megabases(Mb), covered by 8 STR markers spaced an average of 1.9cM apart. In Stage 2, 20 SNPs were added (avg. spacing 0.5cM), narrowing the region by more than 50% to 3.15 Mb. Finally, in Stage 3, 6 of the supplemental SNPs were replaced with others that were informative in meioses where recombination events occurred. This reduced the region of interest a further 34% to 2.1Mb. We are now evaluating variants identified in this region for plausibility as autism susceptibility alleles.

2407T

Investigation of GWAS findings in schizophrenia in a case control-and a family sample from Indonesia. *D.B. Wildenauer[1], W. Qin[1], M.D.B. Wildenauer[1], A.A.A.A. Kusumawhardani[2], B. Benyamin[3], S.G. Schwab[4], Indonesia Schizophrenia Genetics Consortium.* 1) CCRN School of Psychiatry, UWA, Claremont, Australia; 2) Dept of Psychiatry, University of Indonesia, Jakarta, Indonesia; 3) Queensland Brain Institute, University of Queensland, Brisbane, Australia; 4) University of Erlangen-Nuremberg, Erlangen, Germany.

Schizophrenia is a devastating mental disorder with onset in early adulthood, affecting not only the individual but also having severe impact on their families and on the socio-economical framework of a society. The relatively high heritability (up to 80%) suggests the presence of genetic susceptibility factors, which may be identified in large case control samples. Population specific susceptibility alleles may exist. Identification of these alleles may aid in gene identification as well as in characterization of different course and outcome in developing and developed countries. We have consecutively ascertained 1081 individuals with schizophrenia and 1111 non-psychiatric controls in five Mental State Hospitals in the area of Jakarta, Indonesia. Diagnosis was made according to the DSMIV criteria by psychiatrists, trained in the use of a structured interview (DIP) in Bahasa Indonesia translation. We used a DNA test panel with 374 SNPs from non-coding regions (Illumina) and characterized all samples in respect to DNA quality, duplications, sampling error. For assessment of ancestral background and removal of ethnical out-layers the programs STRUCTURE and EIGENSTRAT were used. In addition, we have an independent sample of 138 families from Indonesia with 2 or 3 affected siblings(318 affected, 686 individuals in total) available for family based association analysis. We investigated DNA variants located in the CUB Sushi and multiple domains 1 gene (CSMD1), chr 8p23.2, and in the HLA-region on chromosome 6p (Ripke et al; Nat Genet. 2011;43:969–76, Yue et al; Nat Genet. 2011;43:1228–31). In the case control sample, rs10503253, rs10503256 (CSMD1 gene) and rs1635, rs2142731 (MHC region) were associated with schizophrenia (p-values = 0.0097, 0.0066, 0.047 and 0.016, respectively). In addition, rs10503253 produced a p=0.027 in the family sample. Even though limited in sample size, these findings may contribute to evaluation of susceptibility loci detected in recent GWA studies and demonstrate the usefulness of relatively homogeneous samples with different ancestral background.

Association analysis of mitochondrial DNA with suicidal behavior in schizophrenia. *V. De Luca, A. Hassan, N. Hettige, C. Borlido, G. Polsinelli.* Dept Neurogenetics, Univ Toronto, Toronto, ON, Canada.

Mitochondrial dysfunction is caused by DNA mutations in the mitochondrial chromosome or the nuclear chromosomes. Patients with psychiatric illness may carry specific mitochondrial haplotypes. To date, this issue has received little attention in the literature, and mitochondrial DNA has been under-investigated in psychiatric patients. This work describes the association analysis of 42 SNPs in the mitochondrial DNA in 81 patients with diagnosis of schizophrenia who received a comprehensive assessment for suicidal behavior. Lifetime suicide attempt was ascertained with the following standardized instruments: Beck Suicide Ideation Scale and the Columbia-Suicide Severity Scale. The presence of early of trauma was assessed using the CTQ. In our sample there were 40 subjects who attempted suicide at least once in their life. The analysis of the mitochondrial SNPs showed no association with suicide attempt but the SNP T12706C showed a slight trend (p= 0.063). Mitochondrial DNA is not associated with suicide attempt in schizophrenia in this pilot sample however psychiatric disorders, including mood disorders and psychosis should be investigated for association with mitochondrial DNA in future studies.

Application of whole genome resequencing to identify the causative gene for an autosomal recessive oculopharyngodistal myopathy. *M. Taira[1], H. Ishiura[1], Y. Ichikawa[1], B. Ahsan[1], Y. Fukuda[1], J. Mitsui[1], Y. Takahashi[1], K. Higasa[2], J. Yoshimura[2], I. Nishino[3], J. Shimizu[1], S. Murayama[4], E. Uyama[5], S. Morishita[2], J. Goto[1], S. Tsuji[1].* 1) Department of Neurology, The University of Tokyo Graduate School of Medicine, Tokyo, Japan; 2) Department of Computational Biology, The University of Tokyo Graduate School of Frontier Sciences,Tokyo,Japan; 3) Department of Neuromuscular Research, National Institute of Neuroscience National Center of Neurology and Psychiatry, Tokyo, Japan; 4) Department of Geriatric Neuroscience, Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan; 5) Department of Neurology, Kumamoto Takumadai Hospital, Kumamoto, Japan.

[Purpose] Oculopharyngodistal myopathy (OPDM) is characterized by adult-onset of eye and facial muscle weakness, distal muscle weakness and atrophy, and pharyngeal involvement. Since its original description on four Japanese families, patients presenting with similar clinical phenotypes have been described in 23 families by 2011. The modes of inheritance in these families are variable and the causative genes have not been identified. We applied whole genome resequencing to identify the causative gene for an OPDM family with autosomal recessive mode of inheritance. [Methods] A patient and three unaffected siblings born to consanguineous parents were enrolled in the study. We first conducted SNP (single nucleotide polymorphism) genotyping (Affymetrix 100K chip), and parametric linkage analysis using SNP HiTLink (Y Fukuda et al, 2009) and Allegro. Whole genome resequence analysis was carried out by Illumina HiSeq2000. For exons in the candidate regions with low coverages (<= 3X), direct nucleotide sequence analysis was further conducted to identify variants in these exons. [Results] Patient is a 66–year-old male. His initial symptom was dysarthria at the age of 17. When he was 58 years old, restricted eye movement, severe paralysis of facial muscles, difficulty in swallowing, distal upper extremity and proximal-dominant lower extremity muscle weakness, and respiratory failure were noted. Expansion of the GCG repeat sequence in PABPN1 was excluded. Linkage analysis showed approximately 75.9Mb with a maximum LOD score of 1.57. Whole genome resequence analysis showed 3,661,037 single nucleotide variations and 580,832 short insertion/deletions, of which 66,466 and 54,145 were novel, respectively. Among these variants, we identified only one novel nonsynonymous variant in a gene on the candidate regions, substituting threonine for evolutionally conserved alanine. The substitution was not found in 276 Japanese healthy subjects. Mutational analysis of this gene in 6 other patients presenting with similar clinical symptoms of OPDM did not reveal any mutations. [Conclusion] We have identified a putative gene for an autosomal recessive form of OPDM. Further analysis on additional OPDM families will be needed to validate this gene as the causative gene for OPDM.

Glucocerebrosidase Mutations and Dementia with Lewy Bodies. *L. Clark[1], K. Mirzozoda[1], J.H. Lee[1,4,5], R. Mayeux[1,2,3,4,5,6], L.S. Honig[1,4,6].* 1) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY; 2) Department of Pathology and Cell Biology, Columbia University, new York, NY; 3) Center for Human Genetics, Columbia University, New York, NY; 4) Gertrude H. Sergievsky Center, Columbia University, New York, NY; 5) Department of Epidemiology, Mailman School of Public Health, Columbia University, New York, NY; 6) Department of Neurology, Columbia University, New York, NY.

Background: Mutations in the glucocerebrosidase gene (GBA) are a risk factor for clinically-diagnosed Parkinson Disease and for neuropathologically confirmed Dementia with Lewy Bodies (DLB). Our prior work showed that in 187 autopsied brains from controls and patients with DLB and Alzheimer disease (AD), carriers of GBA mutations were more likely than non-carriers to have cortical Lewy bodies regardless of AD pathology. In this study we test whether in a clinic population, GBA mutations relate to DLB. Methods: All subjects enrolled in the Columbia University Alzheimer's Disease Research Center with available DNA underwent full gene sequencing of GBA. This included 432 subjects, of whom 191 (44%) were male and 195 (45%) had dementia, 13 (3%) with clinical DLB. Results: Thirty subjects (6.9%) had 9 different GBA mutations including 8 missense and 1 silent (synonymous); 2 mutations were novel, not reported previously. The most common variants were N370S (8 subjects) and K-27R (10 subjects), and these were strongly non-randomly distributed by ethnicity: 100% (10/10) of K-27R were in non-Caucasians (6 non-Hispanic blacks, 2 Hispanic, 2 other), while 85% (17/20) of the other mutations were in Caucasians, consistent with likely African origins for K-27R, and likely Ashkenazi origin for N370S. Classifying subjects by their described mutation phenotypic effect in terms of Gaucher's disease revealed: 1 silent (I119I), 8 mild (all N370S), 3 severe (2 L444P and 1 R463C), and 18 with unknown phenotypic effect (10 K(-27)R, 5 E326K, 1 W184R, 1 V460L, 1D443N). Overall, 11/432 (2.5%) of tested subjects, or 11/30 (37%) of subjects with a GBA mutation, had mild or severe mutations. Comparison of the 30 mutation-carriers with non-carriers revealed no differences in demographics or diagnoses. However, comparing mild/severe carriers to non-carriers showed an increased risk of DLB (18.2% vs 2.7%; p= 0.04), and trends towards higher proportion of males (64% vs 43%), and higher UPDRS score (10.4±15.5 vs 7.59±12.0). Conclusions: GBA mutations occurred in 7% of subjects; the K-27R signal sequence variant is likely associated with African origin. We did not observe a significant association of GBA mutation carrier status with clinical DLB. But confining the analysis to carriers of mutations known to have a phenotypic effect in Gaucher's disease, did show an association with clinical DLB in this referral population, like that previously demonstrated for autopsy-proven DLB.

2411F

Both ISRE and GAS Interferon regulatory sequences found in chromosome 21 genes that are important in brain development and function. *A. Jagadeesh, J. Nagappa, K. Sampson, H. North, L. Gutman, P. Lenferna de la Motte, M. Sellers, I. Dhanoya, D. Elyaman, J. Husni, L.E. Maroun.* Microbiology and Immunology, St.Matthew's University School of Medicine, Grand Cayman, Cayman islands.

The interferons can cause neuropathology.The cells from a person with trisomy 21 (T21)(Down syndrome(DS))would be expected to show a 50%increase in sensitivity to interferon (IFN) based on the presence on Ch21 of 3 of the 4 main interferon receptor component genes.The expected presence of a 50%increase in IFN receptors on T21 cells has been demonstrated.However,T21 cells are excessively sensitive to IFN action in the range of 5 to 10 fold greater than their euploid counterparts.We test our hypothesis that this greater-than-expected sensitivity could be due to the presence on Ch21 of genes that are a target for IFN up regulation by using online search engines to search for IFN regulatory sequences in or close to Ch21 genes.The control site for IFN-alpha regulated genes is termed the ISRE (Interferon Stimulated Response Element). The comparable site for IFN-gamma regulated genes is termed the GAS(Gamma Activated Sequence).Our strict criteria for labeling a gene as potentially interferon regulated required contiguous homology to at least 11 of 13 or 12 of 15 bases of a known ISRE,plus complete homology to at least one known GAS sequence, all located within the gene or, just upstream of the gene transcription start site. In addition,we consider here only genes potentially involved in brain development, function or dysfunction.To date,the following four genes have been found that meet these stringent criteria (based on homology with documented ISRE/GAS sequences):**DOPEY2:** The distribution of this protein during brain development has led to the suggestion that it plays a role in DS.Sites found:ISRE:FactorB,HLA-A,GAS:FCGR1,ICAM-1.**SIM2:**SIM2is a transcription factor found in the brain regions altered in DS.Sites found:ISRE:MX1,GAS:c-fos67[in tandem with ICAM-1].**PCBP3:**PCBP3 is a splicing factor that can alter the mRNA for Tau,a suspect gene in DS. Sites found:ISRE:BF,HLA-A(present twice),Factor B, GAS:ICAM-1.**RCAN1:**RCAN1 is a regulator of calcineurin.Its aberrant expression is associated with altered neuronal vesicular trafficking.Sites found:ISRE:ISG20,GIP3,IFITM3,GAS:IRF-1.There has been no previous indication in the literature that these genes are IFN regulated. They join a group of genes on Ch21 already shown to be IFN regulated (NCAM2, mir155, MX, and CD18).Together,these genes support the possibility that the supersensitivity of Ch21 cells to the IFNs may be due to the presence on Ch21 of both IFN receptor genes and genes that are a target of IFN action.

2412W

Genome-wide SNP analysis in a large consanguineous Turkish family reveals diagnosis as Unverricht-Lundborg Disease. *U. Ozbek[1], S.A. Ugur Iseri[1], F.N. Tuncer[1], I. Karacan[1], O. Ozdemir[1], G. Altiokka Uzun[2], M. Calik[3], A. Iscan[4].* 1) Genetics Department, Istanbul University, Institute for Experimental Medicine (DETAE), Istanbul, Turkey; 2) Neurology Department, Istanbul University, Istanbul Faculty of Medicine, Istanbul, Turkey; 3) Department of Pediatric Neurology, Harran University, Faculty of Medicine,Sanliurfa, Turkey; 4) Department of Pediatric Neurology, Bezmialem Vakif University, Faculty of Medicine, Istanbul, Turkey.

Progressive myoclonic epilepsies (PMEs) are composed of a rare group of inherited neurodegenerative diseases comprising 1% of all epileptic syndromes that are characterized by myclonic, tonic-clonic seizures, progressive neurological dysfunction, dementia and ataxia. This study highlights a large inbred consanguineous family from Turkey with 6 affected sibs out of 10 having a progressive form of myoclonic epilepsy. Affected individuals have been subjected to physical, neurological and electroencephalography (EEG) examinations with consultation on family history. Examinations revealed homogenous clinical findings on all affected individuals with tonic seizures starting at age 9. Among the affected sibs, 2 daughters have been confined to wheelchair since the age of 13. The eldest son is wheelchair free, but suffers from recurrent atonic (dropping) seizures. All affected sibs exhibit mental retardation, except for the two youngest sons. EEG recordings display generalized epileptiform activity for affected individuals, which are accompanied by normal cranial magnetic resonance imaging available for 3 affected sibs. All affected and 3 unaffected members from this family were genotyped using Illumina Human HumanCytoSNP-12 BeadChip (300K). The genotype data were delineated using easyLinkage Plus software platform, where Pedcheck was used to determine Mendelian genotyping errors and GeneHunter was used both to calculate multipoint lod scores under the assumption of autosomal recessive inheritance and to construct haplotypes. Analyses revealed a locus on chromosome 21q22 with a lod score of 3.86. The linkage peak encompassed a region of 16.64 cM between rs4816712 and rs2183593. Cystatin B (CSTB) gene was found to reside under this peak and has been screened for mutations in all members of this family, since dodecamer repeat expansions in the promoter region of this gene have been ascribed to the onset of a subtype of PME; Unverricht-Lundborg Disease (ULD). PCR amplification of the first exon and 5′ UTR of this gene has marked a lower threshold copy number for the onset of ULD. Our findings enabled the accurate diagnosis of this family as ULD patients, which were initially thought to be a PME family. This finding will be used as a preventative approach for future offsprings from the mutation carriers within this family.

***CRHR2* differentially modulates anxious temperament and plasma cortisol in a rhesus macaque model of childhood anxiety.** *G.L. Fawcett[1,2], M. Raveendran[2], J.A. Oler[4,5], A.S. Fox[6,7], S.E. Shelton[4,5], N.H. Kalin[4,5,6,7], J.M. Cheverud[8], D.M. Muzny[2], R.A. Gibbs[1,2], J. Rogers[1,2,3].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Southwest National Primate Research Center, San Antonio, TX; 4) Department of Psychiatry, University of Wisconsin, Madison, WI; 5) HealthEmotions Research Institute, University of Wisconsin, Madison, WI; 6) Department of Psychology, University of Wisconsin, Madison, WI; 7) Waisman Laboratory for Brain Imaging and Behavior, University of Wisconsin, Madison, WI; 8) Department of Anatomy and Neurobiology, Washington University in St. Louis, St. Louis, MO.

Development of anxiety and depression are influenced by the corticotrophin releasing hormone (CRH) pathway. Genetic associations have been identified for clinical anxiety, depression, and suicide for *CRHR1*. Work in animal models has indicated a role for *CRHR2* in anxious temperament, although human studies provide conflicting evidence (Villafuerte, et al. 2002, Ishitobi, et al., 2012). We used a well validated rhesus macaque model to assess anxiety (n=441) by examining anxious temperament (AT), a composite phenotype including blood cortisol measurements, freezing behavior, and vocalization behavior among juveniles in response to a brief mildly stressful human intruder challenge. AT shows strong heritability, as do freezing and vocalization: freezing (h2=0.56, p=1x10–7), vocalization (h2=0.46, p=5x10–6), and AT (h2=0.50, p=1.8x10–6). Cortisol heritability was low but nearly significant (h2=0.11, p=0.06). We analyzed each of these traits using multiple regression analyses performed in SOLAR and using 48 LD-adjusted SNPs identified by exon and putative promoter targeted re-sequencing. For AT, we identified strong association of one non-synonymous SNP (p=0.015 (additive, dominance-minor)) in the first exon for *CRHR2* and of a non-synonymous SNP (p= 0.005 (additive)) in the last exon for *CRHR2*. We observed a highly complex interaction of *CRHR2* SNPs influencing AT and individually with each of the three component traits that comprise AT. We identified a complicated genetic architecture comprised of multiple contributing polymorphisms, with different SNPs in *CRHR2* influencing different aspects of the composite phenotype, but the primary contributions coming from effects on vocalization and/or freezing. Two SNPs associated with AT also contributed to variation in cortisol (*SNP44874* p=0.008 (additive) and *SNP49411* p=0.034 (dominance-major)). Further work will investigate other aspects of the genetic architecture of AT and its components, as well as examine the influence of *CRHR2* on brain metabolism in the hippocampus and amygdala.

Deregulation of neuronal cytoskeleton dynamics and androgen receptor gene pathways converge to aberrant synapse modulation in autism. *K. Griesi Oliveira[1], D. Y. Sunaga[1], L. A. Cruz[1], E. Vadasz[2], M. R. Passos-Bueno[1].* 1) Department of Genetics, Biosciences Inst,Univ Sao Paulo, Sao Paulo, SP, Brazil; 2) Psychiatry Institute, School of Medicine, University of Sao Paulo, Sao Paulo, Brazil.

The identification of autism spectrum disorders (ASD) causes is hampered by their genetic heterogeneity. However, it is evident that, despite genetic heterogeneity, the different genetic alterations leading to ASD are implicated in common molecular pathways or biological processes. In this scenario, the search for differentially expressed genes (DEGs) between ASD patients and controls is a good alternative to identify the molecular etiology of such disorders. Here, we employed genome-wide expression analysis to compare the transcriptome of dental pulp stem cell (DPSC) of idiopathic autistic patients (n=7) and control samples (n=6). A significant proportion of the identified DEGs are expressed in brain (p=0.001) and are involved in mechanisms previously associated to ASD such as protein synthesis, cytoskeleton regulation, cellular adhesion and alternative splicing. Androgen receptor (AR), several of its regulated genes, and CHD8, a gene that participates in AR-mediated transcriptional regulation, have their expression increased in the ASD patients. All these mechanisms ultimately converge to regulation of synapse formation and plasticity, which then could be considered the core alteration in ASD. Based on our results we suggest the use of ASD patients' stem cells transcriptome to better understand the pathways that lead to this disorder.

2415W

Calcium Channel Genes are Associated with Autism Spectrum Disorders. *A. Lu[1], X. Dai[1], R.M. Cantor[1,2].* 1) Department of Human Genetics and Center for Neurobehavioral Genetics, UCLA, Los Angeles, CA; 2) Department of Psychiatry, David Geffen School of Medicine, UCLA, Los Angeles, CA.

Alternation of synaptic homeostasis is a plausible biological process for developing Autism Spectrum Disorder (ASD). Calcium channel genes (CCG) are fundamental to this process, and evidence implicating these genes in ASD has been accumulating. Based on this, we conducted a targeted association study using existing GWAS data and imputation methods to assess potential roles for these genes. A panel of 2,176 SNPs (703 genotyped and 1473 imputed) in 10 CCG that each encodes alpha1 subunit proteins of distinct calcium channels, was tested for association with ASD in 543 multiplex Caucasian families (1,103 trios) from the Autism Genetics Resource Exchange (AGRE) and 1,651 multiplex and simplex Caucasian families (1,678 trios) from the Autism Genome Project (AGP). IMPUTE2 and a combined reference panel from the HapMap3 and the 1,000 Genomes Project were used to increase the coverage density. Family based association was tested using the FBAT software, which controls for population stratification and accounts for the non-independence of siblings within multiplex families. The level of significance was set to provide a Bonferroni correction for the size of this panel. Associated SNPs that exhibited an interaction with sex were tested using a case/pseudocontrol approach. It is striking that two significantly associated SNPs in CACNA1C, a gene with a known mutation that results in the Timothy Syndrome a Mendelian disorder which features of ASD, were identified among others in this panel of common SNPs. These associations provide additional support for the role of common CCG variants in ASD. They also indicate that sequencing studies for rare variants in these genes in ASD families are warranted.

2416T

X-chromosomal dystonia parkinsonism syndrome: Disease-specific sequence change DSC3 of *TAF1/DYT3* multiple transcript system affects dopamine metabolism, vesicular transport, and synapse function. *U. Mueller[1], D. Nolte[1], A. Hofmann[2], J. Schultze[2], T. Herzfeld[1].* 1) Inst Human Genetics, Justus-Liebig Univ, Giessen, Germany; 2) Life and Medical Sciences (LIMES)-Center, University of Bonn, Germany.

The X-chromosomal dystonia parkinsonism syndrome (XDP) is an adult-onset movement disorder. XDP is caused by changes within the *TAF1/DYT3* multiple transcript system. This system is composed of 43 exons, including the 38 exons of *TAF1* and 5 down-stream exons (d1–d5). The 43 exons are transcribed into multiple splice variants that are composed of combinations of*TAF1* and d exons. d exons 2–4 can also be transcribed independently under the control of a specific promoter. Several disease-specific changes were found within *TAF1/DYT3*. Most are located in introns including a SVA transposon in intron 32 of *TAF1*. However, one sequence change, DSC3, is located within an exon (d4). This raises the possibility of a role of DSC3 in the pathogenesis of XDP. We tested this hypothesis in a cell system. Neuroblastoma cells were transfected with expression constructs containing DSC3 (construct d2–d4/DSC3) and wild-type exons d2–d4 (construct d2–d4/wt). Expression profiling was performed. The effect of DSC3 on overall gene expression was dramatic. Expression of 362 genes differs between cells containing d2–d4/wt and cells containing d2–d4/DSC3. Annotation clustering was performed. The three annotation categories with the highest enrichment scores were identified. Annotation cluster 1 (enrichment score 3.32) included genes related to dopamine metabolism, vesicular transport, and synapse function. Twenty-six genes related to Ca^{++} metabolism and function were assigned to annotation cluster 2 (enrichment score 2.53). Genes responsive to stress, mainly mediated by reactive oxygen species (ROS) are grouped in annotation cluster 3. DSC3 suppresses physiologic regulation of these genes by wild-type d2–d4, possibly acting as a regulatory RNA. The data shows a major role of exons d2–d4 in the regulation of genes required for normal brain function. Interference with this role by DSC3 is a likely pathological mechanism in XDP. Disturbance of dopamine function and of Ca^{++} metabolism can explain the movement disorder phenotype; loss of protection against reactive oxygen species may account for the neurodegenerative changes found in XDP.

Identification of microduplications of the *ATRX* gene in Autism Spectrum Disorders. *B.A. Oliveira[1,2,3], I.C. Conceição[1,2,3], C. Correia[1,2,3], P. Jorge[4], R. Santos[4], C. Café[5], J. Almeida[5], S. Mouga[5,8], F. Duque[5,7], G. Oliveira[5,6,7,8], A.M. Vicente[1,2,3].* 1) Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisbon, Portugal; 2) Center for Biodiversity, Functional & Integrative Genomics, Lisboa, Portugal; 3) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 4) Centro de Genética Médica Doutor Jacinto de Magalhães, Porto, Portugal; 5) Unidade Neurodesenvolvimento e Autismo, Centro de Desenvolvimento, Hospital Pediátrico (HP), Centro Hospitalar e Universitário de Coimbra (CHUC), Coimbra, Portugal; 6) Centro de Investigação e Formação Clinica do HP-CHUC, Portugal; 7) Faculdade de Medicina da Universidade de Coimbra, Portugal; 8) Instituto Biomédico de Investigação em Luz e Imagem, Faculdade de Medicina da Universidade de Coimbra, Portugal.

X-linked syndromes and ASD are two very heterogeneous neurodevelopmental conditions that often present intellectual disability (ID) and autistic behaviours in common. Mutations and duplications of the *ATRX* gene, located on Xq21.1, are associated with the alpha-thalassemia/mental retardation syndrome, X-linked (ATR-X syndrome). Most *ATRX* mutations fall in the zinc finger or helicase functional domains, suggesting a link between chromatin remodeling, DNA methylation and gene expression in neurodevelopmental processes. The role of *ATRX* in normal brain may be related to cell survival during early neuronal differentiation, and it is a regulator of alpha-globin gene expression. In 342 Portuguese ASD probands, genotyped as part of a large genomic screening carried out by the Autism Genome Project (AGP) using the Illumina Infinium1M microarray, we noted a considerable number of microduplications including the *ATRX* gene. Such Copy Number Variants (CNVs) were not present in 4964 control subjects of European ancestry with no obvious psychiatric disease history, from available databases. After CNV validation by quantitative PCR, we confirmed a large duplication including *ATRX* in 10 ASD individuals, 2 females and 8 males. The two female probands did not present ID or major dysmorphic features and the CNV was *de novo* in one patient, while the other showed maternal inheritance. In this patient we observed a skewed X-inactivation (8:92) assessed by *HUMARA*assay, not present in the mother or the patient with a *de novo* duplication; origin of the inactivated *ATRX* allele is under study. The duplication in these female patients involved additional genes (*COX7B, PGAM4, MAGT1, TAF9B, ATP7A and PGK1*). In the eight male patients the duplication was much smaller, including only part of the *ATRX* gene, and was *de novo* in five subjects. The clinical presentation of the male patients was heterogeneous, with two individuals with moderate ID, and one showing dysmorphologies not characteristic of the classical ATR-X syndrome. A haematological phenotype is not obvious in any of the 10 patients, but manifestations of alpha-thalassemia may be subtle in individuals with *ATRX* mutations or structural alterations, and the presence of inclusion bodies was not assessed. Our data evidence microduplications of the *ATRX* gene as a likely etiology for ASD in approximately 3% of cases, thus broadening the clinical spectrum of known genetic alterations associated with the disease.

Alanyl-tRNA synthetase mutation in dominant distal hereditary motor neuropathy and Charcot-Marie-Tooth disease. *H. Takashima[1], A. Hashiguchi[1], J. Hu[2], Z. Zhao[1, 2], Y. Higuchi[1], Y. Sakiyama[1], S. Tokunaga[1], Y. Okamoto[1,3], A. Yoshimura[1].* 1) Dept Neurology and Geriatrics, Kagoshima Univ, Kagoshima, Japan; 2) Dept Neuromuscular disease, Third Hospital of Hebei Med Univ Shijiazhuang City, Hebei, China; 3) Dept Molecular Human Genetics Baylor college of Medicine, Houston, TX.

<Objective> Distal hereditary motor neuropathy (dHMN) is also known as distal spinal muscular atrophy or a variant of Charcot-Marie-Tooth disease (CMT).Four aminoacyl-tRNA synthetases (AARSs) have been implicated in CMT/dHMN. Although mutations in AARS cause axonal CMT, no published reports linking AARS mutations to the dHMN phenotype exist. To identify a new genetic cause of dHMN, which is also known as a variant of CMT.In addition, to screen the AARS mutations in dHMN and CMT patients. **Methods** We screened for the mutations of AARS gene in 450 inherited neuropathy patients. We also screened for the mutations of 28 CMT or related pathogenic genes using an originally designed microarray resequencing DNA Chip. The purpose-built GeneChip CustomSeq Resequencing Array (Affymetrix, Inc., Santa Clara, CA) was designed to screen for CMT and related diseases such as spinocerebellar ataxia with axonal neuropathy, and dHMN. To confirm the mutation revealed by our DNA chip, the proband and family members underwent genetic analysis by direct sequencing. **Results and Discussion** We found a mutation c.2677G>A (p.D893N) in a Chinese family with HMN phenotype. All 4 family members considered to be clinically affected proved to have the heterozygous AARS p.D893N mutation, while none of the 4 unaffected relatives harbored this mutation. We found 2 additional mutations (2 novel mutations)in Japanese CMT patients. **Conclusion** An AARS mutation caused dHMN in a Chinese family. AARS mutations result in not only a CMT phenotype but also a dHMN phenotype. AARS mutations were rare cause in Japanese CMT patients.

Association of interleukin 6 gene polymorphisms with genetic susceptibilities to spastic tetraplegia in males: a case-control study. *Q. Xing[1,5], M. Chen[1,5], T. Li[2], S. Lin[1,5], D. Bi[2], D. Zhu[2], Q. Shang[3], C. Ma[3], Q. Li[1,5], L. He[1,5], C. Zhu[2,4].* 1) Institute of Biomedical Science, Fudan University, Shanghai 200032, China; 2) Department of Pediatrics, the Third Affiliated Hospital of Zhengzhou University, Zhengzhou 450052, China; 3) Department of Pediatrics, Zhengzhou Children's Hospital, Zhengzhou 450053, China; 4) Center for Brain Repair and Rehabilitation, Institute of Neuroscience and Physiology, University of Gothenburg, Sweden; 5) Bio-X Center, Key Laboratory for the Genetics of Developmental and Neuropsychiatric Disorders, Shanghai Jiaotong University, Shanghai 200030, China.

OBJECTIVE: To explore the genetic association between the polymorphisms of the interleukin 6 gene (IL6) and cerebral palsy (CP) in Chinese population. METHODS: A total of 542 CP patients and 483 healthy control children were recruited in this study to detect 5 single nucleotide polymorphisms (rs1800796, rs2069837, rs2066992, rs2069840 and rs10242595) in the IL6 locus. Genotyping of SNPs was performed by the MassArray platform based genotyping approach. The SHEsis program was applied to analyze the genotyping data. RESULTS: Of the 5 selected SNPs, no significant allelic and genotypic association was found between CP patients and controls. However, subgroup analysis found significantly difference in allele frequencies between spastic tetraplegia in males compared with controls at rs1800796 (OR=1.39, P=0.033, P=0.099 after SNPSpD correction) and rs2069837 (OR=1.58, P=0.012, P=0.035 after SNPSpD correction). The frequencies of the C allele of rs1800796 and the A allele of rs2069837 were greater in males with spastic tetraplegia than in controls. The two SNPs haplotype rs1800796(G) - rs2069837(G) was also associated with a decreased risk of spastic tetraplegia in males (OR=0.619, P=0.009, P=0.027 after Bonferroni correction). CONCLUSION: These data suggest that the genetic variation of the IL6 gene may influence the susceptibility to spastic tetraplegia in males and its role in cerebral palsy deserves further evaluation in a large-scale and well-designed study.

***ADCYAP1R1* genotype associates with post-traumatic stress symptoms in highly-traumatized African American females.** *L.M. Almli[1], K.B. Mercer[1,2], H. Feng[3], K.N. Conneely[3,4], B. Bradley[1], K.J. Ressler[1,2].* 1) Department of Psychiatry and Behavioral Sciences, Emory University, Atlanta, GA; 2) Howard Hughes Medical Institute, Chevy Chase, MD; 3) Department of Biostatistics and Bioinformatics, Emory University, Atlanta, GA; 4) Department of Human Genetics, Emory University, Atlanta, GA.

Pituitary adenylate cyclase-activating polypeptide (PACAP) and its receptor (PAC1) may be critical mediators of abnormal processes following psychological trauma. Our previous work (Ressler et al., 2011, *Nature*, 470, 492–497) demonstrated that a variant, rs2267735, in the gene encoding PAC1 (*ADCYAP1R1*) is associated with post-traumatic stress disorder (PTSD) in a primarily African American cohort of highly traumatized females. We sought to replicate our previous finding in a replicate sample of 1161 adult African American males and females recruited from the clinics at Grady Memorial Hospital (Atlanta, Georgia). Salivary samples were collected to obtain DNA for genetic analysis. Self-reported psychiatric measures included the PTSD symptom scale (PSS), assessing the extent of PTSD symptom severity over the prior two weeks; Traumatic Events Inventory (TEI), assessing lifetime history of traumatic events; Beck Depression Inventory (BDI), assessing depressive symptoms, and Childhood Trauma Questionnaire (CTQ), assessing three types of child abuse: sexual, physical, and emotional. Genotyping of rs2267735 was conducted using Taqman and Sequenom platforms. Linear regression models were used to test for association under an additive (allelic) model where the number of copies of the “C” allele was allowed to influence the outcome variable. We found no significant main effect for *ADCYAP1R1* genotype on PTS severity in males or females, in contrast to our previous study. However, we found a genotype by trauma interaction on PTS severity in females ($p<0.001$) but not males ($p>0.1$). Moreover, this interaction was significant in females but not males after controlling for depression severity ($p<0.05$), child abuse ($p<0.05$), and depression and child abuse together ($p<0.05$). No significant effects of genotype (or interactions) were found when modeling depression severity when covarying for PTS severity ($p>0.1$), demonstrating the specificity of this variant for PTSD symptoms. In support of our earlier findings, the current results suggest that genetic variation at the *ADCYAP1R1* locus associates with PTS symptom severity, but not depression, among highly-traumatized African American females.

EFHC2 shows female-specific association with autism. *K.M. Tsang, Y. Cheng, J.F. Quinn, L.A. Weiss.* Department of Psychiatry, UCSF, San Francisco, CA.

Individuals diagnosed with autism spectrum disorders (ASD) suffer debilitating social impairment. Weiss et al. (2007) had previously identified EFHC2 as a QTL for social cognition among subjects with Turner syndrome (45, X). These females were presumed to serve as a model for males as they possess a single X-chromosome. We decided to examine the association of this gene in males and females with known social impairment in order to confirm the proposed sex-specific model. Two datasets of autism SNP genotyping data were used. The datasets considered for this analysis had any shared individuals removed from the replication data and were then sorted into trios featuring either affected males or affected females. Within each data-subset, all SNP markers mapping to the EFHC2 region were analyzed using a Transmission Disequilibrium Test. Linkage disequilibrium of 1000 Genomes CEU population data was used to find proxies for significant SNPs, allowing us to replicate our findings across different genotyping platforms. Our results showed association specific to females affected with ASD. We found within AGRE-NIMH SNP Data (Weiss et al. 2009) that two intronic SNPs in EFHC2 are associated with ASD in females (rs1181065 P<0.0012 OR=1.9 and rs9887166 P<0.0063 OR=0.48, N=310 for both markers) but not in the males of this same study (rs1181065 P>0.5, OR=0.94 Psex difference =0.0017 and rs9887166 P>0.09, OR=0.79, Psex difference =0.0153, N=1200 for both markers). In an independent autism sample (Wang et al. 2009), genotyped on a different platform utilizing different markers, we identified proxy markers for each of the associated SNPs in our discovery sample (r^2 >0.8). These two SNPs replicated our findings with significant P-values and consistent odds ratios in females (rs287779 P<0.005 OR=1.6 and rs5953381 P<0.004 OR=0.47, N=347 for both markers) as well as our insignificant findings in males (rs287779 P>0.6 OR=0.96 Psex difference =0.0062 and rs5953381 P>0.1 OR=0.8333 Psex difference =0.0094, N=1205 for both markers). These two sets of markers direct our attention to specific regions of EFHC2 for further investigation, as the second set of SNPs show moderate to high linkage disequilibrium with SNPs identified by Weiss et al. (2007) but the first set of SNPs are independent from the reported markers for social cognition in Turner syndrome.

Ataxia with Oculomotor Apraxia Type 2 in the Canadian Aboriginal Population: Expanding the Disease Distribution. *E.R. Dola[1], J.N. Hartley[1,3], F.A. Booth[2,4], A.A. Mhanni[1,2,3].*1) Genetics and Metabolism, Winnipeg Regional Health Authority, Winnipeg, Manitoba; 2) Department of Pediatrics and Child Health, University of Manitoba; 3) Department of Biochemistry and Medical Genetics, University of Manitoba; 4) Section of Pediatric Neurology, Health Sciences Centre, Winnipeg, Manitoba.

Ataxia with oculomotor apraxia type 2 (AOA2) (OMIM 606002) is an inherited autosomal recessive ataxia caused by mutations in the SETX gene, encoding senataxin, a large 2677 amino acid protein belonging to the DNA/RNA helicase super family. This disease was first described in Japanese and Pakistani families as well as ten French Canadian families known as the Quebec cluster. Here we report on two siblings from a consanguineous family of Canadian Aboriginal descent who presented with progressive ataxia, oculomotor apraxia, increased serum alpha fetoprotein and atrophy of the cerebellar vermis on magnetic resonance imaging. Based on the clinical phenotype, sequencing of the SETX gene was undertaken and revealed a homozygous disease causing mutation (c.1406A>G). This mutation has been previously reported in a consanguineous family from southern Italy. This report supports a pan ethnic occurrence of AOA2, hence this condition should be considered in the differential diagnosis in individuals with ataxia regardless of their ethnicity.

Lamin B1 is a novel regulator of myelin and mediates cell-autonomous neuropathology in a murine model of autosomal dominant leukodystrophy. *M. Y. Heng, L. J. Ptacek, Y. H. Fu.* Neurology, UCSF, San Francisco, CA.

Adult-onset Autosomal Dominant Leukodystrophy (ADLD) is a progressive and fatal neurological disorder characterized by early autonomic dysfunction, cognitive impairment, pyramidal tract and cerebellar dysfunction, and white matter loss in the CNS. ADLD is caused by duplication of the LMNB1 gene with increased Lamin B1 transcripts and protein expression (Coffeen et al., 2000; Padiath and Fu, 2010; Padiath et al., 2006). How over-expression of Lamin B1 leads to myelin defects is unknown. Here, we describe a novel ADLD mouse model that advances our understanding of the pathogenetic mechanism of Lamin B1 over-expression. These mice exhibit cognitive impairment and epilepsy, followed by age-dependent motor deficits. In addition, we found that Lamin B1 is a previously unrecognized regulator of the highly abundant myelin protein, PLP, through interaction with the transcription factor YY1. Mice selectively overexpressing Lamin B1 in oligodendrocytes exhibit marked motor deficits and myelin defects. These studies identify a mechanism by which Lamin B1 overexpression mediates oligodendrocyte cell-autonomous neuropathology in ADLD and implicate Lamin B1 as an important regulator of myelin formation and maintenance during aging.

Weight loss and low serum glucose levels in Machado-Joseph disease/Spinocerebellar ataxia type 3 (MJD/SCA3). *L.B. Jardim[1, 3, 4, 6], G.N. Souza[1], A.D. Russo[1], T.L. Monte[2], R.M. Castilhos[1], A.F.S. Schuh[2, 4], K.C. Donis[1], R. D Avila[1], T.C. Gheno[4, 7], G.V. Furtado[4, 7], D.O.G. Souza[5], M.L. Saraiva-Pereira[1, 4, 5, 7], L.V.C. Portela[5], C.R.M. Rieder[2, 3], J. Dubois[5], J.A.M. Saute[1, 3].* 1) Medical Genetics Service, Hospital de Clinicas de Porto Alegre, Porto Alegre, Brazil; 2) Neurology Service, Hospital de Clinicas de Porto Alegre, Porto Alegre Brazil; 3) Post-Graduation Program in Medical Sciences, Universidade Federal do Rio Grande do Sul, Brazil; 4) Post-Graduation Program in Genetics and Molecular Biology, Universidade Federal do Rio Grande do Sul, Brazil; 5) Department of Biochemistry, Universidade Federal do Rio Grande do Sul, Brazil; 6) Department of Internal Medicine, Universidade Federal do Rio Grande do Sul, Brazil; 7) Genetic Identification Laboratory, Hospital de Clinicas de Porto Alegre, Brazil.

Machado-Joseph disease, or spinocerebellar ataxia type 3 (MJD/SCA3), caused by a CAG repeat expansion (CAGn) at ATXN3, is usually related to a pure neurological phenotype. We have recently described a low body mass index (BMI) and high insulin sensitivity in MJD/SCA3, either directly related to age at onset (AO) or to the CAGn, in this disorder. **Aims**: to study the body mass composition and fasting glucose levels (FG) (as an indirect measurement of insulin sensitivity), and to correlate them with CAGn and clinical variables of disease. **Methods**: antropometry, bio-impedanciometry and glicemic curves, as well as SARA and NESSCA scales, were performed in 44 MJD/SCA3 patients and in 41 healthy controls. **Results**: patients and controls did not differ in age and gender proportions. MJD/SCA3 patients had a m±sd of 35±10 years of AO, 5.7±2 years of disease duration, and 75±3 CAGn. The following data (m±sd) were obtained in cases and in controls: BMI of 24.3±4.3 and 27.4±6.5kg/m2 (p=0.011), lean mass of 74.3±8.5% and 71.9±8.6% (ns), basal metabolic rate (BMR) of 23.2±2.6 and 22.4±2.6cal/kg (ns), FG of 89.2±8.8 and 94.6±8.2mg/dL (p=0.005) and after an oral glucose tolerance test (GTT, 120min), of 88.3±28 and 105.6±32.6mg/dL (p=0.011). Four patients presented symptomatic hypoglycemia at GTT(with <50mg/dL). BMI was significantly correlated to CAGn (R=-0.475, p=0.001), AO (R=0.485, p=0.001), NESSCA (R=-0.35, p=0.03), but not to sub-item of NESSCA dysphagia, or to SARA. On regression analysis, the main factors determining BMI were CAGn and chronological age. On regression analysis, GTT was determined only by AO. **Discussion**: The loss of weight affects both lean and fat body masses and is detectable since the first years of disease. We have confirmed that low BMI was mainly related to CAGn. GTT levels, used to estimate insulin sensitivity, was partially related to AO. Therefore, whereas weight of loss seem to be a primary manifestation in MJD/SCA3, the increase in peripheral sensitivity to insulin rest to be explained. We speculate if they might act as modifiers of the neurological progression, in MJD/SCA3.

Spinocerebellar ataxias with hypogonadism: Unraveling a rare group of neuroendocrinologic syndromes. *C. Lourenco[1], C. Sobreira[1], V. Cintra[1], R. Giugliani[2], W. Marques, Jr.[1].*1) Neurology, Univ Sao Paulo, Ribeirao Preto, Brazil; 2) Medical Genetics Service, UFRGS, Porto Alegre, Brazil.

Background: The association between cerebellar ataxia and hypogonadism was initially described at the beginning of the XX century in four sibs by Holmes, and named after him "Gordon Holmes syndrome" (OMIM%212840). At that time, it was not possible to determine whether hypogonadism was hypogonadotropic or hypergonadotropic. Although the clinical picture may be similar, the pathogenic mechanisms involved in the two types of hypogonadism are probably different. Here, we present clinical and molecular/biochemical data on nineteen Brazilian patients with cerebellar ataxia and hypogonadism. Material and Methods: Patients were clinically evaluated at our Neurogenetics clinics . Brain MRI, ophtalmological and audiological exams, EMG/NCV studies, hormone and biochemical tests, screening for CDG, karyotype, muscle biopsy with chain respiratory enzyme assays and measurement of coenzyme Q10, molecular tests for Friedreich ataxia and for the most common forms of SCAs were performed. Results: All patients had cerebellar ataxia as the main reason for referral, with a variable age at onset, but most of them (17 out of 19) developed neurologic symptons before 20 years of age. Parents' consanguinity was present in two families; 13 patients had hypergonadotropic hypogononadism.Molecular tests for Friedreich and SCAs were normal in all patients. Optic atrophy and retinochoroidal degeneration were found in five patients; motor axonal neuropathy was present in four patients; two patients had features of lower motor neuron disease in their EMG studies. Cerebellar atrophy with pons or prominent vermis involvement was a constant feature in 16 patients; 3 patients also had leukodystrophy detected at MRI. One family with 4 affected patients have features consistent with a rare neurological disorder, Boucher-Neuhäuser syndrome ; three other unrelated patients had coenzyme Q10 deficiency detected in muscle biopsy; Congenital Disorder of Glycosylation type Ia was identified in one adult patient. The remaining patients had features that may fit in the Gordon-Holmes and Perrault phenotype (ovarian failure with deafness). Conclusions: The association between cerebellar ataxia and hypogonadism comprise hetereogenous entities and better characterize for the first time this disorder in the Brazilian population. Clinical investigation of further cases with this association may help to define the pathological basis of these fascinating neuroendocrinological syndromes.

A neuronal cellular model of 22q11.2 DS exhibits disruptions to the miRNA regulatory pathway and may increase the rate of schizophrenia in individuals with 22q11.2 DS. *W. Manley[1], M.R. Ababon[2], P.G. Matteson[2], J.H. Millonig[2], L.M. Brzustowicz[1].* 1) Department of Genetics, Rutgers University, Piscataway, New Jersey 08854–8095, USA; 2) Center for Advanced Biotechnology and Medicine, UMDNJ, Piscataway, New Jersey 08854.

Schizophrenia is a complex and poorly understood disease caused by the interplay of many environmental and genetic factors. The 22q11.2 deletion syndrome is a disorder that is caused by the microdeletion of part of chromosome 22 leading to a 25–fold greater chance of developing schizophrenia in affected individuals versus the general population. The missing 22q11.2 region contains the DGCR8 gene, which is required for the initial step of miRNA biogenesis. However, the 22q11.2 deletion itself is not sufficient to cause schizophrenia, since 75% of individuals with this deletion do not develop the disease. We hypothesize that the 22q11.2 deletion increases the risk of schizophrenia through alterations in miRNA regulatory networks via depletion of multiple miRNAs. These miRNAs may serve as a protective buffer against the accumulation of deleterious mutations at other schizophrenia risk loci. We have developed a neuronal human cellular model of disruptions to the miRNA regulatory network caused as a result of DGCR8 deficiency. The neuroblastoma cell line SH-SY5Y was transfected via electroporation with GIPZ lentiviral shRNAmir constructs specific for DGCR8 (Open Biosystems). The GIPZ constructs were prepared using PureYield Plasmid MaxiPrep System (Promega) and sequenced (GeneWiz) prior to use. For selection purposes, all constructs contained genes for GFP and puromycin resistance. The levels of DGCR8 gene expression were quantified using the 7900HT Fast Real-Time PCR System (Applied Biosystems) along with Taqman Gene Expression Assays to ensure DGCR8 reduction. We have begun to characterize disruptions to the miRNA regulatory network in this SH-SY5Y cell line transfected with the GIPZ constructs specific for DGCR8 using Taqman Array Human Microarray Cards Version 3.0. Here we present the miRNAs that we have identified to be differentially expressed in transfected cells versus untransfected control cells. We predict that these miRNAs could be involved in the elevated risk of developing schizophrenia in individuals with 22q11.2 deletion syndrome versus the general population. Future studies will focus on determining the biological targets of these miRNAs using miRNA target prediction software.

2427W

Analysis of aging phenotypes from long-term expression of the progeria mutation in the brain. *J. Baek[1], E. Schmidt[1], S. Rodriguez[1], C. Strandgren[1], B. Rozell[2], E. Mugnaini[3], M. Eriksson[1].* 1) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 2) Department of Veterinary Disease Biology, Faculty of Health and Medical Sciences, University of Copenhagen, Denmark; 3) Department of Cell Molecular Biology, Feinberg School of Medicine, Northwestern University, Chicago, USA.

Hutchinson-Gilford progeria syndrome (HGPS, also known as progeria) is an extremely rare genetic disorder characterised by an early onset of premature aging. The affected individuals display no signs of disease at birth, but within their first years of life, they gradually develop an appearance often referred to as aged-like. The most common genetic defect for progeria has been found to be a de novo heterozygote point mutation in exon 11 of the LMNA gene (c.1824C>T; p.G608G). This mutation causes an increased activation of a cryptic splice site, which in turn leads to an aberrant splice product of lamin A, called progerin or lamin AΔ50. Although extensive research has been carried out on progeria due to its potential role as a model for human aging, the focus has been mainly on the most profoundly affected tissues and organs. Interestingly, previous clinical neurological examinations of progeria patients have shown that they have no intellectual problems nor show any signs of neurological defects, which may suggest that the brain is protected from this lethal disease. Therefore, the aim of this study was to investigate the effects of long-term progerin expression by using an inducible, tissue specific transgenic mice model with expression of the most common HGPS mutation, LMNA c.1824C>T; p.G608G, in the brain. Haematoxylin and Eosin, and Fluoro-Jade C stainings were carried out in order to examine histopathological changes and the presence of neurodegeneration in the brain, respectively. In addition, immunofluorescence was carried out to determine the localisation of lamin A/C and B expression in the brain. The findings from this study are of importance as the long-term effects of progerin expression on the brain have never been investigated. Moreover, by better understanding the mechanism(s) of this premature aging, it may be possible to minimise the pathological process observed in progeria, and also to develop potential anti-aging treatments that can restore declined physiological functions associated with normal aging.

2428T

Neurodegeneration and associated phenotypes in adults with 22q11.2 deletion syndrome. *N.J. Butcher[1], T.-R. Kiehl[2], E. Chow[1 3], E. Rogaeva[4], A.E. Lang[5 6], A.S. Bassett[1 3].* 1) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Department of Pathology, University Health Network, Toronto, Ontario, Canada; 3) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 4) Department of Medicine, Centre for Research in Neurodegenerative Diseases, University of Toronto, Toronto, Ontario, Canada; 5) Toronto Western Hospital Research Institute, University Health Network, Toronto, Ontario, Canada; 6) Department of Neurology, University of Toronto, Toronto, Ontario, Canada.

Background: 22q11.2 deletion syndrome (22q11.2DS) is a multisystem genetic syndrome (~1/4000) associated with a hemizygous 22q11.2 deletion. Features of 22q11.2DS include congenital and later onset conditions, including birth defects, intellectual disability, and schizophrenia. Case reports of L-dopa responsive parkinsonism in individuals with 22q11.2 deletions indicate that neurodegenerative disease may be a late-onset feature of 22q11.2DS. The clinical and neuropathological features of neurodegenerative diseases in later adulthood in adults with 22q11.2DS remain largely uncharacterized. Methods: We assessed older adults (aged 30 to 62 years) in a well-characterized cohort of adults with 22q11.2DS for clinical (motor, cognitive, and olfactory), genetic, and neuropathological features of neurodegenerative disease. We reviewed medical and family history for diagnoses of neurodegenerative diseases. Postmortem brain tissue was investigated in five patients using immunohistochemistry for markers of neurodegenerative processes including neural degeneration and abnormal aggregates such as Lewy bodies and amyloid plaques. Results: Compared with the general population, adults with 22q11.2DS (≥50 years) had an elevated prevalence of neurodegenerative disease ($p<0.006$) that could not be attributed to familial genetic risk factors. Motor, cognitive and olfactory deficits previously associated with neurodegenerative diseases in the general population were common. Neuropathological studies of available brain tissue confirmed antemortem diagnoses of Lewy body associated Parkinson disease in two patients. Conclusions: Adults with 22q11.2DS appear to be at elevated risk of developing neurodegenerative disease in mid-adulthood. Side effects from antipsychotic medications and concomitant features of 22q11.2DS may initially mask presenting features and complicate diagnosis in some patients. Functional neuroimaging may help identify patients in asymptomatic or early stages of the disease. While clinical monitoring of adults with 22q11.2DS for neurodegenerative conditions may be indicated, further characterization of the link between Parkinson's disease and 22q11.2DS is needed to help to inform clinical management of adults with 22q11.2DS. Association of 22q11.2 deletions with Parkinson's and other neurodegenerative diseases may provide important new insights into the genetic architecture and pathogensis of these diseases.

CXCR4 (Chemokine Receptor) Expression Analysis In Chronic Cuprizone Mouse Model of Multiple Sclerosis. *G. Celikyapi[1], T. Avsar[1], G. Terzioglu[1], S. Uyar Bozkurt[2], G. Yanikkaya Demirel[3], A. Siva[4], T. Altug[5], E. Tahir Turanli[1,6].* 1) Molecular Biology and Genetics, Istanbul Technical University, Istanbul, Turkey; 2) Marmara University, Neurological Sciences Institute, Pathology Lab, Istanbul, Turkey, Basibüyük, 34840; 3) Yeditepe University, School of Medicine, Medical Microbiology Department, Istanbul, Turkey, Kayisdagi, 34755; 4) Istanbul University, Cerrahpasa School of Medicine, Neurology Department, Istanbul, Turkey, Fatih, 34098; 5) Istanbul Bilim University, Medical Biology and Genetics Department, Istanbul, Turkey, Gayrettepe, 34349; 6) Istanbul Technical University, Molecular Biology and Genetics Department, Istanbul, Turkey, Maslak 34469.

OBJECTIVE: Multiple sclerosis (MS) is a chronic, inflammatory and demyelinating disease which affects the central nervous system. Activation of CXCR4 chemokine receptor is associated with regulation of cell proliferation, migration, maturation and survival in the CNS. Cuprizone is a toxin which has been shown to cause demyelination of major myelinated tracts such as corpus callosum (CC) and cerebellar peduncles of animal models. Demyelination is followed by repair of myelin when cuprizone exposure is ended, but longer feeding periods (> 6 week) lead to chronic demyelination. This study focuses on the changes in CXCR4 expression in brain, which may enlighten the relation between CXCR4 expression and chronic demyelination. METHODS: 80 C57BL/6J mice were fed with chow including 0.2 % cuprizone for 12 weeks. Control mice fed with regular mice chow without Cuprizone. Cuprizone has been removed from the diet in the following 4 weeks. 5 mice were sacrificed biweekly, brain tissues have been obtained and RNA isolation was performed from the corpus callosum area. Expression changes of CXCR4 gene were analyzed via quantitative Real Time PCR with Gapdh and Pgk1 as internal control genes. RESULTS: CXCR4 expresion levels increased between the 3–6 week of cuprizone diet (p=0.0011), whereas it decreased between 6–12 weeks (p<0.001), and slowly increased after the 12. week compared to controls. CONCLUSION: Oligodendrocytes are known to build the myelin sheath and CXCR4 gene is directly related with maturation of Oligodencyte Progenitor Cells (OPC) to oligodendrocytes. In this study we have shown that, CXCR4 expression levels are decreasing with longer (>6week) cuprizone diet. Our results revealed that remyelination process is damaged at early stages of chronic cuprizone diet.

Increased error-related brain activity in youth with obsessive-compulsive disorder and unaffected siblings. *G. Hanna[1], M. Carrasco[2], S. Harbin[1], J. Nienhuis[1], K. Fitzgerald[1], W. Gehring[2].* 1) Dept Psychiatry, Univ Michigan, Ann Arbor, MI; 2) Dept Psychology, Univ Michigan, Ann Arbor, MI.

Background: The pathophysiology of obsessive-compulsive disorder (OCD) involves increased activity in cortico-striatal circuits connecting the anterior cingulate cortex (ACC) with other brain regions. The error-related negativity (ERN) is a negative deflection in the event-related potential following an erroneous response and is thought to reflect ACC activity. This study was done to assess the ERN as a biomarker for OCD by comparing ERN amplitudes in pediatric OCD patients, unaffected siblings of pediatric OCD patients, and healthy controls. Methods: The ERN and correct response negativity (CRN) were measured during an Eriksen flanker task to assess performance monitoring in 40 youth with a lifetime diagnosis of OCD, 19 unaffected siblings of OCD patients, and 40 unrelated healthy comparison subjects ranging in age from 10 to 17 years. ERN and CRN amplitudes were compared between groups using linear regression by the generalized estimating equation method to account for correlated data. Results: Compared to healthy controls, ERN amplitude was significantly increased in both pediatric OCD patients and unaffected siblings. There were no significant group differences in CRN amplitude. ERN amplitude in patients was unrelated to OCD symptom severity, current diagnostic status, or treatment effects. Conclusions: Increased error-related brain potentials were observed not only in pediatric OCD patients but also in unaffected siblings. The results provide evidence that enhanced error-related brain activity may serve as a biomarker for OCD in youth that is independent of the presence of clinical symptoms. The ERN may be a useful quantitative phenotype in genetic linkage and association studies of this complex trait.

Bipolarity in children with dyslexia. *C. C. Mignot[1], F. X. Coude[1,2].* 1) Centre de Pediatrie, Aix-en-Provence, paca, France; 2) Departement de Genetique,Hopital Necker,Paris,France.

OBJECTIVE:Reading impairment(Dyslexia) is a common problem at school. It is present in 8–10% of children in the general population. Learning impairment in children with dyslexia seems to overpass the consequences of reading difficulties and persisted even after partial correction of these difficulties.The purpose of our work was to determine if bipolarity might account for this gap. METHOD: Forty two children (25 males, 17 females; mean age 9.6 years, SD 1.8) diagnosed with Dyslexia were studied. Fifty control children without learning disorders were recruted in the same schools. Executive dysfunction(ED) and bipolariy disorder(BD) indexes were determined using the parental Bipolar Child Questionnaire. Learning impairment(LI) index was determined using the teacher Vanderbilt questionnaire. Leximetry was measured using the french scale of Lalouette. RESULTS: ED was significantly more frequent in children with dyslexia (10.2 vs 1.3, P<0.01) and BD was also significantly elevated in these patients (45.3 vs 20,2, P <0.01). BD and ED indexes were highly correlated. CONCLUSION: Incidence of LI at school was much more dependent upon the level of ED presented by the children than of the reading defect level. Moreover the ED Index is highly dependent of the level of the BD index which means that not only Bipolarity seems frequent in these children and may be the cause, at least partially, of the academic impairment observed at school in children with dyslexia.

Sequential processing deficit as a cognitive endophenotype in a multigenerational family with a severe speech sound disorder. *B. Peter[1], K. Chapman[2], W. Raskind[3, 4].* 1) Speech & Hearing Sci, Univ Washington, Seattle, WA; 2) Communication Sciences and Disorders, University of Utah, Salt Lake City, UT; 3) Medicine, University of Washington, Seattle, WA; 4) Psychiatry and Behavioral Sciences. University of Washington, Seattle, WA.

The purpose of this study was to investigate deficits in sequential processing as an endophenotype in severe speech sound disorder (SSD). SSD is a childhood disorder of impaired ability to acquire clearly understandable speech. A proposed subtype is childhood apraxia of speech (CAS), thought to interfere with motor programming and/or planning. Our previous studies support a genetic etiology of CAS, Mendelian inheritance, and a central deficit in sequential motor processes. Here, we investigate sequential processing deficits in domains beyond motor processing in individuals with familial CAS. Of 10 adults and 14 children from a three-generational family (age 15 months to 66 years), 3 adults and 6 children had past or present SSD. Participants completed part or all of a protocol covering articulation and phonology; tasks requiring sequential processing (alternating syllable production and key presses, imitation of multisyllabic real words, nonwords, and tongue twisters, reading nonwords), and tasks involving less sequential processing (repetitive syllable production and key presses, verbal and nonverbal cognition, sentence imitation, rapid automatic naming, reading real words). During articulation testing, two 3–year-old cousins showed CAS-like speech characterized by mis-sequenced speech sounds (e.g., “boos”/spoon, “wipseen”/swimming), vowel errors (e.g., “wawos”/flowers, “doi”/car), and unusual speech sound substitutions (e.g., “thau”/clown, “fiwee”/crying). A 6–year-old girl and a 7–year-old boy had residual speech sound errors. In all other affected individuals, single-word testing and conversational speech showed normalized speech. Consistent with previous results, deficits in alternating syllables and key presses patterned with SSD affectation. Deficits in the multisyllabic real word, nonword, and tongue twister imitation tasks were seen in all but two affected individuals and one married-in person but not in the remaining unaffected individuals. One affected adult and one affected child showed deficits in nonword reading. Conversely, only three affected individuals showed deficits in any tasks with low sequencing loads. These results are consistent with the hypothesis that sequential processing deficits underlie speech development in CAS as well as motor and linguistic abilities. Next steps are to identify the causal gene in this family with a combination of traditional linkage analysis and next-generation sequencing.

Investigation of the role of serotonin and histamine pathways in the etiology of Tourette's syndrome. *N. Sun[1,2], GA. Heiman[1], L. Deng[1], M. Sheldon[1,3], JC. Moore[1,3], AJ. Toro-Ramos[3], RP. Hart[3,4], Z. Pang[5], JA. Tischfield[1,3].* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Microbiology and Molecular Genetics Program, Rutgers University, Piscataway, NJ; 3) Rutgers University Cell & DNA Repository's NIMH Stem Cell Center, Piscataway, NJ; 4) Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, NJ; 5) Child Health Institute of New Jersey, New Brunswick, NJ.

Tourette's syndrome (TS) is a childhood onset neurodevelopmental and genetic disorder characterized by chronic motor and phonic tics. The etiology of TS is complex and believed to be a result of interactions between multiple genetic and environmental factors. Despite many years of research, identifying risk alleles has been slow. Recent studies have implicated several neurotransmission pathways in the etiology of TS including dopamine, serotonin and histamine pathways. We collected whole blood samples from all five family members of a two-generation pedigree from New Jersey Center for Tourette Syndrome Sharing Repository. We are establishing induced pluripotent stem cell (iPSC) lines from each individual's T cells. We are differentiating individual-specific iPSCs into serotonergic neurons by forced expression of certain transcription factors, for example, Ascl1, Lmx1b and Foxa2 in iPSCs, thus developing neuron-based TS models in vitro. Also, we plan to generate iPSC lines from another TS family, all TS individuals from which have W317X nonsense mutation in their L-histidine decarboxylase (*HDC*) gene. Further differentiation of *HDC* mutant family's iPSCs into histaminergic neurons will enable us to model TS in a histamine pathway-specific manner. Comparison of DNA microarray-generated gene expression patterns of neurons from controls and TS patients within both families may reveal aberrant gene expression in serotonin or histamine neurotransmission pathway in TS and this may lead to the discovery of mutant or epigenetically-modified genes involved in disease causation.

Is DS22q11.2 distal a frequent etiology of Mathematical Learning disability? *M.R.S. Carvalho[1], G.S. Vianna[1,5], L.F.S. Oliveira[2], B.C. Moreira[1], R. Sturzeneker[5], M.J.B. Aguiar[3], L. Leão[4], G. Paskulin[6], P. Zen[6], V.G. Haase[2].* 1) Departamento de Biologia Geral, ICB, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; 2) Departamento de Psicologia, FAFICH, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; 3) Departamento de Pediatria, Faculdade de Medicina, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; 4) Hospital das Clínicas, Faculdade de Medicina, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; 5) Laboratório de Diagnóstico Molecular da BIOCOD BIOTECNOLOGIA; 6) Universidade Federal de Ciências da Saúde de Porto Alegre.

Approximately 6% of the school-aged children have low math achievement (MD). Neurogenetic etiology has been suggested due to the presence of MD in some genetic syndromes such as Williams, SD22q11.2, Turner, Sotos, Silver-Russell, and in girls FMR1. MD is also prevalent among persons with fetal alcohol syndrome. Among the genetic conditions SD22q11.2 is the most common. Approximately, 90% of the patients are hemyzygous for microdeletions spanning a 3Mb chromosomal segment and almost all the remainder of the cases result from a 1.5–2 Mb microdeletion. Atypical microdeletions, larger or smaller, overlapping or not the 3Mb interval, have also been occasionally found. This chromosomal segment is prone to rearrangements due to the presence of a set of eight interspersed repeats spanning, the LCR22a-g, which favor non-allelic homologous recombination. Among 22q11.2DS children with normal intelligence, learning disability is a frequent finding with a pattern of poorer performance in arithmetical than in reading and spelling tasks. No studies have been developed in order to investigate the contribution of 22q11.2DS to MD. This is a population-based study aiming to ascertain the frequency of 22q11.2DS among school children with low Mathematical achievement with or without spelling disability. Prior to the starting, the study was approved by the Ethics in Research Committee of the University. Children were ascertained in the schools through a two step approach. Initially, all the children were submitted to a language + math screening test. Those children scoring bellow the 25 percentile in their classes, as well as normal control individuals, were invited to a second phase, which included intelligence, subtizing, reaction time, Nine-holes Peg test, Rey Complex Figure, Mini-mental state, and an evaluation of math and language functions. Presence of 22q11.2 deletions was ascertained with SALSA P250 MLPA kit and by a multiplex qPCR covering TBX1 and UFD1L genes. One out 75 subjects in MD group had an atypical deletion spanning the LCR22 D-E interval corresponding to 22q11.2 distal deletion syndrome. This deletion was not present among the control individuals. These results suggest that DS22q11.2 distal is one the most common genetic etiologies for MD. DNA methylation alterations in first-episode schizophrenia patients: comprehensive analysis using peripheral blood cells. *M. Nishioka[1, 2], M. Bundo[1], S. Koike[2], C. Kakiuchi[2], T. Araki[3], K. Kasai[2], K. Iwamoto[1].* 1) Department of Molecular Psychiatry, The University of Tokyo, Tokyo, Japan; 2) Department of Neuropsychiatry, The University of Tokyo, Tokyo, Japan; 3) Department of Youth Mental Health, The University of Tokyo, Tokyo, Japan.

Genetic studies on schizophrenia have identified promising candidate genes, but the etiology of schizophrenia was not fully elucidated. Epigenetic alterations could be an additional explanation for its pathophysiological mechanism and several groups have reported the epigenetic alternations in schizophrenia patients. We analyzed DNA methylation status in the peripheral blood cells derived from 18 first-episode schizophrenia patients and 15 healthy controls. The patients were strictly confined to those at the stage of first-episode psychosis, because we hypothesized that epigenetic alterations were different between disease stages. DNA methylation profiles on 27,578 CpG sites were assayed with the Illumina Infinium HumanMethylation27 beads array. The assayed CpG sites were located mainly on the promoter regions, covering 14,475 genes. We identified differentially methylated CpG sites in the first-episode schizophrenia patients using SAM software. We found that DNA methylation alternations preferentially occurred at inside of the CpG island. Ontology analysis revealed that they were enriched in the genes related to nuclear lumen, transcription and nucleotide binding. We also observed differential DNA methylation on the promoters of *HTR1E* and *COMTD1*, which have functional relation with the genes reported in the previous epigenetic studies. Our study suggests that first-episode schizophrenia patients have site-specific epigenetic alterations, which could have functional significance such as regulation of gene expression, in blood cells.

Clinical and molecular genetic analysis in Ullrich congenital muscular dystrophy with dominant and recessive inheritance. *B. Bozorgmehr[1], A. Kariminejad[1], S. Nafisi[2], U. Andoni[3], C. Gartioux[4], C. Ledevil[8], V. Allamand[4,5,6,7], P. Richard[8], M. Kariminejad[1].* 1) Dept Clinical Genetics, K-N Pathology & Genetics Ctr, Tehran, Iran; 2) Shariati Hospital, Tehran-Iran; 3) Hospital Marin-Paris France; 4) UPMC Univ Paris 06, IFR14, Paris, F-75013, France; 5) CNRS, UMR7215, Paris, F-75013, France; 6) Inserm, U974, Paris, F-75013, France; 7) Institut de Myologie, Paris, F-75013, France; 8) AP-HP, Groupe Hospitalier Pitié-Salpêtrière, UF Cardiogénétique et Myogénétique, Service de Biochimie Métabolique, Paris, F-75013, France.

: Ullrich congenital muscular dystrophy (UCMD) corresponds to the severe end of the clinical spectrum of neuromuscular disorders due to mutations in the genes encoding collagen VI. It is characterized by early onset proximal joint contractures, muscle weakness and hyperlaxity of distal joints. It had long been considered a recessive condition with homozygous and compound heterozygous mutations in the COL6A1, COL6A2, and COL6A3 genes. However, patients harbouring heterozygous deletions have been increasingly reported over the last years.We investigated four unrelated Iranian families with six affected children with typical Ullrich Congenital Muscular Dystrophy (UCMD). Two affected sibs carried a homozygous nonsense mutation in exon 12 of COL6A2, while the other patient harboured a large heterozygous deletion of exons 5–8 in COL6A2. The two other affected sibs had homozygote mutation in exon 24 of COL6 A2 and the last was homozygote in COL6 A1.

Epigenomes landscaped by histone H3K9me3 contribute to the pathology of Huntington's disease. *J. Shin[1], J. Lee[2,3], Y. Hwang[4], W. Lee[1], J. Wie[5], K. Kim[4], M. Lee[6], D. Hwang[6], R. Ratan[7], N. Kowall[2,3], I. So[5], J. Kim[1], H. Ryu[2,3,4].* 1) Genome Medicine Institute, Seoul National University College of Medicine, Seoul, South Korea; 2) Veteran's Affairs Boston Healthcare System, Boston, MA 02130, USA; 3) Department of Neurology and Boston University Alzheimer's Disease Center, Boston University School of Medicine, Boston, MA 02118, USA; 4) WCU Neurocytomics Group,Seoul National University College of Medicine, Seoul, South Korea; 5) Department of Physiology and Biomedical Sciences, Seoul National University College of Medicine, Seoul, South Korea; 6) School of Interdisciplinary Bioscience and Bioengineering and Department of Chemical Engineering, POSTECH, Pohang, South Korea; 7) Burke Medical Research Institute, White Plains, NY, USA.

Huntington's disease (HD) is an autosomal dominant neurodegenerative disease caused by an expanded trinucleotide CAG repeat in the gene coding for huntingtin (Htt). Deregulation of chromatin remodeling is linked to the pathogenesis of HD but the mechanism remains elusive. In order to identify what genomes are deregulated by trimethylated histone H3K9 (H3K9me3)-dependent heterochromatin, we performed H3K9me3–ChIP genome-wide sequencing combined with RNA-sequencing followed by platform integration analysis. We found that genomes involving neuronal synaptic transmission including cholinergic receptor M1 (CHRM1), cell motility, and neuronal differentiation pathways are down regulated while their promoter regions are highly occupied with H3K9me3 in HD. Moreover, we validated that CHRM1 gene repression by H3K9me3 impairs Ca2+-dependent neuronal signal transduction in HD. Thus, our data indicates that the epigenetic modifications, such as aberrant H3K9me3–dependent heterochromatin plasticity, directly contribute to the pathogenesis of HD.

2438F

Novel PRRT2 Mutation in an African-American Family with Paroxysmal Kinesigenic Dyskinesia. *M.S. LeDoux[1], J. Xiao[1], P. Hedera[2], A. Puschmann[3], D. Momc{{ak}}ilović[4], S.W. Wu[5].* 1) Neurology, University of Tennessee Health Science Center, Memphis, TN. United States; 2) Neurology, Vanderbilt University, Nashville, TN, United States; 3) Neurology, Skåne University Hospital and Department of Neurology, Lund University, Sweden; 4) Clinic for Child Neurology and Psychiatry, Medical Faculty University of Belgrade, Belgrade, Serbia; 5) Pediatrics, University of Cincinnati, Cincinnati, OH, United States.

Recently, heterozygous mutations in *PRRT2* (Chr 16p11.2) have been identified in Han Chinese, Japanese and Caucasians with paroxysmal kinesigenic dyskinesia. In previous work, a paroxysmal kinesigenic dyskinesia locus was mapped to Chr 16p11.2 - q11.2 in a multiplex African-American family. Sanger sequencing was used to analyze all four *PRRT2* exons for sequence variants in 13 probands (9 Caucasian, 1 Caucasian-Thai, 1 Vietnamese and 2 African-American) with some form of paroxysmal dyskinesia. One patient of mixed Caucasian-Thai background and one African-American family harbored the previously described hotspot mutation in *PRRT2* (c.649dupC, p.R217Pfs*8). Another African-American family was found to have a novel mutation (c.776dupG, p.E260*). Both of these variants are SNindels that arose in regions of mononucleotide repeats and are likely to cause loss-of-function via nonsense-mediated decay of mutant *PRRT2* transcripts. All affected individuals had classic paroxysmal kinesigenic dyskinesia phenotypes. In conclusion, heterozygous *PRRT2* gene mutations also cause paroxysmal kinesigenic dyskinesia in African-Americans. The c.649dupC hotspot mutation in *PRRT2* is common across racial groups.

2439W

Incomplete penetrance versus variable expressivity in del 16p11.2: analysis of cognitive performance and social functioning as quantitative rather than dichotomous traits. *A. Moreno-De-Luca[1,2], S.M. Myers[2], T.D. Challman[2], D.W. Evans[3], R.P. Goin-Kochel[4], E. Hanson[5], R. Bernier[6], L. Green Snyder[7], J.E. Spiro[8], W.K. Chung[9], J.N. Constantino[10], D.H. Ledbetter[1].* 1) Genomic Medicine Institute, Geisinger Health System, Danville, PA; 2) Department of Pediatrics, Geisinger Health System, Danville, PA; 3) Department of Psychology, Bucknell University, Lewisburg, PA; 4) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 5) Department of Psychiatry, Harvard Medical School, Boston, MA; 6) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 7) Children's Hospital Boston, Boston, MA; 8) Simons Foundation Autism Research Initiative, New York, NY; 9) Departments of Pediatrics and Medicine, Columbia University Medical Center, New York, NY; 10) Departments of Psychiatry and Pediatrics, Washington University School of Medicine, Saint Louis, MO.

The recurrent ~600 kb 16p11.2 deletion is one of the most common pathogenic copy number variants (CNVs) among individuals with neurodevelopmental disorders. It was initially identified in patients with autism and/or intellectual disability (ID) and subsequently associated with macrocephaly, obesity, and seizures. Deletion carriers show substantial clinical heterogeneity, including apparently normal individuals, the latter observation interpreted as evidence of incomplete penetrance. To evaluate the impact of this CNV on social functioning and autism features, we studied 20 individuals with *de novo* del 16p11.2 from the Simons Variation in Individuals Project and their non-carrier parents (n=40) and siblings (n=22). Within this group, only 30% (6/20) of probands met full criteria for autism using categorical diagnostic tools (ADI-R and ADOS). We also examined parent reports from the Social Responsiveness Scale (SRS), a quantitative scale that evaluates social awareness, reciprocal social communication, social information processing, and social anxiety, resulting in a T-score ranging from 30 (highly sociable) to 90 (severe social impairment). SRS scores are highly heritable, commonly unrelated to IQ, and continuously distributed in the general population. For the SRS, the mean T-score for probands was 74.5 compared to 47.1 in parents, and 44.5 in siblings. Therefore, this quantitative trait revealed a 2.7 SD shift of mean SRS scores of probands relative to unaffected intrafamilial controls ($p=6.49\times10^{-13}$). These results are very similar to those obtained using full scale intelligence quotient (FSIQ) to assess cognitive functioning in this subset of cases: only 19% met a categorical diagnostic criteria for ID (FSIQ ≤70); however, if viewed as a quantitative trait, FSIQ was 1.9 SD lower in probands compared to their parents ($p=6.72\times10^{-8}$). By using continuous, quantitative traits such as IQ and SRS scores to compare probands with their unaffected, non-carrier relatives, rather than using categorical variables such as DSM diagnoses or qualitative, dichotomous traits (i.e., normal vs. abnormal), we showed that parent-reported social behavior and cognitive function are significantly impacted in a deleterious fashion (2.7 SD on SRS and 1.9 SD on FSIQ) among children with del 16p11.2 when compared to non-carrier relatives. These data may be more consistent with variable expressivity related to genetic/family background rather than evidence of incomplete penetrance.

2440T

How to best phenotype the Broader Autism Phenotype (BAP) in Adults. *T. Nishiyama[1], H. Kishino[2], K. Okada[3], S. Sakai[4], Y. Kamio[5], M. Suzuki[6], K. Adachi[7], S. Sumi[8], M. Kojima[9], S. Suzuki[9].* 1) Clinical Trial Management Center, Nagoya City University Hospital, Nagoya, Japan; 2) Laboratory of Biometry and Bioinformatics, Graduate School of Agriculture and Life Sciences, University of Tokyo,Tokyo, Japan; 3) Department of Psychology, Senshu University, Tokyo, Japan; 4) Department of Child Development, Osaka University, United Graduate School of Child Development, Osaka, Japan; 5) Department of Child and Adolescent Mental Health, National Center of Neurology and Psychiatry, Tokyo, Japan; 6) Department of Psychiatry, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 7) Department of Psychiatric and Mental Health Nursing, Nagoya City University School of Nursing, Nagoya, Japan; 8) Department of Pediatrics, Nagoya Western Rehabilitation Center for Children with Disabilities, Nagoya, Japan; 9) Department of Public Health, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan.

Genome-wide association studies (GWAS) for SNPs and CNVs have thus far succeeded in explaining only a modest fraction of the genetic components of autism spectrum disorders (ASDs) [Mefford HC et al. 2012]. The previous GWAS for ASDs used categorical approach to diagnosis ignores the view that autistic traits are continuously distributed through the general population. If quantitative trait loci (QTL) analysis is to be a successful tool in the search for autism susceptibility genes, then an instrument that can quantify such traits, called the broader autism phenotype (BAP), are required.

So far, four self-administered questionnaires available for measuring BAP, the Autism Spectrum Quotient(AQ) [Baron-Cohen et al. 2001], the Social Responsiveness Scale—Adult Selfreport(SRS-AS) [pre-publication version of the SRS provided by Western Psychological Services], the Broad Autism Phenotype Questionnaire(BAPQ)[Hurley et al. 2007], and the Subthreshold Autism Trait Questionnaires(SATQ)[Kanne et al. 2007] have been developed. The former two contain 50 and 65 items, respectively, and thus may be too lengthy to be included in large genetic studies, whereas the latter two contain 36 and 24 items, respectively, and seem suitable to use in large studies.

Here, to provide evidence that will assist researchers in selecting an instrument for measuring the BAP in genetic studies, we firstly developed the Japanese version for questionnaires that remained undeveloped (the SRS-AS, BAPQ, and SATQ), and compared the all questionnaires for measuring BAP in terms of reliability and validity in a large sample (about 2000 healthy subjects and about 50 ASD subjects).

Based on 223 subjects currently available, all measures showed good reliability and validity. For example, Cronbach's alpha estimates and their 95% confidence intervals (CIs) are SATQ 0.84 (0.79—0.87), SRS-AS 0.95 (0.94—0.96), BAPQ 0.92 (0.89—0.93), and AQ 0.87 (0.84—0.89). As for criterion-related validity, areas under the ROC curve (AUCs) and their 95% CI are SATQ 0.98 (0.95—1.00), SRS-AS 0.98 (0.97—1.00), BAPQ 0.96 (0.91—1.000), and AQ 0.98 (0.96—1.00).This result suggests that all instruments for measuring BAP may be comparable and thus, shorter one can be a useful alternative to the lengthier one.

2441F

Executive dysfunction and bipolarity disorder in school-age children with academic impairment. *F. X. Coude[1,2], C. C. Mignot[2].* 1) Departement de Genetique, Hopital Necker, Paris, France; 2) Ctre de pediatrie, Aix-en-Provence, France.

OBJECTIVE:The study examined executive dysfunction (ED) and bipolarity disorder (BD) in school-age children (7 to 14 years) with academic impairment (AI). MATERIAL:A clinical sample of children diagnosed with academic impairment (n = 92) was compared to a population sample (n = 101) recruted in the same schools on two questionnaires, parental Bipolar Child Questionnaire and teacher Vanderbilt questionnaire. The prevalence of ED and BD in impaired and unimpaired children was examined. RESULTS:Children with AI were significantly more impaired on measures of ED than children without AI (8.6 vs 1.3, P<0.01) and BD index was also significantly elevated in these patients (45.3 vs 12.4, P<0.01). ED and AI Indexes were highly correlated and there was also a significant correlation between BD and ED in impaired patients. CONCLUSION:Children with AI displayed more problems on neuropsychological measures of ED and BP and ED measures were highly dependent of BD index. Therefore bipolarity seems frequent in children and may be an important cause of the learning impairment observed at school.

Identification of a dosage-sensitive brain development gene within the critical region of 1q deletion syndrome. *E.A. Erickson[1,2], W.A. Gahl[2], C. Boerkoel[1].* 1) NIH Undiagnosed Diseases Program Translational Laboratory, Bethesda, MD; 2) Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

Submicroscopic terminal 1q deletion results in a syndrome consisting of severe psychomotor delays, aphasia, hypotonia, microcephaly, corpus callosum abnormalities, and facial dysmorphism. Though previous studies have narrowed the critical region for this phenotype to 1q43–1q44, the deleted genes responsible for the syndrome remain unknown. A potential contributor to this syndrome is the uncharacterized gene SCCPDH, which lies within the 1q44 critical region. We chose to investigate the effects of SCCPDH deletion on early brain development in zebrafish, since their development is easily observed and manipulated. RT-PCR analysis determined that the zebrafish SCCPDH homologue is normally expressed throughout development with its highest expression during the earliest stages. The SCCPDH homologue was knocked down in zebrafish by post-fertilization embryo injection of a synthetic antisense oligomer, or morpholino (MO), designed to bind and block a splice site within SCCPDH pre-mRNA. At 24 and 48 hours post fertilization, the embryos had a dose-dependent defect in midbrain-hindbrain boundary formation and hydrocephalus, respectively. This same phenotype was observed with another MO that inhibits translation of SCCPDH transcripts. Demonstrating that the effects of the MO are specific to SCCPDH knockdown, co-injection of SCCPDH mRNA and the SCCPDH splice-site targeting MO rescued the phenotype; over 70% of the co-injected embryos were morphologically similar to the uninjected control embryos. Interestingly, the overexpression of SCCPDH mRNA alone caused cyclopia and poor brain development. These results indicate that the level of SCCPDH expression is highly regulated and that alterations beyond a threshold can result in abnormal brain development. This work suggests that SCCPDH plays an important role in early brain development and merits further investigation.

Results of genome-wide analyses on neurodevelopmental phenotypes at four-year follow-up following cardiac surgery in infancy. *D.S.K. Kim[1,2], I.B.S. Stanaway[2], R.R. Rajagopalan[1], G.W. Wernovsky[3,4], J.B. Bernbaum[5], C.B.S. Solot[6], N.B. Burnham[7], E.Z. Zackai[8], R.R.C. Clancy[9], S.C.N. Nicolson[10], M.G. Gerdes[11], D.A.N. Nickerson[2], H.H. Hakonarson[12,13], J.W.G. Gaynor[7], G.P.J. Jarvik[1,2].* 1) Department of Medicine, Division of Medical Genetics, University of Washington School of Medicine, Seattle, WA, USA; 2) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA, USA; 3) Division of Pediatric Cardiology, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 4) Division of Critical Medicine, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 5) Division of General Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 6) Center for Childhood Communication, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 7) Division of Cardiothoracic Surgery, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 8) Division of Genetics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 9) Division of Neurology, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 10) Division of Cardiothoracic Anesthesiology, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 11) Division of Psychology, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 12) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 13) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA, USA.

Background: Adverse neurodevelopmental sequelae are reported among children who undergo early cardiac surgery to repair congenital heart defects (CHD). *APOE* genotype has previously been determined to contribute to the prediction of these outcomes. Understanding further genetic causes for the development of poor neurobehavioral outcomes should enhance patient risk stratification and improve both prevention and treatment strategies.

Methods: A prospective observational study with neurodevelopmental evaluation between the fourth and fifth birthdays was performed. Attention and behavioral skills were assessed through parental report. Linear regression was performed to determine the effect of genome-wide genetic variation on neurodevelopmental measures in the fifth year of life in 316 subjects who underwent cardiac surgery before six months of age.

Results: This genome-wide association study identified single nucleotide polymorphisms (SNPs) associated with three neurobehavioral phenotypes in the postoperative children: Attention Deficit-Hyperactivity Disorder-IV (ADHD) Scale for Impulsivity/Hyperactivity, and Child Behavior Checklist (CBCL) Pervasive Developmental Problems (PDPs), and Total Problems. The most predictive SNPs for each phenotype were: a *POC5* intronic SNP, rs2303647, associated with ADHD-IV Impulsivity ($P = 7.93 \times 10^{-7}$), a *SEMA6D* intronic SNP, rs16959924, associated with CBCL/1.5–5 PDPs ($P = 4.08 \times 10^{-7}$), and a *CHL1* intronic SNP, rs2293675, associated with CBCL/1.5–5 Total Problems ($P = 8.85 \times 10^{-7}$). 15 SNPs (6 for ADHD-IV Impulsivity, 5 for CBCL/1.5–5 Total Problems, and 4 for CBCL/1.5–5 PDPs) had $p < 10^{-5}$.

Conclusions: No SNPs met genome-wide significance for our three neurobehavioral phenotypes, though 15 SNPs reached a threshold for suggestive significance ($p < 10^{-5}$). Given the unique nature of this cohort, larger studies and/or replication are not possible. Studies to further investigate the mechanisms through which these newly identified genes may influence neurodevelopment dysfunction are warranted.

Lein[1].* 1) Allen Institute for Brain Science, Seattle, WA; 2) USC, Los Angeles, CA; 3) Zilkha Neurogenetic Institute, Los Angeles, CA; 4) Massachusetts General Hospital; Harvard Medical School, Boston, MA; 5) Yale University, New Haven, CT; 6) UCLA, Los Angeles, CA; 7) NIMH, Bethesda, MD; 8) Institute for Computational Biomedicine, Weill Cornell Medical College, New York, NY.

Systematic efforts to map detailed gene expression patterns in the human brain have been lacking, particularly relating to development. To fill this void, we describe here a consortium project aimed at creating a unique multimodal transcriptional atlas of the pre- and postnatal developing human brain as a publicly accessible online resource for neuroscience, genome and medical research communities. This resource integrates transcriptomic, cellular resolution histology and imaging data in the context of human brain development through a portal for viewing, searching and mining of spatiotemporal gene expression patterns. Illumina RNA-sequencing has been used to generate quantitative transcriptome profiles of hippocampus, amygdala, thalamus, striatum, cerebellum and 11 neocortical regions, spanning early prenatal development through adulthood. This broad spatiotemporal data set is supplemented with a high anatomical resolution microarray analysis of >300 laser microdissected structures from mid-gestational prenatal human brains. Complementing the transcriptome data, a large scale in situ hybridization (ISH) data set was generated to analyze cellular distributions. Finally, de novo prenatal histological reference atlases and MRI and diffusion weighted MRI (DWI) data sets spanning human brain development are being created to provide a neuroanatomical and neurodevelopmental context for understanding spatiotemporally regulated transcriptional programs. As an initial representation of the project, here we present integrated data on the transcriptome analyses by RNA-sequencing and cellular resolution in situ hybridization of the adult human brain. The majority of protein-coding genes are well expressed in the human brain. Comprehensive profiling of microRNA and the discovery of novel transcripts are also demonstrated. Many analyzed transcripts exhibit distinct regional and cellular patterns of expression, providing a neuroanatomical context for understanding transcriptional complexity. We also identified transcripts with allele-specific expression. These public data provide valuable opportunities for relating specific transcriptional programs to processes of human brain development and a normative data set for understanding the genetic basis of neuropsychiatric disease. These data are openly available as the BrainSpan Atlas of the Developing Human Brain via the Allen Brain Atlas data portal (www.brain-map.org) or directly at www.brainspan.org.

Knockdown of putative human autism genes, SHANK3 and SYNGAP1, produces common behavioral phenotypes in zebrafish. *J.E. Dallman[1], R. Kozol[1], Q. Yan[1], H.N. Cukier[2], V. Mayo[2], A.J. Griswald[2], P.L. Whitehead[2], J.L. Haines[2], J.R. Gilbert[2], M.L. Cuccaro[2], E.R. Martin[2], M.A. Pericak-Vance[2].* 1) Biology, University of Miami, Coral Gables, FL; 2) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami FL.

Autism Spectrum Disorders (ASDs) affect about 1 in 110 children according to the Centers for Disease Control, yet the functional links between genetic mutation and behavioral changes characteristic of ASD remain unknown. ASDs are a heterogeneous collection of neuro-developmental disorders that can be caused by variations in a diverse array of genes, including transcription, translation, and synaptic proteins. Patients with ASD share three clinical features: deficits in verbal and non-verbal communication, reduced social interactions, and repetitive motor behaviors. Here, we present functional data from four zebrafish models of ASD. To generate these models, we use splice-site targeted morpholinos to disrupt zebrafish orthologs of SHANK3, a synaptic scaffolding protein, and SYNGAP1, a synaptic GTPase activating protein. SHANK3 and SYNGAP1 were chosen because of mounting evidence that mutations in these genes are causal to ASD in humans. Both SHANK3 and SYNGAP1 are duplicated in the zebrafish genome and all four of these transcripts (shank3, shank3–like, SynGAP, and SynGAP-like) are enriched in zebrafish brain over spinal cord as demonstrated by in situ hybridization. Our results identify a common developmental time period, 48–72 hours post-fertilization (corresponding to a dramatic burst of synaptogenesis throughout the nervous system), when knockdown of either duplicate of SHANK3 or SYNGAP1 causes pronounced disruptions in escape behavior, including spontaneous seizures and unproductive swim attempts. Based on gene expression patterns and morphant behaviors, we are currently testing the hypothesis that altered neuronal activity in descending brain neurons accounts for disrupted motor behaviors in these zebrafish models of ASDs.

Short tandem repeat: A versatile marker in diagnosis of genetic disorders. *S. Muthuswamy, A. Kumar, S. Agarwal.* Genetics, Sanjay Gandhi Post Graduate Inst of Medical Sciences, Lucknow, India.

Short tandem repeats are Simple sequence repeats (SSR) of 1–10bp. They are abundant and evenly distributed throughout the genome; STR is highly stable and polymorphic, they vary in length between the subjects. As well as the fact that several genetic diseases are associated with tri-nucleotide repeats such as Friedreich's ataxia, myotonic dystrophy etc. Therefore these markers are now a day's put-upon in molecular diagnosis to have rapidness in reporting and for the purpose of accuracy. The present study was aimed to provide rapid diagnosis for Down syndrome, Friedreich's ataxia and Myotonic dystrophy with STR markers associated with respective chromosome/gene. QF-PCR with 21st chromosome associated STR markers (D21S11, D21S1411 and D21S1435) are used in diagnosis of trisomy 21 and TP-PCR with primers flanking the triplet repeat of the respective gene for Friedreich's ataxia and Myotonic dystrophy. The heterogeneity of the STR markers was assessed and found suitable for the establishment of QF-PCR. We have started to provide prenatal diagnosis for Down syndrome, in our last one year experience; we tested 95 samples (40 CVS and 55 amniotic fluids) and found none of the fetus positive and results were concordant with karyotyping results. Triplet repeat primed PCR was also accurate in gene level diagnosis of Friedreich's ataxia and myotonic dystrophy, which is confirmed with short and long PCR simultaneously.

Genomic Rearrangements in Idiopathic Cerebral Palsy. *R. Segel[1,3], H. Ben-Pazi[2,3], S. Zeligson[1], A. Fattal-Valevski[4,7], A. Aran[2,3], V. Gross[2,3], N. Shneebaum[4,7], D. Shmueli[5], D. Lev[6,7], L. Blumkin[6,7], S. Perlberg[1], E. Levy-Lahad[1,3].* 1) Medical Genetics Institute, Shaare Zedek Medical center, Jerusalem, Israel; 2) Pediatric Neurology Unit, Shaare Zedek Medical Center, Jerusalem,Israel; 3) Hadassah Medical School, Hebrew University, Jerusalem, Israel; 4) Institute for Child Development and Pediatric Neurology Unit, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel; 5) Jerusalem Child Development Center, Clalit Health Services, Jerusalem,Israel; 6) Metabolic-Neurogenetic Clinic, Wolfson Medical Center, Holon; Israel; 7) Sackler Faculty of Medicine, Tel Aviv University, Ramat Aviv, Israel.

Background: Cerebral Palsy (CP) is a non-progressive motor impairment that is the most common cause of disability in childhood. The worldwide incidence of CP is 2–2.5 / 1,000 live births. While some risk factors for CP are known, the etiology remains largely obscure. We hypothesized that some idiopathic CP cases have a genetic etiology. Recent studies have shown that genomic rearrangements (GRs) have a role in a number of complex pediatric disorders, e.g. mental retardation, autism and epilepsy. The aim of this preliminary study was to assess the role of GRs in individuals with idiopathic CP, using microarray analysis. Methods: Participants were recruited from CP clinics in Israel. We enrolled individuals who were most likely to have a genetic etiology. Inclusion criteria were: 1) non progressive pyramidal or extra pyramidal symptoms beginning before the age of 3 years; 2) brain imaging not characteristic of ischemic damage: normal or with a developmental brain abnormality. Exclusion criteria were targeted at patients with acquired CP: 1) Periventricular leukomalacia (PVL) in patients born prematurely (24–34 weeks gestational age); 2) History of hypoxic ischemic encephalopathy; 3) Hemispheric lesion corresponding to an acquired lesion on imaging studies (i.e. stroke); 4) History of encephalitis or head trauma. Genomic rearrangements were tested using the Affymetrix CytoScan® HD Array and analyzed using ChAS (Affymetrix® Chromosome Analysis Suite). Rearrangements were considered potentially pathogenic if they were de novo, and not reported in databases of genomic variants (DGV). Results: We report analysis of the first 49 cases enrolled. 16/49 had genomic rearrangements: 7 de novo, 3 inherited and in 6 parental testing is ongoing. 5 samples failed. Thus, among completely analyzed cases 7/44 had de novo rearrangements. Analysis of the loci and the genes involved is ongoing, with the goal of identifying common pathways. Discussion: In this preliminary study, we found a high frequency (16%) of de novo GRs in patients with non-acquired CP. Clinically, identifying CNVs with a specific phenotype can end a long quest for diagnosis, and is important for prognosis and genetic counseling. Scientifically, elucidating the role of GRs in CP may aid in understanding CP pathogenesis and may identify specific genes and pathways important for brain development.

Gain of function Na_v 1.7 mutations in patients with small fiber neuropathy. *M.M. Gerrits[1], C.G. Faber[2], J.G.J. Hoeijmakers[2], D.M.L. Merckx[1], H.J.M. Smeets[1], S.D. Dib-Haij[4,5], S.G. Waxman[4,5], I.S.J. Merkies[2,3].* 1) Department of Clinical Genetics, Maastricht University Medical Center, Maastricht, Netherlands; 2) Department of Neurology, Maastricht University Medical Center, Maastricht, Netherlands; 3) Department of Neurology, Spaarne Hospital, Hoofddorp, The Netherlands; 4) Yale University School of Medicine, New Haven, USA; 5) Center for Neuroscience and Regeneration Research, Veterans Affairs Medical Centre, Westen Haven, USA.

Background: Small fiber neuropathy (SFN) often occurs without apparent cause. We have recently described the presence of gain-of-function variants in SCN9A, the gene encoding for the $Na_v1.7$ sodium channel, in 8 patients with idiopathic small fiber neuropathy. In this study a cohort of 165 patients with possible SFN was tested for the presence of SCN9A variants.**Methods:** Patients referred with possible SFN, who met the criteria of ≥ 2 SFN-related symptoms, a normal electromyogram, and an abnormal quantitative sensory testing (QST) and/or reduced intraepidermal nerve fiber density (IENFD) were screened for SCN9A gene variants. Electrophysiology was used to test functional effects of variant channels. **Results:** Twelve patients of the 165 patients who underwent SCN9A gene analyses were found to carry a variant in the SCN9A gene. The frequency of these variants in control populations ranged from zero to 0.9%. In each case, the variant was missense, and the patient was heterozygous for the variant. Five variants were found in more than one patient. Voltage-clamp analysis was performed for four of the variants and they all showed gain-of-function (impaired slow-inactivation, depolarized slow- and fast-inactivation, or enhanced resurgent currents). Current-clamp analysis demonstrated that these variants rendered dorsal root ganglion (DRG) neurons hyperexcitable. **Conclusion:** Missense substitutions in the SCN9A gene, encoding the $Na_v1.7$ sodium channel, are present in a substantial proportion (~7%; 12 of 165) of this cohort. Electrophysiological analysis of the variants revealed gain-of-function in the mutant channels and showed that the variants render DRG neurons hyperexcitable. This implies that SCN9A functional variants may predispose to the development of channelopathy-associated SFN. Analysis of the SCN9A gene should be considered for patients with SFN-related symptoms plus a normal electromyogram, and abnormal QST and/or reduced IENFD.

A New Screening Test for Fragile X Syndrome: Quantitative Measurement of FMRP in Dried Blood Spots. *W.T. Brown, T. Adayev, R. Kascsak, R. Kascsak, C. Dobkin, S. Nolin, G. LaFauci.* Dept Human Gen, NYS Inst Basic Res, Staten Island, NY.

Fragile X syndrome (FXS) is caused by the lack of the Fragile X Mental Retardation 1 protein (FMRP) encoded by the FMR1 gene. In most FX full mutation (FM) subjects, FMRP is not made because of transcriptional inactivation of the gene resulting from an expanded triplet CGG repeat. Early diagnosis of the syndrome is important for early intervention. The laboratory diagnosis of FXS is currently performed using DNA to determine both the length and the methylation state of the CGG repeats in FMR1. This information is then used to infer whether abnormal levels of FMRP are present. The tests often require several days, are expensive, labor intensive, and can be performed only in specialized laboratories. We developed a Luminex-based immunoassay (ELISA) for the direct detection and quantification of FMRP in human and mouse cell extracts (lymphoblastoid cells, fresh human lymphocytes, and mouse brain). FMRP is captured by reacting the samples with X-map microspheres coated with a high affinity anti-FMRP monoclonal antibody (mAb). The microsphere-mAb-FMRP complex is successively reacted with an anti-FMRP rabbit polyclonal antibody (Ab) and with an anti-rabbit-IgG Ab conjugated to phycoerythrin. The fluorescence emitted is a function of the amount of FMRP in the specimen and is detected using a Luminex-200 System. We have adapted our assay for the detection and quantification of human FMRP in Dried Blood Spots (DBS). Drops of blood are spotted onto a collection card, air-dried for few hours. Card preparation requires small blood samples that can be drawn by lancet from the finger of a patient or from the heel or toe of neonate. Furthermore, cards can be stored at room temperature in low gas-permeability plastic bags and send by regular mail to a laboratory for testing. Assays are done in 96–well-plates which allow the simultaneous processing of 40 specimens (in duplicate), and can be completed in 24 hours. Using the minute amount of proteins extracted from DBS, we can accurately quantify FMRP using as the standard a recombinant fusion protein carrying the capture and detection epitope domains of FMRP. The assay can identify male FM FX, and male mosaic FM FX from normal and from premutation (PM) individuals with sensitivity and specificity approaching 100%. Since newborn DBS screening for metabolic diseases is performed routinely, our assay offers for the first time an accurate, simple, economical and fast method to perform neonatal screening for FXS.

Disease specific pathway analysis in Multiple Sclerosis. *T. Avsar[1], M. Durasi[2], S. Saip[3], O.U. Sezerman[2], A. Siva[3], E. Tahir Turanli[1,4].* 1) Molecular Biology and Genetics, Istanbul Technical University, Istanbul, Turkey; 2) Faculty of Engineering & Natural Sciences, Biological Sciences & Bioengineering, Sabanci University; 3) Department of Neurology, Cerrahpasa School of Medicine, Istanbul University, Istanbul, Turkey; 4) Molecular Biology and Genetics Department, Science and Letter Faculty, Istanbul Technical University, Istanbul, Turkey.

Multiple sclerosis (MS) is a chronic inflammatory demyelinating disorder of the central nervous system (CNS) with various degrees of axonal damage. The aim of this study is to identify clinical subtype specific novel protein biomarkers in the CSF and serum samples of MS patients to reveal disease pathways. We compared CSF and serum samples of 35 CIS, 45 RRMS, 20 PPMS and 18 controls including healthy subjects and other neurological disease samples for novel protein biomarkers. For all samples, 2D-PAGE analysis by using different pH and molecular weight ranges were performed. At least 4 times differently expressed protein spots were identified by PDQuest® software and removed from the gel for MALDI-TOF-MS protein identification step. The results of proteomic studies were confirmed by both ELISA and western blot methods for the selected candidate proteins. Protein levels of clinically different MS subtypes were compared with control groups and with each other by using ANOVA test. Further, KEGG pathways analysis was done with genes corresponding the proteins from proteomic study in order to identify relevant disease specific molecular pathways. Proteomic studies revealed in total 73 different proteins comparing to control groups and disease subtypes. ELISA and western blot results confirmed the results for selected proteins (Transthyretin ($p<0.01$), Chain A-Alpha 1 Anti-trpsin ($p=0.039$), Apolipoprotein A4 ($p<0.01$), Apolipoprotein E ($p<0.01$) alpha 2 macroglobulin ($p=0.023$), human alpha 1 acid glycoprotein ($p=0.041$) and prostaglandin D2 synthase ($p<0.01$). Common differentially expressed proteins within each clinical subtype and in all MS cases are listed (Table-1). Finally, KEGG pathway analysis revealed statistically significant over-representation of the processes of Tryptophan metabolism, B cell receptor signaling pathway, Epithelial cell signaling in Helicobacter pylori infection. Proteomic investigation in CSF and serum samples of clinically different MS patients and controls revealed a number of proteins from different protein families that are differentially expressed in clinically different MS subtypes when compared to controls. Some are common for all disease subtypes but some are specifically expressed in only certain disease subtypes. Furthermore KEGG analysis revealed the disease related pathways indicating B cell contribution to the disease.

Diagnosing complex neurological disease by next-generation sequencing (NGS). *K. Haugarvoll[1,2], S. Johansson[3], C. Tzoulis[1,2], B.I. Haukanes[3], C. Bredrup[4], H. Boman[3], P.M. Knappskog[3], L.A. Bindoff[1,2].* 1) Dept Neurology, Haukeland Univ Hosp, Bergen, Norway; 2) Department of Clinical Medicine, University of Bergen, Norway; 3) Center for Medical Genetics and Molecular Medicine, Haukeland Univ Hosp, Bergen, Norway; 4) Department of Ophthalmology, Haukeland University Hospital, Bergen, Norway.

A correct diagnosis is pivotal to understand and treat neurological disease. Rare diseases may pose a formidable diagnostic challenge, especially when they present with a complex phenotype including clinical features that may overlap between several disorders. Herein we employ next-generation sequencing (NGS) to identify the cause of disease in two patients. The patients are siblings with a complex adult onset syndrome comprising peripheral neuropathy, epilepsy, relapsing encephalopathy, bilateral thalamic lesions on MRI, type 2 diabetes mellitus, retinal pathology and tremor. We applied clinical and genealogical investigation, homozygosity mapping and exome sequencing in order to achieve a diagnosis in these two patients. We suspected a recessive genetic defect as the cause disease in these two siblings of healthy, albeit genealogically related parents. Homozygosity mapping revealed three shared homozygous regions. Subsequently, we performed exome sequencing. Both patients were homozygous for a novel c.367G>A mutation (p.D123N) in the AMACR-gene. The genetic diagnosis of α-methylacyl-coA racemase deficiency was confirmed by demonstrating markedly increased pristanic acid levels in blood (169 µmol/L, normal <1.5 µmol/L). Revision of sequential MRI images from our patients reveals specific chronic degeneration of cerebellar afferents and efferents. A correct diagnosis of α-methylacyl-coA racemase deficiency, an autosomal recessive peroxisomal disorder with accumulation of pristanic acid, was reached utilizing NGS. Six adult patients with α-methylacyl-coA racemase deficiency have been reported to date. Importantly, patients with this disorder may benefit from restricted dietary phytanic and pristanic acid intake. This study highlights the potential role of NGS in improved diagnosis of neurological disorders.

Elevations of pro-inflammatory cytokines/chemokines in patients with Aicardi-Goutières Syndrome. *J.L. Schmidt[1, 2], A. Takanohashi[1], M. Prust[2], K.F. Gold[3], J. Wang[3], H. Gordish-Dressman[1], G. Rice[4], H. Gornall[4], M. Bloom[5], Y.J. Crow[4], P. Lebon[6], K. Nagaraju[1], A. Vanderver[1, 2].* 1) Center for Genetic Medicine Research, Children's National Medical Center, Washington, DC, USA; 2) Department of Neurology, Children's National Medical Center, Washington, DC, USA; 3) Department of Biostatistics, Children's National Medical Center, Washington, DC, USA; 4) Genetic Medicine, University of Manchester, Manchester Academic Heath Science Centre, Central Manchester University Hospitals, Manchester, UK; 5) Hospitalist Medicine Division, Children's National Medical Center, Washington, DC, USA; 6) Department of Virology, Hospital St Vincent de Paul, Paris, France.

Background: Aicardi-Goutières Syndrome (AGS) is a heritable neurologic disorder with genetic heterogeneity (TREX1, RNAseH2A, RNAseH2B, RNaseH2C and SAMHD1). Mutations in the involved genes are hypothesized to result in accumulation of endogenous nucleic acids, triggering an IFNα mediated innate immune response in the brain. Cerebrospinal fluid (CSF) elevations of interferon alpha (IFNα) and other isolated cytokines have previously been associated with AGS. However, these biomarkers are established only in CSF and are known to decrease with age. This study explores a panel of cytokines in plasma and CSF in patients at different ages, to establish signatures of cytokines and chemokines most predictive of AGS disease. Methods: Plasma from 22 subjects with mutations in TREX1, RNAseH2 or SAMHD1 were assayed for cytokines and chemokines using the MILLIPLEX™ MAP Immunobead system, and compared to results from 8 age-matched normal controls. Cerebrospinal fluid of 11 subjects with mutation proven AGS was tested in an identical manner and compared to results from, 8 age-matched controls. Results: Significant elevations were seen in a panel of 23 cytokines in AGS CSF, and in Flt-3L, IP-10, IL-12p40, IL-15, TNF and sIL-2ra in both AGS patient plasma and CSF relative to controls. Additionally, this cytokine signature was able to correctly cluster a majority of AGS cases based on CSF values. While the majority of cytokines decreased exponentially with age, a smaller subgroup, including IP-10, had persistent elevations beyond early childhood. Conclusion: AGS patients have plasma and CSF elevations of proinflammatory cytokines/chemokines such as in Flt-3L, IP-10, IL-12p40, IL-15, TNF and sIL-2ra. These proinflammatory cytokines and chemokines may be considered for use as diagnostic and therapeutic markers of disease.

2453F

Strategy for genotyping triplet repeats unstable sequences. *S. Lindo_Samanamud[1,2], O. Ortega[1], M. Cornejo-Olivas[1,3], V. Marca[1], P. Mazzetti[1,4].* 1) Neurogenetics Research Center, Instituto Nacional de Ciencias Neurologicas, Lima, Peru; 2) School of Genetics and Biotechnology, Universidad Nacional Mayor de San Marcos, Lima, Peru; 3) UW International Fogarty Scholars and Fellow's Program in Peru. Lima, Peru; 4) Shool de Medicine. Universidad Nacional Mayor de San Marcos, Lima, Peru.

Introduction In triplet repeat diseases with unstable microsatellites and a high content of cytosine, PCR is not useful because of the generation of alternative structures. As a consequence of this abnormal expansion, the region containing the triplet is methylated, as are other regions nearby, promoter regions for example. **Objectives** To modify cytosine-rich repeat sequences to allow PCR amplification; and further designing specific primers, to differentiate the methylation status of modified regions, the one containing the triplet and the nearby regions.**Methods** After appropriate informed consent, DNA of the FMR1 gene from 8 healthy subjects (four female and four male) was modified with sodium bisulfite. Subsequently, using bioinformatics tools, we performed: 1) A simulation of alternative structures of the unstable microsatellite in the 5′-UTR region, 2) After localization of the CpG islands, we generate specific primers which hybridize with the new (modified) expanded microsatellite sequence of the gene (Primers NM) and specific primers that hybridize to the new sequence containing CpG islands (Primers M) in the promoter. Finally, both of these sequences were amplified by PCR. **Results** Modified DNA was obtained after chemical treatment with sodium bisulfite. Alternative structures of the sequence of the microsatellite were characterized as described. The modified unmethylated diclucleotides CG (now UG) on the FMR1 gene were identified by the NM primers by PCR. Those on the FMR1 promoter were identified by the M primers. Male samples were primer M (promoter) negative and primer NM (triplet repeat) positive and normal female ones were primer M positive and primer NM negative.Primers NM flank the region with the abnormal expansion and allow counting triplet size count **Conclusions** We designed a potential alternative method for amplification of cytosine rich microsatellite sequences. Combining bisulfite modification(CG to UG) and primers binding to the unmethylated gene and the methylated promoter of the FMR1 gen, we were able to recognize the status of the gene and its promoter in normal men and women. This method will potentially allow differentiating between normal, premutation and full mutation status. Further studies are needed in DNA samples from individual with expanded microsatellites.

Cleavage and polyadenylation specificity factor 1 (CPSF1) regulates alternative splicing of interleukin 7 receptor (IL7R) exon 6. *S.G. Gregory[1,2,3], I. Evsyukova[2,4], S. Bradrick[2,5], M.A. Garcia-Blanco[2,3,5].* 1) Center for Human Genetics; 2) Department of Molecular Genetics and Microbiology; 3) Department of Medicine; 4) Department of Biochemistry; 5) Center for RNA Biology, Duke University Medical Center.

Interleukin 7 receptor, IL7R, is expressed exclusively on cells of the lymphoid lineage and its expression is crucial for the development and maintenance of T cells. While transcriptional regulation of IL7R expression has been widely studied, its posttranscriptional regulation has only recently been uncovered. Alternative splicing of IL7R exon 6, the only exon that encodes the transmembrane domain of the receptor, results in membrane-bound (exon 6 included) and soluble (exon 6 skipped) IL7R isoforms, respectively. Interestingly, the inclusion of exon 6 is affected by a single-nucleotide polymorphism associated with the risk of developing multiple sclerosis, a prototypic demyelinating disease of the central nervous system. Given the potential association of exon 6 inclusion with multiple sclerosis, we investigated the cis-acting elements and trans-acting factors that regulate exon 6 splicing. We identified multiple exonic and intronic cis-acting elements that impact inclusion of exon 6. Moreover, we utilized RNA affinity chromatography followed by mass spectrometry to identify trans-acting protein factors that bind exon 6 and regulate its splicing. These experiments identified cleavage and polyadenylation specificity factor 1 (CPSF1) among protein binding candidates. A consensus polyadenylation signal AAUAAA is present in intron 6 of IL7R directly downstream from the 5′ splice site. Mutations to this site and CPSF1 knockdown both resulted in an increase in exon 6 inclusion. Correspondingly, CPSF1 depletion had no effect on a minigene with a mutation in the intronic polyadenylation site. 3′RACE and RT-PCR experiments on RNA from Jurkat cells suggested that the intronic AAUAAA site is utilized at low frequency by the polyadenylation machinery to produce a novel polyadenylated mRNA isoform. Our results suggest that competing mRNA splicing and polyadenylation may regulate exon 6 inclusion and resultant levels of functional IL7R produced. Since the intronic polyadenylated isoform of IL7R is predicted to be translated into a membrane-bound protein product with a shortened, signal transduction-incompetent cytoplasmic tail, this may be relevant for both T cell biology and development of multiple sclerosis.

Functional analysis of *ASNS* variant identified in progressive microcephaly and brain atrophy patients. *Y. Hitomi[1], E.K. Ruzzo[1], D.L. Silver[2], Y. Anikster[3,4], D.B. Goldstein[1,2].* 1) Center for Human Genome Variation, Duke University School of Medicine, Durham, NC; 2) Department of Molecular Genetics and Microbiology, Duke University School of Medicine, Durham, NC; 3) Edmond and Lily Safra Children's Hospital, Sheba Medical Center, Ramat Gan, Israel; 4) The Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel.

We previously analyzed a specific genetic variant in two Israeli families that presented with a seemingly similar and potentially newly described congenital microcephaly condition. Whole-exome sequencing was applied to both families, and the sequence data identified that all three patients shared a homozygous nonsynonymous variant located in the *asparagine synthetase*(*ASNS*) gene that was absent in over 300 sequenced controls. The protein encoded by this gene is involved in the synthesis of asparagine from aspartate. In this study, we sought to characterize the functional consequences of the *ASNS* variant detected in the patients. Variant *ASNS* cDNA clones were generated by mutagenesis and transfected into monkey kidney cell line COS-7, human kidney cell line HEK-293, and human neuroblastoma SH-SY5Y. Although quantities of exogenous *ASNS* mRNA were similar between variant and wildtype alleles, the variant form of the ASNS protein product was drastically diminished in these transfectants in a lysosomal degradation system-dependent manner. Patient's fibroblast from the skin also showed no ASNS protein product. These results strongly suggested that the nonsynonymous variant in *ASNS* accounts for the pathogenesis. In this presentation, we will also discuss the morphological abnormalities of the brain in the *Asns* deficient mice. Additionally, the efficiency of glutamate metabolism and glutamate-related cytotoxicity in induced pluripotent stem cells (iPSc)-derived neuron which has been obtained from patient's skin fibroblast will be also discussed. These analyses illustrate that straightforward functional work can significantly facilitate the interpretation of whole-exome sequence data, and facilitates the discovery of novel therapies for such central nervous system (CNS) disorders by identification of the molecular mechanism of pathogenesis.

2456F

Impaired PPARδ function underlies mitochondrial demise and neurodegeneration in Huntington's disease: mechanistic basis and therapeutic implications. *A.S. Dickey[1], V.V. Pineda[2], A. Buttgereit[1], M.M. Torres[2], T. Tsunemi[1], A.R. La Spada[1,3,4].* 1) Pediatrics, University of California, San Diego, La Jolla, CA; 2) Laboratory Medicine, University of Washington, Seattle WA; 3) Cellular & Molecular Medicine, University of California, San Diego, La Jolla, CA; 4) Neurosciences, University of California, San Diego, La Jolla, CA.

Huntington's disease (HD) is a progressive autosomal dominant neurodegenerative disorder characterized by involuntary movements, cognitive decline, and psychiatric illness. HD arises from a CAG - polyglutamine repeat expansion in the coding region of the huntingtin (htt) gene. Recent studies have shown that the mitochondrial dysfunction in HD results from transcriptional dysregulation of peroxisome proliferator-activated receptor gamma coactivator-1–alpha (PGC-1α). As a transcriptional regulator, PGC-1α positively modulates nuclear receptor transcription factors including the three PPARs, α, γ, and δ. Of these, PPARδ is the most abundantly expressed in the CNS, although its functional relevance in this tissue is not defined. With the discovery that retinoic acid binds to PPARδ to mediate pro-survival effects, PPARδ may be responsible for promoting a variety of survival / repair processes in neurons. When an unbiased screen for htt interacting proteins yielded PPARs as candidate interactors, we evaluated the different PPARs, and demonstrated an interaction between htt and PPARδ in co-transfection studies. We found that htt and PPARδ interact in HD striatal neurons, and in the brains of BAC-HD transgenic mice, and we mapped the interaction domain on PPARδ to the “hinge” domain. PolyQ-htt repressed PPARδ-mediated transactivation in ST-Hdh cells and primary neurons from BAC-HD mice, but could be rescued by over-expression of PGC-1α or PPARδ. These studies revealed that both a PPARδ-selective ligand and retinoic acid elicited PPARδ-mediated transactivation in neurons. Furthermore, activation of retinoic acid receptor (RAR) transactivation was favored in HD striatal-like neurons and BAC-HD primary cortical neurons. Indeed, studies in BAC-HD primary neurons confirmed that modulation of retinoid binding protein expression levels promoted cell death and mitochondrial dysfunction when RAR signaling was agonized, while augmentation of PPARδ-mediated transactivation boosted cell survival and mitochondrial function. Microarray analysis of PPARδ-regulated genes in the striatum of HD patients and controls confirmed that PPARδ targets are altered in early symptomatic HD patients. Our results indicate that impaired PPARδ function in the CNS contributes to HD neurodegeneration, and suggest that modulation of the PGC-1α - PPARδ pathway is an attractive therapeutic strategy for HD and related neurodegenerative disorders characterized by mitochondrial dysfunction.

NHEJ1 deficiency causes abnormal development of the cerebral cortex. *B. EL WALY[1,2], E. BUHLER[2,3,4,5], M.R. HADDAD[1,2], F. WATRIN[2,3,4,5], L. VILLARD[1,2].* 1) Inserm, U910, Marseille, France; 2) Aix-Marseille Université, Faculté de Médecine Timone, Marseille, France; 3) Inserm, U901, Marseille, France; 4) INMED, Parc Scientifique de Luminy, Marseille, France; 5) Plateforme postgénomique INMED INSERM, Parc Scientifique de Luminy, Marseille, France.

The NHEJ pathway repairs the DNA double strand breaks (DSBs), specifically in postmitotic cells. The NHEJ1 gene is a DNA repair factor essential in that pathway. Mutations in NHEJ1 cause immunodeficiency associated with microcephaly and growth retardation in humans. We previously identified a mutation in the NHEJ1 gene in a patient presenting a malformation of the cerebral cortex consisting of diffuse polymicrogyria (PMG) combined with heterotopic nodules, and showed that the NHEJ1 mRNA was preferentially expressed in the telencephalic ventricular and subventricular zones during the development in humans (Cantagrel et al. 2007). Using shRNAs and in utero electroporation, we now studied the impact of Nhej1 dowregulation on cell survival and cerebral cortex development. We show that Nhej1 downregulation leads to massive cell death in vivo and in vitro. We also show that Nhej1 downregulation disrupts neuronal migration visualized at embryonic stages by a massive accumulation of heterotopic neurons in the intermediate zone. We also show that Nhej1 downregulation cause abnormal development of cortical layers visualized at postnatal stages by reduction of cortical superficial layers width. The excessive cell death observed when Nhej1 is underexpressed likely explains the severe microcephaly phenotype of patients presenting a mutation in the NHEJ1 gene, and the disruption of neuronal migration and cerebral cortex development may explain the cortical malformation presenting in our PMG patient. Taken together, our results reveal that the Nhej1 protein is necessary for cortical neurons survival and proper cortical development.

***KCTD13* is a major driver of mirrored neuroanatomical phenotypes associated with the 16p11.2 copy number variant.** *C. Golzio[1], J. Willer[1], M. E. Talkowski[2,3], E. C. Oh[1], Y. Taniguchi[5], S. Jacquemont[4], A. Reymond[6], M. Sun[2], A. Sawa[5], J. S. Gusella[2,3], A. Kamiya[5], J. S. Beckmann[4,7], N. Katsanis[1,8].* 1) Center for Human Disease Modeling and Dept of Cell Biology, Duke University, Durham, NC; 2) Molecular Neurogenetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Boston MA, USA; 3) Departments of Neurology and Genetics, Harvard Medical School, Boston MA, USA; 4) Service de Génétique Médicale, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 5) Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore MD, USA; 6) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 7) Department of Medical Genetics, University of Lausanne, Lausanne, Switzerland; 8) Department of Pediatrics, Duke University, Durham, NC.

Copy number variants (CNVs) are major contributors to genetic disorders. We have dissected a region of the 16p11.2 chromosome— which encompasses 29 genes—that confers susceptibility to neurocognitive defects when deleted or duplicated. Overexpression of each human transcript in zebrafish embryos identified *KCTD13* as the sole message capable of inducing the microcephaly phenotype associated with the 16p11.2 duplication, whereas suppression of the same locus yielded the macrocephalic phenotype associated with the 16p11.2 deletion, capturing the mirror phenotypes of humans. Analyses of zebrafish and mouse embryos suggest that microcephaly is caused by decreased proliferation of neuronal progenitors with concomitant increase in apoptosis in the developing brain, whereas macrocephaly arises by increased proliferation and no changes in apoptosis. A role for *KCTD13* dosage changes is consistent with autism in both a recently reported family with a reduced 16p11.2 deletion and a subject reported here with a complex 16p11.2 rearrangement involving *de novo* structural alteration of *KCTD13*. Our data suggest that *KCTD13* is a major driver for the neurodevelopmental phenotypes associated with the 16p11.2 CNV, reinforce the idea that one or a small number of transcripts within a CNV can underpin clinical phenotypes, and offer an efficient route to identifying dosage-sensitive loci.

miR-137 expression in schizophrenia and bipolar disorder brains. *I. Guella, A. Sequeira, B. Rollins, F. Torri, M.P. Vawter, F. Macciardi.* Department of Psychiatry and Human Behavior, University of California Irvine, Irvine, California, United States of America.

MicroRNAs (miRNAs) are small non-coding RNAs that act as potent regulators of gene expression. In a recent GWAS the rs1625579 SNP, located downstream of miR-137, was reported as the strongest new association with schizophrenia (Ripke S et al., 2011). Two independent SZ imaging-genetic studies (Potkin SG et al., 2010) found miR-137 to be 1 of 3 miRNAs with target genes significantly enriched for association. Strikingly, this miRNA has been implicated in regulating both adult neurogenesis and neuronal maturation. We investigated the miR-137 expression levels in the dorsolateral prefrontal cortex (DLPFC) of postmortem brain tissue from 2 independent cohorts: 1) 27 subjects (10 control (CTR), 8 schizophrenia (SZ), 9 bipolar disorder (BD)) collected at the UCI Brain Bank; and 2) 99 subjects (33 CTR, 35 SZ, 31 BD) obtained from the Stanley Medical Research Institute (SMRI). Within the UCI cohort, we observed a statistically significant difference in the miR-137 expression across the 3 groups, with the BD having a higher expression (2.01 fold increase) and the SZ a lower expression (0.69 fold decrease) compared to the control group. We were not able to replicate the BD significant results in the SMRI collection, but it is interesting that in both cohorts we noticed a reduced miRNA-137 expression in SZ. The rs1625579 genotypes of 107 samples were next investigated for an association with miR-137 expression. MiR-137 was increased 1.18 fold in heterozygous TG compared to the homozygous TT subjects in a joint analysis of the 2 cohorts, although this difference did not achieve statistical significance (p=0.19). When controls only were analyzed, in the joint analysis, the miR-137 expression was 1.41 fold higher in TG subjects compared to TT (p=0.036). In conclusion, expression changes were observed for miR-137 in BD and SZ, and an effect of rs1625579 on expression was noted, but only in the control group. The lack of significance in case-control analysis of miR-137 expression is likely due to the variability of the expression levels across cohorts, and to the small sample size of the UCI cohort. We have thus far investigated the DLPFC where our results suggest a possible association between the T risk allele of rs1625579 and decreased miR-137 expression. Future studies are needed to better explain the within subject expression variability, to explore in other brain regions the miR-137 expression, and the genotype association with miR-137 expression.

Common gene co-expression network analysis in schizophrenia and bipolar disorder. *S. Hong[1], X. Chen[3], L. Jin[1], M. Xiong[2].* 1) School of Life Science, Fudan University, Shanghai, Shanghai, China; 2) School of Public Health, The University of Texas Health Science Center at Houston; 3) Departments of Psychiatry and Human Genetics, Virginia Commonwealth University.

Schizophrenia and bipolar disorders were recognized as two main diagnostic categories of the most severe psychiatric disorders. Though the psychotic features and clinical diagnosis of these two diseases were different, there were more and more studies supporting sharing some genetic mechanisms between them. In the previous studies, most of the co-expression network construction methods only focused on using a Gaussian graphical model to estimate a single co-expression network for each type of tissue samples. However, those methods cannot unmask the underlying heterogeneity between networks with some shared structures and estimate a co-expression network shared by two types of tissue samples or two diseases. Recently, a Joint Estimation of Multiple Graphical model to preserve the common structure of networks from heterogeneous data has been developed. We adapted this model to our study and constructed the co-expression networks underlying both schizophrenia and bipolar disorder. RNA-seq was applied to 31 schizophrenia, 25 bipolar and 26 normal samples in this study. We identified 76 differential expressed genes between metal disorders (schizophrenia and bipolar) and normal with q-value less than 0.01. Then, we used a joint multiple graphical model to identify a co-expression network shared by both schizophrenia and bipolar disorder. Most of genes in the common network were previously reported to be suspected genes to both schizophrenia and bipolar, such as SNAP25, PVALB, RGS4, GABRA1 and NPAS3. Our results showed that this method was very useful to reveal the shared network between diseases which were supposed to share the same etiology.

Delusion-associated SNPs in NRG3 Show Regulatory Potential, Dysregulate NRG3 Splicing and Differentially Bind to Nuclear Proteins. *M. Zeledón[1,2,3], M. Taub[5], N. Eckart[1,2], R. Wang[1], M. Szymanski[1,2], P. Chen[6], A. Pulver[3,4], J.A. McGrath[3,4], P. Wolyniec[3,4], D. Avramopoulos[1,3], A. Sawa[3], D. Valle[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Predoctoral Training Program in Human Genetics, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 5) Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 6) Department of Medical Genetics, National Taiwan University Hospital, Taipei City, Taiwan.

Schizophrenia (SZ) is a severely disabling psychiatric disease that affects 1% of the world's population. Symptoms include dysfunctions in cognition, thought/belief (delusions), perception/sensation (hallucinations) and affect. Previously, our group reported a linkage peak for SZ (NPL of 4.7) at 10q22 in the Ashkenazi Jewish (AJ) population and, in a follow-up fine mapping association study in the AJ, found strong evidence of association between a quantitative phenotypic trait “delusion” and three intronic SNPs in the 5' end of *NRG3* (Fallin *et al*, 2003; Chen *et al*, 2009). Two other independent groups have replicated our findings, making *NRG3* a strong candidate gene for a subtype of schizophrenia with delusions. To identify causative variants, we sequenced the 162 kb LD block covering the 5' end of *NRG3* and containing the three associated SNPs in 47 AJ SZ patients at either extreme of the delusion quantitative trait. We identified 5 SNPs with minor alleles on the implicated haplotype and significantly overrepresented in high delusion patients. We tested these for regulatory potential. In transient transfection assays with dual luciferase reporters, we found that the delusion associated alleles of rs10883866 and rs60827755 showed significantly and reproducibly decreased and increased (3–4 fold) expression of a reporter gene respectively, compared to the common allele. This effect was consistent in a variety of cell types including primary rat cortical neurons. To test whether these changes are due to differential binding of DNA regions containing the alleles to nuclear protein, we performed electrophoretic mobility shift assays. We determined that the 21 bp including and surrounding the SNPs consistently bind to nuclear proteins and binding is influenced by the genotype of the SNP. These results are consistent with data from Eckart *et al*. (abstract submitted to this conference) that suggest SNPs in *NRG3* perturb expression of *NRG3* isoforms. In summary, we have identified cis-acting regulatory motifs that modify *NRG3*expression and that account for the association with delusions, have regulatory potential, and bind to nuclear proteins. We are currently addressing the identity of the nuclear proteins that bind these regulatory motifs. We anticipate that these experiments will allow us to move from genetic observations to deciphering the mechanistic pathways that may lead to risk for SZ or modifications of the SZ phenotype.

USF1 regulates sleep and circadian traits in humans. *H.M. Ollila[1], K.M. Rytkönen[2], K. Silander[1], M. Perola[1], V. Salomaa[1], M. Härmä[3], S. Puttonen[3], T. Porkka-Heiskanen[2], T. Paunio[1].*1) National Institute for Health and Welfare, Finland, Helsinki, Finland; 2) Institute of Biomedicine, Physiology, University of Helsinki, Finland; 3) Finnish Institute for Occupational Health, Helsinki, Finland.

OBJECTIVES: Epidemiological studies show association between sleep duration and lipid metabolism. Our aim was to characterize gene variants that regulate both metabolism and sleep. One such candidate is USF1 that regulates the expression of several lipid genes and has a similar structure as canonical circadian transcription factors. We studied the polymorphisms in USF1 gene region with sleep duration and coping with circadian stress in Finnish population based samples combined with gene expression and USF1 knock out animal model. MATERIALS AND METHODS: The known USF1 variants that had previously been associated with lipid traits were studied with sleep and coping with circadian stress. The analyses were performed in a Finnish population based sample with no sleep problems (N=1085) and Finnair workers (N=1415). RNA expression from mononuclear leucocytes was measured in additional 584 individuals. EEG recordings from USF1 knock-out animals were performed. RESULTS: The genetic analysis identified that the USF1 polymorphisms associated with sleep duration in the healthy individuals. The same variant associated with coping with circadian stress in Finnair workers. Gene expression analysis showed that those individuals carrying minor allele had higher USF1 expression. Finally, EEG analysis showed distinct changes between USF1 knockout and wild type littermates. CONCLUSIONS: Our results show that the allelic variants of USF1 associate with sleep duration and coping with circadian stress. The finding may reflect the shared roots of sleep and metabolism. The shared genetic background between sleep and metabolism may at least partially explain the mechanism behind the well-established connection between diseases with disrupted metabolism and sleep.

Sodium channel mutations and epilepsy. *J.E. O'Brien, M.H. Meisler.* Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Voltage-gated sodium channels are members of a large gene family that includes the neuronal channels *SCN1A*, *SCN2A*, *SCN3A*, *SCN8A*, *SCN9A* and *SCN10A*. Mutations of *SCN1A* are a major cause of Dravet syndrome, a severe early-onset epileptic encephalopathy. *SCN2A* has been implicated in generalized epilepsy with febrile seizures plus and benign familial neonatal-infantile seizures, *SCN3A* in cryptogenic pediatric partial epilepsy, and *SCN9A* in other febrile seizures. A heterozygous null mutation in *SCN8A*, one of the most abundant sodium channels in the brain, was found in a family with cognitive impairment (Trudeau et al, J Med Genet 2006), but no seizure phenotypes were previously attributed to human *SCN8A*. We studied a proband with epileptic encephalopathy characterized by early-onset, features of autism, intellectual disability, ataxia, and SUDEP (sudden unexplained death in epilepsy) (Veeramah et al, AJHG 2012). Whole genome sequencing of the proband, her parents, and her unaffected brother identified a *de novo* heterozygous missense mutation in *SCN8A*, c.5302A>G, (p.Asn1768Asp), that alters an evolutionarily conserved residue. The mutant channel demonstrated hyperexcitability consistent with the dominant phenotype in the heterozygous proband. *SCN8A* contains an alternatively-spliced, neuron-specific exon that is essential for generation of active channel protein. We found that the Rbfox splice factors contribute to neuron-specific generation of full length channel protein (O'Brien et al, Mol Cell Neurosci 2012). We also identified a novel interaction of the cytoplasmic N-terminus of *SCN8A* with the microtubule-associated protein Map1b that appears to function in channel trafficking (O'Brien et al, J Biol Chem 2012). *SCN8A* is the fifth sodium-channel gene found to contrubute to seizure disorders. Generation of a mouse model carrying the p.Asn1768Asp mutation is in progress. (Supported in part by NS34509 and GM007544.).

Phosphorylation and Regulation of FMRP. *M. Santoro[1], S. Warren[1,2].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Departments of Biochemistry and Pediatrics, Emory University School of Medicine, Atlanta, GA.

Fragile X syndrome, the most common form of inherited intellectual disability, results from a lack of Fragile X Mental Retardation Protein (FMRP). FMRP is a selective mRNA-binding protein and plays a key role in synaptic plasticity. In neurons, FMRP represses translation of its target mRNAs but allows translation to proceed upon receipt of specific synaptic signals. In the hypothalamus, activation of mGluR receptors causes FMRP to derepress translation of its target mRNAs, resulting in a burst of local protein synthesis, internalization of AMPA receptors, and long term depression. In vitro experiments indicate that FMRP's activity is regulated by the phosphorylation status of a specific serine (S499 in mice; S500 in humans). In order to more fully investigate the translational regulation of FMRP we are developing Fmrp knock-in mice containing phosphomimic forms of FMRP. A Ser499Ala mutation results in an amino acid replacement that structurally resembles unphosphorylated FMRP, whereas a Ser499Asp mutation structurally mimics the phosphorylated serine. The Ser499Ala strain has been created while the Ser499Asp strain is currently under development. Ser499Ala is expected to phenocopy a null mutation - increased translation of FMRP targets, excessive AMPAR internalization, and overactive mGluR signaling. The Ser499-Asp protein is expected to show the opposite phenotype but, since the corresponding mutation has not been seen in humans, it is difficult to predict what the phenotype might be. We will report biochemical and neurobiological aspects of these two novel Fmr1 mutant mice.

The *cis*-regulatory effect of an Alzheimer's disease-associated polymorphic poly-T locus on expression of *TOMM40* and *APOE* genes. *O. Chiba-Falek[1,2,3], C. Linnertz[1], W. Gottschalk[1,2], D. Crenshaw[1,2], M. Lutz[1,2], J. Allen[3], S. Saith[3], M. Mihovilovic[1], L. Anderson[1], K. Welsh-Bohmer[2], A. Roses[1,2,4].* 1) Dept Med/Neurology, Duke Univ, Durham, NC; 2) Joseph and Kathleen Bryan ADRC, Duke Univ, Durham, NC; 3) Institute for Genome Sciences & Policy, Duke Univ, Durham, NC; 4) Zinfandel Pharmaceuticals, Chapel Hill, NC.

Differential gene expression controlled, in part, by polymorphisms in non-coding regions of the genome, may contribute to the pathogenesis of complex human traits including late-onset Alzheimer's disease (LOAD). We studied the TOMM40-APOE genomic region that has been associated with the risk and age of disease onset of LOAD to determine if a highly polymorphic intronic poly-T within this region (rs10524523, hereafter `523') affects the expression of APOE and TOMM40 genes. Alleles of this poly-T variant are classified as short (S), long (L) or very long (VL) based on the number of T residues. We evaluated differences in APOE-mRNA and TOMM40-mRNA levels as a function of `523' genotype in two brain regions from APOE ε3/3 Caucasian autopsy confirmed LOAD cases and normal controls. Expression levels of both genes were significantly increased with disease. In temporal cortex (TC) from both Normal (n = 42) and LOAD (n = 66) subjects, APOE and TOMM40 mRNA levels were higher in `523'VL-homozygotes compared to S-homozygotes. The association between higher TOMM40 and APOE expression and the VL allele was also observed in matched occipital (OCC) tissues (n=34 Normal and 69 LOAD subjects). Differences in mean expression according to the `523' genotype in the TC and OCC samples for both TOMM40 and APOE mRNAs approached statistical significance. Expression levels for both mRNAs decreased with age, but the contribution of age to the variation in transcript level was not statistically significant. Gender, tissue source or PMI were not associated with transcript level. We used a luciferase reporter system to test the effect of the `523' locus, in the native genomic context, on gene expression. In agreement with the human brain mRNA analysis, the VL (34 T residues) `523' polyT resulted in significantly higher expression than the S (16 T residues) polyT in both HepG2 cells and SH-SY5Y neuroblastoma cells. This effect was greater in the SH-SY5Y cells than in the hepatoma cells, hinting at tissue-specific modulation of the `523' polyT locus. These results suggest that the `523' locus may contribute to LOAD susceptibility by modulating the expression of TOMM40 and/or APOE transcription. Elucidating the mechanism by which this locus affects LOAD may lead to the identification of novel, tractable drug targets or modalities for treating, preventing or delaying onset of this devastating disease.

2466W

Apolipoprotein E ε4 as a factor in the evaluation of the genetic risk of Alzheimer's dementia in Filipinos. *M. Daroy[1], C. Casingal[1], C. Mapua[1], D. Florendo[1, 2], R. Matias[1, 3], J. Dominguez[2], St. Luke's Dementia Study Group.* 1) Research and Biotechnology Div, St. Luke's Medical Center, Quezon City, NCR, Philippines; 2) Memory Center, International Institute of Neurosciences, St. Luke's Medical Center, Quezon City, NCR, Philippines; 3) Medical Affairs Division, United Laboratories, Inc., Mandaluyong City, NCR, Philippines.

Alzheimer's dementia is a growing threat to the rapidly increasing elderly population worldwide. In the Philippines, there are 3.8 million people above 65 years old who are at risk of developing AD. This report presents the results of a cross-sectional study to determine the genotypic distribution of ApoE in affected and unaffected groups of Filipinos, who either consulted in the hospital for Alzheimer's dementia, or were screened in a community setting. Peripheral blood was collected from a total of 600 subjects, composed of 124 patients who consulted at the Memory Center of St. Luke's Medical Center, Quezon City and 476 individuals who participated in a community-based cohort. DNA from the buffy coat was analyzed for ApoE genotype by PCR-RFLP (Hha I) method. The most frequent genotype for both groups was ε3/ε3: 51.6% for the hospital group and 66.6% for the community group. The clinical profile of all the subjects is: 96 with Alzheimer's dementia, 110 with mild cognitive impairment, 369 with no dementia, and 25 with diagnoses other than dementia. In this group of Filipinos, the ApoE ε4 allele is significantly associated with risk for Alzheimer's dementia, compared with the no dementia group, with a p-value of 0.0481 and an odds ratio of 1.611. The frequencies of the risk ε4 allele were as follows: 14.1% for those diagnosed with Alzheimer's dementia, 9.1% for those with mild cognitive impairment, 9.2% for those with no dementia, and 6.0% for those with diagnoses other than dementia. These results suggest that the detection of the presence of the ApoE ε4 allele could be a useful tool for the assessment of genetic risk for Alzheimer's dementia in Filipinos when integrated with the patient's clinical data and family history.

2467T

Functional Testing of Schizophrenia Associated Variants in *NOS1AP*. *CT. Ramirez[1], N. Wratten[1], Y. Huang[2], A. Dulencin[3], J. Millonig[3], VJ. Vieland[2], AS. Bassett[4], LM. Brzustowicz[1].* 1) Dept Gen, Rutgers Univ, Piscataway, NJ; 2) Battelle Ctr Math Med, Res Inst Nationwide Child Hosp, Columbus, OH; 3) Department of Neuroscience and Cell Biology, University of Medicine and Dentistry of New Jersey, Piscataway, NJ; 4) Department of Psychiatry, University of Toronto and Centre for Addiction & Mental Health, Toronto, Ontario, Canada.

Schizophrenia is a major neuropsychiatric disorder that affects approximately one percent of the general population. Although the etiology of schizophrenia is unknown, family, twin and adoption studies have demonstrated that schizophrenia is a predominantly genetic disorder with a high heritability. We previously reported highly significant evidence of linkage to chromosome 1q21–23 in a set of Canadian families of European descent, identified *NOS1AP* as the candidate gene from this region contributing to risk of schizophrenia in our sample, and identified three SNPs with strong evidence of association to schizophrenia. These SNPs were tested for regulatory functions using a Dual Luciferase Reporter Assay with the native *NOS1AP*-promoter. rs12742393 demonstrated regulatory activity and produced significant allelic expression differences in two different human neural cell lines, SK-N-MC and PFSK-1. Statistical analysis under the PPL framework of eight SNPs in strong LD with rs12742393 revealed a haplotype block of four SNPs in complete LD with each other (rs4557949-rs1158803-rs4145621-rs12084492) and with strong evidence of association to schizophrenia. Additional statistical analysis revealed that a haplotype consisting of rs12742393 and this block produced even stronger evidence for association than rs12742393 or this block alone, suggesting that an interaction between two or more SNPs could modulate NOS1AP gene expression. rs4145621 has been tested for regulatory activity and produced no evidence of being a functional variant in the human cell lines. Preliminary data suggest that rs4557949 is also not a functional variant.Further testing of the two remaining SNPs in the haplotype and all four SNPs using different cell confluency levels may reveal potential contributions to regulatory function that could be important in schizophrenia expression.

***MIR137*, a candidate gene for schizophrenia: identification of targets and downstream effects.** *A.L. Collins[1], R.J. Bloom[1], Y. Kim[1], P.F. Sullivan[1,2].* 1) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Findings from the Psychiatric GWAS Consortium (PGC) have identified significant and replicated association for a region on chromosome 1 near *MIR137* (rs1625579; $p=1.6\times10^{-11}$; the second top hit in the PGC GWAS). Unpublished studies increase the significance of this finding to $p=1.3\times10^{-12}$. Genome-wide significant associations have also been identified for genes with confirmed miR-137 target sites (*CACNA1C*, *TCF4*, *CSMD1*, and *C10orf26*). miR-137 is implicated in other psychiatric disorders (intellectual disability with autism spectrum disorders, Alzheimer's, and mouse models of Rett syndrome). Combined with indications that miR-137 plays an important role in neuronal differentiation and proliferation, it is imperative that we understand miR-137 function. Therefore, we aim to identify potential (direct or indirect) targets of miR-137, to elucidate a pathway altered in schizophrenia. Human neural stem cells (ReNcell-VM) were transduced with lentiviral vectors for overexpressing and inhibiting miR-137 (and the respective controls). Transduction efficiencies approached 100% for all vectors. For overexpression, miR-137 levels are increased by ≥ 40X. For inhibition, miR-137 is sequestered, therefore testing of established targets of miR-137 (e.g., *MIB1* and *MITF*) is in progress to verify the functionality of the inhibition. We are now testing RNA and protein levels of candidate genes (predicted targets of miR-137 plus genes implicated by schizophrenia GWAS) to determine the impact of miR-137 dysregulation. To identify novel downstream effects, we completed RNA-seq from cells transduced with the miR-137 overexpression vector or control (analysis in progress). RNAseq for inhibition is in progress. Comparison of predicted binding sites and direction of alteration will yield a candidate list of direct versus indirect targets. miRNAs are intriguing candidates in complex disease, as the ability to regulate hundreds of genes may allow identification of many other contributors to disease pathogenesis. Moreover, identification of members of the network regulated by miR-137 could identify critical participants in schizophrenia pathogenesis. Additional work to identify translationally inhibited targets will be needed to further our understanding of this micro-RNA. Nonetheless, elucidation of a pathway or pathways regulated by miR-137 could provide a myriad of potential targets for pharmaceutical intervention.

Schizophrenia mir137 Risk Genotype is Associated with DLPFC Hyperactivation. *T.GM. van Erp, I. Guella, M.P. Vawter, F. Torri, J. Fallon, F. Macciardi*, S.G. Potkin*.* Department of Psychiatry and Human Behavior, UCI, Irvine, CA.

Background. A recent large genome-wide association study (Ripke et al. 2011) confirmed findings from a prior gene set enrichment analysis (Potkin et al. 2009) in implicating MIR137-dysregulation in the etiology of schizophrenia, but the functional sequelae of MIR137 dysregulation remain to be determined. **Methods.** Functional magnetic resonance imaging scans on 50 schizophrenia patients and 66 age and sex-matched healthy volunteers were acquired while subjects performed a Sternberg Item Response Paradigm with memory loads of 1, 3, and 5 items. Functional image processing was performed as previously reported (Potkin et al. 2009). We extracted dorsolateral prefrontal cortex (DLPFC) retrieval activation for the working memory load of 3 items, for which hyperactivation had been shown in schizophrenia patients compared with controls. The implicated MIR137 SNP (rs1625579) was genotyped (schizophrenia: GG n=0, GT n=10, TT n=40; healthy volunteers: GG n=2, GT n=15, and TT n=49). Frequency distributions of MIR137 (rs1625579) alleles were examined using the Fisher's Exact Test. Mixed model regression analyses were performed to examine the effects of diagnosis and genotype on DLPFC activation while controlling for effects of sex, age, and site. **Results.** Patients did not have a higher percentage of MIR137 risk (rs1625579 T) alleles than controls. Patients showed significantly higher DLPFC activations compared with controls. Individuals with a MIR137 TT genotype showed significantly higher DLPFC activations than those with a GG/GT genotype, independent of diagnosis. **Conclusion.** Compared with individuals with the MIR137 GG or GT genotype, individuals with the MIR137 TT genotype show DLPFC hyperactivation as measured with functional magnetic resonance imaging during working memory. The MIR137 TT schizophrenia risk genotype is associated with the schizophrenia risk phenotype DLPFC hyperactivation commonly considered a measure of brain inefficiency.

Aminoacyl-tRNA synthetases (ARSs) are ubiquitously expressed enzymes responsible for ligating amino acids to cognate tRNA molecules. Mutations in four genes encoding an ARS have been implicated in inherited peripheral neuropathy with an axonal pathology, suggesting that all ARS genes are relevant candidates for disease in patients with related phenotypes. Here, we present results from a mutation screen of the histidyl-tRNA synthetase (*HARS*) gene in a large cohort of patients with peripheral neuropathy. These efforts revealed a rare missense variant (p.Arg137Gln) that resides at a highly conserved amino acid, represents a loss-of-function allele when evaluated in yeast complementation assays, and is toxic to neurons when expressed in*C. elegans*. In addition to the patient with peripheral neuropathy, p.Arg137Gln *HARS* was detected in three individuals by genome-wide exome sequencing. We therefore conclude that p.Arg137Gln *HARS* is a pathogenic allele with incomplete penetrance. These findings suggest that *HARS* is the fifth ARS locus associated with axonal peripheral neuropathy. Implications for identifying ARS alleles in human populations and assessing them for a role in neurodegenerative phenotypes will be discussed.

Neuronal expression of FIG4 and neurodegeneration. *G.M. Lenk[1], C.J. Ferguson[2], M.H. Meisler[1].* 1) Human Gen, Univ Michigan, Ann Arbor, MI; 2) Neuroscience Program, Univ Michigan, ANn Arbor, MI.

FIG4 is a ubiquitously expressed phosphatase that regulates the level of the signaling lipid PI(3,5)P2. Null mutation of *Fig4* in the mouse results in spongiform degeneration of brain and peripheral ganglia, defective myelination, and juvenile lethality. Recessive mutations of human *FIG4* result in a severe form of Charcot-Marie-Tooth neuropathy (CMT4J). Most patients with CMT4J are compound heterozygotes with one null allele and the missense mutation Ile41Thr. This mutation impairs interaction with the scaffold protein VAC14, destabilizing the FIG4 protein (Lenk et al, PloS genetics, 2011). Neurons from *Fig4* mutant mice contain enlarged vacuoles derived from the endosome/lysosome pathway and astrocytes accumulate proteins involved in autophagy. We used transgenic mouse models to distinguish the contributions of neurons and glia to spongiform degeneration in the *Fig4* null mouse. Wildtype *Fig4* expression was directed by the neuron-specific NSE promoter and the astrocyte-specific GFAP promoter in *Fig4* null transgenic mice. Neuron specific expression of *Fig4* was sufficient to rescue the cellular and neurological phenotypes including spongiform degeneration, gliosis, and juvenile lethality (Ferguson et al, HMG, 2012). CNS hypomyelination was also rescued by the neuron-specific transgene (Winters et al, J Neurosci, 2011). Expression of Fig4 in astrocytes prevented accumulation of autophagy markers in acstrocytes, but this did not prevent spongiform degeneration or lethality. To confirm the role of neurons in the spongiform degeneration, we generated a floxed allele of *Fig4* and crossed it with mice expressing the Cre recombinase from the neuron-specific synapsin promoter. Mice with conditional inactivation of *Fig4* in neurons developed spongiform degeneration by 30 days and exhibit premature lethality. The data demonstrate that expression of *Fig4* in neurons is necessary and sufficient to prevent spongiform degeneration. Therapy for patients with FIG4 deficiency will therefore require correction of the deficiency in neurons. (Supported by GM24872 and The Hartwell Foundation).

Global mapping of FUS-binding sites and global profiling of FUS-mediated RNA metabolisms in the mouse brain. *K. Ohno[1], A. Masuda[1], S. Ishigaki[2,4], Y. Fujioka[2], Y. Iguchi[2], M. Katsuno[2], A. Shibata[1], F. Urano[3], G. Sobue[2,4].* 1) Neurogenetics, Nagoya University Graduate School of Medicine, Nagoya, Japan; 2) Neurology, Nagoya University Graduate School of Medicine, Nagoya, Japan; 3) Program in Gene Function and Expression, University of Massachusetts Medical School, Worcester, MA; 4) CREST, Japan Science and Technology Agency, Kawaguchi, Japan.

Aberrations of FUS are causally associated with familial and sporadic amyotrophic lateral sclerosis and frontotemporal lobar degeneration (ALS/FTLD). FUS is a multifunctional protein that has been involved in several steps of gene expression regulation especially for transcription and RNA splicing. FUS belongs to the FET family of RNA-binding proteins, which includes FUS, Ewing's sarcoma (EWS), and TATA-binding protein-associated factor (TAFII68). FUS is present in polymerase II transcription complexes that function in the transcription process. Interestingly, FUS inhibits the acetyltransferase activities of CREB-binding protein (CBP) and p300 on cyclin D1 (*Ccnd1*) in HeLa cells. Both CBP and p300 are co-activators of multiple classes of signal-dependent transcription factors and the FUS/CBP/p300 interactions result in the inhibition of histone-acetyltransferase activities followed by repression of transcription. Moreover, FUS is involved in the splicing machinery by cooperating with other splicing factors like serine/arginine-rich (SR) proteins, SRm160, and PTB. These observations suggest that compromised effects of FUS on transcription and alternative splicing could lead to neuronal cell degeneration in FUS-associated ALS and FTLD.

In an effort to understand the global roles of FUS on RNA metabolisms in neuronal cells, we analyzed exon arrays of mouse primary cortical neurons after knocking down *Fus*. We also identified FUS-binding RNA segments in the mouse cerebrum using the high-throughput sequencing of RNA isolated by crosslinking immunoprecipitation (HITS-CLIP). We observed no distinct FUS-binding motifs in the CLIP tags. We, however, found that FUS-binding sites tend to form stable secondary structures. Positional analysis of FUS-binding sites in relation to alternative splicing events disclosed scattered binding of FUS to and around the alternatively spliced exons with noticeable FUS-binding peaks in the downstream introns. We found that FUS are bound to the antisense RNA strand at the promoter regions. Global analysis of these FUS-tags and the expression profiles disclosed that binding of FUS to the promoter antisense strand downregulates transcriptions of the coding sense strand. Our analysis revealed that FUS regulates alternative splicing events and transcriptions in a position-dependent manner.

***Sortilin-related receptor 1* is associated with cognitive impairment in Filipinos.** *C.R. Casingal[1], M.L.G Daroy[1], C.A. Mapua[1], D.J.A. Florendo[1,2], J.C. Dominguez[1], St. Luke's Dementia Study Group.* 1) Research and Biotechnology Division; 2) Memory Center, Institute of Neuroscience, St. Luke's Medical Center, Quezon City, Philippines.

This study investigated the association of 6 *sortilin-related receptor 1 (SORL1)* variants with cognitive impairment. SORL1 SNPs 8, 9, 10, 13, 19 and 23 were genotyped in 484 Filipinos, including 100 Alzheimer's disease (AD) cases, 109 mild cognitive impairment (MCI) cases, 257 with no dementia and 18 with other cases of cognitive impairment, using TaqMan® SNP Genotyping Assays. Cognitive impairment (CI), which includes AD, MCI and other cognitive impairment cases, was associated with SNP 23 (p=0.041). None of the *SORL1* variants was associated with AD. It may be that the association was not detected because of inadequate sample size. SNPs 8, 9, 10 and 23 were associated with MCI, (p=0.028, p=0.034, p=0.034 and p=0.025, respectively). Based on these results, *SORL1* may be used as a biomarker in the early detection or diagnosis of cognitive impairment and other dementias. This study also found an association between SNP 23 and female sex in MCI group, (p=0.033). This suggests that *SORL1* may affect cognitive impairment and the interplay of sex-specific risk factors, sex-specific disease course, and sex-specific survival of a disease, through a female-dependent mechanism. The subjects were also evaluated based on the presence of *APOE-ε4* allele. The findings showed that in the *APOE-ε4* noncarrier group, SNPs 8, 9, 10, 19 and 23 were associated with MCI group, (p=0.030, p=0.050, p=0.050, p=0.031 and p=0.007, respectively). These results support the findings that *SORL1* contributes to an increased risk for cognitive impairment even when the *APOE-ε4* allele is not present.

Identifying neuropsychological and cognitive endophenotypes of schizophrenia-associated exonic variants of NPAS3 and COMT. *L.M. Luoma[1], G. Macintyre[1], F.B. Berry[1,2], D. LaFreniere[3,4], S. Purser[3,4], A. Beierbach[4], P. Tibbo[3,5], D.W. Cox[6], S. Purdon[3,4].* 1) Department of Medical Genetics, University of Alberta, Edmonton, AB, Canada; 2) Department of Surgery, University of Alberta, Edmonton, AB, Canada; 3) Department of Psychiatry, University of Alberta, Edmonton, AB, Canada; 4) Neuropsychology, Alberta Hospital Edmonton, Edmonton, AB, Canada; 5) Department of Psychiatry, Dalhousie University, Halifax, NS, Canada; 6) Department of Medicine, University of Alberta, Edmonton, AB, Canada.

Schizophrenia is a disorder of psychosis characterized by deficits in neurodevelopment, neurotransmission and adult neurogenesis. Although schizophrenia is highly heritable, GWASs to date have identified many variants with low effect size, often with little to no replication. This indicates that genetic heterogeneity may contribute to variability in clinical presentation and therapeutic response of persons with schizophrenia. Identification of specific sub-clinical quantifiable phenotypes (endophenotypes) associated with specific genetic variants would thus be invaluable to investigations of pathogenesis and outcome. Studies of schizophrenia-associated genetic variants have demonstrated links to personality traits, cognitive skills, and discrete behaviours in normal populations. These characteristics have further been associated with vulnerability to psychopathologies such as psychosis. Variants of catechol-O-methyltransferase (*COMT*), involved in metabolism of catecholamine neurotransmitters, affect dopaminergic neurotransmission, cortical thickness, cognitive flexibility and working memory, each of which have been found disrupted in schizophrenia. NPAS3 (neuronal PAS domain containing 3) is a schizophrenia-associated transcription factor implicated in neurodevelopment, adult neurogenesis and neurosignalling. Loss of Npas3 in mice causes altered adult neurogenesis and behaviours which mimic features of schizophrenia. Furthermore, *NPAS3* variants are linked to cross-disorder pleiotropic effects in humans. Endophenotypes of *NPAS3* variants have not yet been identified. Eighty-seven healthy teenagers (mean age 17.68 years) were recruited for cognitive, neuropsychological and genetic analyses to identify endophenotypes linked to schizophrenia-associated exonic variants of *COMT* and *NPAS3*. Individuals carrying the schizophrenia-associated allele of the *COMT* rs4680 (p.V158M) and/or *NPAS3* (p.A552P) variants were identified. The *NPAS3* risk genotype was associated with verbal working memory (p=0.004), and the general index score of the Screen for Cognitive impairment in Psychiatry (SCIP, p=0.039). The *COMT* risk genotype was associated with social anhedonia (p=0.008) and errors on a continuous performance test (p=0.032). In summary, we have identified associations between *NPAS3* and *COMT* risk genotypes and schizophrenia-associated neuropsychological and cognitive parameters that appear to be good candidates for endophenotype markers for psychosis.

Production of IL-6 is altered in primary human macrophages carrying 255Adel *PARK2* gene variation. *R.H.M. Sindeaux[1], A.C. Senegaglia[2], R.P. Munhoz[3], H.A. Teive[3], S. Raskin[1], M.M.A. Stefani[4], M.T. Mira*[1], V.S. Sotomaior*[1].* 1) Core for Advanced Molecular Investigation, Pontifícia Universidade Católica do Paraná/PUCPR, Brazil; 2) Laboratory of Experimental Cell Culture, Pontifícia Universidade Católica do Paraná/PUCPR, Brazil; 3) Department of Neurology, Hhospital de Clínicas, Universidade Federal de Goiás/UFPR, Brazil; 4) Tropical Patholgy at Public Health Institute, Universidade Federal de Goiás/UFG, Brazil.

Variations of the *PARK2* gene that encodes parkin, an E3 ubiquitin-protein ligase, have been implicated as causative of an autosomal recessive early-onset form of Parkinson's disease (AR-EOPD). Multiple biological roles have been assigned to parkin, including modulation of inflammatory responses. Studies have demonstrated altered circulating levels of cytokines, including IL-6, in Parkinson's disease (PD) patients, suggesting a possible involvement of inflammatory/immune-mediated mechanisms in PD pathogenesis. However, direct evidence linking*PARK2* variations to immune response in the context of PD is yet to be produced. The aim of this initiative was to use monocyte-derived macrophages (MDMs) from AR-EOPD patients with*PARK2* spontaneous variations as a model to investigate aspects of immune response. Primary peripheral blood mononuclear cells (PBMCs) isolated from three AR-EOPD patients with*PARK2* variations (P1, presenting exclusively intronic variations; P2, homozygous and P3, heterozygous for a severe, nonsense exon 2 255Adel mutation) and four healthy controls were cultured in vitro for 5 days in order do generate MDMs (approximately 1.5×10^5 cells/ well). An aliquot of the cells was treated with IFNγ + LPS for 24 hours before collection of culture supernatants for IL-6 quantification by ELISA. Data were expressed as the mean ± SD of two assays. MDMs carrying *PARK2* variant 255Adel presented increased IL-6 basal levels (P2: 168.96 ± 1.97 pg/mL; P3: 385.93 ± 2.11 pg/mL) as compared with cells obtained from patient P1 and controls (mean ± SD: 8.91 ± 7.45 pg/mL). When MDMs were activated with IFNγ + LPS, the production of IL-6 by P1 and controls cells increased and IL-6 concentrations became similar across all samples (mean ± SD of all samples: 301.43 ± 18.08 pg/mL). In conclusion, we obtained the first evidence of a biological function for 255Adel *PARK2* variation in the context of AR-EOPD pathogenesis. * These authors share senior authorship; This study was supported by the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Brazil.

Broadening the role of FMRP targets across autism spectrum disorders. *J. Steinberg[1,2], C. Webber[1].* 1) MRC Functional Genomics Unit, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Autism spectrum disorder (ASD) is a complex neurodevelopmental condition with an early age of onset and a prevalence of 0.3%–1%. Although ASD is highly heritable, with studies documenting a role of both *de novo* point mutations and structural variation, the underlying disease mechanism is still unknown. Recently, four studies used exome sequencing to identify *de novo* mutations in patients with autism. Of the identified candidate genes, at least 20% are regulated by FMRP, a protein thought to play a key role in neuroplasticity and neuronal translation. FMRP has been shown to regulate a total of 842 genes via stalling of ribosomal translocation and a significant overlap of these targets with ASD candidate genes has been reported. Furthermore, a loss of function mutation in the gene encoding FMRP itself causes Fragile X syndrome, the leading monogenic cause of ASD.

We have further explored the role of FMRP targets in ASD gene disruptions. Firstly, we use human brain expression data to divide the 842 FMRP targets into four robust modules with distinct spatio/temporal expression patterns, and carry out a functional analysis of each module. Subsequently, we show that both genes disrupted in ASD via balanced chromosomal abnormalities and genes implicated via *de novo* point mutations are enriched in FMRP targets that belong to a particular module showing developmental stage-specific expression. Secondly, we develop a novel test to analyse case/control datasets for disruptions in gene sets of interest. Importantly, this test is sensitive to a multi-hit disease aetiology, statistically robust and has increased power to detect pathway associations compared to existing methods. Applying this test to rare copy number variation (CNVs) in 872 ASD cases and matched unaffected siblings, we provide further evidence for the implication of FMRP targets and a second module enriched in synaptic functioning in ASD. We replicate this result in an expanded CNV dataset of 1124 ASD cases compared to their parents, and in an independent CNV dataset of 561 cases and 1146 unrelated controls.

In summary, we show that different biologically-meaningful modules of FMRP targets play roles in ASD via *de novo* point mutations, balanced chromosomal abnormalities and CNVs.

2477F

Expanded Hexanucleotide GGGGCC Repeat RNA associated with ALS/FTD is sufficient to cause neurodegeneration. *Z. Xu[1,2], M. Poidevin[1], H. Li[2], T. Wingo[3], P. Jin[1].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA, USA; 2) Division of Histology and Embryology, Department of Anatomy, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, People's Republic of China; 3) Department of Neurology, Emory University School of Medicine, Atlanta, GA, USA.

Expansion of GGGGCC hexanucleotide repeat in the noncoding region of chromosome 9 open reading frame 72 (C9ORF72) gene has been found among many families with frontotemporal dementia (FTD) and/or amyotrophic lateral sclerosis (ALS) linked to chromosome 9 (c9FTD/ALS), however, the molecular pathogenesis underlying this expanded repeat remains unknown. Here we developed both mammalian cells and Drosophila model of this expanded hexanucleotide repeat, and showed that the expression of the expanded GGGGCC repeat RNA (30) is sufficient to cause neurodegeneration, suggesting that rGGGGCC-repeat-binding proteins (RBPs) may be sequestered from their normal function by rGGGGCC binding. We further identified Pur α, β and γ as RBPs of rGGGGCC repeat, and show that Pur α and rGGGGCC repeats interact in vitro and in vivo with a sequence-specific fashion that is conserved between mammals and Drosophila. Overexpression of Pur α in mammalian cells and Drosophila could suppress rGGGGCC-mediated neurodegeneration. These results suggest that the expanded rGGGGCC repeat is sufficient to cause the neurodegeneration, and Pur α could potentially play a role in the pathogenesis of ALS/FTD.

An Integrated and Systematic Approach to Autism Pathway Analysis. *Z. Lin[1], SJ. Sanders[2], JK. Lowe[4], DH. Geschwind[4,5], M. State[2], H. Zhao[3].* 1) Computational biology and bioinformatics, Yale University, New Haven, CT; 2) Program on Neurogenetics, Child Study Center, Department of Psychiatry, Yale University School of Medicine, 230 South Frontage Road, New Haven, CT; 3) Department of Epidemiology and Public Health, Department of Genetics, Yale University, New Haven, CT; 4) Program in Neurogenetics and Neurobehavioral Genetics, Department of Neurology and Semel Institute, David Geffen School of Medicine, University of California, Los Angeles, CA; 5) Department of Human Genetics, University of California Los Angeles, Los Angeles, CA.

Introduction Autism spectrum disorder (ASD) is a common, highly heritable neurodevelopment syndrome characterized by fundamental impairments in social communication. Driven by the ability to examine genome-wide expression levels and DNA variations, researchers have used various approaches to identifying the genes contributing ASD risk, including: differential gene expression in autistic and normal brains; common single nucleotide polymorphisms (SNPs) disease association; and recurrent rare de novo single nucleotide variants (SNVs). In this study, we hypothesize that genes carrying risk for ASD are functionally related and thus annotated to a smaller number of pathways, which is present in data across all sample methodologies.**Methods Summary** We have examined exome-sequencing data from 547 families (200 quartets and 347 trios) from the Simons Simplex Collection, microarray genotyping derived from 1273 families (5445 subjects) from Autism Genetic Resource Exchange, and gene expression microarray of 36 post-mortem brain tissue samples (19 autistic cases and 17 controls) from Autism Tissue Project and the Harvard brain bank. We have performed hypothesis testing on annotated pathways instead of individual genes to increase detection power as a result of reduced hypothesis testing. Permutation test based on the number of hits by rare de novo SNVs was performed on each pathway. For the microarray genotyping data, Transmission Disequilibrium Test was performed to acquire p-value for each SNP. The p-value of a gene was based on the SNP with lowest p-value within 50kb. Permutation test based on the mean of p-values of genes in the pathway was performed. Gene Set Enrichment Analysis (GSEA) on the brain expression microarray data was performed to acquire p-value for each pathway. P-values from the three independent datasets were integrated by Fisher's method and a summarized p-value was acquired for each pathway. **Results and Discussion** Our results suggest that signals from the three independent data sources show evidence of significant overlap. After correction for multiple testing, six pathways are identified as showing enrichment. Of these `FocalAdhesion' showed the most significant association (p=0.0067). Genes from the other five pathways showed significant overlap with genes annotated to the focal adhesion pathway and removing these genes left no remaining association. We conclude that disruption of focal adhesion is a primary event in the causation of ASD.

RNA sequencing in iPSC-derived neurons identifies gene expression changes associated with 22q11.2 microdeletion syndrome. *Y. Tian[1,2], S. Pasca[3], J. Ou[1], A. Krawisz[3], J. BernsteinJon[4], J. Rapoport[5], J. Hallmayer[6], S. Horvath[2,7], M. Pellegrini[2], R. Dolmetsch[3], D. Geschwind[1,2,7,8], ACE Genetics Consortium.* 1) Neurogenetics Program, Department of Neurology, David Geffen School of Medicine, UCLA, Los Angeles, CA; 2) Interdepartmental Ph.D. Program in Bioinformatics, UCLA, Los Angeles, CA; 3) Deptartment of Neurobiology, Stanford University, School of Medicine, Stanford University, Stanford, CA; 4) Deptartment of Pediatrics, Stanford University, Stanford, CA; 5) Child Psychiatry Branch, National Institute. of Mental Health, Bethesda, MD; 6) Department of Psychiatry and Behavioral Science, Stanford University, Stanford, CA; 7) Department of Human Genetics, David Geffen School of Medicine, UCLA, Los Angeles, CA; 8) Center for Autism Research and Treatment and Semel Institute, David Geffen School of Medicine, UCLA, Los Angeles, CA.

Genetically defined neurodevelopmental disorders provide a powerful window into the pathogenesis of mental disease. The 22q11.2 microdeletion syndrome is caused by the deletion of a 3 million base-pair region of chromosome 22, and is associated with increased risk of autism spectrum disorders (ASD) and schizophrenia. In this study, we performed genome-wide measurement of RNA expression via deep RNAseq on cortical neuronal precursor cells (NPC) and neurons from induced pluripotent stem cells (iPSC) derived from 22q11.2 deletion cases and normal controls to identify dysregulated molecular pathways at key developmental epochs. We found 453 differentially expressed (DE) genes in neurons and 216 genes in NPCs, which by hierarchical clustering clearly distinguished 22q11.2 deletion cases from controls. Remarkably, 21 DE genes in 22q11.2 deletion neurons and 14 DE genes in NPCs have been previously implicated in idiopathic ASD. Gene Ontology (GO) analysis revealed enrichment of alternative splicing and calcium ion binding. Additionally, by comparing the pattern of gene expression changes that occur during neural differentiation in controls vs. 22q11.2 deletion carriers, we can see an apparent defect in neuronal differentiation in the deletion carriers. We applied Weighted Gene Co-expression Network Analysis (WGCNA) to provide a higher order view of transcriptional dysregulation. We identified 4 gene co-expression modules associated with 22q11.2 deletion, including one having GRIN2B, an autism candidate gene as a hub, which was downregulated in 22q11.2 deletion neurons. These data characterize the network of genes dysregulated in iPSC-derived cells from 22q11. 2 deletion patients during neuronal differentiation and maturation. These patterns provide insight into the pathogenesis of 22q11.2 deletion syndrome and a first step in designing molecularly targeted therapy.

The effects of inherited deletions on neurocognition in Canadian children with 22q11.2 deletion syndrome. *E. Chow[1,2,3], A. Ho[1], D. Young[2], S. Langlois[4,5], C. Cytrabaum[6], A. Rideout[3], S. Dyack[3,7].* 1) Clinical Gen Service, Ctr Addiction & Mental Hlth, Toronto, ON, Canada; 2) University of Toronto, Toronto, ON, Canada; 3) IWK Health Centre, Halifax, NS, Canada; 4) BC Children's Hospital, Vancouver, BC, Canada; 5) University of British Columbia, Vancouver, BC, Canada; 6) Hospital for Sick Children, Toronto, ON, Canada; 7) Dalhousie University, Halifax, NS, Canada.

Background: Because there are no exclusively Canadian data on the neurocognition in children with 22q11DS in the literature, we carried out the current study. Samples: We assessed a total of 56 subjects affected by 22q11DS (25 M, 31 F) and between the ages of 8 to 12 years (mean=9.8 SD =1.9 years) and a total of 26 siblings (14 M, 12 F) also in the same age range (mean= 10.5 SD=1.8 years) from Ontario (n=20 affected and 9 sibling subjects), British Columbia (n=18 affected and 7 sibling subjects), and the Maritimes provinces (n=18 affected and 10 sibling subjects). The 22q11.2 deletion in 11 of the affected children was inherited (all but one maternally), although only 45% were raised by their biological parents. Methods: All subjects were assessed with tests of intellect (WISC-III or IV), academic achievement (WRAT-3), attention/working memory (Connor's CPT, digit span), memory (Rey auditory verbal learning test, CMS-III), motor skills (Purdue pegboard, Trials A), visual spatial skills (Line orientation), and social cognition (Theory of Mind). Test performances were compared between the 22q11DS and siblings subjects, and between 22q11DS subjects with and without an inherited deletion. Results: 22q11DS children performed significantly worse than their siblings on all neurocognitive tests: WISC-III or IV FSIQ (67.5, SD 12.2 vs. 96.4, SD 16.6, $p<0.001$), academics (WRAT3 reading, spelling and arithmetic $p<0.001$), attention (Connor's CPT $p=0.016$, Digit Span $p<0.001$), verbal memory (RAVLT total score $p<0.001$, delayed recall $p= 0.003$; CMS immediate $p=0.016$, delayed recall $p=0.011$), visual spatial memory (CMS immediate $p=0.002$ and delayed recall $p<0.001$), motor skills ($p<0.001$), visual spatial perception ($p=0.012$), and social cognition ($p<0.001$). Children with an inherited deletion had lower FSIQ (71.9 vs 65.8, $p=0.027$), and worse performance in digit span ($p=0.099$), symbol search ($p=0.030$), WRAT-3 spelling ($p=0.035$), and motor skills (non-dominant hand $p=0.041$) than children with a de novo deletion. Although sample sizes were small, the data suggests that children with inherited deletions raised by their affected parent had lower IQ and verbal learning skills than affected children raised by adoptive parents. Conclusions: 22q11DS is associated with a wide range of neurocognitive impairments in childhood and they may be worse in children with an inherited deletion, especially when raised by their affected parent.

2481W

Brain-Derived Neurotrophic Factor (BDNF) Val66Met and Adulthood Chronic Stress Interact to Affect Depressive Symptoms. *R. Jiang, B.H. Brummett, M.A. Babyak, I.C. Siegler, R.B. Williams.* Duke University Medical Center, Durham, NC.

Objective: To examine whether the association between *BDNF* Val66Met and depressive symptom severity is modified by adulthood chronic stress in two independent samples.**Background:** *BDNF* Val66Met polymorphism has been found associated with depression, but the results are mixed, which may be partially attributed to failure to consider environmental factors, such as chronic stress. *BDNF* Val66Met by chronic stress interaction has been studied using childhood stress as a moderator, but has not been widely studied using chronic stress in adulthood. **Methods:** Two independent samples were used: Duke-CG (238 Caucasians) and MESA (5524 Caucasians, African Americans and Hispanics). In the Duke-CG sample chronic stress was operationalized as having the primary caregiving responsibility for a spouse or relative with diagnosed Alzheimer's disease or other major dementia; chronic stress in MESA was defined using a chronic burden score constructed from self-reported problems of health (self and someone close), job, finance and relationships. In both samples, the Center for Epidemiologic Studies of Depression (CES-D) scale was the measure of depressive symptoms. The *BDNF* Val66Met by adulthood chronic stress interaction predicting CES-D was examined using linear regression, adjusted for race, gender, age, BMI, and anti-depressant use in both samples, and data collection site in the MESA sample. **Results:** The main effect of *BDNF*Val66Met genotype on CES-D scores was non-significant ($ps > 0.607$) but the adulthood chronic stress indicator was significant ($ps < 0.001$) in both samples. The *BDNF* Val66Met genotype by adulthood chronic stress interaction was also significant ($ps < 0.039$) in both samples. The impact of chronic stress in adulthood on CES-D scores was significantly larger in individuals with the Val/Val genotype compared to Met carriers. **Conclusion:** We found in two independent samples that depressive symptom levels increased significantly more as a function of adulthood chronic stress among Val/Val carriers than Met carriers that was in a different direction from the moderation observed for childhood stress. If the association of the Val/Val genotype with increased depressive symptoms in adults exposed to chronic stress is confirmed in future studies, persons with the Val/Val genotype and chronic stress exposure could be targeted for interventions designed to reduce risk of depression.

miRNA Expression in the Prefrontal Cortex of Suicide Completers. *J.P. Lopez[1, 2], R. Lim[3], B. Labonte[2], C. Cruceanu[1,2], J.P. Yang[2], V. Yerko[2], C. Ernst[1,2], N. Mechawar[2], P. Pavlidis[3], G. Turecki[1,2].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill Group for Suicide Studies, Douglas Mental Health University Institute, McGill University, Montreal, Quebec, Canada; 3) Department of Psychiatry, University of British Columbia, Vancouver, B.C, Canada.

Suicide is a major public health problem. It was estimated in 2007 that suicide accounts for 1.5% of the total deaths in Canada. Over the last decades, a large body of evidence has shown that individuals who commit suicide have a predisposition that is mediated by neurobiological factors. MicroRNAs (miRNAs) are small non-coding RNAs that regulate gene expression by means of RNA degradation or translational repression. A growing body of evidence supports the role of miRNAs in neuropsychiatric disorders such as schizophrenia and bipolar disorder. Based on this evidence we believe that miRNAs have an important role in the neurobiology of suicidal behaviours. As such, we sought to identify miRNA differences in the brain of suicide completers as compared to controls. We profiled the expression of miRNAs in the prefrontal cortex of suicide completers and controls using miRNA microarrays and quantitative real-time PCR. We identified target genes of the differentially expressed miRNAs using bioinformatics analysis. Finally, we performed functional experiments using miRNA mimics and target protectors on HEK-293T cell lines to confirm the interaction between miRNAs and their targets. Our results revealed an interaction between miR-1202 and the Metabotropic Glutamate Receptor 4 (GRM4) gene in the prefrontal cortex of suicide completers. These results suggest that the relationship between miR-1202 and GRM4 in postmortem brain tissue may be associated with the pathophysiology of suicidal behaviour. Ultimately, our results provide new evidence of the role of miRNAs in neuropsychiatric disorders and a better understanding of the etiology of suicide.

2483F

Distinct gene expression and DNA methylation perturbations in PTSD with severe child abuse versus no PTSD with no child abuse. *D. Mehta[1], T. Klengel[1], K.N. Conneely[4], A.K. Smith[3], A. Altmann[1], M. Rex-Haffner[1], A. Loeschner[1], M. Gonik[1], K.B. Mercer[2], B. Bradley[3,5], B. Müller-Myhsok[1], K.J. Ressler[2,3,6], E.B. Binder[1,6].* 1) Max Planck Institute for Psychiatry, Max Planck Institute for Psychiatry, Munich, Germany; 2) Howard Hughes Medical Institute, Chevy Chase, Maryland, USA; 3) Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, USA; 4) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA, USA; 5) VA Medical Center, Atlanta, GA, USA; 6) Yerkes National Primate Research Center, Atlanta, GA, USA.

The aim of the current study was to interrogate the influences of the environment on gene expression profiles by characterizing biological differences in PTSD after severe child abuse versus PTSD after adult trauma. A total of 396 trauma-exposed individuals were included in the study. Whole blood gene expression and DNA methylation was measured on Illumina Human-HT12v3 and HumanMethylation 450k arrays. Analysis was performed in R. Expression levels of 741 transcripts were significantly associated with current PTSD severity. However, only 2% of these transcripts were associated with PTSD in both groups after accounting for adult trauma severity. Expression differences were also reflected in DNA methylation differences. DNA methylation differences were observed in 69.3% of the transcripts significantly regulated by PTSD with child abuse but for only 33.6% transcripts selective for PTSD without child abuse. Functional annotations revealed distinct biological pathways enriched among the two distinct expression profiles. The observations that non-overlapping transcriptional profiles and biological pathways seem to be affected in the two PTSD groups and that changes in DNA methylation appear to have a much greater impact in the early trauma group may reflect differences in the pathophysiology of PTSD after exposure to early trauma. Stratification by environmental variables such as timing, type and severity of trauma might therefore be essential for the identification of robust biomarkers for PTSD. T.

2484W

Frequency of polymorphisms of the alcohol dehydrogenase enzyme (ADH1B and ADH1C) and aldehyde dehydrogenase enzyme (ALDH) in the Brazilian population. G*.P.M. Antonialli, B. Coprerski, R.M. Minillo, M.P. Migliavacca, D. Brunoni, A.B.A. Perez.* Clinical genetics, Federal University of Sao Paulo, Sao Paulo, Brazil.

Introduction: Alcohol dependence is a major social and economic problem worldwide. The influence of the polymorphisms in the code regions of the alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) enzyme is well characterized as a risk factor for alcohol dependence in some populations. There are different classes of ADH, the classes I (ADH1A, ADH1B e ADH1C) and II are responsible for the great part of the metabolism of the ethanol ingested. The ALDH is presented in the mitochondrial form (ALDH2), which has two isoforms, and in the cytosolic form (ALDH1). Until this moment few studies were performed to try to establish the frequency of these polymorphisms in the Brazilian population. Purpose: To determine the frequency of ADH1B (ADH1B*2 - Arg48His and ADH1B*3 - Arg370Cys), ADH1C (ADH1C*2 - Ile350Val) and ALDH2 (ALDH2*2) polymorphisms in a healthy Brazilian population and also compare with the frequency of other populations. Methods: DNA was isolated from peripheral blood of 202 healthy patients, of which 101 were male and 101 were female divided by ethnicity. DNA was amplified by PCR reaction, digested by specific restriction enzyme and analyzed by gel electrophoresis. Results: The following genotype frequencies were found for each polymorphism: ADH1B*2: 87,13% ADH1B*1/1 and 12,87% ADH1B*1/2. ADH1B*3: 89,69% ADH1B*1/1 and 10,31% ADH1B*1/3. ADH1C*2: 40,10% ADH1C*1/1; 49,01% ADH1C*1/2 and 10,89% ADH1C*2/2. ALDH2*2: 98,02% ALDH2*1/1 and 1,98% ALDH2*1/2. The genotype distribution of the ADH1B, ADH1C and ALDH2 enzyme polymorphism of the population studied were similar to those described in some white European and American population, but quite different from the frequency described in Asians. The frequencies found for this ADH polymorphism were similar to those described in previous Brazilian studies. The only allele that showed a statistically significant association by ethnicity was the ALDH2*2, which was more frequent in the descendants of Eastern ($p<0,0001$). There were no significant differences in the genotype distribution between both sexes. Conclusion: These results will be fundamental to future Brazilian epidemiological studies on the influence of these polymorphisms in several diseases, including alcoholism and Fetal Alcohol Syndrome.

2485T

Serotonin transporter (SLC6A4) and receptor (5-HT2A) gene polymorphisms in healthy Brazilian individuals with diverse ethnic backgrounds. *B. Coprerski[1,2], M. P. Micliavacca[1], A. B. A. Perez[1], A. P. P. Costa[2], D. Brunoni[1,2].* 1) Clinical Genetics, Federal University of Sao Paulo, Sao Paulo, Brazil; 2) Biology and health department, Makenzie Presbiterian University, Brazil.

Introduction: Autism is a heterogeneous syndrome defined by the commitment in three areas (social interaction, language and communication) and the presence of repetitive and stereotyped patterns of behavior and interests. Intense genetic-clinical and systematic research sets up to 30% of causes. The heritability of idiopathic cases showed 90% and are explained by epistatic multifactorial mechanism. Hyperserotonemia in 30% of patients and the improvement of symptoms with drugs that inhibit serotonin reuptake put this system as possibly involved. In this line have been investigated genes of the transporter (SLC6A4, located at 17q11.2) and receptor 2A (5HT2A, located at 13q12-q21) of serotonin. Objective: To determine allele frequencies and the hypothesis of preferential association of four polymorphisms of serotonin in patients with PDD and controls. Material and Methods: Three polymorphisms of the SLC6A4 gene were studied: The polymorphism deletion/insertion of 44 bp in the promoter region, known as 5-HTTLPR, a polymorphism of 17 bp variable number of tandem repeats (VNTR) in intron 2 and a single base polymorphism (SNP) in the 3 `untranslated (UTR) of 5-HTT gene. For the 5HT2A gene T102C SNP was studied. DNA was extracted and genotyped for each polymorphism. We analyzed 116 patients with PDD for the four polymorphisms and 239 controls. The cases were analyzed by the instruments ASQ and ABC as to the higher susceptibility to repetitive behaviors and stereotyped. Results and Conclusion: There was no statistically significant evidence for the distribution of genotypes in both cases and controls. Regarding the number of stereotypes, both in the ASQ and the ABC there was no significant difference in genotype distribution. The sample is in Hardy-Weinberg equilibrium. Further studies with larger sample and better definition of some endophenotype will be required to demonstrate the possible implication of these polymorphisms in the etiology of autism.

Regulatory effects of genes associated with Schizophrenia. *N. Eckart[1], R. Wang[2], J. McGrath[2], P. Wolyniec[2], M. Zeledòn[1], M. Szymanski[1], A. Pulver[2], D. Valle[1], D. Avramopoulos[1,2].*1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Psychiatry, Johns Hopkins University, Baltimore, MD.

Schizophrenia (SZ) is a common complex psychiatric disorder with high heritability. GWAS experiments have begun to identify associated SNPs; however, the true causative variants and their pathophysiological mechanisms are largely unknown. As in other disorders, the majority of the SZ associated SNPs are in non-coding regions and likely reflect regulatory variation. We hypothesized that many reported disease-associated variants disrupt the regulation of gene expression and explored this hypothesis in 187 postmortem brain samples from the temporal lobe of donors without brain pathology. We focused our study on a total of 14 SNP markers, 2 associated with SZ, 6 with both SZ and bipolar disorder, and 6 SNPs in *NRG3*, a gene we previously reported to be associated with certain phenotypic features of SZ. Using transcript specific primers and RT-qPCR, we measured the levels of known alternative transcripts of the gene closest to each of the 14 SNPs in RNA extracted from our samples. We used a generalized linear model including age, sex, and plate to find correlations between the genotypes and the total and relative expression of the gene's alternative mRNA transcripts. We found significant correlations for three SNPs (rs1006737 in *CACNA1C*; rs10748842 in *NRG3*; rs7899151 in *NRG3*). For*CACNA1C*, we found the genotypes of rs1006737, previously reported to be associated with both SZ and BP, were correlated with expression of all *CACNA1C* transcripts. For *NRG3*, we found the genotype of rs10748842 was associated with the relative abundance of *NRG3* alternative transcripts. Previously, our group showed that rs10748842 genotype correlated strongly with the “delusion” phenotypic factor in SZ. An effect of rs10748842 on relative the same alternative transcript of *NRG3* has been independently reported by others in the prefrontal cortex. Finally rs7899151 which we studied because of its correlation with the “disorganization” factor of SZ showed a correlation between genotype and a different *NRG3* alternative transcript. We conclude that non-coding variants associated with disease often mark regulatory haplotypes that can also involve alternative splicing. Further studies to examine the functional consequences of variation within these haplotypes are important to better understand the mechanisms of pathogenesis.

Genome-wide association study of 32,143 individuals reveals several novel associations in schizophrenia. *C. O'Dushlaine[1], S. Ripke[1,2], J. Moran[1], K. Chambert[1], P. Sklar[3], S. Purcell[1,2,3], C. Hultman[4], S. McCarroll[1], P. Sullivan[5], Swedish Schizophrenia Consortium.* 1) Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT, Cambridge, MA, 02142; 2) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, 02114; 3) Division of Psychiatric Genomics, Department of Psychiatry, Mount Sinai School of Medicine, NY, NY 10029; 4) Department of Medical Epidemiology, Karolinska Institutet, Stockholm, Sweden; 5) Departments of Genetics, Psychiatry, and Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 27599.

BackgroundSchizophrenia is a genetically complex and clinically heterogeneous disorder. Several large-scale genome-wide association meta-analyses have discovered 14 independent loci with genome-wide significant association. Here, we present results from the latest and largest such study, representing an increase in sample size of 59% over previous studies. Our primary study consisted of 5,001 cases and 6,243 controls ascertained from Sweden. The genetic data were imputed into HapMap3 and 1000 Genomes data and analyzed using logistic regression with MDS covariates. **Methods/ Results** We compared the results to already published data from the collection from the Psychiatric GWAS Consortium (excluding the Swedish cohorts, 8,832 cases and 12,067 controls of European ancestry). First, we performed polygene testing (Purcell, 2009) to assess variants of lesser effect. Second, we first compared directionality in SNPs with high-significance ($p<10-4$) via a sign test. After showing excellent concordance in both directions (sign test), we meta-analyzed these two result-sets in a sample of 13,833 cases and 18,310 controls. We found increased evidence of association for many previously implicated loci in addition to evidence for novel loci: in total we find 14 LD-independent SNPs with genome-wide significance. An additional 31 LD-independent SNPs with $p<10-6$ are now under investigation in a replication dataset. Finally, we conducted gene-based and pathway analyses to test for aggregate-level associations, possibly in the presence of allelic and/or locus heterogeneity. Our gene-based tests recapitulate many of the top GWAS hits but also highlight additional loci of interest. Pathway analysis using KEGG, Gene Ontology and TargetScan datasets, revealed several highly significant associations, most notably relating to postsynaptic density in addition to the previously-reported Cell Adhesion Molecule Pathway. Intriguingly, of 87 microRNA families tested (range of 2–200 genes), 26 had a pathway p-value <10-4, potentially implicating additional microRNAs in schizophrenia. We confirm enrichment of association among targets of mir137 ($P=1.8e-9$) and find that 45 of 299 targets with at least one SNP have a gene p-value ≤ 0.05. **Discussion** Our results confirm previous associations in schizophrenia and yield new insights at both the gene and pathway level, together representing major steps forward in understanding the molecular pathophysiology of schizophrenia.

2488T

Genome Wide Association Study Reveals Genes Influencing the Rate of Cognitive Decline Among Persons With Alzheimer's Disease are Distinct From Those Associated With Disease Risk. *R. Sherva[1], Y. Tripodis[1], D. Bennett[2], L.A. Chibnik[3], P.K. Crane[4], P. de Jager[3], L.B. Farrer[1], J. Shulman[3], R.C. Green[3].* 1) Boston University, Boston, MA; 2) Rush University Medical Center; 3) Harvard Medical School; 4) University of Washington.

Substantial inter-individual variability exists in the longitudinal disease trajectories of Alzheimer's disease (AD) patients, some of which may be due to genetic factors. In a discovery sample of 303 AD cases recruited in the AD Neuroimaging Initiative (ADNI), we performed a genome wide association study on the outcome of rate of change in the Alzheimer's Disease Assessment Scale-cognitive subscale (ADAS-cog) measured longitudinally at six month intervals for up to four years after disease onset. Genetic association was assessed with interaction terms between SNPs and time with AD using linear regression models solved by generalized estimating equations to account for correlated observations within individuals. Several SNPs were significantly associated with rate of progression after correcting for multiple tests and genomic inflation, including SNPs in α-catenin 2 (CTNNA2) (rs6738962, $P=1.2\times10-8$), which regulates the stability of synaptic contacts in the hippocampus, and spondin 1 (SPON1) (rs11607537, $P= 7.2\times10–11$), which binds to the amyloid precursor protein and inhibits its cleavage by beta secretase. Minor alleles at both of these SNPs were associated with slower decline in ADAS-cog. A SNP 4KB upstream of rs11607537 was associated with more rapid decline in an independent sample of 323 AD cases from the Religious Orders Study and Rush Memory and Aging Project (rs11606345, $P=0.002$) using a different cognitive phenotype and analytic model. The SNP was also associated with a slower rate of amyloid β-40 (but not Aβ-42) accumulation in cerebrospinal fluid ($P = 0.001$), and slower rates of decline measured by the Rey Auditory Verbal Learning Test ($P = 0.008$) and the Mini-Mental State Examination ($P = 0.003$). None of the previously identified variants that predict the risk of developing AD were associated with rate of progression after correcting for multiple tests, indicating genes influencing the rate of cognitive decline after disease onset are different from those which influence mechanisms leading to disease.

2489F

Genome-wide scan for Copy Number Variation association with Age at Onset of Alzheimer's Disease. *K. Szigeti[1], D. Lal[1], Y. Li[2], R. Doody[2], K. Wilhelmsen[3], L. Yan[4], S. Liu[5], C. Ma[4], Texas Alzheimer Research and Care Consortium.* 1) Dept Neurology, University at Buffalo, Bufalo, NY; 2) Depts of Molecular and Human Genetics, Neurology Baylor College of Medicine, Houston, TX; 3) Dept Neurology, University of North Carolina, Chapel Hill, NC; 4) Department of Bioinformatics, University at Buffalo, Buffalo, NY; 5) Roswell Park Cancer Institute, Buffalo, NY.

Alzheimer's disease is a progressive neurodegenerative disease with high prevalence imposing a substantial public health problem. The heritability of AD is estimated at 70 % forcasting potential of using genetic biomarkers for risk stratification in the future. Several large scale GWAS studies using high frequency variants identified 10 loci accountable for only a fraction of the estimated heritability. To find the missing heritability systematic assessment of the various mutational mechanisms will need to be performed. This copy number variation genome-wide association study with age at onset of AD identified 14 CNVs corresponding to 11 chromosomal regions that may contribute to the heritability of AAO of AD. Two CNV events are intragenic causing a deletion in ACTG2 and CPNE4. In addition, to further study the mutational load at the 10 known susceptibility loci, CNVs overlapping with these loci are also catalogued. We identified rare small events overlapping CR1 and BIN1 in AD and NC with opposite CNV dosage. The CR1 events are consistent with previous reports. Larger scale studies with deeper genotyping specifically addressing copy number variation are needed to evaluate the significance of these findings.

2490W

Utilizing eQTL networks to identify genes relevant to autism in the 16p11.2 region. *Y. Cheng, W. Lauren.* Department of Psychiatry and Institute for Human Genetics, University of California, San Francisco, San Francisco, CA.

Copy number variants (CNVs) in the 16p11.2 region were identified by Weiss et al. 2008 as associated with autism in three independent datasets, and repeated shortly thereafter by Kumar et al. 2008 using a different approach with a subset of the same discovery sample. To date, none of the 25 annotated genes in the 16p11.2 region have proven responsible for the autism phenotype. Here, we utilized expression quantitative trait loci (eQTL) networks to identify autism genes in the 16p11.2 region. We first used control lymphoblast cell line (LCL) genome-wide expression (21 16p11.2 genes with expression data available) and genetic data in SCAN (Gamazon et al. 2009) to map 1) the single nucleotide polymorphisms (SNPs) associated with expression level of each of the 21 genes in trans, and 2) the SNPs located in the 16p11.2 region that were associated with the expression of other genes in trans. The resulting SNPs were organized into eQTL regions (with regions considered the same across networks if they had >100kb overlap) and subsequently tested for association with three SNP datasets and seven CNV datasets in idiopathic autism (16p11.2 CNV carriers excluded). We discovered significant overlap between eQTL networks of SPN, CORO1A, PPP4C, CDIPT, C16orf54, TBX6, KCTD13, ALDOA, MAZ and autism-specific CNVs in at least two CNV datasets. In addition, significant SNP sets were identified for the eQTL networks of SPN, CDIPT, MVP, YPEL3, TBX5, HIRIP3, KIF22, and MAZ in at least one SNP dataset. 16p11.2 genes shared upstream eQTL regions. For example, putative eQTL regions that were associated with the expression of at least five 16p11.2 genes include the following genes: CSDM1, CBLN2, FAM135B, NRG3, A2BP1, LINC004659, MACROD2, PTPRT, ROBO2, GRIN2B, and several multi-gene regions: USH2A / ESRRG, C3orf19 / C3orf20, RAB31 / TXNDC2 / VAPA, 19q13.32 (eleven genes). A similar analysis of the non-overlapping 16p11.2 eQTLs (that could be more confidently assigned to a single gene) suggested that only ALDOA showed significant association with autism in two CNV datasets, and thus might possess an independent regulatory network. In summary, our results indicated that a number of 16p11.2 genes were co-regulated by common upstream genes critical to neurodevelopment and their expression network was associated with common and rare variants in autism. Our data also suggest that multiple genes in the region may function together or in similar processes to contribute to autism.

2491T

A genomic instability model of autism: global copy number burden associated with autism. *N. KATIYAR[1], S. Girirajan[1,2], A. Srikanth[1], K.H. Yeoh[1], S.J. Khoo[1], F. Tassone[3], R. Hansen[3], I. Hertz-Picciotto[3], E.E. Eichler[2], I.N. Pessah[3], S.B. Selleck[1], M.D. Ritchie[1].* 1) Bioinformatics and Genomics, The Pennsylvania State University, STATE COLLEGE, PA; 2) Department of Genome Sciences, University of Washington Medical School, Seattle, WA; 3) The Medical Investigations of Neurodevelopmental Disorders Institute, University of California at Davis Medical Center, Sacramento, CA 95817, USA.

Recent work has demonstrated an elevated frequency of large, rare copy number variants (CNVs) in a number of neurodevelopmental disorders, including autism spectrum disorder (ASD), schizophrenia, and developmental delay. However, the global load of deletions or duplications per se, and the relationship between total copy number burden and the clinical manifestation of autism/ASD has not been well documented. We examined CNVs in 554 children aged 2–5 years who either had full syndrome autism (AU) or were typically developing (TD) controls from the population-based CHildhood Autism Risks from Genetics and Environment (CHARGE) study. All cases were confirmed clinically on both the Autism Diagnostic Inventory-Revised and the Autism Diagnostic Observation Schedule. Similarly, all controls were confirmed to have typical cognitive and adaptive function and screened negative for ASD on the Social Communication Questionnaire. We interrogated 107 genomic regions flanked by segmental duplications (genomic hotspots) for events >50kbp and the entire genomic backbone for variants >300 kbp using a custom targeted DNA microarray. This analysis was complemented by a separate study of five highly dynamic, hotspot regions previously associated with autism or developmental delay syndromes using a finely-tiled array platform providing a high resolution for CNV detection (>1 kbp) in 142 gender and ethnicity-matched AU and TD children. In both studies, a significant increase in total copy number burden (measured as total base pairs affected by burden) was associated with AU/ASD, represented principally as large duplication events. Significantly elevated levels of burden remained even after removal of rare, known and likely, pathogenic events. These findings were replicated using data from previously published work on CNVs measured for a number of neurodevelopmental disorders, including ASD (Simons Simplex Cohort, SSC). Our data suggest a mechanistic bias toward duplications in the etiology of ASD and emphasizes the importance of genomic instability in neurodevelopmental disorders. While we were not able to identify the parent of origin or the extent to which these duplications were amplified de novo, this study does demonstrate how higher resolution can provide more refined results. This study provides an exciting new approach to pursue in the exploration of the complexity of autism and other neurodevelopmental disorders.

The impact of glutamate and gamma-aminobutyric acid receptor signaling in non-syndromic autism. *A. Mohamed-Hadley[1], D. Hadley[1], Z. Wu[1], C. Kao[1], A. Kini[1], J. Glessner[1], R. Pellegrino[1], C. Kim[1], K. Thomas[1], H. Hakonarson[1,2], AGP Consortium.* 1) The Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, USA; 2) Division of Genetics and Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA.

Autism is a complex heterogeneous disorder that is strongly heritable. While several variants have been associated with autism, they only explain a small fraction of the disease heritability. Here, we compare genome-wide copy number variation in over 6.7K patients diagnosed with autism spectrum disorders (ADSs) to over 12.5K neurologically normal controls. The results demonstrate enriched CNV burden that most significantly impacts specific gamma-aminobutyric acid (GABA) receptors and receptors within the metabotropic glutamate receptors (mGluR) pathway impacting ~6% of patients with ASDs. Interestingly, postsynaptic metabotropic glutamate receptors and GABA-B receptors, which are known to functionally interact with each other to regulate glutamate mediated excitatory transmission in the brain, have recently been implicated in autism and genetic defects in multiple GABA receptor genes have also been shown to be associated with the common form of autism. More recently, mGluR5 functional activity was shown to be central in defining the axis of synaptopathophysiology in rare syndromic autism. Although the importance of mGluRs has been repeatedly demonstrated in ADHD, a highly co-incident symptom within the autism spectrum, our study is the first to demonstrate defective mGluR network in the more common non-syndromic autism. We provide evidence of a role for both GABA and mGluR receptor activity in ASDs, with both pathways serving as attractive targets for therapeutic rescue in patients with ASDs that harbor these specific mutations. Functional studies underway are anticipated to better define their individual roles and the interaction of their component genes within these important genetic networks in the pathogenesis of autism.

Chromosome 15q11.2 is associated with schizophrenia risk in a set of patients. *D. Rudd[1], M. Axelsen[2], S. Casey[2], S. Mugge[2], N. Andreasen[2], T. Wassink[2].* 1) Dept Genetics, Univ Iowa, Iowa City, IA; 2) Dept of Psychiatry, University of Iowa, Iowa City.

Schizophrenia is characterized by positive and negative symptoms that include hallucinations, delusions and disorganized thought as well as flat affect and decreased speech. Genomic copy number variation (CNV) has been found to underlie and increase risk for a large number of neuropsychiatric disorders like schizophrenia. This project focuses on identification and characterization of pathogenic CNVs in a sample set of 457 schizophrenia patients and 290 psychiatrically healthy controls. To date, 167 probands and 101 controls have been genotyped using the Affymetrix Genome-Wide Human SNP 6.0 Arrays and analyzed for CNVs with Genotyping Console and PennCNV. CNVs were compared between cases and controls and cross-referenced with the Database of Genomic Variants. The proximal arm of chromosome 15 contains canonical segmental duplications that predispose the region to CNV formation, but only recently have disease-associated CNVs been reported between the two most proximal breakpoints (BPs), BP1 and BP2. Here we report three case subjects that have a ~1Mb deletion of the BP1–BP2 region at chromosome 15q11.2. The BP1–BP2 deletion encompasses the four genes CYFIP1, NIPA1, NIPA2 and GCP5, is present in three probands, two of which were maternally inherited, but not in controls. All CNVs of interest were validated by qPCR or NimbleGen 385K whole-genome array CGH. The four genes within the CNV have previous association with Prader Willi syndrome, Angleman syndrome, autism and schizophrenia and are often inherited from a mildly or unaffected parent. CYFIP1 is of primary interest due to its direct interaction with the Fragile X Mental Retardation Protein (FMRP) and its reported role in regulation of neuronal translation during brain development. NIPA1, NIPA2 and GCP5 are also expressed in the brain. To see if the CNV unmasked any recessive variants on the remaining allele, that allele was sequenced and no such variants were identified. It is unlikely that the 15q11.2 CNV alone is pathogenic because it is such a common region of variation. Therefore each case was investigated further for other compelling CNV hits, based on a “multi-hit” CNV hypothesis where multiple CNVs as a group are pathogenic to schizophrenia. The two probands with maternal inheritance of the deletion were further analyzed for sporadic secondary CNVs. Examples of other compelling CNVs are a de novo duplication of four exons of ATXN2 de novo duplication of two exons CACNA1B and DLGAP2.

Genome-wide Copy Number Analysis on Schizophrenia in Han Chinese. *E. WONG[1], A.W. Butler[1,5], Q. Wang[4], S.S. Cherny[1,2,3], T. Li[4], P.C. Sham[1,2,3].* 1) Department of Psychiatry, the University of Hong Kong, Hong Kong SAR, China, Hong Kong; 2) Centre for Genomic Sciences, the University of Hong Kong, Hong Kong SAR, China, Hong Kong; 3) State Key Laboratory for Brain and Cognitive Sciences, the University of Hong Kong, Hong Kong SAR, China, Hong Kong; 4) The Mental Health Center & Psychiatric laboratory, West China Hospital, Sichuan University, Chengdu, Sichuan, China; 5) MRC SGDP Centre, Institute of Psychiatry, King's College London, UK.

Schizophrenia is a highly heritable, severe psychiatric disorder affecting approximately 1% of the world population. Apart from common variants observed in genome-wide association studies, a number of studies suggested that rare copy number variations (CNV) are rare high-penetrant mutations that increase risk of schizophrenia, and also of a range of other psychiatric disorders including autism and mental retardation. The majority of copy number variation studies on schizophrenia were performed on population with European ancestry. To examine if there are population specific loci to confer risk of schizophrenia, we performed a genome-wide CNV analysis on 381 Han Chinese patients with schizophrenia and 869 controls with no major disorder. We observed a higher global burden of duplication in schizophrenic patients than in controls (All CNVs: 2.3 fold, with empirical p-value = 1 x10-8; rare CNVs: 1.4 fold, with empirical p-value = 3.2 x10-5). As rare CNV events are more likely to be pathogenic, we performed rare CNV analyses in the genic and non-genic regions. There is a non-genic region on 10p14 showed moderate significance, with an empirical adjusted p-value 0.000136. Duplications with average length of 124kb were observed in 8 schizophrenia patients but not in controls. For those CNV regions previously reported associated to schizophrenia, we did not observe similar increased burden of microdeletions or microduplications. Instead of conferring risk to schizophrenia, some of those regions are highly variable in the Han Chinese, suggesting them to be common CNV regions in the population. One of these regions was on 16p11.2, in which 674 CNVs in total were observed in our cases and 873 CNVs in controls, consisting of two common CNV regions. Apart from examining the previously reported CNV regions, we also evaluated genes that are suggested to be associated to schizophrenia.

Rare copy number variants in schizophrenia and bipolar disorder in a Latino Population. *C. Xu[1], A.N. Blackburn[2], S. Gonzalez[1], E.C. Villa[3], M. Ramirez[1], J. Zavala[1], M. Rodriguez[1], C. Camarillo[1], J. Ordonez[1], R. Armas[2], S.A. Contreras[4], R.J. Leach[5], D. Flores[6], D. Jerez[7], A. Ontiveros[8], H. Nicolini[9], D. Lehman[2], M. Escamilla[1].* 1) Psychiatry and Neurology, Texas Tech University Health Sciences Center, El Paso, TX; 2) University of Texas Health Science Center San Antonio TX; 3) University of Texas at El Paso, TX; 4) Department of Psychiatry, University of Texas Health Science Center at San Antonio, San Antonio, TX; 5) Department of Cellular and Structural Genetics, University of Texas Health Science Center at San Antonio, San Antonio, TX; 6) Los Angeles Biomedical Research Center at Harbor, University of California Los Angeles Medical Center, Torrance, CA; 7) Centro Internacional de Trastornos Afectivos y de la Conducta Adictiva, Guatemala, Guatemala; 8) Instituto de Información e Investigación en Salud Mental AC, Monterrey, N.L., México; 9) Grupo de Estudios Médicos y Familiares Carracci, S.C., México, D.F., México.

Purpose: Rare copy number variants (CNVs) have been implicated in neuropsychiatric disorders. We aimed to establish whether burden of CNVs was increased in schizophrenia (SC) and bipolar disorder (BP), and to investigate whether identified CNVs were enriched for loci previously identified for SC and BP in the Latino population. Material and Methods: We undertook a genome-wide analysis of CNVs in 843 subjects including 208 BP, 195 SCZ and 440 unrelated matched controls of Mexican or Central American ancestry from the Southwest United States, Mexico, and Guatemala using Illumina HumanOmni1M-Quad array with 1.1 million markers. A number of quality assurance steps were conducted to filter problematic samples entirely and correct the Log R Ratio data. Two algorithms, SNP and Variation Suite 7 (SVS) and PennCNV, were used to identify CNVs. After quality control, we retained 799 subjects for further analysis. Results: Among high confidence CNV calls defined by both calling algorithms and overlapping for at least 95% of their length, we observed 18 rare CNV deletions between 10 kb to 131 kb in length that were present solely or more often in SC, BP cases than in controls. We confirmed 6 CNV regions that had previously been reported in BP and SC (1q41, 3q26.31, 3q27.1, 4q34.3, 7q31.1, and 7q36.3), and observed 10 novel deletions on 1q31.1, 2q, 5q, 10q26.13 and 11q23.2 in this Hispanic population. Interestingly, two CNV regions at 17q21.31 that were observed in 4 cases and 1 control (202 kb duplication) and 2 BP subjects (121 kb deletion), were located within 2Mbp of our previous linkage peak for SC in the same population (Escamilla et al., 2009). Using SVS algorithm alone, we also identified 9 deletions (ranges between 113.5–1900 kb in at least three subjects) in cases but not controls on 1p36.21, 2p11.2, 3p12.3, 7q11.21, 10q21.1, 15q11.2, 18p11.32, and 22q11.22-23. We also observed duplications at least 3 subjects, ranges between 147–464 kb in cases only on 1p21.1, 10q11.22, 12q14.2, 15q11.2–11.3, 16p11.2-11.1, and 22q11.23. We are performing independent methods to confirm the CNV calls in this population. Conclusion: To our knowledge, this would be the first study of the discovery of CNVs associated with BP and SC in the Latino population. Future replication in the same population and target genome sequencing on these novel CNV regions may finally provide a definitive genomic location for genes that may predispose to BP and SC.

Genome-wide CNV (copy number variation) analysis of narcolepsy in the Japanese population. *M. Yamasaki[1], T. Miyagawa[1], H. Toyoda[1], K. Seik Soon[1], A. Koike[2], T. Sasaki[3], Y. Honda[4], M. Honda[4,5], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Central Research Laboratory, Hitachi Ltd, Tokyo, Japan; 3) Department of Physical and Health Education, Graduate School of Education, The University of Tokyo, Tokyo, Japan; 4) Japan Somnology Center, Neuropsychiatric Research Institute, Tokyo, Japan; 5) Sleep Research Project, Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan.

Human narcolepsy is a sleep disorder, characterized by sleepiness, cataplexy and rapid eye movement (REM) sleep abnormalities. Narcolepsy is caused by a reduction of neurons that produce orexin (hypocretin) neuropeptide. The disease usually begins during adolescence and affects 0.16–0.18% of the general population in Japan and 0.02–0.06% of the populations in the United States and Europe, with men and women equally affected. It is reported that narcolepsy was strongly associated with the human leukocyte antigen (HLA) class II region: *HLA-DRB1*1501-HLA-DQB1*0602* haplotype. The HLA association is thought to be a necessary condition but not sufficient. Recently, rare and large copy number variations (CNVs) have been reported to play a role in the etiology of several neuropsychiatric disorders. Since narcolepsy is considered as a neurological disorder, we aimed to assess the possible association with rare and large CNVs. DNA microarray data (Affymetrix 6.0) and two CNV detection software applications (Birdsuite and PennCNV-Affy) were utilized to detect CNVs in 462 Japanese narcoleptic patients and 562 healthy individuals. Overall, we found significantly enriched rare and large CNVs (frequency ≤1%, size ≥30kb) in the patients (case-control ratio of CNV count = 1.39, $P = 3.80\times10^{-4}$ by Birdsuite). The enrichment of rare and large CNVs in the patients was confirmed by another CNV detection software application (PennCNV-Affy). *PARK2* (parkinson protein 2, E3 ubiquitin protein ligase) region showed a significant association with narcolepsy. Four patients were assessed to carry duplications of the gene region, while no controls carried the duplication, that was further confirmed by quantitative PCR assay. Moreover, a pathway analysis of rare and large CNVs revealed enrichments in lipid catabolic process, ion transport, immune response and acetyltransferase activity, which partially agree with the analysis of our SNP-based GWAS data. This study provided the first report for the risk of multiple rare CNVs in the pathogenesis of narcolepsy.

Integrating GWAS and protein-protein interaction network identifies a subnetwork implicated in Alcohol Dependence. *S. Han[1], B.Z. Yang[1], H. Kranzler[2,3], F. Lindsay[4], H. Zhao[5], J. Gelernter[1].* 1) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 2) Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA; 3) VISN 4 MIRECC, Philadelphia VAMC, Philadelphia, Pennsylvania, USA; 4) Departments of Medicine (Biomedical Genetics), Neurology, Ophthalmology, Genetics & Genomics, Biostatistics, and Epidemiology, Boston University Schools of Medicine and Public Health, Boston, Massachusetts, USA; 5) Departments of Genetics, Biostatistics, Statistics, Yale University School, New Haven, CT.

Family and twin studies have established a genetic contribution to alcohol dependence (AD). However, few AD susceptibility genes have been identified and successfully replicated. In the current study, we aimed to integrate genomewide association studies (GWAS) and human protein-protein interaction (PPI) networks to identify a subnetwork of interacting genes that may work together to contribute to the risk of AD. Using two GWAS datasets from the Study of Addiction: Genetics and Environment (SAGE) and the Collaborative Study on the Genetics of Alcoholism (COGA), we first performed a dense module search within the human PPI network to construct a subnetwork enriched for genes associated with AD, followed by association tests between the subnetwork and AD in five independent case-control samples, including the European-American (EA) (1453 AD and 1217 controls) and African-American (AA) (708 AD and 442 controls) samples from the merged SAGE and COGA dataset, randomly selected samples (795 AD and 1433 controls) from the genomewide association study of alcohol use and alcohol use disorder in Australian Twin-Families (OZ-ALC), and our collected EA (1021 AD and 473 controls) and AA (1641 AD and 1367 controls) samples. We established a subnetwork of 39 genes that are not only enriched for genes associated with AD, but also are collectively associated with AD in both EAs ($P<0.0001$) and AAs ($P=0.0008$) from SAGE and COGA samples. We further replicated the association in three other independent case-control samples, including the Euroepan-ancestry Austalian twin sample ($P=0.0003$), our EAs ($P=0.004$) and and our AAs ($P=0.005$). Functional enrichment analysis of the genes in the subnetwork revealed biological mechanisms that may underlie some of the genetic risk for AD, such as cation transport, ion transport, synaptic transmission and transmission of nerve impulse. In conclusion, we identified a subnetwork implicated in AD that is biological meaningful and highly reproducible, and may provide important clues to future research into the etiology and treatment of AD.

APP associated with late-onset Alzheimer disease in autopsy-confirmed dataset. *T. Montine[1], G.W. Beecham[2], R. Rajbhandary[2], K.L. Hamilton[2], A.C. Naj[2], E.R. Martin[2], R. Mayeux[3], J.L. Haines[4], L. Farrer[5], G. Schellenberg[6], M.A. Pericak-Vance[2], The Alzheimer Disease Genetics Consortium.* 1) Department of Pathology, University of Washington, Seattle, WA; 2) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 3) Taub Institute of Research on Alzheimer's Disease, Columbia University, New York, NY, USA; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA; 5) School of Medicine, Boston University, Boston, MA, USA; 6) School of Medicine, University of Pennsylvania, Philadelphia, PA, USA.

Background: Late-onset Alzheimer disease (LOAD) is a highly heritable neurological disease with several known genetic risk loci (APOE, CR1, etc). With the exception of APOE, these loci were identified using GWAS in large datasets and have small effects on risk (e.g., odds ratios ~= 1.1). However, phenotypic heterogeneity may obscure the true effects of these and other loci. To investigate this concern we performed a GWAS between autopsy-confirmed cases (ACC) and controls and compared the results to a GWAS of clinically identified cases (CIC) and controls. Methods: Samples were derived from 12 cohorts that are part of the Alzheimer Disease Genetics Consortium. Genotyping was performed on high-density genotyping chips and imputed to a 1000 Genome Project map. Logistic regression was performed within each cohort and METAL was used to meta-analyze across cohorts. Datasets consisted of 4,854 neuropathology confirmed cases and 8,264 controls (ACC set) and 5,190 clinically identified cases and 7,400 controls (CIC set). Both control sets included a mix of clinically identified and neuropathology confirmed controls. Results: Most known LOAD loci were confirmed in both the ACC and CIC analyses with at least nominal association ($p<0.05$); the lone exception being EPHA1, whose effect trended in the reported direction, but did not reach statistical significant association in the autopsy dataset (p-value=0.20). There were no novel associations that met a genome-wide correction for multiple-testing in either analysis. There were however several loci with strong association ($p <5\times10\text{-}6$) in the ACC analysis that were not associated in the CIC analysis. Notably, common variants in the amyloid precursor protein (APP) were associated with autopsy cases (rs4817090, OR=0.85, $p=2.4\times10\text{-}6$), but not with clinic-based cases (OR=0.98, p=0.55). Conclusion: While it is known that rare variation in APP can lead to early-onset forms of AD, this study is the first to implicate common variants in APP in a large case-control study. It suggests common variation in APP may influence LOAD pathology in a way that a more heterogeneous clinic-based sample may not be adequately powered to detect, and confirms the utility of an autopsy-confirmed dataset. To further follow-up we are examining association with more detailed neuropathology features, and investigating more stringently defined autopsy-confirmed cases and controls.

An Association Study Comparing Children with Extreme High and Extreme Low Obsessive-Compulsive Traits in the General Population. *P.D. Arnold[1], V. Sinopoli[2], J. Crosbie[1], L. Park[2], A. Dupuis[3], A. Paterson[2], R.J. Schachar[1].* 1) Dept Psychiatry, Hosp Sick Children, Toronto, ON, Canada; 2) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 3) Program in Child Health Evaluative Sciences. Hospital for Children, Toronto, ON, Canada.

Objective: Obsessive- Compulsive disorder (OCD) is a common, debilitating and phenotypically heterogeneous disorder which has been shown to be more highly heritable when symptoms begin in childhood or adolescence. OC symptoms are quantitative traits, continuously distributed in the general population and ignoring the quantitative nature of OCD may reduce the power of genetic association studies comparing OCD patients to controls, particularly if controls are unscreened. The goal of the study was to utilize a novel and cost-effective design in which we conduct a GWAS comparing children on the extreme high and extreme low ends of a quantitative distribution of OC traits measured in the general population. Methods: The sample consisted of 16,099 children and adolescents recruited from the community. Self- and/or parent-report data on obsessive-compulsive (OC) symptoms was collected from all participants. From 7545 unrelated children and adolescents of European Caucasian descent, we selected individuals with the highest (top 10 per cent, N=755) and extreme lowest (bottom 10 per cent, N=755) scores on OC symptoms after controlling for age and gender. Genotyping is being conducted using the Illumina Omni 2.5 beadchip. In addition, we have genotyped the serotonin transporter linked polymorphic region (5HTTLPR) including an insertion/deletion polymorphism and rs25531, variants which in combination have been shown to influence SLC6A4 expression. Quality control analyses were conducted using PLINK, including multidimensional scaling (MDS) for population structure and the Cochrane-Armitage trend test for detection of association. Results: To date, we have analyzed the 5HTTLPR and identified no significant association (p=0.15) between high- and low- expressing genotypes of promoter variants in this region and OC traits. The GWAS is ongoing and results will be available at the time of the presentation. Quality control analyses on an initial set of 191 individuals resulted in 7/191 exclusions due to low call rate; (n=2), sex discrepancy (n=1) and non-European ancestry based on MDS plots (n=4). Conclusions: This research has the potential to increase our ability to identify candidate variants for future biological investigation, to facilitate the understanding of the mechanism by which genetic risks result in OCD. This will be the first report of the utility of performing a genome-wide study of quantitative OC traits.

2500T

Irish high-density schizophrenia families are enriched for common polygenic effects. *T.B. Bigdeli[1], S.A. Bacanu[1], B.T. Webb[1], B.S. Maher[2], D.L. Thiselton[1], B. Wormley[1], F.A. O'Neill[4], D. Walsh[5], A.H. Fanous[3,1], B.P. Riley[1], K.S. Kendler[1].* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 2) Department of Mental Health, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 3) Washington VA Medical Center Washington, D.C; 4) Department of Psychiatry, Queens University, Belfast, UK; 5) The Health Research Board, Dublin, Ireland.

Although the combined evidence of family, twin, and adoption studies supports a substantial aggregate genetic component for schizophrenia, there is no evidence of either Mendelian inheritance in affected families nor genes of large effect in the general population. Recent genome wide association studies (GWAS) of schizophrenia provide strong support for a substantial common polygenic contribution of a large number of small effects. However, the respective contributions of rarer or structural variation have not yet been realized. Of interest herein is the supposition that the occurrence of multiple cases in a family supports segregation of a transmissible genetic risk factor, as opposed to de novo mutations having given rise to sporadic cases. We sought to assess the predictive value of polygenic findings reported by the Psychiatric GWAS Consortium (PGC), as applied to a sample of Irish high-density Schizophrenia families (ISHDSF). Using genome-wide SNP data available for affected and unaffected relatives, as well as a larger panel of imputed SNP genotypes, per-individual polygenic risk scores were constructed based on the PGC analysis. Per-family averages, calculated from the normalized scores for all family-members were shown to be elevated (mean Z-score=0.424, SD=0.761). This enrichment for common effects remained significant following permutation of simulated PGC datasets and recalculation of per-individual scores ($P_{permutation}$=0.01). Polygenic scores were found to be increased among probands (mean Z-score=0.425) compared to their non-psychotic relatives (mean Z-score=0.341, SD=0.891). However, comparison of mean scores by categorical diagnoses of psychotic illness revealed greater enrichment among less-severely affected relatives of probands (mean Z-score=0.649, SD=1.007). Because families were clustered geographically, we addressed whether the observed enrichment could exhibit regional differences. These findings indicate a non-random distribution of family means across the historical counties of the Republic of Ireland and Northern Ireland. In summary, we have demonstrated empirically that the unaffected members of multiply-affected schizophrenia families may be enriched for widely-replicated, common polygenic effects. Furthermore, between-family differences in patterns of enrichment among psychotic and non-psychotic relatives highlights an apparent heterogeneity of genetic architecture in schizophrenia.

Genome Wide Association Study for Maternal Effects in Autism. *S. Buyske[1], E.S. Stenroos[2], W.G. Johnson[2].* 1) Statistics & Biostatistics, Rutgers Univ, Piscataway, NJ; 2) Neurology, Univ of Medicine & Dentistry of New Jersey-Robert Wood Johnson, Medical School, Piscataway, NJ.

Maternally acting gene alleles (MAGAs) are hypothesized to act in mothers prenatally to alter the fetal environment and affect the phenotype in offspring, independently of whether or not they are inherited by the fetus. Some evidence of MAGAs in autism has been found using a candidate gene approach, but there appear to be no published genome-wide association studies for any trait on MAGAs. We conducted a genome-wide analysis for MAGAs using existing data from the Autism Genetic Resource Exchange (AGRE) on the Illumina Hap550 array in 825 families and identified a region of chromosome 3p24.3 that might contain one or more MAGAs. A log-linear analysis based on asymmetries in parental genotypes showed rs12487874, intronic in the *RTFN1* gene, as genome-wide significant (p=8.01e-09) for a maternal effect with no evidence of child effect. Analysis of existing data from the Autism Genome Project (AGP) in 948 families (excluding AGRE subjects) on the Illumina 1M array showed that rs12636481, 88kb from rs12487874, was highly significant (p = 7.89e-15) for a maternal effect with no evidence of child effect; rs12487874 did not pass quality control in the AGP study. A second locus was genome-wide significant for a maternal effect with no evidence of child effect in the AGP study: rs2741849 in an intronic region of the *PPP1R12B* gene on 1q32.1 (p = 4.03e-10); this region is poorly covered by the Hap550 array. Follow-up work based on imputated genotypes using a 1000 Genomes Project reference panel is underway.

Analysis of putative pathogenic CNVs in autistic patients of Portuguese origin. *I.C. Conceição[1,2,3], B.A. Oliveira[1,2,3], C. Correia[1,2,3], J. Coelho[1], C. Café[4], J. Almeida[4], S. Mouga[4,5], F. Duque[4,6], G. Oliveira[4,5,6,7], A.M. Vicente[1,2,3].* 1) Instituto Nacional de Saúde Dr Ricardo Jorge, Lisbon, Portugal; 2) Center for Biodiversity, Functional & Integrative Genomics, Lisboa, Portugal; 3) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 4) Unidade Neurodesenvolvimento e Autismo, Centro de Desenvolvimento, Hospital Pediátrico (HP); Centro Hospitalar e Universitário de Coimbra (CHUC), Coimbra, Portugal; 5) Instituto Biomédico de Investigação em Luz e Imagem, Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal; 6) Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal; 7) Centro de Investigação e Formação Clinica do HP-CHUC, Coimbra, Portugal.

Recent reports by the Autism Genome Project (AGP) consortium and other groups show that Copy Number Variants (CNV), while individually rare, collectively may explain a large fraction of the etiology of Autism Spectrum Disorders (ASD). The goal of this study was to establish the relevance for ASD etiology of potentially pathogenic CNVs identified in a Portuguese population sample by the AGP whole genome CNV analysis. A total of 14218 CNVs were identified in 342 Portuguese probands (35 females, 307 males), genotyped by the AGP using the Illumina Infinium1M SNP microarray. From these, we selected 936 CNVs that did not overlap more than 50% with approximately 8000 controls in available databases. These CNVs range from about 5 Kb to 1.9 Mb, and 52% are deletions (del), while 48% are duplications (dup). Larger CNVs (>500 Kb) are more frequently duplications than deletions; also, the ratio of dup/del for CNVs that do not include any genes is approximately 40/60, while for CNVs with more than three genes the ratio is inverted (60/40). These 936 CNVs were inspected for recurrence rates in this population and inclusion of ASD-implicated or candidate genes, or other genes of relevance for brain function. Particularly interesting CNVs were validated by qPCR in patients and relatives, and breakpoint mapping was performed by Long-range PCR. ASD genes like *SHANK3*, *NRG1*, *CNTNAP2* were identified in, respectively, 1, 2 and 1 probands. Genes such as *ATRX* and *DPYD*were duplicated and deleted, respectively, in 10 and 22, patients, but not in controls. The same is true for *NRP1*, *VAULTRC2* (a vault RNA) and the 5q13.2 region. Two genes from the*Annexin* family (*ANXA1* and *ANXA7*) were also exclusively duplicated or deleted in autistic patients. *ANXA1*, known to have a neuroprotective role against inflammation, is present in 4 patients but not in controls from databases or in 410 Portuguese controls. Analysis of clinical presentation did not identify any specific symptom patterns or associated co-morbidities that might specifically characterize any of these CNVs. Segregation analyses in families and correlation with the presence of mild broad spectrum signals in relatives is ongoing. This exhaustive analysis of CNVs for clinical interpretation is necessary for the efficient translation of this knowledge into clinical practice, aiming at the development of molecular tools that may assist behavioral screening procedures for early diagnosis in ASD as well as genetic counseling.

2503T

GWAS Identifies Biologically Relevant SNP Associations with Sexual Partnering Behavior. *J. Gelernter[1, 2], H.R. Kranzler[3], R. Sherva[4], R. Koesterer[4], L. Almasy[5], H. Zhao[1], L.A. Farrer[4].* 1) Yale University School of Medicine, New Haven, CT; 2) VA CT Healthcare Center, West Haven, CT; 3) University of Pennsylvania School of Medicine, Philadelphia, PA; 4) Boston University School of Medicine, Boston, MA; 5) Texas Biomedical Research Institute, San Antonio, TX.

The specific factors influencing human sexual partnering are poorly understood. Arguably, in the pre-modern era, multiple mating may have been tied to selection for traits related to survival including resistance to infection and starvation, strength, and certain behaviors. Recently, we completed a GWAS using the Illumina Omni-Quad microarray in ~5800 African- and European-American (AA and EA) participants in genetic studies of alcohol, cocaine, and opioid dependence. Subjects were interviewed using the Semi-Structured Assessment for Drug Dependence and Alcoholism (SSADDA) - an instrument that covers all major DSM-IV diagnoses as well as other numerous psychiatric and lifestyle traits. One of these is the response to: “How many sexual partners have you had in your life?” Association of age-adjusted residuals of this variable with more than 3 million SNPs reliably imputed using the 1K Genomes reference panel was tested in each sex*population subgroup using generalized estimating equations. Results from subgroup analyses were combined by meta analysis. SNPs with p-values <1E-06 were genotyped in a replication sample of ~2300 subjects. Genomewide-significant results were obtained for 13 SNPs including ones that map to genes coding proteins involved in reproductive-related functions (e.g., rs74738626 in KCNU1 which encodes a testes-specific K+ channel [p=1.2E-12], rs78227383 in NME5, a nucleoside diphosphate kinase which may have a specific function in the phosphotransfer network involved in spermatogenesis [p=4.0E-11 in EAs only], and rs76221611 in CCND2 which encodes cyclin D2, shown to be highly expressed in ovarian and testicular tumors [p=3.3E-11 in AAs only]), immune response (e.g., rs2709778 in GARS which encodes gylcyl-tRNA synthetase shown to be a target of autoantibodies in human autoimmune diseases [p=1.0E-10 in males only]), and other genes of biological interest (e.g., rs10849971 in ALDH2, an alcohol-metabolizing enzyme that is also an alcohol dependence risk locus [p=9.6E-09 in females only]). These findings have clear implications with respect to normal sexual function and potentially for risk of sexually transmitted disease.

A genome wide association study (GWAS) of alcohol dependence (AD) using a hybrid design. *L.M. Hack[1], A.E. Adkins[1], B.T. Webb[2], B.S. Maher[3], D.G. Patterson[4], D. Walsh[5], C.A. Prescott[6], D.M. Dick[1,2], K.S. Kendler[1,2], B.P. Riley[1,2].* 1) Department of Human and Molecular Genetics, Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 2) Department of Psychiatry, Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 3) Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA; 4) Shaftesbury Square Hospital, Belfast, Northern Ireland, United Kingdom; 5) Health Research Board, Dublin, Ireland; 6) Department of Psychology, University of Southern California, Los Angeles, CA, USA.

Background: The powerful, systematic, and unbiased GWAS has been successful in identifying replicated susceptibility variants for numerous complex diseases. Compared to several other psychiatric disorders, the total sample size for GWAS of AD is more modest with individual samples in the range of 500–2500 individuals. Our sample is comparably sized (total N= 1934) and consists of related cases and unrelated, lightly screened controls. **Methods:** The cases are from the Irish Affected Sib Pair Study of Alcohol Dependence and were diagnosed using DSM-IV criteria. Genotyping was conducted using the Affymetrix V6.0 array by three separate genotyping core facilities. Because artifacts are a known issue when combining samples genotyped at multiple sites, genotypes were called using BeagleCall, which considers both allele signal intensities and LD information. After quality control filtering, the sample contained 712 cases, 1762 controls, and 676,736 SNPs for analysis. The within-site and cross-site duplicate error rates were 0.0043% and 0.0054%, respectively. Methods for analysis using the hybrid design are not widely implemented and the optimal analysis approach is being investigated. Here we present results from an independent case control analysis consisting of 433 cases and 1762 controls. The analysis was conducted in PLINK using logistic regression with age and sex as covariates. **Results:** While no SNP reached genome-wide significance (p<7.39×10^{-8}), there were 4 SNPs in high LD within chromosome 15 in the suggestive range (p=10^{-7}-10^{-5}) that fall within *RYR3*, which encodes an intracellular calcium channel. Of the three ryanodine isoforms in humans, RyR3 is the most highly expressed in the brain (Giannini et al., 1995). The ryanodine family of receptors has been shown to modulate BK channels, which were implicated in AD and alcohol-related traits in previous GWA as well as model organism studies of ethanol behaviors (Chavis et al., 1998; Davies et al., 2003; Edenberg et al., 2010; Kendler et al., 2011). Furthermore, proteins in the ryanodine family have been found to interact with proteins in the CLIC family, intracellular chloride channels implicated in acute ethanol behaviors in model organisms (Song et al., 2010; Bhandari et al., 2012). **Discussion:** We have identified a locus associated with AD that should be followed-up in independent samples. Studies in model organisms of this gene are currently being pursued within the VCU Alcohol Research Center.

2505W

Genetic analysis of tobacco use in the Swedish Twin Registry: Genome wide association studies of cigarette and snus consumption. *PA. Lind[1], D. Cesarini[2], DJ. Benjamin[3], PD. Koellinger[4], PKE. Magnusson[5], M. Johannesson[6], SE. Medland[1].* 1) Quantitative Genetics, Queensland Inst Med Res, Herston, Australia; 2) Center for Experimental Social Science, Department of Economics, New York University, New York, NY, USA; 3) Department of Economics, Cornell University, Ithaca, NY, USA; 4) Department of Applied Economics, Erasmus Universiteit Rotterdam, Rotterdam, Netherlands; 5) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 6) Department of Economics, Stockholm School of Economics, Stockholm, Sweden.

To identify genetic risk variants associated with increased nicotine intake through cigarette smoking and Swedish snus (oral smokeless tobacco) use, we performed genome-wide association studies (GWAS) for the number of cigarettes smoked per day (CPD) and boxes of snus consumed per week (BOXWK) in 4,100 (51% male) and 1,054 (male) unrelated individuals respectively from the Swedish Twin Registry. Association was conducted using both genotyped (Illumina OmniExpress) and imputed (1KGP-EUR-vI.3, MAF >1%) single nucleotide polymorphisms (SNPs) using both PLINK and Merlin, adjusting for age and sex, followed by gene and pathway enrichment analyses. Although no SNP reached genome-wide significance in either analysis, fifteen achieved P-values < 1 × 10^{-5} for CPD, including 10 variants located near or within the *CHRNA5-CHRNA3-CHRNB4* locus on chromosome 15q25. Fourteen SNPs achieved P-values < 1 × 10^{-5} for BOXWK, with 8 located on chromosome 4q21. There was little or no evidence for association between snus use and 15q25 variants (P ≥ 0.05). Secondary pathway analyses found several addiction-related pathways were enriched for SNPs associated with CPD and BOXWK. We report the first GWAS of snus use for which the underlying genetic basis is largely unknown. While both behaviours are important sources of nicotine intake within the Swedish population, we have shown that the pattern of association with CPD and BOXWK is different at the individual SNP level. While further replication is required, particularly for snus use, the identification of susceptibility loci and biological pathways will be important in characterizing the biological mechanisms that underpin both snus consumption and cigarette smoking.

Genome-wide association study for intracranial aneurysm in the Japanese population. *S. Low[1], A. Takahashi[1], M. Kubo[2], Y. Nakamura[3].* 1) Laboratory for Statistical Analysis, Center for Genomic Medicine, RIKEN, Tokyo, Japan; 2) Laboratory for Genotyping Development, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 3) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Aneurysmal subarachnoid hemorrhage (aSAH) is the most serious subtype of stroke. Genetic factors have been known to play an important role in the development of intracranial aneurysm (IA), some of which further progress to subarachnoid hemorrhage (SAH). In this study, we conducted a genome-wide association study (GWAS) to identify common genetic variants that are associated with the risk of IA, using 1383 aSAH subjects and 5484 control individuals in the Japanese population. We selected 36 single-nucleotide polymorphisms (SNPs) that showed suggestive association (P <1 × 10^{-4}) in the GWAS as well as additional 7 SNPs that were previously reported to be associated with IA, and further genotyped an additional set of 1048 IA cases and 7212 controls. We identified an SNP, rs6842241, near *EDNRA* at chromosome 4q31.22 (combined P-value = 9.58 × 10^{-9}; odds ratio = 1.25), which was found to be significantly associated with IA. Additionally, we successfully replicated and validated rs10757272 on *CDKN2BAS* at chromosome 9p21.3 (combined P-value = 1.55 × 10^{-7}; odds ratio = 1.21) to be significantly associated with IA as previously reported. Furthermore, we performed functional analysis with the associated genetic variants on *EDNRA*, and identified two alleles of rs6841581 that have different binding affinities to a nuclear protein(s). The transcriptional activity of the susceptible allele of this variant was significantly lower than the other, suggesting that this functional variant might affect the expression of EDNRA and subsequently result in the IA susceptibility. Identification of genetic variants on *EDNRA* is of clinical significance probably due to its role in vessel hemodynamic stress. Our findings should contribute to a better understanding of physiopathology of IA.

Genome-wide association study identified susceptibility loci associated with nicotine dependence in a Japanese population. *D. Nishizawa[1], K. Shinya[1], J. Hasegawa[1], N. Sato[2,3], F. Tanioka[4], H. Sugimura[3], K. Ikeda[1].* 1) Addictive Substance Project, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 2) Department of Clinical Nursing, Hamamatsu University School of Medicine, Hamamatsu, Japan; 3) Department of Tumor Pathology, Hamamatsu University School of Medicine, Hamamatsu, Japan; 4) Department of Pathology, Iwata City Hospital, Iwata, Japan.

Objectives: Many genetic and environmental factors can be involved in the etiology of nicotine dependence (ND). To date, several candidate genetic variations have been identified to be associated with smoking behaviors and vulnerability to ND. These were found mostly by investigating single nucleotide polymorphisms (SNPs) on each gene related to phenotypes of concern or by genome-wide association studies (GWAS), which treat genetic markers in the whole genome, conducted for subjects with European ancestry. However, genetic factors have not been reportedly investigated for Japanese population utilizing whole-genome genotyping arrays. We comprehensively explored genetic contributors to ND by GWAS in Japanese. **Methods**: Subjects were 300 patients who visited Iwata City Hospital. A number of participants involved in this study had various smoking habits and filled in a questionnaire leaflet containing various questions. Whole-genome genotyping was performed for 300 samples with iScan System (illumina, San Diego, CA) and the BeadChip HumanCytoSNP-12 v2.0. A two-stage GWAS was conducted using 150 samples for each stage to investigate the association between genotype distributions and severity of ND, which was measured by scores of the Fagerström Test for Nicotine Dependence (FTND), a test that yields a continuous measure of ND, the Tobacco Dependence Screener (TDS), consisting of 10 questions, and the numbers of cigarettes smoked per day (CPD). **Results and Conclusion**: In association study between over 200,000 marker SNPs and FTND, TDS, and CPD, none of the SNPs were found to reach the genome-wide significant level and the *P*-values were no less than 10^{-6} in all analyses. However, several potent SNPs were found in loci that have not been highlighted, as well as in loci that include known candidate genes resulted from previous GWAS. Among them was *CSMD1*, CUB and Sushi multiple domains 1, which appeared in top ranks of our GWAS results for all the three phenotypes examined. Although future studies with larger sample size is required, these results will serve to discover genetic factors contributing to ND and smoking behavior specific to Japanese population in addition to those common to other populations.

Genome-wide Meta-analysis of Autism Spectrum Disorders (ASD) Supports *A2BP1* as an ASD Candidate Gene. *Y.S. Park[1,2], J. Jaworski[1], I. Konidari[1], P. Whitehead[1], M.L. Cuccaro[1], E.R. Martin[1,2], J.L. Haines[3,4], M.A. Pericak-Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL, USA; 3) Vanderbilt University School of Medicine, Vanderbilt University, Nashville, TN, USA; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

Recent genetic studies have identified both common and rare genetic variations contributing to autism spectrum disorders (ASD) in multiple genes including *RELN*, *FOXP2*, and *SHANK3*. However, much of the genetic contribution of this highly heritable disorder (h^2>0.9) remains unidentified. We conducted a genome-wide association study of 2,995 affecteds and 7,057 unaffecteds in order to identify novel genetic associations of common SNPs to ASD. Our discovery data set included 620 families (694 affected individuals) ascertained and genotyped at John P. Hussman Institute for Human Genomics and Vanderbilt Center for Human Genetics Research, as well as 696 families (1,240 affected individuals) ascertained and genotyped at Autism Genetics Resource Exchange. The analysis of the discovery data set alone has been published elsewhere (Ma et al., *Annals of Human Genetics*, 2009). Our replication data set included 1,065 families (1,061 affected individuals) ascertained and genotyped by Simons Simplex Collection. Sample genotyped data were imputed up to a common set of 7,560,685 SNPs with IMPUTE2 v.2.1.2 using the 1,000 Genomes Project June 2011 Release as a reference. Generalized estimating equations were used with covariate adjustments for sex and population substructure. While no SNP associations met the threshold for genome-wide significance ($p<5\times10^{-8}$), 10 SNPs demonstrated associations of p<0.001 from the joint meta-analysis of all data sets and showed p<0.05 in both discovery and replication analyses. Of these 10 SNPs, 3 SNPs were in introns of a chromosome 16 gene *A2BP1* (rs3095508, meta-p=6.829×10^{-4}; rs42189 meta-p=8.038×10^{-4}; and rs811919 meta-p=9.188×10^{-4}). *A2BP1* is a known and compelling ASD candidate gene and a recent study has shown an evidence of dysregulated splicing of*A2BP1*-dependent alternative exons in the ASD brain using transcriptome analysis (Voineagu et al., *Nature*, 2011).

2509T

A polygenic analysis of autism, depression and schizophrenia risk alleles' effect on reproductive fitness in the general population. *R.A. Power[1], R. Uher[4], S. Ripke[3], C.M. Lewis[1], P. McGuffin[1], P. Lichtenstein[2], H. Wallum[2].* 1) Social Genetic & Developmental Psychiatry Centre, Institute of Psychiatry, London, United Kingdom; 2) Karolinska Instiutet, Sweden; 3) The Analytic and Translational Genetics Unit, Massachusetts General Hospital, U.S.A; 4) Brain Repair Centre, Dalhousie University, Halifax, Canada.

The schizophrenia paradox has long existed in psychiatric research: how does a disorder remain highly prevalent if also highly heritable and damaging to an individual's reproductive fitness? Following from previous work showing increased fecundity in relatives of those with psychiatric illnesses, we looked for a similar molecular signal. With progress in genome-wide association studies, it is now possible to directly examine how risk alleles affect reproductive fitness in the general population. While few causal loci have been replicated for psychiatric disorders, methods using aggregate scores of risk alleles have been reasonably successful in explaining a significant proportion of variance in affection status. In this analysis we tested for an association between polygenic scores for autism, depression and schizophrenia with number of grandchildren in the general population. Using data from the Psychiatric GWAS Consortia analysis of autism, depression and schizophrenia, polygenic scores were constructed within a Swedish dataset of 6,219 individuals born in 1910–43. The Swedish Multi-Generation Register was used to identify their grandchildren. Linear regression was then used to test for association between polygenic scores for the disorders and number of grandchildren. Autism and depression scores weren't associated with reproductive fitness at any threshold for significance. As it has been suggested depression risk variants reflect `plasticity alleles', we tested for a difference in mean variance in fitness across depression scores. The results were in the expected direction with increased variance for those with increased depression score but not significant (p=0.11). Greater schizophrenia scores were associated with fewer grandchildren (p=0.008), explaining 0.11% of the variance. This association was not driven by extreme scores or a sex specific effect. These results exacerbate the schizophrenia paradox by increasing the negative selection against schizophrenia risk alleles, particularly as only a portion of the heritability of schizophrenia is captured by the polygenic score. The results may reflect deleterious mutations that lead both to schizophrenia and also behavioural deviations that are sub-clinical but severe enough to reduce fitness. This might be evidence for the need to better screen controls for sub-clinical features or to view psychosis on a continuum. Overall there is no evidence for balancing selection for these disorders.

2510F

Maternal genetic effects on autism risk: results from the Early Markers for Autism (EMA) study. *J.F. Quinn[1], L.C. Croen[2], L.W. Weiss[1].* 1) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 2) Autism Research Program, Kaiser Permanente Division of Research, Oakland, CA.

Purpose: Studies of main genetic effects in autism have failed to explain the high heritability estimates for the disease suggested by classical twin studies and by correlation of broader autism phenotypes within families. Recently, researchers have begun to study the prenatal maternal environment as a risk factor in autism (PMID 18262386; 22012245; 18571628; 21810230). We hypothesize that maternal genetic effects, including an interaction between maternal and filial genetic variation (transgenerational epistasis), may influence susceptibility to autism. Methods: To test our hypothesis of maternal genetic effects in autism, we examined a sample of 400 maternal-filial duos where the child has been diagnosed with autism and 400 matched control duos where the child does not have autism. Using the Affymetrix Axiom EUR array, we genotyped our samples at approximately 600k single nucleotide polymorphisms (SNPs). We performed two novel genome-wide association studies: first, we compared the mothers who had given birth to an autistic child to the control mothers (maternal genetic main effects); second, we considered the maternal-filial genotype combination at each marker and performed several tests to see if the relative proportion of genotype combinations differed between case and control duos (transgenerational epistasis). Specifically, at each locus we compared case and control cohorts using three models: 1) comparing the proportion of duos that have identical genotypes, 2) comparing the proportion where the mother possesses an allele that her child does not possess, and 3) comparing the proportion where the child possesses an allele that the mother does not possess. Results: No results were genome-wide significant (P < 5e-8). For the test of maternal genetic main effects, we found variation within or nearby the following genes to be significant at the $P < 10^{-5}$ level: *MAML2, KRT18P55, and XK*. For the tests of transgenerational epistasis, we found variation within or near the following genes to be significant at the $P < 10^{-5}$ level in at least one of our three models: *C4orf37, INSC, SLC7A8, GABRB3, GOT2, PALM2, KIAA0430, SLC14A2, SEMA3C, LY86, and CDH11*. In addition, we found variation in or near the following genes previously implicated in autism to be significant at the $P < 10^{-4}$ level in at least one of our three models: *MACROD2, NRXN1, RELN, GRIN2B, and PCDH9*. We intend to follow up our results from this discovery cohort through replication.

Genome-wide pathway analysis in multiple cohorts implicates histone genes and inflammation in hippocampal atrophy. *V.K. Ramanan[1,2,3], L. Shen[2,4], J.D. West[2], S. Kim[2], S.L. Risacher[2], K. Nho[2], Y. Wang[2], J. Wan[2], T.M. Foroud[1,4], L.A. Farrer[5], A.J. Saykin[1,2,4], The Alzheimer's Disease Neuroimaging Initiative (ADNI).* 1) Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 2) Center for Neuroimaging, Department of Radiology and Imaging Sciences, Indiana University School of Medicine, Indianapolis, IN; 3) Medical Scientist Training Program, Indiana University School of Medicine, Indianapolis, IN; 4) Center for Computational Biology and Bioinformatics, Indiana University School of Medicine, Indianapolis, IN; 5) Department of Medicine (Biomedical Genetics), Boston University School of Medicine, Boston, MA.

Hippocampal volume loss is a known marker of prodromal and incident Alzheimer's disease (AD) and of other clinical states with impaired memory and cognition. Importantly, the genetic susceptibility architecture underlying hippocampal atrophy is not yet known and may involve multiple loci with differential effects across the structure's distinct subfields. To identify functional gene sets whose variants exhibit collective effects on hippocampal volume, we performed pathway analyses (Ramanan et al. *TIG* 2012) of genome-wide association study (GWAS) data in three independent cohorts with control, AD, and mild cognitive impairment or cognitive complaint participants (combined $N > 1000$). Volumes for whole hippocampus and 5 hippocampal subfields were extracted from MP-RAGE MRI scans using the FreeSurfer software and were adjusted for age, gender, education, handedness, and intracranial volume. Following genotype imputation and quality control, an additive model GWAS was performed for each volumetric phenotype in each cohort using Plink. All analyses employed a 1% minor allele frequency threshold and included diagnosis as a covariate. Gene-based p-values accounting for gene size and linkage disequilibrium were calculated within each GWAS using GATES (Li et al. *AJHG* 2011). Pathway analyses on these p-values were performed with GSA-SNP (Nam et al. *NAR* 2010) using gene sets from multiple pathway databases, and the false discovery rate (FDR) was applied to correct for multiple comparisons. A total of 35 pathways exhibited enrichment of association ($p_{FDR} < 0.05$) to a regional volume. In particular, pathways containing genes related to histones and regulation of DNA structure, repair, and transcription were enriched across several regions in multiple cohorts (smallest $p_{FDR} = 1.34 \times 10^{-7}$). Genetic variation in these pathways may impact susceptibility to epigenetic histone modifications related to learning and memory. Other enriched pathways included genes involved in immune response and cytokine signaling, such as *TNF*, and genes involved in synaptic plasticity for learning and memory, such as *NFKB* and *RXRA*. Subsequent analyses of plasma and cerebrospinal fluid analytes in one cohort revealed significant correlations between hippocampal volumes and candidate markers for stress and inflammation. Further investigation of the interactions between inflammation and DNA integrity in hippocampal development and neurodegeneration appears warranted.

2512T

Dissection of genetic architecture of bipolar disorder and schizophrenia: Results from a combined dataset of nearly 40,000 individuals. *S. Ripke[1], D.M. Ruderfer[2], Psychiatric Genomics Consortium.* 1) Analytic and Translational Genetics Unit, Mass Gen Hosp, Boston, MA; 2) Division of Psychiatric Genomics, Department of Psychiatry, Mount Sinai School of Medicine, NY, NY.

Background Bipolar disorder (BP) and schizophrenia (SCZ) are two chronic debilitating psychiatric illnesses that together affect ~3% of the world's population. They have been dichotomized since the early part of the century and this distinction has been maintained in research and epidemiology until very recently. A major aim of the Psychiatric Genomics Consortium is to quantify the extent of common genetic variation across distinct psychiatric diseases. Here, we present the insights generated by the SCZ / BP working group in better understanding the specific loci shared by both diseases as well as those that discern the two. Methods Genotypes were present for all individuals and were obtained from a variety of Illumina and Affymetrix arrays. Imputation was performed using the Beagle software. All analyses were done using dosage data in Plink. Results We analyzed a dataset of 39,202 independent individuals by combining the PGC SCZ sample (9,369 cases and 8,723 controls) and the PGC BP sample (10,410 cases and 10,700 controls). All subjects were distinct and independent. As reported in previous literature, we find highly significant polygenic overlap across disorders and many shared associated loci. Several follow-up analyses were performed in order to dissect the signal at regions/genes of interest for disease specificity. Furthermore we investigated the presence of genetic loci with significantly different effects by comparing odds ratios as well as creating a disease only dataset and performing GWAS with SCZ as case and BP as control. Finally we are investigating the impact of mood symptoms in SCZ, as well as psychosis in BIP, on overall polygenic overlap between the two disorders. Discussion Our data show that large cross-disorder datasets can be a powerful resource for understanding the shared genetic architecture of these disorders and ultimately will help in defining the differences in molecular function and treatment.

2513F

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: Genome-Wide Association Study of Anxiety Disorders. *L. Shen[1], T. Hoffmann[2], M. Kvale[2], L. Sakoda[1], D. Ranatunga[1], L. Walter[1], S. Sciortino[1], D. Ludwig[1], Y. Banda[2], S. Hesselson[2], P. Kwok[2], R. Risch[2], C. Schaefer[1].* 1) Division of Research, Kaiser Permanente Northern California, Oakland, CA; 2) Institute for Human Genetics, UCSF, San Francisco, CA.

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging (GERA) cohort includes over 100,000 individuals with comprehensive longitudinal medical records along with genome-wide genotype data. As such, it provides an unprecedented opportunity to conduct a number of genome-wide association studies (GWAS) of psychiatric disorders. Acute stress disorder (ASD), post-traumatic stress disorder (PTSD), and panic disorder are prevalent, persistent and disabling anxiety disorders. Numerous candidate gene studies have been published with inconsistent findings. As yet there have been no large GWA studies of these anxiety disorders. We conducted the first GWAS of stress disorders, combining ASD and PTSD in one GWAS, and the first large scale GWAS of panic disorder as another. The studies were limited to non-Hispanic whites; both cases and controls were genotyped on the custom Affymetrix Axiom EUR arrays with 674,518 SNPs. We identified a total of 6177 combined ASD and PTSD cases with two or more psychiatric diagnoses of ASD and/or PTSD; 23.6% of the cases had five or more ASD or PTSD diagnoses; 77.6% of cases were female. The GERA cohort supplied 63,613 controls. In an analysis using an additive model that controlled for age, gender, and ancestry, no SNP associations reached genome-wide level of significance (5 × 10-8). However, a suggestive association was found with a SNP in an intergenic region on chromosome 10 near the ANKRD20A gene (OR=1.11, P=1.42×10-7), as well as neighboring SNPs. A total of 1483 persons with two or more diagnoses of panic disorder and 75,379 controls were included in the GWAS of panic disorder. Over 50% of the cases had five or more diagnoses of panic disorder; 72.3% of the cases were female. Cases and controls were unscreened for other major axis I psychiatric disorders. In an analysis using an additive model that controlled for age, gender, and ancestry, no SNP associations reached genome-wide level of significance (5 × 10-8). Additional studies with larger samples may help in identifying important loci for these disorders. GWAS of psychiatric disorders remain challenging.

2514W

Genome-wide association of structural MRI data in a large, normally developing, pediatric population. *P.M.A. Sleiman[1,2,3], T. Satterthwaite[4], K. Ruparel[4], C. Kim[1], R. Chiavacci[1], M.E. Calkins[4], R.C. Gur[4], R.E. Gur[4], H. Hakonarson[1,2,3].* 1) Center Applied Genomics, CHOP, Philadelphia, PA; 2) Division of Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA; 3) Dept Pediatrics, Perelman School of Medicine, Univ of Pennsylvania, Philadelphia PA; 4) Brain Behavior Laboratory, Perelman School of Medicine, Univ of Pennsylvania, Philadelphia PA.

We carried out a genome-wide association study of subcortical brain volumes derived from the structural MRI data of ~1390 normally developing children and young adults aged between 8 and 21. All subjects were recruited into the study from the greater Philadelphia area, imaged on the same scanner at the University of Pennsylvania and the resulting data processed through the same pipeline to ensure homogeneity. Volumetric data for five subcortical regions, amygdala, caudate, hippocampus, putamen and thalamus were scaled to account for differences in intracranial volume and tested for association as quantitative traits in linear models. All samples were genotyped on either Illumina HH550, HH610 or OmniExpress arrays at the Center for Applied Genomics and imputed to ~37M SNPs against the 1KGP data. The first 1000 samples were used as the discovery cohort and the following 390 subjects, increasing to 500, as the replication cohort. Genetic ancestry was determined by principal component analysis and the first 10 principal components included as covariates in the regression to adjust for population stratification. Copy number variants were called for each individual from the gene chip data and tested for association against the quantitative traits using the Nexus software package. The analysis revealed several loci that show genome wide association with specific subcortical volumes in our pediatric dataset. These data suggest that individual brain regions may be under individual genetic control. Copy number variation analysis is underway and the results will be presented together with the association data.

Gene-Based Analyses of Attention Deficit Hyperactivity Disorder (ADHD) GWAS Data. *I.D. Waldman[1], S.V. Faraone[2], Psychiatric Genomics Consortium: ADHD Subgroup.* 1) Dept of Psychology, Emory University, Atlanta, GA; 2) Depts of Psychiatry and of Neuroscience & Physiology, SUNY Upstate Medical University, Syracuse, NY.

Attention Deficit Hyperactivity disorder (ADHD) is a highly heritable disorder, which has led researchers to search for underlying genetic risk factors via both candidate gene studies and, more recently, large-scale Genome Wide Association Scans (GWAS's). Many extant candidate gene studies have yielded mixed results, while recent GWAS's have yielded some suggestive findings but no genome-wide significant results. Two possible reasons for this are the relatively small sample sizes of the first generation of ADHD GWAS's and the small effect sizes of individual SNPs that show suggestive association. These small effects are consistent with those for other psychiatric disorders and medical conditions, and have led geneticists to utilize several alternative analytic methods, such as analyses of haplotypes and gene pathway or network analyses. Alternative analytic techniques that are relatively underutilized are omnibus gene-based analyses that simultaneously evaluate the statistical significance of the association between a trait or disorder and multiple SNPs within particular genes and their flanking regions. These methods have the advantage that they greatly reduce the number of statistical tests performed and hence involve a gene-based rather than SNP-based threshold for genome-wide significance. In this study, we apply such gene-based analyses of association to the second generation of ADHD GWAS data. Specifically, we included data from 6669 parent-offspring trios and 3744 cases and 11552 controls from 9 ADHD GWAS samples and performed gene-based analyses of ADHD diagnosis and symptom dimensions using the program VEGAS, which combines SNP-based p-values with information on LD among the SNPs within each gene and its 50 kb flanking region to obtain an association p-value for each gene. We demonstrate that this gene-based analytic method yields evidence for association that is at least as strong as conventional SNP-based methods and in many cases is much stronger.

Genome-wide association study of bipolar disorder with a history of binge eating. *S.J. Winham[1], S. McElroy[2], S. Crow[3], M. Frye[4], C. Colby[1], D. Walker[4], D-S. Choi[4], M. Chauhan[5], J.M. Biernacka[1,4].* 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Lindner Center of HOPE, Mason, OH; 3) Department of Psychiatry, University of Minnesota; 4) Department of Psychiatry and Psychology, Mayo Clinic, Rochester, MN; 5) Department of Psychiatry and Psychology, Mayo Clinic Health Systems, Austin, MN.

Bipolar disorder (BD) has been reported to be associated with obesity-related measures including eating disorders and body mass index (Wildes et al, 2007). In particular, a positive association between BD and binge eating disorder has been identified (McElroy et al, 2011). To date, multiple genome wide association (GWA) studies of BD have been performed. However, potential gene-environment interactions between SNPs and obesity-related factors have not been investigated for BD, and factors such as body mass index have not been considered as covariates or potential confounding factors in GWA studies of BD. We utilized publically available data from the Bipolar Disorder Genome Study Consortium (BiGS), part of the Genetic Association Information Network (GAIN), to investigate if genetic variants influencing BD are dependent on presence of a binge eating (BE) history. After quality control, we performed GWA analyses of 729,454 SNP markers using 1001 European American bipolar cases and 1034 mentally healthy controls. We first performed a GWA analysis of gene-environment interaction using a case-only approach; assuming independence between SNPs and BE, this analysis identifies SNPs associated differentially with BD depending on presence of BE. We also performed GWA analyses stratified by bipolar subtype: mentally healthy controls were separately compared to only cases with the presence (n=206) or absence (n=723) of BE. The rate of BE in bipolar cases in the analyzed GAIN data was 22.2%. In the genome-wide gene-environment interaction analysis, the top ranking SNP was rs6006893, in an intron of the PRR5 gene (OR=2.25, p=6.5E-7). PRR5 is a subunit of mTORC2, which may be implicated in obesity. When comparing BD cases with BE to controls, the strongest signal was rs13233490, which is 603kbp upstream of PER4, a pseudogene which may be related to circadian rhythm; the minor allele at this SNP was associated with higher odds of developing the bipolar + BE subtype (OR=6.37, p=3.9E-7). SNP rs2367911 in CACNA2D1, related to CACNA1C, was also highly ranked (OR=3.29, p=1.6E-6). This study demonstrates the importance of phenotypic sub-classification in genetic studies of complex psychiatric traits, and lays the groundwork for further genome-wide investigations of obesity-related measures in bipolar patients. Samples from the Mayo Clinic Bipolar Biobank will be utilized in future studies to examine potential genetic effects underlying both BP and obesity-related measures.

Variation in Genes Related to Cochlear Biology is Strongly Associated with Adult-onset Deafness in Border Collies. *J.S. Yokoyama[1], E.T. Lam[2], A.L. Ruhe[3,4], C.A. Erdman[1], K.R. Robertson[4], A.A. Webb[5,6], D.C. Williams[7], M.L. Chang[8], M.K. Hytonen[9], H. Lohi[9], S.P. Hamilton[1], M.W. Neff[3,10].* 1) Department of Psychiatry and Institute for Human Genetics, University of California, San Francisco, CA, USA; 2) Institute for Human Genetics, University of California, San Francisco, CA, USA; 3) Neurogenomics Division, The Translational Genomics Research Institute, Phoenix, AZ, USA; 4) Veterinary Genetics Laboratory, University of California Davis, Davis, CA, USA; 5) CullenWebb Animal Neurology and Ophthalmology Centre, New Brunswick, Canada; 6) Department of Clinical Neuroscience, Faculty of Medicine, University of Calgary, Calgary, AB, Canada; 7) School of Veterinary Medicine, University of California Davis, Davis, CA, USA; 8) Department of Anthropology, University of Oregon, Eugene, OR, USA; 9) Department of Veterinary Biosciences and Research Programs Unit, Molecular Medicine, University of Helsinki and Folkhälsan Research Center, Helsinki, Finland; 10) The Van Andel Research Institute, Grand Rapids, MI, USA.

Purpose: The domestic dog suffers from hearing loss that can have profound impacts on working ability and quality of life. We have identified a type of adult-onset hearing loss in Border Collies that appears to have a genetic cause, with an earlier age of onset (3–5 years) than typically expected for aging dogs (8–10 years). Studying this complex trait within pure breeds of dog may greatly increase our ability to identify genomic regions associated with risk of hearing impairment in dogs and in humans.

Methods: We performed a genome-wide association study (GWAS) to detect loci underlying adult-onset deafness in a sample of 20 affected and 28 control Border Collies. To further localize disease-associated variants, targeted next-generation sequencing (NGS) of one affected and two unaffected dogs was performed. We then performed targeted genotyping of additional cases (n=23 total) and controls (n=101 total) and for an independent replication cohort of 16 cases and 265 controls to validate NGS findings.

Results: We identified a region on canine chromosome 6 that demonstrates extended support for association surrounding SNP Chr6.25819273 (p-value = 1.09×10^{-13}). Through targeted NGS and genotyping of additional dogs, we identified variants in *USP31* that were strongly associated with adult-onset deafness in Border Collies, suggesting the involvement of the NF-κB pathway. We found additional support for involvement of *RBBP6*, which is critical for cochlear development. These findings highlight the utility of GWAS-guided fine-mapping of genetic loci using targeted NGS to study hereditary disorders of the domestic dog that may be analogous to human disorders.

Genome-wide association study of Korean patients with autism spectrum disorder. *H. Yoo[1,2], S. Kim[7], M. Park[8], I. Cho[9], S. Cho[1,2], B. Kim[1,2], J. Kim[1,2], S. Park[1,2], D.H Geschwind[3,4,5,6], Y. Kwak[10], J.K. Lowe[3,4,5], Korean Autism Genetic Study Consortium.* 1) Department of Psychiatry, Seoul National University Bundang Hospital, Seongnam, Gyeongi, Korea; 2) Deparment of Psychiatry, Seoul National University College of Medicine, Seoul, Korea; 3) Neurogenetics Program and Department of Neurology, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA 90095, USA; 4) Center for Autism Research and Treatment, Semel Institute, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA 90095, USA; 5) Center for Neurobehavioral Genetics, Semel Institute, University of California, Los Angeles, Los Angeles, CA 90095, USA; 6) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA 90095, USA; 7) Department of Pharmacology, College of Medicne, Eulji University, Daejon, Korea; 8) Department of Preventive Medicine, College of Medicine, Eulji University, Daejon, Korea; 9) Department of Psychiatry, Gacheon University of Medicine and Science, Incheon, Korea; 10) Department of Psychiatry, Jeju University, Jeju, Korea.

Objectives: To identify genetic factors underlying autism spectrum disorder (ASD) in a Korean cohort through 1) a genome-wide association study (GWAS) for qualitative ASD, 2) a GWAS for related quantitative behavioral traits, and 3) analysis of population structure between Koreans, Chinese and Japanese. Methods: Subjects with ASD were diagnosed based on DSM-IV-TR, using the Korean versions of the ADOS and ADI-R (Lord et al. 1994; Lord et al. 1997). A total of 146 patients were genotyped on the Affymetrix 5.0 platform. Genotype data were filtered for <5% missingness/sample or / SNP; MAF>0.01; HWE p>0.0001. Cases were verified as unrelated using identity-by-descent estimation in PLINK v1.07. Genotype data for n=858 sex-matched controls were drawn from the Korea Association Resource database. For quantitative traits, we explored three domains and five factors (Social interaction, Preoccupation, Aggression, Visuospatial Ability/Memory, Reading/Drawing) from the Korean ADI-R and analyzed quantitative association with EMMAX. Population structure was examined using multi-dimensional scaling (MDS; PLINK v1.07). Five SNPs with the lowest p-values in the exploratory GWAS and 61 tag SNPs within 100kb of the best-associated SNP on chr2q35 (MAF>0.1; $r^2 \geq 0.8$ in HapMap3 Asians) were genotyped using a GoldenGate™ Assay and tested for family-based association (FBAT v2.0.2) in an expanded cohort of 250 Korean families with ASD. Results: 1) GWAS of n=142 cases (87.4% autism, 79.55±33.74 months, 14.7% female) and n=858 controls revealed strong association between ASD and three correlated SNPs on chr2q35 (rs10932677, $p=6.91 \times 10^{-8}$; rs17773965, $p=1.60 \times 10^{-7}$; rs4674113, $p=1.06 \times 10^{-6}$). 2) The quantitative association test shows significant association of Visuospatial Ability/Memory with rs1278259 at chr10q26.2 (nominal $p=8.15 \times 10^{-7}$. Bonferroni-corrected p= 0.004). 3) MDS analysis confirms that Asians are clearly separated from other eight ethnic groups in HapMap3. Analysis of Asians alone shows that the Korean, Chinese, and Japanese populations fall into distinct groups. 4) In the family-based validation, rs2241196 was associated with ASD in an additive model (nominal p<0.01; adjusted p<0.05 after FDR). Conclusion: We observed strong associations between SNPs on chr2q35 and ASD in a Korean cohort.

2519F

Combined Genome-wide Association Study of Tourette Syndrome and Obsessive-Compulsive Disorder. *D. Yu[1,2,3,4], TSAICG, IOCFGC, TS GWAS Consortium.* 1) Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetics Research, Massachusetts General Hospital, Boston, MA; 2) Tourette Syndrome Association International Consortium for Genetics (TSAICG); 3) International Obsessive Compulsive Disorder Foundation Genetic Consortium (IOCFGC); 4) TS GWAS Consortium.

Tourette syndrome (TS) and obsessive-compulsive disorder (OCD) are developmental neuropsychiatric disorders that are frequently co-morbid and thought to be etiologically related. Both disorders are inherited in a non-Mendelian fashion, and the identification of definitive TS and OCD susceptibility genes remain elusive. Here, we report a combined genome-wide association study (GWAS) of TS and OCD using European ancestry samples previously employed in independent TS and OCD GWAS studies, including 1286 TS cases, 1437 OCD cases, and 6638 ancestry-matched controls. In addition to general European descent individuals, these samples also include three population isolates, Ashkenazi Jews from North America and Israel, French Canadians from Quebec, Canada, and Afrikaners from South Africa. Following imputation of SNPs from the 1000 Genomes Project using IMPUTE2, no SNPs achieved genome-wide significance ($P < 5.0 \times 10^{-8}$), with the top hit being rs76879034 on chromosome 3 within *ITGA9* ($P = 9.94 \times 10^{-7}$). The top distribution of LD-pruned SNPs ($P < 0.001$) were significantly enriched for eQTLs in frontal cortex and methylation QTLs (mQTLs) in cerebellum, whereas no enrichment in lymphoblast cell lines was detected, implicating their potential involvement in gene expression and regulation in the brain and in the etiology of TS and OCD. Strong evidence for a polygenic component was found in 1279 non-isolate European OCD cases with matched controls ($P = 2.0 \times 10^{-4}$), explaining 3.3% of the phenotypic variance. By contrast, only borderline significance for polygenicity was found in 776 non-isolate European TS cases (P = 0.06), which is most likely due to the smaller number of TS samples. Unexpectedly, we did not detect a substantial shared polygenic component between TS and OCD, suggesting that these two phenotypically and pathophysiologically related disorders may arise through divergent causal pathways.

2520W

Genome-wide significant evidence of association of a *NUP153* missense variant with familial late-onset Alzheimer's disease (LOAD). *A.R. Parrado[1], B. Hooli[1], K. Mullin[1], L. Gotta[1], M. Mattheisen[2], C. Lange[2], L. Bertram[3], R.E. Tanzi[1].* 1) Genetics and Aging Research Unit, Mass General Institute for Neurodegenerative Disease (MIND), Department of Neurology, Massachusetts General Hospital, Charlestown, MA, USA; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA, USA; 3) Max-Planck Institute for Molecular Genetics, Berlin, Germany.

Alzheimer's disease (AD) is the most common form of dementia in the elderly. LOAD cases with increased familial aggregation, are assumed to harbor susceptibility alleles at a higher frequency than unaffected family members, therefore genetic association analysis focused on families is a favorable strategy that can lead to improve power to detect susceptibility loci. We set out to identify single nucleotide polymorphisms (SNPs) in the genome that associate with risk or protection for LOAD. For this purpose, we performed a genome-wide association study on two large well characterized independent cohorts containing families of self-report European descent, the National Institute of Mental Health (NIMH) Genetics Initiative (410 families; 1342 subjects) and the National Repository of Research on Alzheimer's disease (NCRAD, 331 families; 1099 subjects), using the Affymetrix Genome-Wide Human SNP Array 6.0 which includes ~900K genomic SNPs. We performed a genome-wide SNP association analysis using PBAT/FBAT. We report p-values from the Liptak test statistic, which utilizes all available information. The Liptak method attains higher power levels, than the traditional FBAT approach, by combining the Z-statistics that correspond to the p-values of the family-based test (the within family information) with the rank-based p-values for population-based analysis (the between family information). We identified a nucleoporin 153kDa (*NUP153*) missense SNP on chromosome 6 with genome-wide significant evidence for association (Liptak $p = 4 \times 10^{-8}$) with LOAD in the NCRAD sample. This association with *NUP153* has not previously been reported with LOAD. Replication of the *NUP153* signal was achieved (FBAT p = 0.005) in an independent (NIA-LOAD) family sample (503 families; 1764 subjects), but was not confirmed in the NIMH sample. Additionally, meta-analysis, combining p-values from NCRAD, NIMH, NIA-LOAD, GenADA, and TGEN2, identified other genes containing SNPs with suggestive evidence of association ($p < 0.001$) with LOAD: *POU2F3*, *IL1RAP*, and *NOTCH2*. This study represents an extensive genome-wide screen for SNPs associated with susceptibility to LOAD. *NUP153* is involved in nuclear import and export of proteins and RNA. Recently, *NUP153* has been implicated in guarding genome integrity by promoting nuclear import of 53BP1. This novel association of a *NUP153*missense variant with risk for LOAD may provide valuable pathogenetic clues regarding the etiology and pathogenesis of AD.

Beta-Amyloid Toxicity Modifier Genes and the Risk of Alzheimer's Disease. *S.L. Rosenthal[1], X. Wang[1], M.M. Barmada[1], F.Y. Demirci[1], O.L. Lopez[2, 3], M.I. Kamboh[1,2].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Alzheimer's Disease Research Center, University of Pittsburgh, Pittsburgh, PA; 3) Department of Neurology, University of Pittsburgh, Pittsburgh, PA.

Late-onset Alzheimer's disease (LOAD) is a neurodegenerative disease, affecting 1 in 8 people over age 65 in the United States. Risk of developing this complex disease has been repeatedly linked to *APOE* polymorphisms, while other genes including *PICALM, CLU, BINI1, CD2AP, CR1, CD33, EPHA1, ABCA7,* and *MS4A4A/MS4A6E* have been implicated in more recent genome-wide association studies (GWAS). Aβ plaques develop in the brains of LOAD patients and are considered to be a pathological hallmark of this disease. Recently 12 new Aβtoxicity modifier genes (*ADSSL1, PICALM, SH3KBP1, XRN1, SNX8, PPP2R5C, FBXL2, MAP2K4, SYNJ1, RABGEF1, POMT2,* and *XPO1*) have been identified (*Science* 2011; 334: 1212-3) that potentially play a role in LOAD risk. In this study, we have examined the association of 222 SNPs in these 12 candidate genes with LOAD risk in 1291 Caucasian American LOAD cases and 938 age-matched, cognitively normal Caucasian American controls. Single site and haplotype analyses were performed using PLINK. Following adjustment for *APOE* genotype, age, sex, and principal components, we found single nucleotide polymorphisms (SNPs) in the *PPP2R5C, PICALM, SH3KBP1, XRN1,* and *SNX8* genes that showed significant associations (P<0.05) with the risk of LOAD. The top SNP was located in intron 3 of *PPP2R5C* (P=0.009017), followed by an intron 19 SNP in *PICALM* (P=0.0102). Haplotype analysis revealed significant associations (P<0.05) in 5 genes (*ADSSL1, PICALM, PPP2R5C, SNX8*, and *SH3KBP1*). Our data indicate that genetic variation in these new candidate genes affects the risk of LOAD. Further investigation of these genes, including additional replication in other case-control samples and functional studies to elucidate the pathways by which they affect Aβ, are necessary to determine the degree of involvement these genes have for LOAD risk.

2522F

WTCCC3 and GCAN: A genomewide association scan of Anorexia nervosa. *V. Boraska[1,2], C.M. Bulik[3], D.A. Collier[4], P.F. Sullivan[3], E. Zeggini[1], Genetic Consortium for Anorexia Nervosa, Wellcome Trust Case Control Consortium 3.* 1) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, United Kingdom; 2) Medical School University of Split, Split, Croatia; 3) University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; 4) Kings College London, London, United Kingdom.

Anorexia nervosa (AN) is a debilitating and potentially life-threatening mental illness. The Genetic Consortium for Anorexia Nervosa (GCAN) is a 20-country consortium dedicated to identifying genes that influence AN. As part of the Wellcome Trust Case Control Consortium 3 (WTCCC3), we conducted the largest genome-wide association study (GWAS) for any eating disorder ever performed. A GWAS was performed to identify unequivocal evidence of associations between DNA sequence variations and AN. All cases met DSM IV diagnostic criteria for AN (excluding amenorrhea) and were genotyped using the Illumina 660W-Quad array. Genotyping was completed on 2907 AN cases and 14,860 controls originating from 15 different countries of European ancestry. Controls were carefully selected to match for ancestry of each AN site. Individual association analyses were carried out across 15 strata. Eleven association analyses were conducted per stratum: one with no principal components (PC) adjustment and the others adjusted for up to 10 PCs. On the basis of QQ plots, lambda values and 54 population stratification SNPs, we selected the best analysis per each stratum for the fixed-effects meta-analysis. Only one stratum needed an adjustment for PC1. The genome-wide significance threshold was set to 5×10-8. One SNP on chr5 exceeded genome-wide significance. An additional 94 SNPs, derived from 65 independent signals, had p-values < 10-4. Most of these SNPs are in the frequency and effect size classes expected for common diseases. Replication of SNPs, representing each independent signal, is currently underway in 2400 samples of European origin and 900 Japanese samples. For strong/replicated findings, GCAN is well positioned to immediately pursue genomic, transcriptomic, molecular biological, and epidemiological studies in humans. Cross disorder analyses with psychiatric disorders and obesity are planned. Furthermore, functional analysis of human anorexia genes in mice will provide novel insights in the neurobiological mechanisms underlying this perplexing psychiatric disorder.

2523W

Novel approach to genome wide association meta-analysis for bipolar disorder reveals network of calcium channel and calcium signaling genes including epistatic effects. *V.J. Vieland[1], K.A. Walters[1], K. Tobin[2], M.A. Azaro[2], A. Hare[2], Y. Huang[1], S-C. Seok[1], T. Lehner[3], L.M. Brzustowicz[2].* 1) Battelle Ctr Math Med, Res Inst Nationwide Child Hosp, Columbus, OH; 2) Dept of Genetics, Rutgers Univ, Piscataway, NJ; 3) National Institute of Mental Health, Bethesda, MD.

A small number of calcium channel genes have previously been implicated in bipolar disorder (BP) and other psychiatric disorders; in the largest GWAS to date [Sklar et al. Nat Genet 2011], the smallest p-value occurred for a SNP in the voltage-gated calcium channel gene (V-GCCG) *CACNA1C*. We initially analyzed BP GWAS data from GAIN (N=390 cases, 890 controls, European ancestry (EA) only) combined with BP family data (N=306 multiplex families) from the NIMH repository, for combined association-linkage analysis under the PPL framework. Among SNPs with posterior probability of linkage and trait-marker LD (PPLD) > 5%, or the top 188 SNPs (0.02% of total), were three of four genes in the $\alpha 2\delta$ subunit of another V-GCCG (*CACNA2D4*, *CACNA2D3*, *CACNA2D1*, PPLD=95%, 7%, 6% respectively). Because the PPLD measures evidence against as well as in favor of association with a small prior probability of association (0.0004), these signals all stand out above background noise. Pathway analysis in IPA showed calcium signaling to be the highest scoring Canonical Pathway (-log (p-value)=3.8) among the genes implicated by the 188 SNPs. We then undertook genome-wide meta-analysis including an additional 6 data sets from the PGC (total N=3328 cases, 4017 controls, EA only). The PPL framework parameterizes an underlying genetic model allowing for dominant, recessive, or intermediate inheritance, variable allele frequencies and heterogeneity, and integrates over these parameters for a model-free analysis *within* each set of data; results are then accumulated *across* data sets using Bayesian sequential updating. This allows for differences in underlying trait parameters and levels of allelic association between studies, and can yield different rank ordering of SNPs compared to standard “mega”- or meta-analysis. We corroborated the salience of calcium signaling in the full PGC data set (IPA -log(p-value)= 3.2) as well as associations to the 3 $\alpha 2\delta$ V-GCCGs, and also picked up *CACNA1B*, *CACNA1A*, *CACNA1S*,*CACNB2* (PPLDs = 24%, 13%, 14%, 19%); results indicated considerable heterogeneity between data sets. In an initial set of two-locus analyses, we detect evidence of epistastic effects on the BP phenotype between the calcium-dependent activator of secretion gene *CADPS*, a calcium binding protein that regulates exocytosis of synaptic vesicles in neurons, and *CACNA2D1*,*CACNA2D4* and *CACNA1A*, respectively. Analyses to detect additional BP-related interactions within this gene family are ongoing.

2524T

Constructing a prediction model for bipolar disorder using genome-wide association dataset. *L. Chuang, C. Kao, P. Kuo.* Institute of Epidemiology and Preventive Medicine, Taipei, Taiwan.

Genome-wide association (GWA) data have provided large amount of genetic information for exploring pathogenesis of complex traits. Bipolar disorder is one of the common psychiatric disorders with high heritability around 0.6 to 0.8. So far, the determination of bipolar disorder diagnosis still largely depends on subjective report of symptoms, rather than valid biological or laboratory tests. Recently, machine learning approaches are popular in association studies to reveal not only marginal effects but also gene-gene or higher dimensional interactions for the risk of genetic variants on trait of interest. The current study aimed to construct and validate a genetic prediction model for bipolar disorder using machine learning approaches in large-scale GWA datasets. We used the GWA bipolar data from the Genetic Association Information Network. Random Forest algorithm was applied to calculate the importance of each genetic variant for bipolar disorder with two indexes, conditional importance and Gini impurity. We selected the top 150 of union of the two indexes. Markers were then evaluated in logistic regression with step-wise selection to identify the final set of 135 genetic variants to construct the prediction model for bipolar disorder. The area under the receiver operating characteristic curve of our predictive model reached 0.932 (95% confidence interval, 0.922–0.942). The optimal cut-off value for corresponding predictive score was 130, with a high sensitivity (0.836) and specificity (0.865) to distinguish bipolar disorder patients from controls. After conducting leave-one out cross-validation, the error rates of discrimination in healthy controls and bipolar disorder patients were 0.135 and 0.164, respectively. In conclusion, using GWA data with random forest procedures, we constructed a prediction model for bipolar disorder. With further validation and replication, such application may eventually benefit clinical diagnosis to provide a reliable and rapid screening for the risk of developing bipolar disorder.

2525F

Involvement of the PTCHD1 gene in autism and intellectual disability. *K. Mittal[1], K. Sritharan[1], J. Ross[2], A. Vaags[3], S. Scherer[3], A. Noor[4], J. Ellis[2], J. Vincent[1].* 1) Molecular Neuropsychiatry and Development Laboratory, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Developmental & Stem Cell Biology Program The Hospital for Sick Children, MaRS Centre, TMDT Toronto, Ontario, Canada; 3) The Centre for Applied Genomics The Hospital for Sick Children, MaRS Centre, TMDT Toronto, Ontario, Canada; 4) Department of pediatrics and laboratory medicine, The Hospital for Sick Children, Toronto, Ontario, Canada.

A number of candidate genes for autism spectrum disorder have been identified through recent copy number variant (CNV) studies. Our lab reported CNVs in the X-chromosome PTCHD1 (patched-related) gene, in autism spectrum disorder (ASD) and in intellectual disability (ID) (Noor et al., 2010). Since then, several additional families with exonic deletions have been identified. There are also additional reports with upstream deletions of PTCHD1. These new CNVs will be discussed. Systematic sequencing of PTCHD1 among 900 ASD probands and 225 ID patients showed 5 missense changes in ASD and two missense changes in ID. However, the presence of several of these mutations in the 1000 genomes and NHLBI exomes datasets provides evidence against the involvement of some of them. An additional 500 probands from autism and Intellectual disability are being sequenced for additional mutation identification. Human PTCHD1 has 3 exons, however the UCSC Genome Browser suggests two different splice variants. The large isoform resulting in a 888 amino acid protein (PTCHD1a) and the smaller isoform from just exons 1 and 2, resulting in a 361 amino acid protein (PTCHD1b), however we were unable to find any supporting evidence for PTCHD1b, but instead found evidence of a cerebellar isoform of 542 amino acids resulting from exclusion of exon 2 (PTCHD1c), as well as evidence of an upstream exon. The presence of the 888 and 542 amino acid isoforms appears to be supported by western blot data. We have now developed induced pluripotent stem cells from members of the 167Kb deletion family (Noor et al., 2010)-these splice variants were present in iPS cell-derived neuronal precursor cells from the mother's wild type allele, but not from the proband. Co-localization of PTCHD1 in neuronal cells and in cilia in 10T1/2 cells is also currently under investigation. A full update will be presented.

2526W

Genetic schizophrenia risk variants jointly modulate total brain and white matter volume. *A.F. Terwisscha van Scheltinga[1], S.C. Bakker[1], N.E.M. van Haren[1], E.M. Derks[2], J.E. Buizer-Voskamp[1], H.B.M. Boos[1], W. Cahn[1], H.E. Hulshoff Pol[1], S. Ripke[3], R.A. Ophoff[1,4], R.S. Kahn[1], Psychiatric GWAS Consortium.* 1) University Medical Centre Utrecht, Utrecht, Utrecht, Netherlands; 2) Department of Psychiatry, Academic Medical Centre, University of Amsterdam, Amsterdam, the Netherlands; 3) Center for Human Genetic Research, Massachusetts General Hospital, Boston, United States of America; 4) Center for Neurobehavioral Genetics, University of California, Los Angeles, United States of America.

Background Thousands of common single nucleotide polymorphisms (SNPs) are weakly associated with schizophrenia. It is likely that subsets of disease-associated SNPs are associated with distinct heritable disease-associated phenotypes. Therefore, we examined the shared genetic susceptibility modulating schizophrenia and brain volume.

Methods Odds ratios for genome-wide SNP data were calculated in the sample collected by the Psychiatric GWAS Consortium (8,690 schizophrenia patients and 11,831 controls, excluding subjects from the present study). These were used to calculate individual polygenic schizophrenia (“risk”) scores (PSSs) in an independent sample of 152 schizophrenia patients and 142 healthy controls with available structural MRI scans.

Results In the entire group, the PSS was significantly associated with total brain volume (R2=0.048, p=1.6×10-4) and white matter volume (R2= 0.051, p=8.6×10-5) equally in patients and controls. The number of (independent) SNPs that substantially influenced both disease risk and white matter (n=2,020) was much smaller than the entire set of SNPs that modulated disease status (n=14,751). From the set of 2,020 SNPs, a group of 186 SNPs showed most evidence for association with white matter volume and an explorative functional analysis showed that these SNPs were located in genes with neuronal functions.

Conclusions These results indicate that a relatively small subset of schizophrenia genetic risk variants is related to the (normal) development of white matter. This in turn suggests that disruptions in white matter growth increase the susceptibility to develop schizophrenia.

PET scans with [^{11}C]Flumazenil demonstrate a downregulation of the $GABA_A$ receptor availability in fragile X syndrome patients. *F. Kooy[1], I. Heulens[1], C. D'Hulst[1], N. Van der Aa[1], K. Van Laere[2].* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Div. Nuclear Medicine, University Hospital and Katholieke Universiteit Leuven, Leuven, Belgium.

Expansion of a CGG repeat at the FRAXA site silences the expression of the FMR1 gene and so causes the fragile X syndrome, a frequent form of inherited mental impairment. In addition to a significantly lower IQ, patients are characterized by specific dysmorphic features and behavioral abnormalities including increased anxiety, hyperactivity and autistic-like features. Epileptic seizures are common. Over the last 2 decades, the function of the causative gene has been studied intensively. The gene appears involved in diverse cellular processes, including RNA transport and stability, protein translation and RNA interference. Of particular interest from a therapeutic perspective is the observation that the imbalance between the inhibitory and excitatory signaling is compromised in the disorder and that this aberrant signaling can explain many, if not all clinical symptoms in patients. Genetic rescue experiments and drug trials with glutamatergic and gabaergic drugs in animal models have convincingly shown that a correction of the imbalance is able to revert some of the symptoms. Trial in patients have shown a potential improvement in condition only in the most severely affected group of patients and, so far, no direct evidence for abnormalities in either the glutamatergic or the gabaergic system in patients has been provided. Using positron emission tomography (PET) with [^{11}C]Flumazenil, a known $GABA_A$ receptor antagonist, as a radioligand we determined the amount of $GABA_A$ receptors in the brain of 10 fully characterized fragile X patients and 10 controls. We found an overall 6–17% decrease in $GABA_A$ receptor availability, with was significant in most brain regions. Examining the data of individual patients, it is striking that a reduction is present in only about half of our patients. Our data confirm that the GABAergic system is involved in the pathophysiology of the fragile X syndrome and provide a possible explanation why some patients respond to therapy while others do not.

δ-catenin is Genetically and Biologically Associated With Cortical Cataract and Future Alzheimer-Related Structural and Functional Brain Changes. *G. Jun[1,2], J.A. Moncaster[3], C. Koutras[9], S. Seshadri[4,7], J. Buros[1], A.C. McKee[4,5,8,10], G. Levesque[11], P.A. Wolf[4,6,7], P.St. George-Hyslop[9,12], L.E. Goldstein[3,4,5,8], L.A. Farrer[1,2,4,6,8].* 1) Medicine (Biomedical Genetics Section), Boston University, Boston, MA; 2) Ophthalmology, Biostatistics, Boston University, Boston, MA; 3) Psychiatry, Boston University, Boston, MA; 4) Neurology, Boston University, Boston, MA; 5) Pathology & Laboratory Medicine, Boston University, Boston, MA; 6) Epidemiology, Boston University, Boston, MA; 7) Framingham Heart Study, Boston, MA; 8) Alzheimer's Disease Center, Boston University, Boston, MA; 9) Tanz Centre for Research in Neurodegenerative Diseases, University of Toronto, Ontario, Canada; 10) Geriatric Research Education Clinical Center, Bedford Veterans Administration Hospital, Bedford, MA; 11) Neurosciences Research Centre-CHUL, Universite Laval, Quebec, Canada; 12) Cambridge Institute for Medical Research, University of Cambridge, Cambridge, UK.

Multiple lines of evidence suggest that specific subtypes of age-related cataract (ARC) and Alzheimer disease (AD) are related etiologically. To identify shared genetic factors for ARC and AD, we estimated co-heritability of quantitative measures of cataract subtypes with AD-related brain MRI traits among 1,466 participants of the Framingham Study who had a brain MRI scan approximately ten years after the eye exam. Cortical cataract (CC), but not other cataract subtypes, was found to be co-heritable with future development of AD and with several MRI traits, especially temporal horn volume (THV, ρ=0.24, $P<10^{-4}$). Based on the hypothesis that genetic variants with pleiotrophic effects for CC and THV can be identified in preclinical stages of brain dysfunction, we conducted a genome-wide association study using mid-age dementia-free subjects from the Framingham Offspring Study (N=1,249) whose mean ages at the eye exam and MRI exams were 51 and 61 years, respectively. A genome-wide study testing association of 187,657 single nucleotide polymorphisms (SNPs) with the joint outcome of CC and THV identified genome-wide significant association with CTNND2 SNPs rs17183619, rs13155993 and rs13170756 ($P<2.6\times10^{-7}$). These SNPs were also significantly associated with joint outcomes of CC and scores on several highly heritable neuropsychological tests ($5.7\times10^{-9} < P < 3.7\times10^{-6}$). Statistical interaction was demonstrated between rs17183619 and APP SNP rs2096488 on CC (P=0.0015) and CC-THV (P=0.038). A rare CTNND2 missense mutation (G810R) 249 base pairs from rs17183619 altered δ-catenin localization and increased secreted amyloid-β1-42 in neuronal cell culture. Immunohistopathological analysis of lens tissue obtained from two autopsy-confirmed AD subjects and two non-AD controls revealed elevated expression of δ-catenin in epithelial and cortical regions of lenses from AD subjects compared to controls. Our findings suggest that genetic variation in delta catenin may underlie both cortical lens opacities in mid-life and subsequent MRI and cognitive changes that presage the development of AD.

Genes, Brain and Cognition in Down Syndrome. *J.R. Korenberg[1], L. Dai[1], S. Gouttard[2], J. Edgin[3], L. Nadel[3], E.K. Jeong[4], J. Anderson[5], G. Gerig[2].* 1) Center for Integrated Neuroscience and Human Behavior, and Department of Pediatrics, University of Utah, Salt Lake City, UT 84112, USA; 2) School of Computing, University of Utah, Salt Lake City, UT; 3) Department of Psychiatry, University of Arizona, Tucson, AZ; 4) UCAIR, School of Medicine, University of Utah, Salt Lake City, UT; 5) Department of Neuroradiology, University of Utah, Salt Lake City, UT.

Down syndrome (DS) is the prototype of human aneuploidy and a major concern for the development of novel therapeutics. Despite decades of research, no genes have been linked to specific features, and no treatment for the cognitive deficits has been developed. Treatment of DS requires multidisciplinary studies linking the genetic, neuroanatomical (MRI), neural circuitry (DTI), and neurocognitive features of DS. Data on MRI/DTI for 12 DS and 9 age, gender matched controls has been collected and analyzed. MRI results showed that white and grey matter are proportionately decreased in non-normalized IC volumes in DS. In an anterior-posterior gradient, white is more decreased than gray in all lobes. In addition, DTI tractography shows first evidence for abnormal development of motor tracts and arcuate fasciculus, substrates for visuo-motor cognitive functions and language. A significant part of this appears to be not just numbers of axons but actual diffusion both in the direction of axonal flow and radially, implicating a moving target, myelination. Therefore, even if white matter volumes are decreased early in development, there appear to be in the adult, additional myelination defects that are ongoing and approachable. Finally, neuropsychological and IQ data are collected for 12 DS and correlated with their MRI data. Our pilot results suggest that DS performance on the paired associates learning test (CANTAB; total errors and mean trials to success) is correlated with decreased normalized white matter. Abnormal intrinsic connectivity networks in DS revealed significant increases in local (regional homogeneity) greatest in limbic and deep gray nuclei and in regions less than 4 cm distant. In contrast long range connections showed reduced functional correlation in DS. These findings suggest that white matter is possibly a new therapeutic focus for DS that may in part be reflected in decreased long range connectivity and therefore abnormal interactions between default and attention networks, in part accounting for executive deficits and impaired processing speed in DS. These results provide unprecedented characterization of the neural and genetic systems disturbed in DS, and will result in novel targets and clinical assays to develop therapeutics to improve cognitive function in DS.

The non-invasive quantification of muscle degeneration in facioscapulohumeral muscular dystrophy with fast bound-pool fraction imaging: a 3.0T MRI study. *H.R. Underhill[1], S.D. Friedman[2], V.L. Yarnykh[3], D.W.W. Shaw[2].* 1) Division of Medical Genetics, University of Washington, Seattle, WA; 2) Department of Radiology, Seattle Children's Hospital, Seattle, WA; 3) Department of Radiology, University of Washington, Seattle, WA.

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant muscular dystrophy with progressive muscle degeneration, atrophy and fatty replacement. Selective muscle involvement in FSHD complicates clinical evaluation. Magnetic resonance imaging (MRI) studies have non-invasively measured fatty infiltration as a possible surrogate for muscle deterioration; however, fatty infiltration is a late stage and may be beyond intervention. Edema has also been studied, but it is not clear the extent or consistency of edema in the disease process. We hypothesized that fast bound-pool fraction imaging (FBFI), a new quantitative MRI technique that directly measures alterations in tissue structural organization, may be sensitive to an earlier pathophysiologic stage in FSHD. FBFI exploits the effects of magnetization transfer (MT) to specifically measure the fraction of protons bound to macromolecules (i.e. the bound-pool). In addition, lipids do not contribute to MT thereby giving FBFI the potential to isolate alterations in diseased muscle in FSHD independent of the signal from fat. We first developed and optimized FBFI on a 3.0T clinical scanner using *in vivo* leg muscles in a healthy control and an FSHD patient. Subsequently, 6 FSHD and 8 healthy controls were imaged. Sequences used to calculate the pixel-based bound-pool fraction included: MT images (SPGR, TR/TE=45/6 ms) acquired with variable off-resonance saturation pulses (=4, 12, 96 kHz) and a nominal flip angle of 950°; B_0 and B_1 maps to account for magnetic- and RF-field non-uniformity, respectively; and R_1 maps via the variable flip-angle method. In FSHD, muscle groups without fatty infiltration were isolated, which identified 2 subgroups: 1) healthy appearing muscle with a similar bound-pool fraction as seen in controls (10.3±0.5% vs. 10.4±0.3%, p=0.68); and 2) muscle with a significantly reduced and more variable bound-pool fraction compared to controls (6.4±1.3% vs. 10.4±0.3%, p=0.001). In both normal and diseased muscle there was no correlation between the bound-pool fraction and signal intensity on STIR (TR/TE/TI=4200/60/210 ms), a qualitative MRI technique used to identify edema. These findings offer evidence that FBFI is identifying changes in FSHD muscle before fatty infiltration is seen and not directly related to edematous changes. FBFI may allow direct, quantitative monitoring of muscle deterioration in FSHD and provide a new biomarker for disease progression and/or response to therapy.

Neural Cell Adhesion Gene Variation and Brain Morphometry in Alzheimer's Disease. *K.N. Holohan[1,2], S.L. Risacher[2], S. Swaminathan[1,2], J.D. West[2], M. Inlow[3], S.K. Conroy[2], V. Ramanan[1,2], T. Foroud[1], L. Shen[2], A.J. Saykin[1,2], Alzheimer's Disease Neuroimaging Initiative (ADNI).* 1) Medical and Molecular Genetics, Indiana University-Purdue University Indianapolis, Indianapolis, IN; 2) Center for Neuroimaging, Indiana University-Purdue University Indianapolis, Indianapolis, IN; 3) Rose-Hulman Institute of Technology, Terre Haute, IN.

Two genes coding for neural cell adhesion molecules, *CDH8* and *NXPH1*, have been associated with magnetic resonance imaging (MRI) measures of hippocampal volume or grey matter density change, which are both biomarkers of Alzheimer's disease (AD). Polymorphisms in neural cell adhesion genes could provide protection against volume loss via more effective adhesion, or accelerate loss due to weaker adhesion, as well as influence other cellular processes. Therefore, we hypothesized that neural cell adhesion pathway gene variants influence risk of developing AD and the phenotypic expression of atrophy on structural MRI. Participants included Caucasian individuals from the Alzheimer's Disease Neuroimaging Initiative (ADNI), with available MRI and genome-wide association study data (N= 737). Age, gender, *APOE* e4 allele carrier status, and total intracranial volume were included as covariates. Based on previous results and literature data-mining, we compiled lists of candidate genes, one including interacting cadherins with cerebral expression (16 genes), and one containing other interacting neural cell adhesion genes (13 genes). Single nucleotide polymorphisms (SNPs) within 2,000 base pairs of selected genes with minor allele frequencies greater than ten percent were analyzed in PLINK in gene level sets for association with hippocampal volume. One cadherin gene, *CDH19*, survived Bonferroni correction ($p<0.003125$); this gene has not been previously associated with any disease. The SNP driving this signal was rs508987 (p=0.0003). Whole brain voxel-based analysis demonstrated a significant association in the right putamen ($p<0.005$, 50 voxel extent threshold). Individuals with C alleles had higher gray matter density in this area than individuals with two T alleles, possibly indicating a protective effect. Another ongoing study in our lab using pathway analysis of ADNI individuals with psychometric memory scores implicated neural cell adhesion. Since this analysis did not include *CDH19*, we analyzed rs508987 and found that it was significantly associated (p=0.0167) with memory score change from baseline to six months, though interestingly it was not correlated with the baseline score. This may indicate that hippocampal volume is a more sensitive indicator of neural cell adhesion-related pathology than neuropsychological testing. Currently we are working to replicate these results in another study cohort; preliminary results are promising.

Genetic interactions in focal adhesion and extracellular matrix pathways are associated with increase in ventricle size over time in the Alzheimer's Disease Neuroimaging Initiative cohort. *M. Koran[1,2], S. Meda[3], M. Sivley[1], T. Thornton-Wells[1].* 1) Center for Human Genetics and Research, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN; 2) Medical Scientist Training Program, Ph.D. Program in Human Genetics, Vanderbilt University School of Medicine, Nashville, TN; 3) Olin Neuropsychiatry Research Center, Harford Hospital, Hartford, CT.

Recent genetic studies in late onset Alzheimer disease (LOAD) have led to the discovery of genetic risk factors but the investigation of gene-gene interactions (GxG) has been limited. Genetic studies often use binary disease status as phenotype but studies of complex disease require rich phenotypic information that can be mapped to distinct genetic etiologies, which may involve GxG or gene-environment interactions. For brain-based diseases, neuroimaging data can provide such quantitative traits (QTs). Many QTs in LOAD have been shown to correlate with disease status and to have greater sensitivity in detecting early pathology. In this study, we tested for association of GxG with AD-related longitudinal MRI measures from the Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort. We applied a pathway-driven approach in which only pairs of SNPs from genes belonging to a common biological pathway were tested. We used linear regression in INTERSNP software to test the ability of 151 million SNP-SNP models to predict 12-, 24- and 36-month annual atrophy rates of 15 different brain regions implicated in AD structural pathology. The most significant results were seen in the right and left inferior lateral ventricles (RILV & LILV). 575 significant SNP-SNP interactions were identified in the RILV and 316 were seen in the LILV; 7 SNP-SNP interactions replicated over two of the three time points in the RILV. Four GxG replicated across time and in both the RILV and LILV: SLIT3-EPHB1, and SV2C, FN1, and ITGA1 each interacting with LAMC1. Three of these 4 GxG replicates belonged to the extracellular matrix (ECM) receptor interaction KEGG pathway, and 2 of the 4 belonged to the focal adhesion (FA) KEGG pathway. Using a pathway based approach for GxG associated with AD related QTs, we were able to identify interactions that not only replicated over time but also over location. We then were able to use current knowledge of pathway interactions to deduce a plausible biological context for these significant interactions. There is a theory in AD that neuron loss is mediated through FA signaling. Proteins involved in FA are activated by β-amyloid and communicate with the ECM to induce cell cycle activation, which activates the loss of cell adhesions and leads to subsequent cell death. The ECM and FA pathways were implicated in AD-related neuron loss seen as MRI measurement changes in this study, supporting the relationship between FA and neuron loss in AD etiology.

Gene Expression of GABA Receptors and Regulators in Peripheral Blood of a Drug Naïve First-Episode Psychosis sample. *V.K. Ota[1, 2], C.S. Noto[2], A. Gadelha[2], M.L. Santoro[1,2], J.J. Mari[2], M.I. Melaragno[1], M.A.C. Smith[1], Q. Cordeiro[3], R.A. Bressan[2], S.I. Belangero[1,2].* 1) Morphology and Genetics, UNIFESP, Sao Paulo, Sao Paulo, Brazil; 2) LiNC - Laboratorio Interdisciplinar de Neurociências Clínicas, UNIFESP, Sao Paulo, Sao Paulo, Brazil; 3) Departamento de Psiquiatria, Irmandade da Santa Casa de Misericórdia de São Paulo, Sao Paulo, Sao Paulo, Brazil.

BACKGROUND: Schizophrenia is a severe mental health disorder with a high heritability. The investigation of patients during their first episode of psychosis (FEP), particularly before taking any antipsychotic medication, opens avenues for understanding this clinically and genetically complex disease and avoiding harmful progression. The study of gene expression levels in peripheral blood may yield biomarkers for mental disorders, which will be of great value because brain tissue is not readily accessible. Since cortical dysfunction in schizophrenia and related disease may be associated with changes in GABAergic circuitry, in this study we aimed to compare the expression levels of GABA receptors and regulatory genes, in whole blood of eight drug-naïve FEP patients and seven healthy controls. METHODS: Whole blood was drawn from patients and controls during clinical evaluations into tubes containing RNA stabilizer solution Expression levels of GABRA1, GABRA2, GABRA3, GABRB1, GABRB2, GABRD, GABRE, GABRG1, GABRG2, GABRP, GABRQ, GABRR1, GABRR2 and GAD1 were assessed with the Human Neurotransmitter Receptors and Regulators RT2 Profiler™ PCR Array System, which is based on SYBR Green detection. For data analysis, we compared 2-Ct values between FEP and control group using Wilcoxon test. RESULTS: Seven of the 14 genes (GABRA2, GABRA3, GABRB2, GABRE, GABRG1, GABRP, and GABRR1) presented undetectable expression levels in whole blood, and, hence were excluded from the analyses. Significant downregulation in FEP of one gene was noted (GABRD: Fold regulation=-2.24; p=0.008). Moreover, GAD1 was also downregulated, but no statistical difference was detected (Fold regulation=-2.02; p=0.132). DISCUSSION: These preliminary results indicated downregulation of two genes: GABRD, which encodes a subunit of GABA-A receptor, and GAD1, the gene encoding a key enzyme for GABA synthesis (GAD67). Alterations in GAD1 mRNA in cerebral and cerebellar cortex of schizophrenia patients were reported previously. To our knowledge, this is the first study to investigate expression levels of these genes in peripheral blood of drug-naïve FEP patients, though in a small sample size. In conclusion, our preliminary findings suggest that dysregulation of expression levels of GABAergic genes may be involved in the pathophysiology of schizophrenia and may be possible biomarkers for its diagnosis.

Effect of DRD1 rs4532 polymorphism on treatment resistant schizophrenia. *L.MN. Spindola[1], V.K. Ota[1,2], A. Gadelha[2,3], A.F. Santos Filho[3], M.L. Santoro[1,2], D.M. Christofolini[1], F.T.S. Bellucco[1], J.J. Mari[3], M.I. Melaragno[1], M.A.C. Smith[1], R.A. Bressan[2,3], S.I. Belangero[1,2].* 1) Disciplina de Genética, Departamento de Morfologia e Genetica, Universidade Federal de Sao Paulo, Sao Paulo, SP., Brazil; 2) Laboratório Interdisciplinar de Neurociências Clínicas (LiNC), Departamento de Psiquiatria, Universidade Federal de Sao Paulo, Sao Paulo, Brazil; 3) Departamento de Psiquiatria, Universidade Federal de Sao Paulo, Sao Paulo, Brazil.

Schizophrenia is a complex disease with genetic and environmental factors interacting to develop the disease. Dysregulation of dopaminergic neurotransmission is involved in the pathophysiological processes of schizophrenia and, hence, some studies have investigated the role of genes encoding dopamine receptors. Positron Emission Tomography (PET) studies have been demonstrated that dopamine receptor D1 dysfunction was associated to cognitive impairments and negative symptoms in schizophrenia. Regarding therapeutics aspects, the overall treatment response is still limited and it is estimated that 20–30% of patients who have schizophrenia do not respond to treatment with conventional antipsychotics. The aim of this study was to investigate the association between DRD1 rs4532 (A/G) polymorphism and schizophrenia diagnosis and treatment resistant (TR) schizophrenia. We have analyzed 178 patients with schizophrenia, consisting of 59 TR and 65 non-TR, and 266 healthy controls. The subjects were genotyped for rs4532 polymorphism by TaqMan probe based real time PCR assay. Although we have not find association between rs4532 polymorphism and schizophrenia (p=0.690), we found an association between G-allele and TR schizophrenia (p= 0.001; OR= 2.71; 95% CI=1.48–4.96). Reinforcing this finding, for genotypes, we found a dose-response gradient with risk increasing with the number of G-allele copies and with GG-homozygous presenting a five-fold risk compared to AA-homozygous (p=0.014; OR=5.037; 95% CI= 1.39–18.26) with an intermediate result for AG-genotype (p=0.037; OR= 2.491; 95% CI=1.06–5.88), setting the common AA-genotype as reference. Our result suggests a possible role of DRD1 rs4532 polymorphism on TR schizophrenia, with G-allele being the genetic risk factor. Although the association of this polymorphism and schizophrenia is controversial, its effect on some phenotypes has been demonstrated, such as tardive diskenesia, negative symptoms and response to clozapine treatment. Therefore, rs4532 polymorphism may be a potential pharmacogenetic marker for treatment response to antipsychotic drugs, influencing directly on clinical treatment outcome.

2535W

Genetic Risk Factors (CHRNA5-CHRNA3-CHRNB4) and Smoking Cessation Among Hospitalized Patients with Acute Myocardial Infarction. *LS. Chen[1], PA. Lenzini[2], RG. Bach[3], JA. Spertus[4], LJ. Bierut[1], S. Cresci[3].* 1) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO; 2) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 3) Department of Medicine, Washington University School of Medicine, St. Louis, MO; 4) Mid America Heart Institute, University of Missouri - Kansas City, Kansas City, MO.

Objective: Smoking is an important, modifiable risk factor for acute myocardial infarction (MI). However, active smoking and the inability to quit are both common among patients hospitalized with acute MI. Existing research suggests that nicotinic receptor genes are associated with smoking quantity and cessation success. This study tests whether variants in these genes are associated with smoking cessation among patients hospitalized with an acute MI. Methods: Using data from the Translational Research Investigating Underlying disparities in acute Myocardial infarction Patients' Health Status study (TRIUMPH), a prospective 24-center observational registry of acute MI treatment and outcomes, we ascertained current vs. former (quit ≥30 days before presentation) smoking status during the index hospitalization. After confirming consistent genetic effects across European and African Americans (EA and AA), pooled analysis using logistic regression to model the association between smoking cessation and CHRNA5-CHRNA3-CHRNB4 variants (rs680244, rs16969968), adjusting for age, sex, race, and history of alcohol abuse. Results: In the genetic sample of TRIUMPH, 595 EA and 194 AA subjects were current smokers vs. 631 and 110, respectively, who were former smokers. Genetic variants in the CHRNA5-CHRNA3-CHRNB4 region, rs680244 (A) and rs16969968 (A), were associated with smoking cessation, but in opposite directions (OR=1.198, 95% CI=1.017–1.412, p=0.0078 and OR=0.780, 95% CI=0.649–0.937, p=0.0303, respectively). There was a borderline significant association between rs680244 (A) and smoking quantity among current smokers (β[SE]=0.083[0.05], p-value=0.0982). Conclusions: Among patients hospitalized with acute MI, those carrying high-risk genetic variants in CHRNA5-CHRNA3-CHRNB4 were less likely to have successfully quit before hospitalization. By identifying a genetic group with heightened risk for cessation failure, this work may support efforts to identify patients for enhanced, personalized smoking cessation treatment.

STXBP1 and KCNQ2 are mutated in the majority of patients having Ohtahara syndrome that does not evolve into West syndrome. *M. MILH[1,2,3], C. LACOSTE[4], J. SUTERA-SARDO[1,2,3], S. AUVIN[8], M.A. BARTHEZ[6], A. KAMINSKA[9], A. ROUBERTIE[5], D. VILLE[7], C. BADENS[2,3,4], B. CHABROL[1,2,3], L. VILLARD[1,2].* 1) Neurologie Pédiatrique, Hôpital d'Enfants La Timone, Marseille, France; 2) Aix Marseille Université, Faculté de Médecine, Marseille, France; 3) Inserm, U910, Marseille, France; 4) Dpt de Génétique Médicale et de Biologie Cellulaire, Hôpital d'Enfants La Timone, Marseille, France; 5) Neuropédiatrie, Hôpital Gui de Chauliac, Montpellier, France; 6) Neuropédiatrie, CHU de Clocheville, Tours, France; 7) Neuropédiatrie, Hôpital Femme Mère Enfant, Bron, France; 8) Neuropédiatrie, Hôpital Robert Debré, Paris, France; 9) Neuropédiatrie, Hôpital Necker, Paris, France.

Ohtahara syndrome (OS) is a rare early onset epileptic encephalopathy characterized by the association of frequent seizures (mostly epileptic spasms and partial seizures) with an EEG showing a so-called {{oq}} suppression-burst {{ea}} pattern, i.e bursts of paroxysmal activity alternating with periods of flatness of the traces. The pronostic is poor, with drug resistant epilepsy and evolution into West syndrome (Ohathara et al. 2003). Most OS cases are in relation with a brain structural abnormality (lissencephaly, hemimegalencephaly, Aicardi syndrome...), but OS also occurs in an apparently normal brain. Among this group of OS patients without any brain structural abnormality, several genetic causes have been identified : ARX mutations were the first mutations described for OS; SLC25A22 homozygous mutations have been described in two consanguineous families; de novo heterozygous mutations of STXBP1 have been found in about 10% of OS patients (Saitsu et al.); de novo mutations of KCNQ2 have been found in about 10% of patients having an early onset epileptic encephalopathy, from whom more than a half had an Ohtahara syndrome (Weckhuysen et al. 2012). We prospectively collected a cohort of 100 patients with an early onset epileptic encephalopathy, among which 38 had OS. In order to identify key clinical features and perform genotype-phenotype correlations, we screened the known genes in our cohort. We did not find any mutation in ARX or SLC25A22 while 6 patients were mutated for STXBP1 and 8 patients were mutated for KCNQ2. We have already shown that the course of the epilepsy was unexpected in patients having a mutation of STXBP1, with a remission of the epilepsy in the majority of the patients, despite the persistence of non epileptic movements disorders and severe cognitive impairment (Milh et al. 2011). Interestingly, the course of the epilepsy was similar in the patients having a mutation of KCNQ2, with a dramatic decrease in seizure frequency occurring during the first year, together with an amelioration of the EEG. In both groups, no patient evolved into West syndrome, although this has classically been described for OS patients. Selecting OS patients that do not evolve into West syndrome we found a mutation of STXBP1 or KCN2 in 14 patients. These findings indicate that STXBP1 and KCNQ2 mutations account for the majority of OS patients that do not evolve into West syndrome.

Identification of LRRK2 p.G2019S disease modifiers. *J. Trinh[1], D. Evans[1], C. Thompson[1], A. Donald[1], B. Shah[1], C. Szu Tu[1], F. Pishotta[1], C. Vilarino-Guell[1], R. Amouri[2], F. Hentati[2], R. Gibson[3], M. Farrer[1].* 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Neurologie, Institut National de Neurologie, La Rabta, Tunis, Tunisia; 3) GlaxoSmithKline Pharmaceuticals, Research and Development, Harlow, Greenford, Hammersmith, UK.

Parkinson's disease (PD) is an insidious and progressive neurodegenerative disease. It is a global health problem that currently affects 1% of individuals over age 65. Current therapies treat motoric symptoms and not the physiological mechanisms of disease. Mutations in the gene known as leucine-rich repeat kinase 2 (LRRK2) in PD confer the highest genotypic and population attributable risk; LRRK2 p.G2019S is most frequent and found in greater than 30% of Arab-Berber patients in Tunisia. Disease penetrance among carriers is incomplete, resulting in elder asymptomatic carriers and patients with early onset of disease. We hypothesize that there are genetic factors that can modulate the effect of LRRK2 p.G2019S on disease penetrance.

We have recruited clinical data and DNA samples for 602 PD patients from Tunisia. This includes 400 patients with idiopathic PD, 60 affected probands with 70 family members, and 142 sporadic patients with LRRK2 p.G2019S. We estimated the case-control penetrance and familial penetrance of p.G2019S with Kaplan-Meier and kin-cohort analyses respectively. We also compared the clinical motor phenotypes across homozygote, heterozygote and non-LRRK2 p.G2019S carriers. We performed whole-genome-sequencing in 7 early-onset and 7 elder asymptomatic carriers to identify potential genetic modifiers of age of onset.

Disease penetrance for LRRK2 p.G2019S carriers was estimated to be 30% at age 50 and 80% at age 70. Interestingly, a significant difference was observed between genders with the average age at onset for females being 5 years younger than that observed in males in cases and families. This gender bias appears LRRK2 p.G2019S specific. Differences in age at onset between genders were not observed for idiopathic patients. WGS in 14 LRRK2 p.G2019S patients identified ~9×106 variants of which 287 coding changes discriminate between early-onset and asymptomatic groups; a subset have been selected for validation in the larger series to identify polymorphisms that may modulate the phenotypic expression of p.G2019S-linked disease.The age at onset of PD of p.G2019S carriers in this study spans 50 years despite their ethnic, genetic and environmental homogeneity. Some validated targets of WGS appear to modulate age at onset and may highlight novel therapeutic strategies to delay the onset of disease.

***APOE* and *SNCA* predict cognitive performance in Parkinson's disease.** *I. Mata[1,2], J. Leverenz[1,2], J. Trojanowski[3], A. Siderowf[3], B. Ritz[4], S. Rhodes[4], S. Factor[5], C. Wood-Siverio[5], J. Quinn[6], K. Chung[6], A. Espay[7], F. Revilla[7], K. Edwards[8], T. Montine[9], C. Zabetian[1,2].* 1) Dept Neuroscience, VA Puget Sound Healthcare Sys, Seattle, WA; 2) Dept Neurology, University of Washington, Seattle, WA; 3) University of Pennsylvania, PA; 4) UCLA, Los Angeles, CA; 5) Emory University, Atlanta, GA; 6) Portland VA Medical Center, Portland, OR; 7) University of Cincinnati, Cincinnati, OH; 8) Dept Epidemiology, University of Washington, Seattle, WA; 9) Dept. Pathology, University of Washington, Seattle, WA.

Objective: To determine if common variation in the *MAPT, SNCA,* and *APOE* genes is associated with cognitive performance in patients with Parkinson's disease (PD) Background: Cognitive impairment (CI) is an increasingly recognized problem in PD and approximately 80% of patients will develop dementia during the course of the disease. Though there are several well-established susceptibility genes for PD, whether common genetic variation influences risk for CI in PD has not yet been determined. Design and Methods: We recruited 937 PD patients from six academic centers in the U.S. All study participants underwent psychometric testing that assessed performance in four major cognitive domains: memory (HVLT), language (phonemic and semantic verbal fluency), visuospatial skills (Judgment of Line Orientation), and executive function (Letter-Number Sequencing and Trail Making Test Parts A and B). Subjects were genotyped for single nucleotide polymorphisms (SNPs) in three genes; two (*MAPT* and *SNCA*) known to alter risk for PD and one (*APOE*) reported to associate with cognitive function in PD. Linear regression was used to test for association between genotype and cognitive performance (at baseline) adjusting for sex, years of education, disease duration, and age at testing. Results: The*APOE* ε4 allele was associated with lower performance on HVLT immediate (p= 0.0002) and delayed recall (p=0.02), semantic verbal fluency (p=0.02), Letter-Number sequencing (p=0.006), and Trail Making B-A (p=0.007). The *SNCA* SNP rs356219 was correlated with performance on HVLT immediate (p=0.02) and delayed recall (p=0.02). The *MAPT* H1/H2 haplotype was not associated with scores on any tests. Conclusion: Our data indicate that *APOE* ε4 is an important predictor of cognitive performance in PD across multiple domains, and *SNCA* exhibits an effect on memory-related tasks. The latter observation suggests that *SNCA* is both a susceptibility gene for PD and modifier of cognitive function in patients with an established diagnosis of PD. These results serve as proof of principle that common genetic variation influences cognition in PD and provide a rationale for expanding future studies to a genome-wide scale.

Abnormal Responses to Visual Cortex Activation in Early Stage Huntington Disease Patients using 31P-NMR Spectroscopy. *F. Mochel[1,2,3], TM. Nguyen[1], D. Deelchand[4], D. Rinaldi[1], R. Valabregue[5], C. Wary[3,6], A. Durr[1,2], PG. Henry[4].* 1) Inserm UMR S975, Institut du Cerveau et de Moelle, Hôpital Pitié-Salpêtrière, Paris, France; 2) AP-HP, Département de Génétique, Hôpital La Salpêtrière, Paris, France; 3) Université Pierre et Marie Curie, Paris, France; 4) University of Minnesota, Center for Magnetic Resonance Research, 2021 6th Street SE, Minneapolis MN, USA; 5) CEntre de NeuroImagerie de Recherche, Institut du Cerveau et de la Moelle, Hôpital La Salpêtrière, Paris, France; 6) Laboratoire de RMN, Institut de Myologie, Hôpital La Salpêtrière, Paris, France.

Objective: To test the hypothesis that brain energy metabolism is abnormal in patients at an early stage of Huntington disease (HD). Background: Energy metabolism has been a major focus of HD research for many years due to several observations in both patients and models of the disease. However, there are currently no in vivo biomarkers of brain energy metabolism in HD. Methods: We coupled noninvasive 31P-NMR spectroscopy with activation of the occipital cortex in order to measure the levels of ATP, phosphocreatine (PCr) and inorganic phosphate (Pi) before, during and after a visual stimulus. We studied 15 HD patients at an early stage of the disease (mean motor UHDRS= 18 ±9) and 15 age- and sex-matched controls. Results: In controls, we observed an 11% increase in Pi/PCr ratio (p=0.024) and a 13% increase in Pi/ATP ratio (p=0.016) during brain activation, reflecting increased ATP synthesis and ADP levels. Subsequently, controls had a return to baseline levels during recovery (p=0.012 et 0.022 respectively). In HD patients, both Pi/PCr and Pi/ATP ratios were unchanged during and after visual stimulation, reflecting altered mitochondrial bioenergetics. In addition, in HD patients the ratio of Pi/ATP correlated with the UHDRS score during the activation (p=0.014) and recovery periods (p=0.009), while Pi/PCr ratio correlated with the UHDRS score during recovery (p=0.016), reflecting a correlation between brain energy metabolism and disease severity in HD. Conclusions: 31Phosphorus nuclear magnetic resonance spectroscopy could provide functional biomarkers of brain energy deficit to monitor therapeutic efficacy in Huntington disease.

Sympathovagal balance in Major Depressive Disorder: influence of the BDNF and 5-HTTLPR (serotonin transporter) polymorphisms. *A. Perez[1], A.R. Brunoni[2], B. Coprerski[1], D. Brunoni[1].* 1) Centro de Genetica Medica, Unifesp - EPM, Sao Paulo, Brazil; 2) Centro de Pesquisas Clínicas, 3o andar Hospital Universitário, USP.

Major depressive disorder (MDD) is a clinical condition whose core symptoms are depressive mood and anhedonia. In recent years, several biological markers have been identified for MDD such as decreased heart rate variability (HRV). Other biomarkers such as the polymorphisms of the Brain Derived Neurotrophic Factor (BDNF) and serotonin transporter (5-HTTLPR) genes have also been associated with depression. Decreased heart rate variability (HRV), the Val66Met polymorphism of the brain-derived neurotrophic factor (BDNF) gene and the short variant of the repeat length polymorphism, serotonin transported-linked polymorphic region (5-HTTLPR) have been associated in the pathophysiology of major depressive disorder (MDD) and anxiety. Nevertheless, the relationship of BDNF, 5-HTTLPR and HRV in depressed patients have not yet been explored. Therefore, we explored such relationship in 120 drug-free, moderate-to-severe patients with acute MDD. This study was approved by the Local and National Ethics Committee (protocols 873/08 and 991/10) and it is registered in the clinicaltrials.gov database (NCT01033084). We genotyped BDNF and 5-HTTLPR polymorphisms and assessed HRV in a cross-sectional study. General linear models were performed, using 4 HRV indexes (SDNN, RMSSD, LF and HF) as dependent variables and BDNF, 5-HTTLPR, age, gender, depression severity and anxiety as independent variables. Although we did not observe main effects of BDNF and 5-HTTLPR on HRV, we found specific gene × gene interactions: in fact, the Val/Val l/l and Val/Met s-carrier genotypes exhibited higher HRV whereas the Val/Met l/l and Val/Val s-carrier genotypes presented lower HRV. These effects were even more marked when controlling for co-morbid anxiety. Our results suggest that there is a genetic 5-HTTLPR × BDNF interaction that modulates sympathovagal balance in depressed patients; therefore, decreased HRV observed in MDD patients could also be explained via genetic mechanisms. Such genetic interaction can also play a role in modulating cardiac autonomic functions, and also on sympathovagal impairment in individuals on antidepressant treatment. Supported by FAPESP: 11/08960-8.

Complex genetic scores can predict smoking cessation success and uptake of addictive substance use. *G. Uhl[1], D. Sisto[1,2], D. Walther[1], W. Eaton[2], N. Ialongo[2], J. Rose[3].* 1) Dept Molec Neurobiology, NIDA/NIH, Baltimore, MD; 2) Dept of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore MD; 3) Center for Nicotine and Smoking Cessation Reserach, Duke University, Durham NC.

Validated genotype scores that predict relevant clinical outcomes represent major goals of complex genetics. Addiction vulnerability and abilities to quit smoking are phenotypes with substantial heritabilities, complex genetic underpinnings, few major gene influences and several modest sized GWAS datasets. We now report validation of an established, 12063SNP v1.0 smoking cessation success genotype score, developed using data from 3 smoking cessation clinical trials, in a new smoking cessation clinical trial and describe striking differences in the score in individuals who display differing developmental trajectories of use of common addictive substances. In a cessation study, v1.0 genotype scores predicted ability to quit with p = 0.00056 and area under ROC curve 0.66. About 43 vs 13% quit in the upper vs lower genotype score terciles. Latent class growth analyses of a developmentally-assessed sample identified three latent classes based on substance use. Higher v1.0 scores were associated with a) higher probabilities of participant membership in a latent class that displayed low use of common addictive substances during adolescence (p = 0.0004) and b) lower probabilities of membership in a class that reported escalating use (p = 0.001). These results suggest that: a) we have identified genetic predictors of smoking cessation success, b) genetic influences on quit success overlap with those that influence the rate at which addictive substance use is taken up during adolescence and c) individuals at genetic risk for both escalating use of addictive substances and poor abilities to quit may provide especially urgent focus for prevention efforts. (Support NIDA IRP, DA009897 (WE) and 4R37DA011796-11 (NI), private funding through JHBSPH and grant to Duke University (PI, Dr. Rose) from Philip Morris, USA for work performed prior to January, 2012).

Integrated Copy Number and Gene Expression Analysis Detects a CREB1 Association with Alzheimer's Disease. *N. Sule[1], Y. Li[2], I. Shefer[2], C. Shaw[2], S. Powell[3], B. Dawson[2], S. Zaidi[4], K. Bucasas[2], J. Lupski[2], K. Wilhelmsen[5], R. Doody[4], K. Szigeti[6].* 1) Pathology, Roswell Park Cancer Institute, Buffalo, NY; 2) Dept Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Dept Pathology, Methodist Hospital, Houston, TX; 4) Dept Neurology, Baylor College of Medicine, Houston, TX; 5) University North Carolina, Chapel Hill, NC; 6) Dept Neurology, University at Buffalo, Buffalo, NY.

Background: A study to test the hypothesis that in a genetically heterogeneous disorder such as sporadic Alzheimer disease, utilizing gene expression as a quantitative trait (eQTL) and CNVs as a genetic marker map within the same individuals increases the power to detect relevant loci. Methods: Discovery cohort comprised of 24 AD and 15 neuropathologically normal control temporal lobes simultaneously typed for gene expression and CNV state. These data were integrated to perform a CNV-gene expression case-control association analysis. A replication cohort comprised of 377 AD and 193 normal control subjects from the Texas Alzheimer Research Consortium was analyzed to verify candidate findings by a genotype only case-control analysis accounting for both APOE and gender as additional covariates. Subsequently we performed differential gene expression between the deletion carrier and diploid AD cases and annotated the differentially expressed gene. We also assessed whether there is a cell type specific difference in the expression of CREB1 between the deletion carrier and diploid AD brain specimens using three CREB-1 specific antibodies. Results: Using this approach an 8 kb deletion was identified that contains a PAX6 binding site on chr2q33.3 upstream of CREB1 encoding the cAMP responsive element binding protein1 transcription factor. The association of the CNV to AD was confirmed by a case-control replication study. We identified 350 differentially expressed genes including CREB1 targets. Conclusions: Using disease state information together with gene expression as an eQTL and cis-genotype (CNV state) within the same individuals is a powerful method to detect association with disease in a genetically heterogeneous disorder. This method could serve as an alternative approach to genome-wide association studies to identify risk alleles with modest effect sizes.

Genetic modifiers of EEG brain activity during sleep in humans. *S. Warby[1], H.E. Moore IV[1], O. Carrillo[1], J. Faraco[1], L. Lin[1], P.E. Peppard[2], T. Young[2], E. Mignot[1].* 1) Center for Sleep Sciences and Medicine, Stanford University, Palo Alto, CA. 94025; 2) School of Medicine and Public Health, University of Wisconsin-Madison, Madison, WI 53726.

The brain generates complex patterns of electrical activity that can be measured on an electroencephalogram (EEG) and thought of as an individual EEG fingerprint. Sleep EEG measures the dramatic and predictable changes in basal brain activity associated with sleep stages. These progressive changes in activity over the course of the night are inherent in the neuronal circuitry and are the result of a complex dialogue between the cortex and subcortical structures. We are developing tools to measure distinct features with the EEG signal, such as sleep spindles, in order to better understand their genetic basis. Sleep spindles are a 0.5–2 second burst of cortical activity that occurs predominately in stage 2 sleep. They are most often identified by visual inspection of the EEG but can be measured by analyzing power in the sigma range (12–16Hz). Recently, spindles have been implicated in sleep arousal thresholds, brain plasticity, learning and memory consolidation. Significant alterations in spindle frequency have been observed in many disorders such as schizophrenia, epilepsy, autism, and neurodegenerative disorders. Although very little is known about sleep spindles at the genetic level, twin studies suggest that sigma power and spindle density are highly heritable traits. The purpose of this study is to perform a genome wide association study for sleep spindle characteristics in the normal human population. Sleep spindles were measured as sigma power in stage 2 sleep from 1,876 EEG studies collected longitudinally from 1,300 adult individuals from the Wisconsin Sleep Cohort. Longitudinal correlation of sigma power over 4 years within and individual is high (r2 >0.75), consistent with the idea that spindles are stable and trait-like. Genotyping was performed genome-wide using Affymetrix 6.0 genechip and direct Taqman genotyping. Genetic associations will be determined using an additive genetic model and linear regression with subject age, sex, BMI, and medications as potential covariates. We find significant effects of age and interactions with several drug categories including benzodiazepines, sedatives and blood pressure medications. Genome-wide gene association may identify several loci implicated in the regulation spindles and reveal support for the genetic control of sleep spindles in humans. Further studies are needed to replicate and extend on genetic findings and to examine gene-environment interactions.

The eQTLs in language-related genes reveal a gene × gene interaction between BDNF and PCDH17 in the human brain. *N. Li[1], S.Y. Cheong[1], M. Goode[1], S.A. Petrill[2], A.S. Bassett[3], L.M. Brzustowicz[4], C.W. Bartlett[1].* 1) The Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital and Department of Pediatrics, The Ohio State University, Columbus, OH; 2) Department of Human Development and Family Science, The Ohio State University, Columbus, OH; 3) Department of Psychiatry, University of Toronto, Toronto CA; 4) 4Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ.

Background The genetics of language, a uniquely human trait, is challenged by limited options for research in animal models. Recent studies on language impairment have replicated several genes in language related traits but finding the functional alleles that underlie the genetic signals still challenging though postmortem human brain samples may be a powerful tool for finding those genetically functional alleles. We propose that finding expression quantitative trait loci (eQTLs) in the human brain may provide strong candidate SNPs for future mechanistic studies. The eQTL data from five-replicated language related genes (ATP2C2, CMIP, CNTNAP2, FOXP2, PCDH17) were used to search expression SNPs. Additionally, brain-derived neurotrophic factor (BDNF) plays an important role in neuronal plasticity and is associated with working memory, which is crucial for language processing. A gene × gene (GxG) interaction with BDNF functional SNP (rs6265) was shown previously with PCDH17 to substantially increase risk for specific language impairment (Simmons et al 2010). We sought to determine if this interaction could be demonstrated at the gene expression level. Methods 1177 individuals from seven publicly available brain eQTL datasets were employed for analysis. SNPs from 1000 genome Phase I Integrated Release Version 2 Haplotypes were imputed to create a common marker map across studies. The posterior probability of linkage disequilibrium was used for analysis of the five language-related genes. Results An eQTL in PCDH17 was found to be consistent across by multiple probes/datasets (PPLD=49–67%), and in CNTNAP2 an eQTL was consistent across by multiple probes/datasets (PPLD=11–14%). Several additional possible eQTLs were suggested in CNTNAP2 and CMIP. PCDH17 and BDNF were found to be negatively correlated across multiple probes in both genes (-0.42 to -0.12) with p-values ranging from 0.04 to 2.2×10^-13. GxG interaction analysis of SNPs in the extended promoter region of PCDH17 (up to 100kb upstream) yielded a maximized LOD of 2.6 suggesting an interaction between BDNF genotypes and PCDH17 expression. Discussion This is the largest human brain eQTL study, derived from the existing publicly available datasets, and it has identified novel eQTLs in language related genes. SNPs discovered in this dataset represent logical targets for future studies of language related traits. Key Words: expression quantitative trait loci; language; gene-gene interaction.

The *KIAA0319* gene is associated with language progression more than its level. *S. Tezenas du Montcel[1,2], B. Feng[3], C. Barr[4], B. Falissard[2], M. Boivin[3], G. Dionne[3].* 1) ER4 Modeling in Clinical Research, University Pierre et Marie Curie-Paris 6, Paris, France; 2) INSERM U669, France; 3) Université Laval, Quebec City, Canada; 4) Toronto Western Research Institute, Canada.

Language is a complex behavior with a genetic basis in line with caregivers and stimulation from the child environment. Based on twin studies, the heritability of language skills in the preschool years is modest, around 20%, but appears more substantial at the lower end of the continuum. Over the course of development, the heritability of language skills increases to around 50%. Although we know heritability changes over time, the heritability of the slope of progression has never been tested until now. A chromosome 6 region including the *DCDC2*, *VMP*and *KIAA0319* genes has been associated with language-related skills and reading disability. In this study, we estimated the heritability of language development and the influence of chromosome 6 candidate genes on language progression with data from the Quebec Newborn Twin Study (QNTS). Participants were 1086 twins assessed on language skills at 18 and 30 months, and 5, 7 and 8 years of age. SNPs for the 3 candidate genes on chromosome 6 (*DCDC2, VMP, KIAA0319*) were genotyped for both twins. Autoregressive Latent Trajectory model adapted to twin data and candidate genes were used. Non-parametric trajectory models were also fitted and the influence of the candidate genes on the trajectories were tested. We found that, although the mean level of language was mainly due to shared environment, the heritability of language development (the slope from 18 months to age 8 years) was high (56%), with a moderate involvement of common environment (28%). In addition we identified three trajectories of language development: 1) typical language skills, stable across ages (40.3% of the sample), 2) high language skills, stable across ages (51.3%), and 3) poor language skills with a mild recovery upon school entry (8.4%). The poor language skill trajectory (versus the other two) was associated with 3 SNPs of the *KIAA0319* gene. In conclusion, the developmental slope of language progression from 18 months to age 8 years appears more heritable than differences in language skills. In addition, children with language skills below the normal range over this period recover partially upon school entry, but belonging to this group is associated with the*KIAA0319* gene which has already be shown to be associated with reading disorders.

Genome-wide association of executive function in a normally developing pediatric cohort. *J.J. Connolly[1], P.M. Sleiman[1,2,3], R.C. Gur[4], M.E. Calkins[4], D.J. Abrams[1], R.M. Chiavacci[1], H. Qiu[1], F.D. Mentch[1], R.E. Gur[4], H. Hakonarson[1,2,3].* 1) Ctr Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA; 2) Division of Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA; 3) Dept Pediatrics, Perelman School of Medicine, Univ of Pennsylvania, Philadelphia PA; 4) Brain Behavior Laboratory, Perelman School of Medicine, Univ of Pennsylvania, Philadelphia PA.

We conducted a genome-wide association study (GWAS) of scores on the Penn Conditional Exclusion Test (PCET), a computerized measure of executive function that examines abstraction and concept formation. The PCET is an `odd-one-out' paradigm, requiring participants to decide which of four objects does not belong to a specific category (e.g. size, shape, and thickness of a line). A cohort of 8,500 participants aged 8–21 years were divided into discovery (the first 5000 participants) and replication sets (~3,500 participants). Scores were corrected for age and sex, and linear regression used to examine accuracy and speed. Variants at one locus on chromosome 5 survived multiple testing correction for PCET speed measures, and were also associated with speed in the replication set. These mapped to the ERRBB2IP gene. The most significantly associated SNP was a missense mutation—S1112L—at a highly conserved base. The ERBB2IP protein, commonly referred to as Erbin, has been implicated in a variety of neuronal functions, including regulation of L-type voltage-gated Ca2+ channels at the synapse, and regulation of NRG1 and signaling/myelination. Replication efforts are underway and results will be presented together with further characterization of the protein.

Lipidomic profiling in Lewy body disease brain autopsies carrying Lysosomal Storage Disorder gene variants. *N. Parmalee[1], R.B. Chan[1], N. Park[2], E.P. Cortes[3], J.P. Vonsattel[1,3], K. Marder[1,2,4], L. Honig[1,2,4], J.H. Lee[1,2], G. Di Paolo[1], L. Clark[1].* 1) Department of Pathology and Cell Biology & Taub Institute for Research on Alzheimer's Disease, Columbia Univ, New York, NY; 2) Gertrude H. Sergievsky Center, Columbia Univ, New York, NY; 3) New York Brain Bank, Columbia University, New York, NY; 4) Department of Neurology, Columbia University, New York, NY.

Objective: To determine the relationship of Glucocerebrosidase (GBA) and other lysosomal storage disease (LSD) gene variants to lipid profiles and Lewy Body (LB) and Alzheimer disease (AD) pathology. Background: Mutations in the LSD gene, glucocerebrosidase (GBA), are associated with LB disorders (LBD). We hypothesized that other LSD genes in the same biochemical pathway may also represent susceptibility genes for LBD. Four genes Glucocerebrosidase (GBA), Hexosaminidase A (HEXA), Sphingomyelin phosphodiesterase 1(SMPD1) and mucolipin 1 (MCOLN1) and their lipid substrates and products were analyzed. Methods: Brain tissue from 243 autopsies from the NYBB at CU included: 128 brains with primary neuropathological diagnoses of LB disorders with or without AD changes, 79 brains with AD without significant LB pathology, and 36 control brains with neither LB or AD pathologies. To capture rare variants (MAF<1%), all four LSD genes were sequenced in 243 autopsies. Rare variant analysis was performed using the CCRaVAT program. Liquid chromatography-mass spectrometry (LC/MS) was used to profile grey matter lipid extracts from the primary motor cortex (BA4) of brain autopsy material from a subset of samples (n=46: 18 controls, 8 AD, 8 LBD and 12 LBD with LSD variants). Quantification of a total of approximately 200 lipid species, representing 14 major lipid classes was performed. Results: Several variants that we identified in LBD subjects including, N370S (GBA), L444P (GBA), c.1278insTATC, (HEXA), c.672+30T>G (HEXA), P330R (SMPD1) and E515V (SMPD1) have been reported previously as mutations in patients with LSD. Multiple variants in GBA, SMPD1 and MCOLN1 were significantly associated with LB and LBVAD pathology (p range: 0.01 - 6.45×10-5) but not with AD. Several classes of lipids were significantly altered in LBD LSD mutation carriers compared to LBD (wildtype), controls and AD autopsy samples ($p<0.05$). In LBD autopsy samples carrying GBA mutations we observed significant changes in a number of glycosphingolipids, including GM3, monohexosylceramide and ceramide, compared to LBD without GBA mutations, controls and AD autopsy samples. Conclusion: Lipid profiling in LBD autopsy samples carrying GBA mutations (N370S, 84insGG, D409H and R463C) revealed accumulation of several lipid classes. Since α-synuclein can be degraded via the lysosome (CMA), our study suggests that lysosomal impairment may lead to accumulation of α-synuclein and LB formation.

Study of plasma metabolites levels in discordant sibling pairs with autism. *G. Malerba[1], R. Wang-Sattler[2], E. Trabetti[1], J. Adamski[3,4], P. Prandini[1], L. Xumerle[1], C. Zusi[1], A. Pasquali[1], R. Galavotti[1], P.F. Pignatti[1], T. Illig[2,5], The Italian Autism Network (ITAN).* 1) Life and Reproduction Sciences, University of Verona, Verona, Verona, Italy; 2) Research unit of Molecular Epidemiology, Helmholtz Zentrum München, 85764 Neuherberg, Germany; 3) Institute of Experimental Genetics, Genome Analysis Center, Helmholtz Zentrum München, 85764 Neuherberg, Germany; 4) Chair of Experimental Genetics, Technische Universität München, Munich, Germany; 5) Hannover Unified Biobank, Hannover Medical School, 30625 Hannover, Germany.

Autism spectrum disorders (ADS) are a group of pervasive neurodevelopmental disorders whose etiology is not known. Metabolomics might help in giving new insights about the pathogenesis of the disease. In this study, within the frame of the Italian Autism Network (ITAN, 1), plasma samples of 39 discordant ASD sibpairs, composed by an autistic male child and his unaffected brother, were measured for 188 metabolites concentration based on targeted metabolomics approach with the *AbsoluteIDQ™* p180 kit (BIOCRATES Life Sciences AG, Innsbruck, Austria). We found four metabolites concentration differed significantly between affected and non affected children (paired t-test, age-adjusted): carnitine (p=0.035), ornithine (p=0.012), hexoses (p=0.026) and PC ae C40:4 (p=0.041). Although after correction for multiple testing none of the 4 associations remained statistically significant it is noteworthy that pathways involving two of the metabolites here reported (carnitine and ornithine), whose association was significant before the adjustment, have been described associated with the autistic phenotype (2,3). In particular previous studies reported a lower plasma levels of carnitine in autistic patients as in the present study and mutations in genes involved in the synthesis of carnitine, and urea cyclic disorders associated with mental retardation and cognitive impairment. This exploratory study suggests that dysregulation of carnitine and urea cyclic disorders might be associated with ASD and that future genetic investigations should focus on these pathways in detail. Moreover the four identified metabolites might serve as candidate biormarkers for autism phenotypes. References 1) Prandini et al., 2012. Genome scan for cognitive trait loci of dyslexia: Rapid Naming and Rapid Switching of Colors, Letters and Numbers. *W.H. Raskind[1,2], K. Kevin Rubenstein[3], M. Matsushita[1], V.W. Berninger[4], E.M. Wijsman[1,3].* 1) Depts of Med; 2) Psychiatry and Behavioral Sciences; 3) Biostatistics; 4) Educational Psychology, Univ Washington, Seattle, WA.

Dyslexia is a complex learning disability with strong evidence for a genetic basis. Deficits can persist into adulthood. Strategies that may be useful for dissecting the genetic basis of dyslexia include study of component phenotypes, which may simplify the underlying genetic complexity, and an analytic approach that accounts for the multilocus nature of the trait to guide the investigation and increase power to detect loci. Here we present results of a genome scan of several measures of Rapid Automatized Naming (RAN) and Switching (RAS) as component phenotypes in a sample of 260 2–4 generation pedigrees (~2040 individuals, ~1775 with phenotypes, ~1120 genotyped) selected through a dyslexic proband. Scores from the Wolf RAN/RAS tests were used (Letters, Numbers, and Colors naming; and Letters/Numbers and Letters/Numbers/Colors Switching), after adjustment for age, age^2, cohort, and gender. We used an MCMC-based oligogenic trait model for both initial segregation analysis and for subsequent joint segregation and linkage analysis in a genome scan. Bayes' factors (BF) for linkage were used for evaluation of evidence for linkage.

Covariates explained 57–65% of the phenotypic variance, with speed for test completion slower in males than females, increasing with age in children, and decreasing again with age in adults. Correlations between adjusted trait values were high, ranging from a low of 0.55 (e.g., RAN Colors and RAN Letters) to 0.95 (e.g., RAS Letters/Numbers and RAN Letters). Oligogenic segregation analysis identified a small number of quantitative trait locus models (QTLs) that are sufficient to explain the inheritance of some of the adjusted traits. In the genome scans, the strongest linkage signals were obtained on chromosome (chr) 2 (RAN Letters, BF=59, 81 cM), chr 10 (RAN Colors, 47 cM) and chr 1 (RAS Letters/Numbers, BF=30, 63 cM). Notable signals were also obtained at two close positions on chr 12 (RAS Colors/Letters/Numbers, BF=26, 95 cM; and RAN Numbers, BF=24, 115 cM). Based on modeling studies of individuals with and without dyslexia, RAN letters is thought to be a phenotype for phonological loop and RAS is thought to be a phenotype for supervisory switching attention of working memory. Identification of the genes involved in RAN and RAS performance is therefore of great interest. Fine mapping of these 5 regions is ongoing.

Identification of genes and pathways regulated by epigenetic mechanisms in determining general intelligence (*g*) of inbred mice. *P. Cha[1], K. Kobayashi[1], Y. Ando[1], C. Yu[1], S. Yamagata[2], K. Okada[3], J. Sese[4], K. Takao[5], T. Miyakawa[6], T. Toda[1].* 1) Division of Neurology/Molecular Brain Science, Kobe University Graduate School of Medicine, Kobe, Hyogo, Japan; 2) Admission Research Unit, National Center for University Entrance Examinations; 3) Department of Psychology, Senshu University, Kanagawa, Japan; 4) Department of Computer Science, Tokyo Institute of Technology, Tokyo, Japan; 5) Center for Genetic Analysis of Behavior, Section of Behavior Patterns, National Institute for Physiological Sciences, Aichi, Japan; 6) Division of Systems Medical Science, Institute for Comprehensive Medical Science, Fujita Health University, Aichi, Japan.

To study epigenetic regulation of general intelligence (*g*), 39 inbred mice raised under similar environmental conditions were subjected to five behavioral tests. 11 parameters measuring performance of mice that reflect their cognition were analyzed by using principal component analysis. The first principal component (PC1) explains 24.4% of variance in cognition and is highly correlated with average score of mice in behavioral tests (IQ score) (R^2=0.83). Hippocampal RNAs obtained from the 5, 12, and 8 mice consistently classified as having high, medium, and low cognition, respectively, by PC1 score and IQ score were subjected to microarray gene expression analysis. 17 genes showed at least 1.3-fold difference in expression between mice with high and low cognition (FDR<0.30), including two genes (*Ldlr* and *Stxbp2*) that were down-regulated and 15 genes (*e.g. Rab39, Rapgapl1, Hist1h3d, Vcl, Osbpl6,* etc) that were up-regulated in high cognitive mice. Pathway-based analysis of the expression data revealed that most genesets (GS) enriched in high cognitive mice play important roles in protein synthesis, indicating that memory consolidation or long-term potentiation might occur actively in hippocampus of mice with high cognition. By contrast, most GS enriched in low cognitive mice play important roles in transmembrane transport, extracellular matrix and regeneration of vesicles. A number of genes in GS implicated in our study have been reported to be associated with cognitive impairments. Our findings not only provide insights into genes and pathways regulated by epigenetic mechanisms in determining "*g*", but may also deepen our understanding on various disorders associated with cognitive impairments.

2551T

Quantitative linkage analysis with the endophenotype of social responsiveness identifies genome-wide significant linkage to a narrow region at 8p21.3. *J.K. Lowe[1,2,3,7], D.M. Werling[4,7], J.N. Constantino[5,7], R.M. Cantor[3,6,7], D.H. Geschwind[1,2,3,6,7].* 1) Neurogenetics program and Department of Neurology, University of California, Los Angeles, Los Angeles, CA; 2) Neurogenetics Program and Center for Autism Research and Treatment, Semel Institute, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA; 3) Center for Neurobehavioral Genetics, Semel Institute, University of California, Los Angeles, Los Angeles, CA; 4) Interdepartmental PhD Program in Neuroscience, Brain Research Institute, University of California, Los Angeles, Los Angeles, CA; 5) Departments of Psychiatry and Pediatrics, Washington University School of Medicine, St. Louis, MO; 6) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA; 7) ACE Genetics Consortium.

Diminished social responsiveness (SR) is one of the three core deficits in autism spectrum disorder (ASD), a heterogeneous neurodevelopmental trait with a strong genetic component. We performed quantitative linkage and association analyses for SR as measured by the Social Responsiveness Scale (SRS). SRS is a 65-item questionnaire completed by a teacher or parent, assessing interpersonal behavior, communication, and repetitive/stereotypic behavior in children ages 4–18 years. Using nearly 500 families from the Autism Genetics Research Exchange (AGRE) repository, we performed a genome-wide linkage scan and identified genome-wide significant multi-point quantitative linkage to SRS on chr8p21.3 (LOD 5.16). The peak SNP (rs6587004) lies in an intronic region of *GFRA2* (glial cell line-derived neurotrophic factor (GDNF) family receptor α-2), which encodes a cell-surface receptor for neurotrophic factors involved in neuron survival and differentiation. The one-LOD interval encompassing the linkage peak spans 966 kb and contains 16 genes. We report single-marker and haplotype association findings under the linkage peak and replication studies of the linkage signal in an independent data set. Interestingly, this chr8 peak co-localizes with suggestive linkage signals for ASD as a qualitative trait in a larger set of AGRE families (n>800) as well as in a subset of families with at least one female affected offspring (n=315). These data support the use of quantitative intermediate traits such as SR to increase power by reducing heterogeneity in a complex trait such as ASD and identifies a highly significant, narrow linked region on chr8p21.3.

2552F

Nonpathogenic traits: a study of susceptibility to sympathetic yawning. *E.T. Cirulli, A.J. Bartholomew, D.B. Goldstein.* CHGV, Duke Univ, Durham, NC.

While extensive efforts continue to be made to understand the genetics of human diseases, both common and rare, there has been much less serious effort dedicated to understanding the genetic bases of traits that comprise everyday differences among healthy individuals, many of which are of great interest biologically. We propose to systematically measure everyday, non-disease phenotypes in a large cohort of healthy volunteers and to search for the genetic correlates of those phenotypes via whole-exome sequencing. Here, we have chosen to study sympathetic yawning as an example nonpathogenic trait that could offer great insight into the genetics of empathy. In controlled studies, approximately 40% of healthy volunteers will yawn when presented with a visual stimulus of someone yawning or a written account of yawning. No other human trait exhibits a mimicry response that is so difficult to control, stressing the importance of characterizing the specific biological processes that contribute to this unusual effect. These sympathetic yawns do not occur in humans until ~5 y of age and have been shown to be impaired in diseases such as schizophrenia and autism, indicating that differences in this trait between humans may be genetic and relevant to disease. We showed a 3 minute video clip of yawning stimuli to over 100 healthy volunteers for whom we have already collected extensive demographic and intelligence data; the volunteers were not observed but were asked them to click a button every time they yawned. We found that approximately 50% of the healthy volunteers yawned in response to the video, with the number of yawns ranging from 1 to 10. Surprisingly, we found a strong association for subjects with higher levels of education to be less likely to yawn; when correcting for this effect, we found a suggestive trend for more intelligent individuals to be more likely to have sympathetic yawns in response to the video. Interestingly, this effect was education only influenced whether or not the subjects yawned and did not influence how many times they yawned. Our future work will focus on expanding this study to additional individuals and to comparing the measurements to genotypes from whole-exome sequence data. We will also begin to measure additional nonpathogenic traits, such as night visual acuity and face recognition, with the eventual goal of identifying genetic variants that contribute to the control of biologically important, nonpathogenic traits.

2553W

Combined genetic analysis of DNA methylation and gene expression in schizophrenia identifies disease susceptibility loci. *K.R. van Eijk[1,2], M.P.M. Boks[2], S. de Jong[3], E. Strengman[2], R.S. Kahn[1], S. Horvath[4], R.A. Ophoff[1,3,4].* 1) Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, The Netherlands; 2) Department of Medical Genetics, University Medical Center Utrecht, The Netherlands; 3) Center for Neurobehavioral Genetics, University of California Los Angeles, Los Angeles, CA; 4) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA.

Emerging evidence suggests that epigenetic variation such as DNA methylation plays a role in schizophrenia susceptibility. DNA methylation is known to affect gene expression and may thereby contribute to the development of schizophrenia. We performed a study in whole blood with the goal to gain a better understanding of relationships between genetic variation and DNA methylation profiles in schizophrenia patients and healthy controls. To examine the association between DNA methylation and genetic variants, genome-wide genotype and DNA methylation (27K Illumina array) data was obtained from whole blood of 260 schizophrenia patients and 250 healthy controls. For a subset of these subjects array-based gene expression data was also available. By combining epigenetic and gene expression data we identified 661 CpG sites in the genome that are differentially methylated between schizophrenia patients and unaffected controls, and of which methylation status is associated with gene expression levels; moreover, these genes are also differentially expressed between cases and controls. Genetic analysis revealed that 7% of these CpGs are under local (cis) genetic control. We hypothesized that identification of biological relevant links between DNA methylation and gene expression in the context of disease may be an efficient way to identify disease susceptibility loci that are under genetic control (methylation QTLs, mQTLs). We used the available results of the large Psychiatric Genomics Consortium (PGC) schizophrenia genome-wide association (GWA) study to examine whether the observed mQTLs indeed represent susceptibility loci. Overall, we observed significant enrichment of schizophrenia association signal of mQTLs with most pronounced effects for those loci that are also associated with differential gene expression in cases and controls. While this enrichment was already visible when using nominal significant thresholds ($p<0.05$ in PGC) the effects were amplified at more stringent values (e.g. p<1e-4). We identified five disease-associated loci that control DNA methylation in cis, which in turn affect gene expression in a case/control study. Interestingly, one of these loci was previously implicated in the PGC schizophrenia GWA study. Our results suggest that enrichment of biological signal by combining genetic, epigenetic and gene expression profiles from whole blood may be an efficient approach to identify disease susceptibility loci for neuropsychiatric traits.

2554T

Infantile-onset dystonia and juvenile parkinsonism associated with spastic paraplegia caused by mutations in SPG11. *G. Yoon[1,2], B. Baskin[3], M. Tarnopolsky[4], P. Rebeiro[3], B. Banwell[2], P. N. Ray[3].* 1) Div Clinical & Met Gen, Hosp Sick Children, Toronto, ON, Canada; 2) Division of Neurology, The Hospital for Sick Children, Toronto, Canada; 3) Division of Molecular Genetics, The Hospital for Sick Children, Toronto, Canada; 4) Neuromuscular and Neurometabolic Clinic, McMaster University, Hamilton, Canada.

The hereditary spastic paraplegias (HSPs) comprise a genetically and clinically heterogeneous group of neurodegenerative disorders characterized by progressive spasticity, weakness and hyperreflexia of the lower limbs. Mutations in SPG 11 are estimated to account for up to 50% of all recessively inherited HSP, and cause a complex phenotype. We describe a 17 year old girl, born to non-consanguineous parents of mixed Dutch, Polish and Ukrainian descent, who presented with episodic dystonia at 18 months but otherwise normal motor and language development in early childhood. Prenatal and perinatal course was normal, and the family history was non-contributory. She was formally diagnosed with a learning disability at 7 years. She developed a mildly spastic gait at 10 years, which progressively worsened by age 13. At that time she became stiff, developed bradykinesia, and her cognitive function became noticeably worse. At 17 years of age she had developed significant dysarthria, swallowing difficulties and required assistance for most activities of daily living. Physical exam revealed masked facies, bradykinesia, cogwheel rigidity, lower extremities weakness, spasticity and extensor plantar response. She initially responded well to a trial of Levodopa at age 14 years, with improvement of the Parkinsonian symptoms, however by age 17 years, her symptoms had progressively worsened, with increasing rigidity, spasticity and cognitive decline. An MRI of the brain revealed mild diffuse cerebral volume loss, periventricular white matter lesions and thinning of the anterior corpus callosum. Array-CGH, metabolic studies and CSF neurotransmitter analysis were normal. Molecular genetic testing on genomic DNA from blood for the common spinocerebellar ataxias, PINK1, PARK2, and DYT1 was negative. Further molecular analysis of SPG11 revealed a heterozygous c.3664_3665insT (p.Lys1222IlefsX15) mutation. Subsequent mRNA analysis using RT-PCR and sequencing of muscle tissue revealed a novel r.4667_4774del mutation, which caused deletion of exon 27 in the SPG11 transcript, and deletion of 36 amino acids (p.Tyr1556_Val1592delinsPhe) in the SPG11 protein. Levodopa-responsive juvenile Parkinsonism is a rare but increasingly recognized feature of hereditary spastic paraplegia caused by SPG11 mutations. Molecular analysis of muscle tissue may be indicated in patients with a heterozygous mutation but typical features of this condition.

2555F

CNV detection from affymetrix axiom SNP chips in the early markers for autism study. *G. Desachy[1], L. A. Croen[2], L. A. Weiss[1].* 1) Psychiatry, UCSF, San Francisco, CA., USA; 2) Autism Research Program, Kaiser Permanente Division of Research, Oakland, CA.

Purpose:

Autism Spectrum Disorder (ASD) is a highly heritable neurodevelopmental disorder. Although previous research has shown that both single nucleotide polymorphisms (SNPs) and copy number variants (CNVs) contribute to psychiatric disorders including autism, few genetic causes of autism have been identified. Because the new Affymetrix Axiom EUR array (Hoffmann et al., 2011) has not been designed for CNV detection, our primary aim was to develop a method to make copy number calls from this SNP microarray data, and then to follow up deletions or duplications of potential interest for autism risk.

Methodology:

Normalization of the raw intensity data is based on two steps. First, there is a quantile normalization step to make individuals' intensity data comparable (Bolstad, 2001). The second step consists of transforming the probe intensities into Copy Number (CN) calls by subtracting the estimated background signal for each allele of each SNP and then by scaling to estimated copy number (i.e. heterozygotes have median CN=1 for each allele, homozygotes have median CN=2 for one allele and CN=0 for the other allele). A Hidden Markov Model (HMM) is used to make the CNV calls from the normalized data. Due to the variability in the data and the fact that consecutive SNPs are not independent, we implement the HMM on 5-SNP-moving-median data and instead of single SNP data. We developed the methodology through testing on HapMap samples with established CNV calls from other methods.

Results:

We discovered several deletions in regions that might be of great interest because of the genes they include: one case with a deletion on chr8p23.1 (*CSMD1*, previously found to be associated with speech delay, autism and learning difficulties - Glancy et al., 2008) and one case with a deletion on chr9p24.1 (*PTPRD*, previously showing suggestive association in a genome-wide SNP study - Weiss et al., 2009).

Prioritization of whole exome sequencing in Parkinson Disease. *J. Farlow[1], H. Lin[1], K. Hetrick[2], H. Ling[2], E. Pugh[2], K. Bowling[3], P. Jain[3], Y. Liu[1], K. Doheny[2], R.M. Myers[3], T. Foroud[1].*1) Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 2) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 3) HudsonAlpha Institute for Biotechnology, Huntsville, AL.

Parkinson Disease (PD) is the second most common incurable progressive neurodegenerative disease behind Alzheimer's Disease. Despite being relatively common, the genetic etiologies of PD remain largely unclear, with causative mutations identified in fewer than 5% of patients and risk alleles accounting for only a fraction of the population attributable risk. Identification of additional genes important in disease risk could provide insights about the pathogenesis of PD, as well as options for more accurate ante mortem diagnosis, presymptomatic testing and therapeutic interventions. Whole exome sequencing (WES) was performed in 33 families, which included 92 individuals affected with PD based on UK Brain Bank Criteria and 3 possible PD cases. All samples were sequenced (Agilent© SureSelect™ 50Mb Human All Exon Kit) at one of two centers, with one family sequenced at both centers for quality assurance. Application of Genome Analysis Tool Kit (GATK) quality filters resulted in 149,055 single nucleotide variants (SNVs). Nonsynonymous SNVs within an exon having an allele frequency of <3% in at least one of three gene databases (RefSeq, UCSC, Ensembl) were retained. After removing variants that were not predicted to be deleterious by at least one of three protein prediction programs (SIFT, Polyphen2, MutPred) or that were not in a highly conserved region (Gerp), 20,276 variants remained. Further filtering was performed based on Mendelian inheritance (autosomal dominant or recessive), leaving 10,419 SNVs. A prioritization strategy involving Gene Ontology structural and functional annotations, normal brain expression data (Allen Brain Atlas), and the number of families in which variants in the gene of interest was found generated a list of 59 SNVs in 18 genes. Identified variants included a novel SNV located within LRRK2, a gene already implicated in PD pathogenesis. While several WES studies have been successful at identifying genes important to rare diseases, few have examined how to produce a list of candidate genes contributing to a complex disease from WES data. We show that using a rigorous family-based approach with a prioritization strategy combining rich bioinformatics resources is a powerful method to prioritize candidate genes for a complex disease like PD. Sequencing of these candidate genes in additional familial PD patients is required to validate the utility of this approach.

High yield of massively parallel sequencing in autosomal recessive intellectual disability in 23 families: identification of the causative mutation in 12 families. *R. Abou Jamra[1], R. Buchert[1], S. Uebe[1], H. Tawamie[1], S.H. Eck[2], E. Graf[2], K. Eberlein[1], J. Bauer[1], EM. Dill[1], C. Blumentritt[1], F.F. Brockschmidt[3], M.M. Nöthen[3,4], J. Schumacher[4], A. Ekici[1], T. Strom[2,5], A. Reis[1].* 1) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Bavaria, Germany; 2) Institute of Human Genetics, Helmholtz Center Munich, German Research Center for Environmental Health, Neuherberg, Germany; 3) Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 4) Institute of Human Genetics, University of Bonn, Bonn, Germany; 5) Institute of Human Genetics, Klinikum rechts der Isar, Technische Universität München, Munich, Germany.

To elucidate the genetics of autosomal recessive intellectual disability (ARID), we undertook systematic autozygosity mapping in 69 large, consanguineous families from Syria. We focused on 23 families with smaller candidate regions of sizes between 10 and 45 Mb. After enriching the exomes with the Agilent SureSelect Kit (6 exomes using the 38Mb and 17 using the 50Mb versions), we undertook massively parallel sequencing of the index patients on Solexa (six index patients) and on SOLiD platforms. Subsequently we validated variants by Sanger sequencing and tested them for segregation. We clarified the etiology in four families by identifying pathogenic mutations in the known intellectual disability genes AIH1, ALDH5A1, GPR56, and HGSNAT. Additionally, we described one new ARID gene, AP4S1, and in this context characterized the AP4 deficiency syndrome (Abou Jamra et al., Am J Hum Genet 2011). Furthermore, in seven families we identified convincing mutations (two in-frame deletions and four missense mutations) in EDC3, c9orf4, FAR1, HMG20A, NCAPD2, PPFIA1, and SPATA5. Those mutations were excluded in 280 ethnically matched controls and in silico analysis predicted pathogenic effects in all cases. The function of SPATA5 is unknown, while all other genes are highly expressed in brain and are reported to be relevant for neuronal function. In 11 families the underlying mutation remained undetected. However, as a consequence of the enriching method, part of the targeted nucleotides was not or not properly covered. To identify the mutations in the rest of the families, ensuring complete and high coverage of all exons in the linkage regions, we therefore designed targeted sequencing enriching sets (Agilent, SureSelect) and analysed the products on a SOLID5500xl platform. Those sequences yielded a significantly better variation call (average of 40% more exonic variation). Validation using Sanger sequencing and extensive bioinformatic analysis of all new variants and genes are currently ongoing. We showed that linkage analysis followed by targeted enriching and massively parallel sequencing is an effective method to identify mutations of autosomal recessive intellectual disability.

Identification of Rare Variants in Childhood Onset Schizophrenia using Exome Sequencing. *A. AMBALAVANAN[1], S.L. Girard[2], J. Gauthier[2], L. Xiong[2], A. Dionne-Laporte[2], D. Spiegelman[2], E. Henrion[2], O. Diallo[2], A. Levert[2], P.A. Dion[2], J. Rapoport[3], R. Joober[1], G.A. Rouleau[2].* 1) Douglas Mental Health University Institute, McGill University, Montreal, Quebec, Canada; 2) Centre de Recherche du Centre Hospitalier de l'Université de Montréal (CRCHUM), and Department of Medicine, University of Montreal, Montreal, Quebec, Canada; 3) Child Psychiatry Branch, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland, USA.

Background: Childhood Onset Schizophrenia (COS) is a rare severe form of schizophrenia for which, though highly heritable, definitive genetic causes remain elusive. The linkage and association studies of COS have been ineffective in attempting to identify explicit risk variants. We hypothesized that rare de novo mutation in different genes account for a portion of COS individuals. The approach is to identify the causative gene with an enrichment of rare variants from a set of twenty trios (proband and parents) by targeted capture of the exome and massively parallel sequencing of each individual in the family. **Methods:** We capture the whole exome using the Agilent SureSelect enrichment kit (50Mb). We used massively-parallel paired-end sequencing to resequence the exome of each individual on a Solid4 system. We prioritized coding variants which are found only in the affected children within the family. Our best candidate identified variants are validated by Sanger sequencing in the proband and both parents. **Results:** We found rare nonsynomymous, synonymous, splicing and frame shifting denovo variants identified in the coding regions. These potential variants are being validated with Sanger sequencing and further to explore the genes leading to affect the major biochemical pathway.**Conclusions:** We believe that insights from the identification of COS genes may help to device diagnostic tools which in turn may help to intervene earlier before the onset of symptoms which ultimately lead to the identification of therapeutic avenues for better treatment.

2559W

The Asp620Asn mutation of VPS35 in Japanese patients with typical Parkinson disease. *M. Ando[1], M. Funayama[1,2], Y. Li[2], K. Kashihara[3], Y. Murakami[4], N. Ishizu[5], C. Toyoda[6], K. Noguchi[7], T. Hashimoto[8], N. Nakano[9], R. Sasaki[10], Y. Kokubo[10], S. Kuzuhara[11], K. Ogaki[1], C. Yamashita[1], H. Yoshino[2], H. Tomiyama[1,12], N. Hattori[1,2,12].* 1) Neurology, Juntendo University, Tokyo, Tokyo, Japan; 2) Research Institute for Diseases of Old Age, Graduate School of Medicine, Juntendo University, Tokyo, Japan; 3) Department of Neurology, Okayama Kyokuto Hospital, Okayama, Japan; 4) Department of Neurology, Saiseikai Kurihashi Hospital, Saitama, Japan; 5) Department of Neurology, Saitama National Hospital, Saitama, Japan; 6) Department of Neurology, Jikei Daisan Hospital, Tokyo, Japan; 7) Department of Neurology, Kakio Kinen Hospital, Tokyo, Japan; 8) Hashimoto Clinic, Osaka, Japan; 9) Department of Neurosurgery, Kinki University Hospital, Osaka, Japan; 10) Department of Neurology, Mie University Graduate School of Medicine, Tsu, Mie, Japan; 11) Department of Medical Welfare, Faculty of Health Science, Suzuka University of Medical Science, Suzuka, Mie, Japan; 12) Department of Neuroscience for Neurodegenerative Disorders, Juntendo University School of Medicine, Tokyo, Japan.

Background Vacuolar protein sorting 35 (VPS35) was recently reported as a causal gene for late-onset autosomal dominant Parkinson disease (ADPD) using exome sequencing. To date, VPS35 mutations have been detected only in Caucasians with Parkinson disease (PD). The aim of the present study was to determine the incidence and clinical features of Japanese PD patients with p.Asp620Asn (D620N) substitution of VPS35 known as a potentially disease-associated mutation of PD. Methods We investigated the p.D620N (c.1858G>A) mutation in 300 Japanese index patients with ADPD by direct sequencing. We also examined 433 patients with sporadic PD (SPD) and 579 controls by High Resolution Melting analysis. Results The p.D620N mutation was detected in three patients with ADPD (1.0%), one patient with SPD (0.23%), and none of the control subjects. Haplotype analysis suggested at least three independent founders for Japanese patients with the p.D620N mutation. Patients with VPS35 mutation showed typical tremor-predominant PD. Conclusion We reported Asian PD patients with VPS35 mutation. The frequency of the p.D620N mutation of VPS35 is almost the same level or slightly higher in Japan compared to the previous populations studies from Western countries. Still VPS35 mutations are infrequent, p.D620N substitution may be a mutational hotspot across different ethnic groups. Based on the clinical features, VPS35 should be analyzed in patients with PD, especially ADPD or tremor-predominant PD.

2560T

The Autism Sequencing Consortium: Autism gene discovery in >20,000 exomes. *J.D. Buxbaum[1], M.J. Daly[2], B. Devlin[3], T. Lehner[4], K. Roeder[5], M.W. State[6] for the Autism Sequencing Consortium.* 1) Mount Sinai Sch Med, New York, NY; 2) Broad Institute and Harvard Medical School, Boston, MA; 3) University of Pittsburgh, Pittsburgh, PA; 4) National Institute of Mental Health, National Institutes of Health, Bethesda, MD; 5) Carnegie-Mellon University, Pittsburgh, PA; 6) Yale University, New Haven, CT.

Background: There have been tremendous advances in the elucidation of the genetic contribution to autism spectrum disorders (ASD), highlighting the contribution of rare genetic variation, placing limits on the risk conferred by common variation, underscoring the role of de novo mutation, confirming a high degree of genetic heterogeneity, demonstrating pleiotropic effects of syndrome-associated mutations, and identifying an increasing number of specific genes and loci conferring risk. The Autism Sequencing Consortium (ASC) was formed in 2010, in anticipation both of the tremendous impact next generation technologies would have on ASD genomics as well as the many challenges the field would face as a consequence. **Methods:** The ASC sites will be jointly sequencing 9,000 ASD individuals and a total of almost 30,000 samples. Some 25% of the samples are complete, with 65% of the samples to be completed in 12 months. The ASC is managed by a Coordinating Committee and includes multiple working groups to achieve the ASC aims. **Results:** A recent open meeting of investigators, funders and other stakeholders crystallized the plans around molecular approaches in ASD (see video cast at http://videocast.nih.gov/pastevents.asp). Prospective data sharing has led to the simultaneous publication of three papers that benefited significantly from prepublication data-sharing. These studies identified several new ASD genes based on recurrent deleterious de novo mutations while developing frameworks for evaluating statistical significance for such variation. In addition, they estimate the number of ASD genes at ~500 that can be discovered using de novo variation as a filter and highlight the role of advanced paternal age in de novo mutation. The ASC Bioinformatics Hub now hosts several thousand exomes for ASC analyses. We will present further analyses of published and unpublished data, tackling both theoretical and empirical issues involving gene- and site-specific mutation rates and their interpretation.**Discussion:** The current focus of the ASC is gene discovery because it represents a first research step towards understanding the pathogenesis of ASD and developing pharmacological strategies for treating the core symptoms of ASD and etiologically related neurodevelopmental disorders.

Host genetic contribution to development of progressive multifocal leukoencephalopathy in the presence of immune suppression or immune-modulating drugs. *J. P. Carulli[1], C. Sun[1], S. Szak[1], C. Organ[1], A. G. Day-Williams[1], C. Liu[2], H. H. Ackerman[3], T. Olsson[4], F. Piehl[4], P. Cinque[5], C. S. Tan[6], I. J. Koralnik[6], R. P. Viscidi[7], L. Gorelik[1], K. Simon[1], P. Duda[8], T. Harris[1], S. Bushnell[1], T. Compton[1].* 1) Translational Medicine, BiogenIdec, Cambridge, MA; 2) Framingham Heart Study, Framingham, MA; 3) Department of Statistics, University of California, Berkeley; 4) Department of Neurology, Karolinska Institute, Stockholm, Sweden; 5) Division of Infectious Diseases, San Raffaele Scientific Institute, Milan, Italy; 6) Division of Neurovirology, Beth Israel Deaconess Medical Center and Harvard University Medical School, Boston, MA; 7) Johns Hopkins University, Baltimore, MD; 8) Clinical Development, BiogenIdec, Cambridge, MA.

Progressive Multifocal Leukoencephalopathy (PML) is a rare and often fatal demyelinating disease caused by the JC polyomavirus. JC virus has a reported seroprevalance ranging from 30% to 80% in adult populations worldwide, but PML is very rare and occurs primarily under immune suppression or on treatment with immune-modulating drugs. Prior to the development of anti-HIV drugs, roughly 5% of AIDS patients developed PML. More recently PML has been observed, albeit rarely, in patients taking a number of immune-modulating drugs, including natalizumab (anti-VLA4) for multiple sclerosis (MS). PML can also occur in patients with primary immune deficiencies including Hyper IgE, Hyper IgM, and Wiskott-Aldrich Syndrome, or even with occult or minimal immunosuppression. To test the hypothesis that host genetic variation contributes to development of PML in immune suppressed and/or drug-treated subjects without clinically diagnosed primary immune deficiencies, we have performed a genome-wide association scan using Illumina 610K chips of 109 AIDS-PML cases with 1200 healthy volunteers as controls. We have also completed whole genome sequencing of 15 subjects with MS who developed PML while being treated with natalizumab and 30 MS controls treated with natalizumab for two years or more without developing PML. Both studies were limited to subjects of European descent. The genome-wide association scan indicates that common genetic variation, including copy number changes inferred from the SNP data, does not make a large contribution to development of PML: no SNPs or CNVs reach genome-wide significance. However, genome sequence data reveal rare single nucleotide variants and structural variants that may contribute to PML susceptibility. Putative PML associated variants identified in whole genome sequences are being evaluated for population frequency relative to 1,000 genomes data, validated by genotyping or Sanger sequencing, and further screened at the molecular level in a panel of healthy volunteer and MS DNA samples. Our analysis suggests a complex and genetically heterogeneous contribution to this rare adverse event.

2562W

Disruption of a large intergenic non-coding RNA in subjects with neurodevelopmental disabilities. *C. Ernst[1], M. Talkowski[2], J. Gusella[2], C. Morton[3].* 1) McGill University, Montreal, Quebec, Canada; 2) Center for Human Genetic Research, Harvard Medical School, Boston, MA; 3) Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Large intergenic non-coding (linc) RNAs represent a novel class of ribonucleic acid whose importance in human disease remains undefined. We identified a severely developmentally delayed 16 year-old female with karyotype 46,XX,t(2;11)(p25.1;p15.1)dn in the absence of clinically significant copy number variants (CNVs). DNA capture followed by next-generation sequencing of the translocation breakpoints revealed de novo disruption of a single non-coding gene on chromosome 2, LINC00299, whose RNA product is expressed in all tissues measured, but most abundantly in brain. Among a series of additional, unrelated subjects referred for clinical diagnostic testing who showed CNV affecting this locus, we identified one with an intragenic, exon-crossing deletion in association with neurodevelopmental abnormalities. No deletion of LINC00299 was seen in any of 5,969 normal adults. Together, these subjects with disruption of LINC00299 implicate this particular non-coding RNA in brain development and raise the possibility that, as a class, abnormalities of lincRNAs may play a significant role in human developmental disorders.

A rare haplotype containing two AKAP9 missense mutations identified by whole-exome sequencing is associated with risk of Alzheimer Disease in African Americans. *M.W. Logue[1,6], M. Schu[1], B.N. Vardarajan[1], J. Farrell[1], C.T. Baldwin[1,7], M.D. Fallin[8], L.A. Farrer[1,2,3,4,5,6].* 1) Biomedical Genetics, Boston Univ Sch Med, Boston, MA; 2) Neurology, Boston Univ Sch Med, Boston, MA; 3) Opthalmology, Boston Univ Sch Med, Boston, MA; 4) Genetics and Genomics, Boston Univ Sch Med, Boston, MA; 5) Epidemiology, Boston University Sch of Public Health, Boston, MA; 6) Biostatistics, Boston University Sch of Public Health, Boston, MA; 7) Center for Human Genetics, Boston University Sch of Medicine, Boston, MA; 8) Epidemiology, Johns Hopkins University School of Public Health, Baltimore, Maryland.

Previously, we demonstrated that, apart from variants in *APOE* and *ABCA7*, common gene-based SNPs associated with Alzheimer disease (AD) in Caucasians are not risk factors for the disorder in African Americans (AA). To identify functional AD risk variants that are enriched in AAs, we performed whole-exome sequencing (WES) of 7 AA cases from the Multi-Institutional Research on Alzheimer Genetic Epidemiology (MIRAGE) Study, which consists of primarily discordant sibling pairs. WES data were obtained using an Illumina GA IIx sequencer and subsequently mapped to the human genome using BWA. Variant calling with GATK revealed a total of 431 novel (according to dbSNP build 131) non-synonymous SNPs that were observed in more than one subject. Of these, 64 SNPs from 58 genes were prioritized for genotyping based on predicted functionality, potential relevance to AD, and gene-network analysis. Forty-four of these variants were successfully genotyped in 435 AA cases and 422 cognitively normal age-matched AA controls from the MIRAGE and Genetic and Environmental Risk Factors for Alzheimer Disease among African Americans (GenerAAtions) studies. Nominally significant associations were observed with several variants including two non-synonymous variants (rs144662445 and rs149979685) in *AKAP9* (p=0.004 and 0.038, respectively) These SNPs have not been observed in white non-Hispanics, occur at < 1% frequency in AAs according to the ESP database, and are in very high LD. Seven subjects were doubly heterozygous (DH) for these two SNPs, all of them cases. All DH mutations were observed on the same background haplotype. Six other subjects (5 cases and 1 control) were identified which have the same background haplotype and one of the mutations. We are currently performing Sanger sequencing to determine whether or not these individuals are in fact DH. *AKAP9* encodes a kinase anchor protein which is expressed in the hippocampus, cerebellum, and the cerebral cortex. We are currently performing functional studies to determine the mechanisms by which these SNPs might influence AD risk. This study demonstrates how small-scale sequencing projects in diverse ethnic populations can lead to new hypotheses about disease pathogenesis.

Transposable elements (TE) in schizophrenia: evolutionary analysis and hypothesis for a functional role. *F. Macciardi[1, 4], M. Vawter[1], T. VanErp[1], F. Torri[1], B. Lerer[3], E. Osimo[4], J.A. Knowles[5], S.G. Potkin[1], C. Pato[5], M. Pato[5], S. Gaudi[2].* 1) Dept of Psychiatry & Human Behavior, University of California, Irvine, Irvine, CA; 2) Istituto Superiore di Sanità, Roma, Italy; 3) Hadassah Medical Organization-Hebrew University, Jerusalem, Israel; 4) Universita' degli Studi di Milano, Milan, Italy; 5) Dept of Psychiatry, University of Southern California, Los Angeles, CA.

Introduction: Protein-coding genes in the human genome account for 2% of the total sequence, the noncoding genome accounting for the remaining 98%. Of this large part, Transposable Elements (TEs) represent about 45 to 48%, with an increased architectural complexity within and around brain-related genes. TEs have been implicated in playing a key role in dynamically cis-regulating both genome development and function in recent studies. Since the majority of genome wide association studies (GWAS) in Schizophrenia (SZ) have mapped disease-associated variants to noncoding regions, with an alleged regulatory role, and most variants fall within well-conserved TEs, we are interested to understand how TEs may be implicated in the etiology of SZ. Methods: Our aim is to investigate a possible functional relationship between TEs and genes identified as “best” candidates for Schizophrenia, via SNP mapping or CNV analyses. After in-silico analysis of the genomic architecture of TEs and TE-derived Transcriptional Start Sites (TSS) within and around these SZ-associated genes, we have performed a target resequencing of these genomic regions, and initial whole genome and tissue-specific RNA-sequencing in a sample of SZ and CTRL subjects, to look for differences between who do or do not present the associated risk variants. We then made an evolutionary analysis of TEs and their putative regulated genes. Finally, using DNA variants that may work as eQTL proxies for differential expression of TEs and genes, we looked for differences in fMRI cognitive-based performances in an independent sample of patients and controls. Results and conclusion: We found preliminary evidence of alternative regulation of tissue-specific gene expression in schizophrenic patients vs controls. Using AHI1 (Torri et al, 2010) as an example, we found a peculiar architecture of Alu, Line1 and other TE elements across the gene region, with a brain-specific expression pattern that looks regulated by TE-derived TSS. Only evolutionary recent TEs show a potential regulatory effect for SZ-related genes, as well as marked sequence differences for both DNA and tissue-specific RNA transcriptome between cases and controls. Our results strongly suggest that any investigation of SZ risk genes must include a detailed analysis of TE distribution and expression, and that it is perhaps only through inclusion of these elements that psychiatric diseases will be fully understood.

2565W

Whole-genome sequencing of 50 LRRK2 G2019S carriers discordant for Parkinson's disease. *C.Y. McLean, E. Drabant, E. Harrington, C.B. Do, N. Eriksson.* 23andMe, Inc., Mountain View, CA.

Parkinson's disease is a neurodegenerative disorder that affects over 6 million people worldwide. Over 20 SNPs have been associated with Parkinson's disease susceptibility. The most common known association is the LRRK2 G2019S mutation, with a population frequency ranging from under 1% in Asians to 40% in North African Arabs. G2019S is present in both familial autosomal dominant and sporadic Parkinson's disease and has an estimated penetrance of 30–100%. Higher penetrance estimates in familial cases suggest the presence of additional genetic or environmental penetrance modifiers. We performed whole-genome sequencing on 50 unrelated European individuals concordant for the presence of the LRRK2 G2019S mutation, the absence of the Parkinson's-associated GBA N370S and L444P mutations, and the absence of family history of Parkinson's disease. The cohort, drawn from consenting 23andMe customers, comprises 50 individuals: 37 affected by Parkinson's disease and 13 healthy controls. The median age of onset for affected individuals is 56 (range 38–85). The median age of healthy controls is 66 (range 58–95). Whole-genome sequencing was performed on DNA extracted from bio-banked saliva samples. Individuals were sequenced to a median mapped depth of 45-fold coverage (range 34–52), spanning a median of 97.9% of the genome (range 97.8–98.2%). Mutational burden was similar in cases and controls: a median of 3.59M SNPs and 599k indels arise per genome, in agreement with previous estimates of individual human variation. Concordance between mutations identified by whole-genome sequencing and chip genotyping exceeds 99.7% for all samples. Premature stop codon mutations occur in a median of 96 genes (range 81–114). This study demonstrates the power of the innovative 23andMe customer database for generating research cohorts of interest, confirms the feasibility of generating accurate whole-genome sequencing data from saliva, and provides a rich data set that may help identify genomic differences between LRRK2 G2019S carriers discordant for Parkinson's disease.

Cumulative Mutation Load in PDZ Domains 4, 5, and 6 of Glutamate Receptor Interacting Protein 2 in Autism. *T. Niranjan[1,2], A. Adamczyk[1], M. Han[1], R. Mejias[1], R. Rose[1], H. Bravo[3,4], M. Taub[4], C. Schwartz[5], D. Valle[1,6], R. Huganir[7], T. Wang[1,6].* 1) McKusick-Nathans Institute of Genetic Medicine, The Johns Hopkins University, Baltimore, MD; 2) Predoctoral Training Program in Human Genetics, The Johns Hopkins University School of Medicine, Baltimore, MD; 3) Center for Bioinformatics and Computational Biology, Department of Computer Science, University of Maryland, College Park, MD; 4) Department of Biostatistics, Bloomberg School of Public Health, The Johns Hopkins University, Baltimore, MD; 5) Greenwood Genetic Center, Greenwood, SC; 6) Department of Pediatrics, The Johns Hopkins University School of Medicine, Baltimore, MD; 7) Department of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD.

Glutamate Receptor Interacting Proteins 1 and 2 (GRIP1/2) are homologous, neuronal scaffolding proteins that interact with multiple binding partners via seven PDZ domains. We had previously identified multiple gain-of-function variants at PDZ domains 4, 5, and 6 (PDZ4-6) of GRIP1 that are associated with altered GRIP1 function in Yeast-2-Hybrid and neuronal recycling assays. To further assess the role of GRIP1/2 in autism, we sequenced exon-containing regions of *GRIP2* in large cohorts of autism patients (n=480) and ethnically matched normal controls (n=480). The study identified a moderate but statistically significant increase in the cumulative burden of non-synonymous mutations ($p < 0.05$, Fisher's Exact) at PDZ4-6 of GRIP2. Mutation burdens of two other functional domain regions, PDZ1-3 and linker-PDZ7, did not show significant difference between cases and controls. PDZ4-6 forms a conserved functional unit that interacts with several neuronal proteins including AMPA glutamate receptors 2 and 3 (GluA2/3), Liprin-α, and ephrinB1/2. Direct binding of PDZ4-6 of GRIP1/2 with the c-terminal domains of GluA2/3 play important roles in GluA2/3 recycling and synaptic organization. Four of the eight non-synonymous coding variants at PDZ4-6 in our autism cohort were found in families with two or more affected sibs of discordant genotype (heterozygous versus wild type) for the respective variants. Intriguingly, sibs who carry GRIP2 non-synonymous variants show more severe deficits in reciprocal social interactions and verbal communication based on their ADI-R test scores as compared to sibs who do not carry these non-synonymous variants. Functional analysis using Yeast-2-Hybrid indicates that all eight non-synonymous variants of GRIP2 show altered binding capacity to GluA2/3. Results of this study support a role of functional GRIP2 variants at PDZ4-6 in the genetic susceptibility to autism. Further *in vitro* and neuron-based assays should help elucidate the mechanisms of GRIP1/2-mediated glutamate signaling disturbance in autism spectrum disorders.

Candidate genes for sleepwalking from exome sequencing in an autosomal-dominant family. *B. Schormair[1,2,3], H. Slawik[4], B. Frauscher[5], T. Mitterling[5], E. Graf[1,2], T. Wieland[1,2], B. Högl[5], T.M. Strom[1,2], M. Wiegand[4], T. Meitinger[1,2], J. Winkelmann[1,2,3].* 1) Institute of Human Genetics, Helmholtz Zentrum München—German Research Center for Environmental Health, Neuherberg, Germany; 2) Institute of Human Genetics, Technische Universität München, Munich, Germany; 3) Department of Neurology, Technische Universität München, Munich, Germany; 4) Department of Psychiatry and Psychotherapy, Technische Universität München, Munich, Germany; 5) Department of Neurology, Innsbruck Medical University, Innsbruck, Austria.

Sleepwalking (OMIM %613938) is a common childhood parasomnia (prevalence of 26%) that seldom persists into adulthood (prevalence of 3%). There is clear evidence for a genetic basis of the disease. Twin studies have shown a higher concordance rate in monozygotic compared to dizygotic twins and a linkage study has identified a candidate region on chromosome 20, but no responsible gene has been identified yet. We performed exome sequencing in a sleepwalking family of 9 individuals (4 affected, 5 unaffected) with an autosomal-dominant inheritance pattern of the disease. All affected subjects had childhood onset of symptoms which persisted into adulthood. We sequenced two affected siblings and the unaffected mother using Agilent Sure Select All Exome Kit for enrichment and Illumina 100bp paired-end reads for DNA sequencing. We generated on average 14.9Gb of sequence per individual with 89% of the target sequence covered at least 20x and only 0.94% uncovered. For candidate variant identification, we used an autosomal-dominant disease model and looked for heterozygous variants shared by the affected siblings. We focused on missense, nonsense, splice-site, stoploss and frameshift variants and excluded all variants present in dbSNP135, the 1000genomes data, and in an in-house control exome database of unrelated phenotypes. Subsequently, we excluded those variants shared by the two siblings but also found in the unaffected mother. This approach left 47 variants for co-segregation analysis in the pedigree. Of these 47 variants, 5 were compatible with the disease segregation pattern observed in the pedigree. The respective candidate genes include components of the complement system and transcription factors important for the expression of immunoglobins. Based on the often discussed association of sleep and immune system function, these are interesting candidates. In order to identify the true causal gene, we have sequenced the variant-containing region of the candidate genes (200bp of sequence up- and downstream of the variant) in a cohort of 30 sleepwalking cases, but did not find further mutations in these genes. Larger samples of sleepwalking cases are needed to test the potentially causal variants.

Winkelmann[1,2,3].* 1) Institut für Humangenetik, Helmholtz Zentrum München, Munich, Germany; 2) Neurologische Klinik und Poliklinik, Klinikum rechts der Isar, Technische Universität München, Munich, Germany; 3) Institut für Humangenetik, Technische Universität München, Munich, Germany; 4) Paracelsus Elena Klinik, Kassel, Germany; 5) Neurologische Klinik, Georg August Universität, Göttingen, Germany; 6) Neurologische Klinik, Medizinische Universität, Innsbruck, Austria; 7) Institut für Epidemiologie, Westfälische Wilhelms Universität, Münster, Germany; 8) Neurologische Klinik, Charité Universitätsmedizin, Berlin, Germany; 9) Neurologische Klinik, Phillips Universität, Marburg, Germany; 10) Klinik für Psychiatrie und Psychotherapie, Albert Ludwigs Universität, Freiburg, Germany; 11) Klinik für Neurologie, Medizinische Universität Wien, Vienna, Austria; 12) Institut für Epidemiologie, Helmholtz Zentrum München, Munich, Germany; 13) Max-Planck Institut für Psychiatrie, Munich, Germany.

Background: Restless legs syndrome (RLS) is a common and genetically complex neurologic disorder characterized by nightly dysesthesias in the legs leading to sleep disturbances. Although GWAS have identified genetic risk factors, a large portion of the heritability remains unsolved and might be attributed to rare and very rare variants (MAF<5%) of strong effect. To date, no such variant is known for RLS. Methods: To assess the role of rare variants at the known GWAS loci, we screened the coding regions and exon-intron boundaries+-10bp of *MEIS1*,*PTPRD*, *BTBD9*, *MAP2K5*, *SKOR1*, *TOX3* and *BC034767* in 188 RLS cases and 188 KORA population controls by high-resolution melting curve analysis. DNAs with aberrant melting patterns were Sanger sequenced. Identified variants with a MAF<5% were genotyped in 3265 cases (65.2+-11.3yrs; 29.3% male) and 2944 controls (56.1+-13.3yrs; 48.7% male). Results: We identified 51 non-synonymous, synonymous, and (near-)splice variants (MAF<5%). Overall, 69 patients harbored a rare variant in one of the “RLS genes” compared to 35 controls (p<5×10E-4, McNemar Test). A similar trend was seen for most individual loci and reached statistical significance for MEIS1 (9 cases and 1 control with a rare variant; p<0.02, McNemar Test). Genotyping of the identified variants in 3265 cases and 2944 controls further underscored this finding. Both synonymous and non-synonymous variants with a MAF<1% were more common in individuals with RLS (p<0.01, chi-squared test). However, this result was even more pronounced for non-synonymous variants with a MAF<0.1% (p<1×10E-5, chi-squared test; OR=6.36; 95% CI:2.49–16.27) and for non-synonymous variants at solely the *MEIS1* locus (p<0.005, chi-squared test; OR=2.39; 95% CI: 1.29–4.44). Two single rare MEIS1 variants (p. R272H (p=0.04, allelic test in PLINK; OR=6.44; 95% CI: 0.79–52.39) and p. M453T (p=0.02, OR=2.06; 95% CI: 1.06–3.97)) were significantly associated with RLS prior to correction for multiple testing. Conclusions: Coding variants with a MAF<5% at RLS-GWAS loci are more common in RLS cases than in controls. This finding becomes more pronounced with increasing variant rarity. At the *MEIS1* locus, a spectrum of common and rare, non-coding and coding variants appears to contribute to disease development, supporting the concept of allelic series in complex diseases. Several rare variants emerge as candidates for rare causal RLS variants but await replication and functional assessment.

Exome analysis for early-onset amyotrophic lateral sclerosis with autosomal recessive mode of inheritance. *Y. Takahashi[1], K. Higasa[2], S. Takagi[3], T. Kurita[4], H. Ishiura[1], J. Mitsui[1], Y. Fukuda[1], J. Yoshimura[2], T.L. Saito[2], S. Morishita[2], J. Goto[1], S. Tsuji[1].* 1) Department of Neurology, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Computational Biology, Graduate School of Frontier Sciences, The University of Tokyo; 3) Department of Neurology, The Jikei University Kashiwa Hospital,Chiba, Japan; 4) Department of Neurology, The Jikei University, Tokyo, Japan.

[Background] Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disorder characterized by progressive and systemic motor neuron loss. Approximately 10 % of ALS is familial ALS (FALS) and the remaining 90% is sporadic ALS (SALS). Numerous causative genes have been identified in autosomal recessive FALS (AR-FALS) including *ALS2*, *OPTN*,*SPG11*, *SIGMAR1*. Recently, exome sequencing has been shown to be a highly efficient approach for identifying causative genes for Mendelian diseases. [Purpose]To identify a causative gene for AR-FALS. [Subjects and Methods] A Mongolian pedigree with two affected siblings presenting with early-onset and slowly-progressive ALS was enrolled in this study. Mutations in previously known causative genes for ALS were excluded. Genotyping was performed using Genome-wide Human SNP array 6.0 (Affymetrix). Parametric linkage analysis was conducted employing SNP HiTLink system on the assumption of autosomal recessive mode of inheritance. Exome sequencing was conducted employing SureSelect Human All Exon 50Mb Kit (Agilent) and TruSeq (Illumina) for exon capture, and Genome Analyzer IIx (Illumina) for massively parallel sequencing. [Results]Genome-wide linkage analysis revealed candidate regions with the total length of 470.1 Mb including 4Mb of homozygous regions. Exome analysis revealed 338 non-synonymous single nucleotide variants (SNVs) and 40 indels which were not registered in dbSNP 135 or not present in in-house variant database. Of these variants, only one homozygous variant was consistent with autosomal recessive mode of inheritance, shared only by the two affected individuals. The variant was not found in 276 controls, conserved among species, and predicted as probably damaging with PolyPhen-2. Mutational analysis of the gene in other FALS (n=19) and SALS (n=203) patients did not reveal any homozygous or compound heterozygous mutations. Since 641 exons in the candidate regions were covered by no more than 5x of read depth, these exons need to be further analyzed. [Discussion and Conclusion]The variant identified in this study is likely a pathogenic mutation for a rare form of AR-FALS, although further studies including identification of mutations in other AR-FALS families and functional analyses should be conducted. Large-scale collaborative framework will be needed to further validate the pathogenicity of the mutation. Large-scale collaborative frameworks will be needed to further validate the pathogenicity.

Identification of Candidate Genes Through Analysis of Copy Number Variation in Autism Families from Austria. *J.B. Vincent[1], G. Egger[2], A. Lionel[3], H. Mahmood[1], A. Mikhailov[1], K. Roetzer[2], C. Windpassinger[2], W. Kaschnitz[4], S.W. Scherer[2], E. Petek[3].* 1) Neurogenetics Sect, R30, Ctr Add/Mental Hlth,Clarke Div, Toronto, ON, Canada; 2) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 3) Program in Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON, Canada; 4) Division of General Pediatrics, Medical University of Graz, Graz, Austria.

Autism or Autism-Spectrum-disorders (ASD) is a range of neurodevelopment disorders starting in early childhood, characterized by impairments in communication and reciprocal social interaction, and the presence of restricted and repetitive patterns of behaviour. The contribution of genetic factors to autism is well established by twin studies (Le Couteur et al., 1996), but the kind of genetic transmission is unclear. However, the factor that ASD is a complex non-Mendelian disorder is apparent in most cases. For the current work we recruited 245 family members from 79 ASD families from Styria, Austria. The DNA from probands was run on Affymetrix SNP 6.0 microrarrays to screen for Copy Number Variations (CNVs) in their genomes. Analysis of data was perfomed using Birdsuite, i-Pattern and Genotyping Console, and a list of stringent calls was compared to existing CNV data from over 10,000 Caucasian controls. For stringent calls not present in controls quantitative Real Time-PCR (qRT-PCR) was used to validate the CNVs in the probands and in family members. 15 CNVs from this validated set appear likely to disrupt genes that may be considered good candidates for neuropsychiatric disorders and autism in particular, including AUTS2, DPP6, DLG2, S100B, ARX, DIP2A, GPHN and SH2B1. Several of these genes have also been implicated previously in autism, such as AUTS2, DPP6 and SH2B1, and evidence of their involvement in ASD is growing.

2571W

Genetic and functional study of the disks large-associated protein 2 (DLGAP2) gene as a candidate gene of schizophrenia. *M. Cheng[1], J. Li[2], S. Luu[2], S. Hsu[1], T. Hu[1], H. Tsai[1], C. Chen[3,4,5].* 1) Department of Psychiatry, Yuli Veterans Hospital, Hualien, Taiwan; 2) Department of Psychiatry, Taoyuan Armed Forces General Hospital, Taoyuan, Taiwan; 3) Division of Mental Health and Addiction Medicine, National Health Research Institutes, Zhunan Town, Miaoli County, Taiwan; 4) Department of Psychiatry, Chang Gung Memorial Hospital at Linkou and Chang Gung University School of Medicine, Taoyuan, Taiwan; 5) Institute of Medical Sciences, Tzu-Chi University, Hualien, Taiwan.

Background: A growing evidence indicates that aberrant synaptic dysfunction plays a role in the pathogenesis of schizophrenia. The DLGAP2 gene that encodes the discs, large homolog-associated protein 2 located at the post-synaptic density of neuronal cells involves the neuron synaptic function. This study aimed to investigate whether the DLGAP2 gene is associated with schizophrenia. Methods: We re-sequenced all the exons of the DLGAP2 gene in 523 patients with schizophrenia and 484 non-psychotic controls from Taiwan and conducted a case-control association study and gene functional assay. Results: We identified 19 known single nucleotide polymorphisms (SNPs) in this sample. However, SNP- and haplotype-based analyses showed no association of these SNPs with schizophrenia. We also detected 14 missense mutations and1 amino acid-insertion in this sample, but no increasing burden of these mutations was found in the patient group. Furthermore, we identified 5 private rare variants (c.-69+9C>T, c.-69+13C>T, c.-69+47C>T, c.-69+55C>T and c.-32A>G) at the intron 1 and untranslated exon 2 of the DLGAP2 gene in 5 out of 523 patients but not in 484 control subjects (p=0.03). Computer program predicts that the c.-69+13C>T may change transcription factor binding sites of ATF, HBP, CREB, and the c.-32A>G may change transcription factor binding sites of c-Myc, EcR. Reporter gene assay of the c.-32A>G demonstrated that the c.-32G mutant had a significantly elevated promoter activity than that of wild type. The promoter activity assays of the other 4 rare variants are underway. Conclusion: Our results suggest that multiple private rare variants might occur in the DLGAP2 gene and contribute to the pathogenesis of schizophrenia in some patients.

2572T

Targeted sequencing reveals association of sets of rare variants in novel candidate genes as well as cell adhesion and GTPase regulatory pathways with autism spectrum disorder. *A.J. Griswold[1], J.M. Jaworski[1], S.H. Slifer[1], D.J. Hedges[1,2], R.H. Chung[1], W.F. Hulme[1], I. Konidari[1], P.L. Whitehead[1], J.A. Rantus[1], A.R. Diaz[1], Y.M. Pasco[1], R.M. Tursi[1], S.M. Williams[3], R. Menon[4], M.L. Cuccaro[1,2], E.R. Martin[1,2], J.L. Haines[5], J.R. Gilbert[1,2], J.P. Hussman[6], M.A. Pericak-Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL, USA; 3) Vanderbilt University School of Medicine, Vanderbilt University, Nashville, TN, USA; 4) Rollins School of Public Health, Emory University, Atlanta, GA, USA; 5) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA; 6) Hussman Foundation, Ellicott City, MD, USA.

There is a strong genetic component to autism spectrum disorder (ASD), yet genome-wide association studies (GWAS) have failed to account for a significant portion of ASD heritability. This has led to the hypothesis that rare variants, each with a small effect size, likely explain the genetic complexity of ASD. To identify rare variants contributing to ASD, we have sequenced ASD associated genes and regions in 919 unrelated cases and 854 controls. Targeted regions were chosen as described in Hussman et. al., 2011, and selected using a custom Agilent SureSelect panel covering 17Mb including 1) exons of 681 genes, 2) evolutionarily conserved regions in introns of the genes plus 5kb from their 5 and 3' ends, 3) evolutionarily conserved regions in associated non-genic haplotype blocks, and 4) entire haplotype blocks with association p-values<0.01. Samples were sequenced on the Illumina HiSeq2000, data aligned with BWA, variants called with the GATK Universal Genotype Caller, and annotated using SeattleSeq, PolyPhen2, and SIFT. Analysis focused on 48,575 single nucleotide variants (SNVs) identified in exons or splice junctions including 9,012 SNVs predicted to be “possibly” or “probably” damaging. To assess whether rare exonic SNVs in each targeted gene are associated with ASD, we used the sequence kernel association test (SKAT) that tests for association between sets of SNVs and a phenotype adjusting for population stratification. This analysis showed association with the transcription factor *ZNF24* (p=3.37×10-5) and the NAD synthesis enzyme *NMNAT3* (p=2.52×10-4). Both are excellent ASD candidates. *ZNF24* has been previously implicated in mouse brain development and *NMNAT3* protein is localized to neuronal mitochondria and acts as a neuroprotective agent. Further, performing SKAT across 30 molecular pathways overrepresented in our targeted gene list, detected association with sets of rare exonic SNVs in cadherin binding (p=0.007) and cell adhesion (p=0.009) pathways. When examining only predicted damaging SNVs, we detect nominal association with the GTPase regulator activity pathway (p= 0.04). These results lend further strong support to the role of cadherins and cell adhesion molecules in ASD and support emerging evidence of GTPase regulation as a novel pathway involved in the disorder. Overall, this study supports the hypothesis that sequencing for rare variants is a successful approach to recognize genes and pathways contributing to the etiology of autism.

Multiple hits in the Neuregulin signaling pathway in Schizophrenia. *A. Hatzimanolis[1,2], J. McGrath[1], P. Wolyniec[1], V.K. Lasseter[1], G. Nestadt[1], R. Wang[1], T. Li[3], P. Wong[3], D. Valle[4], A.E. Pulver[1], D. Avramopoulos[1,4].* 1) Department of Psychiatry, Johns Hopkins University, Baltimore, MD; 2) National and Kapodestrian University of Athens, Athens, Greece; 3) Department of Neuropathology, Johns Hopkins University, Baltimore, MD; 4) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Schizophrenia (SZ) is a highly heritable mental disorder affecting 1% of the population but only recently have linkage and association results reached statistical robustness through collaborative efforts. These difficulties may be explained by the contribution of rare variants and gene-gene interactions. *NRG1* and *NRG3*, encoding Neuregulin 1 and 3 and *ERBB4*, encoding their receptor, have been associated with SZ by many groups including ours. Moreover a mouse model lacking BACE1 whose product cleaves NRG1 releasing the extracellular EGF domain shows phenotypes reminiscent of SZ models. These observations led us to hypothesize that a subset of families might show accumulation of damaging functional variants in core NRG signaling components. To test our hypothesis we focused on 10 genes, the 4 above and 6 encoding the components of gamma secretase thought to cleave the cytoplasmic tails of ERBB4 and NRG1 and play a role in cell autonomous signaling. In our linkage data on 123 multiplex families we found increased scores over the 10 genes, marginally higher than would be expected by random selection (p=0.07). We further observed many significant (p<0.05) pair-wise positive correlations of signals consistent with our multiple hit hypothesis. In 24 pairs of distantly affected relatives, we sequenced all exons of the genes and found potentially damaging variants in *APH1A, APH1B, NRG1* and *NRG3*. Interestingly these clustered in just a fraction of the families, with significant correlations between the number of variants present in *APH1B, NRG1* and *APH1A* (best $p<10^{-4}$). The NRG3 variant did not correlate with those in other genes, but it was shared by distant relatives more often than expected. We explored whether the symptoms of individuals carrying variants in the NRG pathway genes differed as reflected in the 9 factors previously described in a principal components phenotypic analysis in our sample. We found that NRG pathway mutations lead to significantly higher impairment factor scores (r=0.42, p=0.0027). Collectively, our data strongly support that in a subset of patients damaging variation in more than one NRG signaling pathway genes leads disease and more severe impairment. Functional characterization of the variants, investigation of more genes in the pathway possible inclusion of regulatory variation is necessary to strengthen this genetic link and lead to a better mechanistic understanding of the contribution of deranged Neuregulin signaling in SZ.

Discovery of Rare Variants of Candidate Genes Related to Nicotine Dependence through Deep Sequencing. *S. Wang[1], W.-Y. Cui[1,2], Z. Yang[1], J. Yang[1], J.Z. Ma[3], T.J. Payne[4], C.A. Hodgkinson[5], D. Goldman[5], M.D. LI[1].* 1) Psychiatry and NB Sciences, University of Virginia, Charlottesville, VA; 2) The State Key Laboratory for Diagnosis and Treatment of Infectious Diseases, The First Affiliated Hospital, School of Medicine, Zhejiang University, Hangzhou, Zhejiang, China; 3) Public Health Science, University of Virginia, Charlottesville VA; 4) Otolaryngology and Communicative Sciences, University of Mississippi Medical Center, Jackson, MS; 5) Laboratory of Neurogenetics, NIAAA, NIH, Bethesda, MD.

Rare variants either within or across genes are believed to act together to influence complex diseases such as nicotine dependence (ND). The increasing availability of massively parallel sequencing offers the opportunity to study the effect of rare variants on complex traits. To identify susceptibility variants for ND, 32 candidate genes implicated in the etiology of ND were selected for target exon sequencing with a pooling approach. A total of 200 sib pairs from the Mid-South Tobacco Family (MSTF) study were divided to 8 pools (50 samples/per pool) based on the ethnic group (100 sib-pairs of either European Americans and African Americans), smoking status (smokers and non-smokers), and Fagerström Test for ND score (light smokers and heavy smokers). Equal amounts of DNA from each sample were pooled, target-captured using custom Agilent arrays, sequenced on a Solexa GA2X at high coverage, and then followed by data analysis, including base quality recalibration and alignment with the BWA program using hg19 assembly build as a reference. Variant callings were conducted using Syzygy designed specifically for a pooling approach. After filtering and mapping, approximately 147 million reads were mapped to the target regions with a median coverage of 106X for each sample included in each pool. Together, we detected about 430 putatively functional variants from the 8 pools. A minimum minor allele frequency of 0.75% and a minimum sequencing reads count of 500 were used as criteria for variant selection. The detected rare variants were ranked according to Polyphen and SIFT scores and allele frequency. Following identification of these variants, we selected 117 putative functional variants for validation using 2000 MSTF and 5000 MST Case-Control (MSTCC) study samples. Of these genotyped variants, 83 were confirmed as rare variants. Among these variants, 71 had an MAF of less than 1%, and 12 had an MAF between 1% and 5%. Case-control-based association analysis was conducted for these variants under different genetic models, revealing that several variants showed significant association with ND (Supported by NIH grant DA-012844).

Rare deletions at the Gephyrin (*GPHN*) locus in Autism Spectrum Disorder and Schizophrenia. *A.C. Lionel[1,2], A.K. Vaags[1], D. Sato[1], M.J. Gazzellone[1,2], H.Y. Chen[1], G. Costain[3], G. Egger[4], S. Walker[1], A. Prasad[1], C.R. Marshall[1,2], E.B. Mitchell[5,6], C. Windpassinger[4], J.B. Vincent[7], B.A. Fernandez[8], S. Kirmani[5], J.C. Hodge[5,6], A.S. Bassett[3,9], S.W. Scherer[1,2].* 1) The Centre for Applied Genomics & Program in Genetics & Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada; 3) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 4) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 5) Department of Medical Genetics, Mayo Clinic, Rochester, Minnesota, USA; 6) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, Minnesota, USA; 7) Molecular Neuropsychiatry & Development Lab, Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 8) Disciplines of Genetics and Medicine, Memorial University of Newfoundland, St. John's, Newfoundland and Labrador, Canada; 9) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada.

Several studies have highlighted the involvement of *de novo* and rare inherited copy number variations (CNVs) and point mutations in the genetic etiology of autism spectrum disorder (ASD), particularly affecting genes encoding proteins involved in the neuronal synaptic complex including those from the neurexin, neuroligin and *SHANK* gene families. Parallel findings of rare mutations affecting some of the same genes (e.g. *NRXN1*, *SHANK3*, *CNTNAP2* etc.) in schizophrenia have suggested the existence of shared genetic risk factors for the two neurodevelopmental disorders. Here, we present clinical and genomic characterization of five unrelated subjects with diagnoses of ASD or schizophrenia, who possess rare *de novo* or inherited heterozygous microdeletions overlapping the *GPHN* gene at 14q23.3. Exonic deletions at the *GPHN* locus are extremely rare in the general population (2 in over 15,000 control individuals). Following up on the CNV findings, we identified rare missense variants in additional ASD cases after sequencing all exons and splice sites of *GPHN* using exome and Sanger sequencing approaches. *GPHN* encodes gephyrin, a key scaffolding protein in the neuronal postsynaptic membrane that is responsible for the clustering and localization of glycine and GABA receptors at inhibitory synapses. Gephyrin complexes directly with the neuroligin proteins NLGN2 & NLGN4, and its function in postsynaptic clustering is mediated by the neurexins. Members of the neurexin and neuroligin gene families have been observed to be mutated in schizophrenia and ASD patients. While homozygous *GPHN* mutations have been reported in connection with autosomal recessive molybdenum cofactor deficiency, this is the first report of rare *GPHN* mutations in ASD and schizophrenia. Our findings add to the evidence linking neuronal synaptic genes as etiologic risk factors across a range of neurodevelopmental conditions.

2576F

Reciprocal duplication of the Williams-Beuren syndrome deletion on chromosome 7q11.23 is associated with schizophrenia. *J.G. Mulle[1,2], A.E. Pulver[3,4], J.M. McGrath[3], P. Wolyniec[3], A.F. We have assessed a population of 583 individuals with schizophrenia (SZ) and 1014 controls all of Ashkenazi Jewish descent for copy number variation. Consistent with other studies, we find an excess of large rare variants in SZ cases, with carriers of rare variants larger than 500 kb having a 2.44-fold increase in risk (95% CI: 1.37–4.4, p-value 0.001, Fisher's exact test). For individuals with deletions larger than 1 Mb, the odds ratio increases to 5.1 (95% CI: 1.51–22.1, p-value 0.004, Fisher's exact test). We also find a significantly higher rate of de novo events larger than 500kb compared to control trios (0.74% in controls vs. 2.05% in SZ trios, p-value 0.04). Among our de novo CNV we find a ~1.3 Mb duplication on chromosome 7q11.23, the reciprocal event of the Williams-Bueren deletion. As de novo duplications at this locus were recently reported in autism populations,we were inspired to investigate the frequency in SZ populations. After formal meta-analysis, we find the 7q11.23 duplication in 11 of 14,387 SZ cases (0.076%) and one of 28,139 controls (0.0035%), for a Mantel-Haenszel corrected odds ratio of 10.8 (95% CI: 1.46–79.62, p-value 0.007). In three SZ duplication carriers with detailed retrospective data, there is evidence of severe social anxiety, social withdrawal, or autism-like symptoms prior to SZ onset. Given that WBS cases are highly social with well-developed language skills, it appears there may be a direct quantitative relationship between dosage of the 7q11.23 region and verbal and social abilities.

Assessing the impact of different types of *de novo* rare variation in whole-exome sequenced autism spectrum disorders trio families. *D. Pinto[1,2], M. Fromer[1,2], A. Goldberg[1], S.M. Purcell[1], P. Sklar[1], E. Boerwinkle[3], M.J. Daly[3,4], B. Devlin[3,4], E.H. Cook[3,4], K. Roeder[3,4], R.A. Gibbs[3], G.D. Schellenberg[3], J.S. Sutcliffe[3], M.W. State[4], J.D. Buxbaum[1,3,4] on behalf of the ARRA Autism Sequencing Consortium and the Autism Sequencing Consortium.* 1) Psychiatry, Mount Sinai School of Medicine, New York, NY; 2) Genetics and Genome Sciences, Mount Sinai School of Medicine, New York, NY; 3) Lead Investigators of the ARRA Autism Sequencing Consortium; 4) Lead Investigators of the Autism Sequencing Consortium.

Autism spectrum disorders (ASD) are common complex diseases with a strong genetic component. Cumulative evidence from array-based studies (large CNVs: 5–7% of trios) and pilot whole-exome resequencing studies (SNVs: ~10% of trios) suggests that a substantial proportion of risk for ASD resides in rare de novo variants affecting genes. They include variation across a broad range, from single nucleotide variants (SNVs), insertions/deletions, copy number variation (CNV) and larger chromosome imbalances. Thus, there is the need to develop a platform that can maximize the discovery efforts. We are developing a data storage facility to efficiently process large datasets and an analysis pipeline to accurately call multiple types of variants from exome sequencing data, ranging from SNVs to indels and CNVs, and identify *de novo* coding mutations. Specifically for CNV detection, we are currently analysing exomes from ~350 autism trio families using multiple calling algorithms including XHMM, CoNIFER, Splitread and ExomeCNV. For example, preliminary results from XHMM find 1.5 *de novo* events/ 10 trios. Because each of these methods has different abilities, the use of multiple algorithms should maximize discovery rates and sensitivity, especially for variants smaller than 100kb. Specificity and concordance between callers are obtained from additional experimental validation of rare variants in different size ranges, combined with information from available array CNV data. We will present results from inheritance analyses, *de novo* rates and pinpoint novel autism candidate genes in these families.

2578T

Etiologic rare variants in autism multiplex families: exome and CNVs analyses. *C. Toma[1, 2], A. Tristán[1], A. Hervás[3], B. Torrico[1,2], R. Valdés-Mas[4], N. Balmaña[3], M. Maristany[5], X.S. Puente[4], M. Bayés[6], B. Cormand[1,2].* 1) Department of Genetics, University of Barcelona, Barcelona, Spain; 2) Biomedical Network Research Centre on Rare Diseases (CIBERER), Spain; 3) Child and Adolescent Mental Health Unit, Hospital Universitari Mútua de Terrassa, Spain; 4) Department of Biochemistry and Molecular Biology, University of Oviedo-IUOPA, Spain; 5) Developmental Disorders Unit (UETD), Hospital Sant Joan de Déu, Esplugues de Llobregat, Barcelona, Spain; 6) National Center for Genomic Analysis (CNAG), Barcelona, Spain.

Autism is a severe neurodevelopmental disorder. Twin and family studies suggest high heritability. To date a few autism risk genes have been identified, most of them found on the basis of overlap with other syndromic neurodevelopmental disorders, or because they are involved in chromosomal rearrangements or copy number variants (CNVs). Whole exome sequencing (WES) represents a powerful technology to identify rare single nucleotide variants (SNVs), not studied systematically until recently, that may help to depict the complex genetic architecture of autism. In the present study we performed exome sequencing of 10 autism multiplex families with the aim to identify the inherited pool of rare SNVs and uncover new candidate genes for autism susceptibility. In addition, we performed CNV analysis to exclude families with reported fully penetrant structural variants, but also to consider the whole autism genetic landscape. The 10 multiplex families under study include 41 individuals, with 20 parents and 21 probands that fulfil diagnostic criteria for autism spectrum disorder (ASD). To capture the exome subsets of these individuals we used the NimbleGen SeqCap EZ Exome Library SR kit. The coding exons targeted corresponded to approximately 34 Mb. On average, individuals had 86% of target covered at >20X and 50% at >75X. Nonsense, frameshift and splice-site mutations were included in the Sanger validation phase, whereas missense mutations were previously filtered based on pathogenicity predictions (http://ensembl.org/tools.html). Our selection of inherited variants included mutations present in both affected siblings. Structural variants analysis was performed only in the affected individuals with the CytoScan HD array (Affymetrix). Results from the WES showed the absence of de novo pathogenic mutations in the autistic individuals under study, suggesting, as expected, that inherited mutations have a major role in multiplex families. Our preliminary data confirm that the genetic mechanism at the basis of autism may be the cumulative effect of oligogenic heterozygous variants in several genes. In our study we found variants in genes already associated with syndromic autism such as NF1 and TSC1, but also genes like SCN1A or ANK2, which emerged recently as autism genes from exome sequencing studies. The genes found in WES and in the CNV study will be functionally clusterized to identify pathways involved in the disease.

2579F

Utility of a comprehensive multi-gene testing panel for epilepsy and evaluation of the expectations for whole exome sequencing in these disorders. *G. Richard, E. Butler, D. McKnight, K. Retterer, A. Shanmugham, R. Rubenstein, K. Hruska, E. Haverfield, S. Aradhya.* GeneDx, Gaithersburg, MD.

To address the significant genetic heterogeneity in epilepsy, we developed and validated a targeted diagnostic test combining Next-Generation sequencing and exon-level array CGH for 53 genes associated with major primary and syndromic forms of epilepsy. In 176 unrelated, consecutive clinical cases we identified 190 sequence variants and two exonic deletions. Twenty-five individuals had a variant of definite or possible clinical relevance in more than one gene. Twenty-eight (16%) received a conclusive molecular diagnosis, seven (4%) had a likely mutation, and eight (5%) were heterozygous for a single mutation in an autosomal recessive gene. In 55 individuals (31%), variants of unclear significance were detected and parental testing was recommended. Only 19% of known or predicted mutations were in sodium channel genes. In eight cases results had immediate treatment implications. Therefore, using a comprehensive sequencing and exon array approach yielded known/predicted mutations in 20% of individuals with different epilepsy phenotypes, including unexpected rare disorders. Identifying the genetic cause of epilepsy in negative cases remains challenging. To explore the utility of whole exome sequencing (WES), we analyzed exomes obtained by solution-based capture of 32 unrelated control individuals with non-epilepsy phenotypes, focusing on >230 ion channel genes and >290 epilepsy-related genes. Mean coverage across over 8000 exons was 90X, and on average 1.7 exons/gene showed areas of shallow coverage (<20X). Using a cut-off of 20X, ~92% of published mutations in these genes would be identifiable by WES. However, each of the 32 exomes also contained more than 200 non-synonymous SNPs with allele frequency <1% in 1000 Genomes data, creating challenges for data analysis and interpretation. Given the current challenges of WES, our data suggest the most suitable testing strategy for epilepsy is a targeted, comprehensive multi-gene panel followed by WES if negative.

2580W

Rare variants within *PAX6* enhancer elements are enriched in Rolandic Epilepsy. *L. Addis[1], T. Chiang[2], A. Derkach[2], S. Newhouse[3], S. Dobbins[4], I. Tomlinson[5], R. Houlston[4], L.J. Strug[2, 6], D.K. Pal[1].* 1) Department of Clinical Neuroscience, Institute of Psychiatry, King's College London, London, United Kingdom; 2) Program in Child Health Evaluative Sciences, The Hospital for Sick Children, Toronto, ON, Canada; 3) NIHR Biomedical Research Centre for Mental Health, Institute of Psychiatry, Kings College London, London, United Kingdom; 4) Section of Cancer Genetics, The Institute of Cancer Research, Surrey, United Kingdom; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 6) University of Toronto, Toronto, ON, Canada.

Developmental control genes display complex spatiotemporal and quantitative expression patterns making use of cis-regulatory elements such as enhancers. Errors in expression of these genes leads to developmental disorders. One such gene is the transcription factor *PAX6*, whose control elements are spaced upstream, within introns, and primarily downstream of the gene in the neighboring reverse-oriented transcriptional regulator *ELP4*. This is the ultra-conserved downstream regulatory region, DRR. Using linkage and association in Rolandic Epilepsy (RE) families we mapped Centrotemporal spikes (CTS), the autosomal dominant EEG hallmark of RE (also present in 2–4% of the general population) to the *ELP4-PAX6* region. This region is pleiotropic for Speech-Sound disorder (SSD) in RE. We now sought to uncover the causal variants for CTS and SSD using Illumina NGS (196x read-depth) from long-range PCR of the 650Kb linkage region in 27 RE probands of European origin. We compared the frequency of variants identified in our cases to those from 200 European-ancestry controls sequenced by Complete Genomics (~35x read depth). Quality control filters were the same across the epilepsy and CG datasets. We developed a novel statistic to assess association with variants seen at least once in both the case and control groups, and we determined the need to adjust for platform differences. Using rare variant binning analysis (simple sum test and C-alpha) on SNPs present in both case and control samples with MAF<10%, fourteen variants within *PAX6* enhancer elements were enriched in cases (p=0.022). Five SNPs with potential regulatory function were significant in the *PAX6* and *ELP4* 3'UTR binned region (p=0.015). Rare variants binned by entire gene other than *PAX6* were not significantly different between case and control groups (*DCDC1, DNAJC24, IMMP1L* and *ELP4*). Highest ranked SNPs from single SNP analysis clustered within introns of the neighboring genes *DCDC1* and *DNAJC24*. These variants may be part of an extreme *PAX6* DRR or have an important function in their own right. It will be essential to simultaneously follow-up this alternative hypothesis. Many novel SNPs frequent in cases were found within known DRR regions for *PAX6*; intron 9 and 3 of *ELP4*. All of these variants, as well as other novel SNPs of potential function, are now prioritized for genotyping follow-up in a larger set of 150 RE cases and 300 matched controls with functional work to follow.

Paroxysmal Kinesigenic Dyskinesia with Infantile Convulsions (PKD/IC) is an episodic movement disorder with autosomal dominant inheritance and high penetrance, but the causative gene is unknown. We have now identified four truncating mutations involving the PRRT2 gene in the vast majority (24/25) of well characterized families with PKD/IC. PRRT2 truncating mutations were also detected in 28 of 78 additional families. The PRRT2 gene encodes a proline-rich transmembrane protein of unknown function that has been reported to interact with the t-SNARE, SNAP25. PRRT2 localizes to axons but not to dendritic processes in primary neuronal culture and mutants associated with PKD/IC lead to dramatically reduced PRRT2 protein levels leading ultimately to neuronal hyperexcitability that manifests in vivo as PKD/IC.

2582F

Identification of rare variants under an alcoholism susceptibility linkage peak in a COGA family using whole exome sequencing. *M. Kapoor[1], J. Wang[1], A. Hinrichs[1], S. Bertelsen[1], J. Budde[1], A. Agrawal[1], J. Tischfield[2], L. Almasy[3], M. Schuckit[4], L. Bierut[1], A. Goate[1].* 1) Washington University School of Medicine, St Louis, MO; 2) Department of Genetics/Human Genetics Institute, Rutgers University, Piscataway, New Jersey; 3) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 4) Department of Psychiatry, University of California, San Diego, CA.

Genetic factors may explain as much as 60% of the variance in risk for alcoholism. Genomewide association studies of alcoholism only accounted for small proportion of this variance. We undertook whole exome sequencing to investigate the possible contribution of rare coding variants to susceptibility to alcohol dependence. Finding missing heritability through rare variants is conceptually easy, as it can involve closer scrutiny of genes and regions of interest. Combining the power of traditional linkage studies with next-gen sequencing can help find missing heritability in the form of rare and novel variants. Multiple chromosomal regions have been linked to alcohol dependence and other key phenotypes in our previous studies. In the present study, we have sequenced a trio (two alcohol dependent and one non-dependent control) selected from a large family that has many alcoholic subjects, and showed a very high NPL score on chromosome 2 with DSM-IV diagnosis. We used the SureSelect Human All Exon Kit and protocols provided by Agilent to capture exons, and performed paired-end sequencing on the Illumina GA2 platform. More than 95% of the exome was captured with >8X read depth. A total of 722 variants on chromosome 2 were detected in the affected parent and offspring, but were not present in the unaffected parent. Among these, 83 variants lie under linkage peak and were coding variants. Out of 83 variants, 22 variants had minor allele frequency (MAF) less than 5% in dbSNP and 7 were novel. We validated these 29 variants by genotyping in rest of family members, and in about 4000 cases and controls. Preliminary association analysis using these rare and novel variants helped us to identify 6 variants in 6 genes which may be associated with alcohol dependence. We further sequenced these 6 genes using the targeted capture approach in case-controls and large families to determine enrichment of functional rare variants among alcohol dependents. Our results showed that linkage information in single family can be useful in identifying the functional rare variants enriched in hetrogenous and complex phenotype like alcohol dependence and related traits.

2583W

Deep Resequencing of 9 Confirmed Late-Onset Alzheimer Disease (LOAD) Loci Identifies Multiple Genomic Regions with Potentially Functional Variants. *J.R. Gilbert[1], A.C. Naj[1], L. Wang[1], M.A. Kohli[1], K.L. Hamilton[1], R. Rajbhandary[1], P.L. Whitehead[1], R.M. Carney[2], B. Levin[2], E.A. Crocco[2], C.B. Wright[3], G.W. Beecham[1], E.R. Martin[1], S. Zuchner[1], J.L. Haines[4], M.A. Pericak-Vance[1].* 1) Hussman Inst for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Psychiatry & Behavioral Sciences, University of Miami, Miami, FL; 3) Evelyn F. McKnight Brain Institute, Department of Neurology, University of Miami, Miami, FL; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Besides *APOE*, recent genome-wide association studies (GWAS) have identified variants in nine genes (*CR1*, *CLU*, *PICALM*, *BIN1*, *EPHA1*, *MS4A4A/6E*, *CD33*, *CD2AP*, and *ABCA7*) that confer LOAD risk. However, it is unclear if there are additional novel or rare variants in or near these genes that contribute to LOAD. We resequenced these genes and surrounding regions to identify functional polymorphisms in 291 LOAD cases and 103 cognitively normal controls. We performed targeted capture (NimbleGen SeqCap EZ probe libraries) and next-generation sequencing on Illumina's HiSeq 2000. Target regions included variants in all LD blocks (r^2>0.80) overlapping the nine genes, with an average span of 368.3 kilobases. We filtered variants on three criteria: (a) functionality (missense, nonsense, or splice-site variant), (b) potentially damaging effect as defined by Polyphen-2, and (c) presence in one or more cases and absence in controls. We also examined common and rare variants together grouping by gene and function and using set-based multilocus association testing (RVASSOC). We identified 28,894 variants across the nine regions, out of which 21,203 were variants of minor allele frequency (MAF) <5% (19,100 with MAF <2%). 14,863 variants (51.4%) were novel. Polyphen-2 rated 247 variants as “probably” or “possibly” damaging, of which 180 were novel. Most of the 247 damaging variants were rare (222 with MAF <5%; 209 with <2%), and a subset (n=145; 129 novel) were present in one or more cases while absent in all controls (average MAF = 0.002). Among the rare, potentially damaging functional variants were three missense variants in *CR1*, four in *BIN1*, three in*CD2AP*, six in *EPHA1*, six in the *MS4A* region, 14 in *ABCA7*, and one each in *PICALM*, *CLU*, and *CD33*. Association testing identified several clusters of variants associated with LOAD including seven variants near *MS4A* (*P*=0.0049), seven variants upstream of *BIN1* (*P*=0.0067), and two sets of missense variants near *CD33* (one in *CD33*, *P*=0.031; one in nearby *CLDND2*,*P*=0.045). Deep resequencing identified multiple rare and novel variants near known LOAD susceptibility genes, suggesting that at least some of these may be contributing to risk of LOAD.

Whole Exome Sequencing in Childhood-onset Schizophrenia. *K. Ahn[1], H. Sung[2], T. Anderson[1], Y. Yao[1], J.L. Rapoport[1].* 1) Child Psychiatry Branch, National Inst Mental Health, NIH, Bethesda, MD; 2) Genometrics Section, Inherited Disease Research Branch, National Human Genome Research Institute, NIH, Baltimore, MD.

Genetic studies of neuropsychiatric illnesses such as childhood onset schizophrenia (COS) have shown that the common disease, common variant hypothesis contributes less to the etiology of neuropsychiatric disorders than previously thought. In contrast, studies of large copy number variants have provided evidence for a larger role of rare, highly penetrant rare variants in COS, which can only be fully explored using the next generation sequencing technology. Whole exome sequencing in 14 COS patients with their unaffected parents was performed with Agilent SureSelect 50 mb capture region and Illumina Hiseq sequencing platform. To test of association for inherited sequence variants in individuals with COS are more likely to harbor inherited rare variants, we employ a few statistical methods of collapsing rare variants by region or gene. These include SKAT, Rare Variant in FBAT, and KBAC. In addition, we explore the parents-origin effects if there is evidence from the rare variant association study. Finally, we perform the pathway analysis for all sequence variants to determine whether the sequence variants identified in COS individuals show enrichment for relevant pathways.

Complete Genome Sequence Based Genetic Analysis of Monozygotic Twins Discordant For Schizophrenia. *C. Castellani, R. O'Reilly, S. Singh.* Department of Biology and Department of Psychiatry, The University of Western Ontario, London, Ontario, Canada.

The reality of individual genome sequencing now offers a new hope in search of the cause(s) of complex diseases. When combined with genetic relationships, individual sequences add an unrivaled proficiency. Given the near identical genetic structure of monozygotic (MZ) twins, any difference between MZ twins discordant for a disease will have a high likelihood of being causal. With this in mind we have sequenced the DNA of six individuals, which includes two pairs of MZ twins discordant for Schizophrenia and one set of parents. Sequencing was carried out using the Complete Genomics Analysis system (Drmanac et al, 2010). The Complete Genomics platform has a 99.999% sequencing accuracy and calls >99% of the reference genome. The sequences were further assessed for accuracy in relation to Affymetrix SNP Array 6.0 results. Genome wide variations including SNPs, indels, and CNVs were assessed. It has allowed us to evaluate the similarities and differences across unrelated individuals, parents and children, as well as between MZ twins. The results show that an individual carries approximately 3.7 million SNPs, 150 CNVs, 400,000 indels. Also, two unrelated individuals differed for 1.5–1.8 million SNPs (~45%), a parent and child differed for 0.9–1.0 million SNPs (~30%) and a pair of MZ twins differed for 100,000 (~3%) SNPs. Differences in the identity of CNVs for the three comparisons were ~45%, ~30% and ~4%, respectively. It should be noted however that a number of these differences will be the result of sequencing errors. Interestingly, CNV and SNP differences between MZ twins affect a set of genes enriched in neurodevelopmental genes, as well as genes that have been already implicated in Schizophrenia. Further, potentially deleterious mutations (in PDE4DIP and LOC339742) were found in both affected patients but not in their unaffected co-twins or parental samples. The results support our strategy and identify patient specific genetic changes that may lead to Schizophrenia. The novel results re-enforce that individual genomes harbor extensive variability, some inherited and others acquired during parental meiosis and/or mitosis during ontogeny. Even MZ twins are not identical and each individual may be a mosaic, potentially carrying different sequence variations in different cells. This is supported by a high mutation rate and the persistence of genetic diseases with a severely reduced fecundity in all human populations.

Exome Sequencing of Extended Pedigrees with Late-Onset Alzheimer Disease (LOAD) Identifies *TTC3* as a Candidate Gene for AD. *K. Hamilton[1], M.A. Kohli[1], A.C. Naj[1], R. Rajbhandary[1], T. Plitnik[1], K. John-Williams[1], P.L. Whitehead[1], J.R. Gilbert[1], E.R. Martin[1], G.W. Beecham[1], J.L. Haines[2], S. Zuchner[1], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human GenomJics, University of Miami Miller School of Medicine, Miami, FL; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Identifying risk genes for Alzheimer's disease (AD) has focused on testing the `common disease-common variant' (CDCV) hypothesis. While common variants like the ε4 allele of *APOE*clearly play a role in AD, there is a growing realization that the CDCV hypothesis is unlikely to explain all the genetic effect underlying AD. One alternative hypothesis invokes multiple rare variants (RV) in one or more genes, each with stronger individual effects than common variants in genes identified under CDCV. We identified a subset of 6 pedigrees from our collection of 61 extended multi-generational, late-onset AD (LOAD) families to test the rare variant hypothesis. The pedigrees have an average six AD-affected individuals, and have been screened to exclude known familial AD mutations in *APP*, *PSEN1*, and *PSEN2* genes. All affected individuals underwent genome-wide high-density genotyping. Whole-exome sequencing was performed on 4–9 affected individuals per pedigree comprising 2–6 cousin or avuncular pairs. The BWA/GATK package was applied for single nucleotide and insertion-deletion variant calling. Genome-wide genotyping results were used to identify regions of high identity-by-descent (IBD) sharing across the genome. This identifies regions of complete IBD sharing among affected samples, indicating regions most likely to harbor segregating LOAD variants. Promising variants were validated by Sanger sequencing. Using this approach, we identified a novel missense variant (Ser1038Cys) in the gene chromosome 21 gene *TTC3*, which encodes tetratricopeptide repeat domain 3 in one extended pedigree examined. This variant is located at a phylogenetically highly-conserved site, and was not identified in an independent set of ~10,000 control alleles. Co-segregation of the risk genotype with affection status within the pedigree was strong (10/10 affected and 2/6 unaffected carriers) within. We have identified a potentially damaging missense change in *TTC3*, a novel biological candidate for AD that warrants further genetic and functional examination. *TTC3*, which encodes an akt- kinase-regulated factor, is located in the Down syndrome critical region, and has been implicated in neuronal differentiation and learning and memory impairment. This work supports the utility of whole-exome filtering approaches for identifying novel candidates for common diseases in heavily-affected pedigrees.

2587T

Exome sequencing reveals de novo gene disruptions in children on the autistic spectrum. *I. Iossifov[1], M. Ronemus[1], D. Levy[1], Z. Wang[1], I. Hakker[1], J. Rosenbaum[1], B. Yamrom[1], Y. Lee[1], G. Narzisi[1], A. Leotta[1], J. Kendall[1], E. Grabowska[1], B. Ma[1], L. Rodgers[1], J. Troge[1], P. Andrews[1], E. Ghiban[1], J. Parla[1], R. Demeter[2], L.L. Fulton[2], R.S. Fulton[2], V.J. Magrini[2], K. Ye[3], J.C. Darnell[4], R.B. Darnell[4,5], E.R. Mardis[2], R.K. Wilson[2], M.C. Schatz[1], W.R. McCombie[1], M. Wigler[1].* 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) The Genome Institute, Washington University School of Medicine, St. Louis, MO; 3) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY; 4) Laboratory of Molecular Neuro-oncology, Rockefeller University, New York, NY; 5) Howard Hughes Medical Institute, Rockefeller University, New York, NY.

The genetic component of autism can be transmitted or acquired through de novo mutation. Previous studies have focused on large-scale de novo copy number events, either deletions or duplications, and have identified a large number of autism candidate genes. Because copy number events often span many genes, discerning which of the genes in the target region contribute to the disorder requires complex network analysis and inference. In contrast, with high-throughput DNA sequencing we can readily search for de novo single nucleotide and small insertion or deletion mutations that affect a single gene. Such mutation is fairly common, approximately one hundred new mutations per child, but with only a few—on the order of one per child—falling in coding regions.

We are collaborating in an ongoing large project for sequencing the exomes of 2,800 families from the Simons Simplex Collection. Our preliminary analysis (Iossifov et.al., *Neuron*, 2012) of ~350 of these families, as well as the reports of three other groups, demonstrated the power of identifying de novo mutations through exome sequencing to implicate autism genes. Among the major results were: (1) strong evidence for the role of likely gene-disrupting (LGD) mutations (nonsense, splice site and frame shifts), with affecteds having twice as many LGDs compared to unaffected siblings; (2) the identification of 127 de novo LGD mutations across the four reports with five genes (*CHD8*, *DYRK1A*, *KATNAL2*, *POGZ*, *SCN2A*) having two de novo mutations in unrelated individuals (`double hits'); (3) estimation of a total number of about 400 autism target genes, with a prediction of ~100 double hits after the whole set of 2,800 families has been processed; and (4) the discovery of a strong association between the targets LGD mutations in autism and *in vivo* targets of the RNA-binding translational regulator FMRP (encoded by FMR1, which results in Fragile X Syndrome when silenced or mutated). In our preliminary assessment, we have not seen evidence for a role of de novo missense mutations or inherited LGD variants in autism pathogenesis, but with a greater sample size we hope to detect such effects (if present). We expect to present the results of the joint analysis of ~1000 families by November 2012.

Secretin receptor and the associated molecular processes relevant to autism spectrum disorder. *K. Kojima, T. Yamagata, A. Matsumoto, M. Saito, E. F. Jimbo, M. Y. Momoi.*Pediatrics, Jichi Medial University, Shimotsuke-shi, Tochigi, Japan.

Secretin is a peptide hormone released from duodenum to stimulate exocrine secretion from pancreas. It also functions as a neuropeptide hormone in the brain. Because secretin receptor (Sctr) deficient mice showed the impairment of social interaction, the involvement of secretin to the pathogenesis of autism spectrum disorder (ASD) is suggested. To investigate the contribution of secretin and its pathway to ASD, we screened SCTR gene for mutations in ASD patients and also analyzed genes regulated by secretin in the mouse brain. (Subjects and methods) (1) We analyzed 200 DNA samples from Japanese ASD patients with the parent's informed consent and Caucasian patients from the Autism Genetic Resource Exchange (AGRE). Each exon and adjacent intron of SCTR was amplified by PCR and subjected to direct sequencing. Base changes detected in ASD samples were screened in 200 Japanese control samples. (2) We injected 1g of secretin into lateral ventriculus of C57BL/6J male adult mice. Three hours after the injection, mRNA was extracted from hippocampus. The expression level of genes was measured using Agilent Expression Array, and data were analyzed by GeneSpring (Agilent Technology). (Results) (1) We detected a missense mutation, P90L in SCTR in one Japanese patient. (2) In mouse hippocampus, expression of oxytocin and vasopressin were markedly elevated after the secretin injection compared to the saline injection. (Discussion) The P90L mutation in SCTR is located in hormone binding domain. Because of the conservative nature of this residue, this mutation can have effect to alter the secretin binding to the receptor and its function. Secretin was reported to activate supraoptic nucleus oxytocin and vasopressin neurons. We showed that secretin stimulated oxytocin and vasopressin expression in hippocampus. These findings suggested the importance of seccretin pathway in the pathogenesis of ASD, that is probably through oxytocin and vasopressin.

Exome Sequencing of Multiplex, Schizophrenic Families Implicate Variants from Chromosome 5q in Neurocognitive Performance. *M.Z. Kos[1], M.A. Carless[1], J. Peralta[1], E.E. Quillen[1], R.C. Gur[2], M.F. Pogue-Geile[3], K. Prasad[4], J. Blangero[1], V.L. Nimgaonkar[4], R.E. Gur[2], L. Almasy[1].* 1) Dept Gen, Texas Biomedical Research Institute, San Antonio, TX; 2) Department of Psychology, Neurology and Radiology, University of Pennsylvania Medical Center, Philadelphia, PA; 3) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA; 4) Department of Psychiatry, University of Pittsburgh Medical Center, Pittsburgh, PA.

Schizophrenia (SCZ) is a highly heritable and severe mental disorder characterized by hallucinations, delusions and cognitive deficits, with a lifetime prevalence of 0.4–0.8%. Although a major genetic underpinning has been incontrovertibly demonstrated by twin, family and adoption studies, with an estimated heritability of up to 80%, the genetic architecture of SCZ is unclear, as results for common variants from genome-wide association studies (GWAS) account for only a small fraction of the disorder's additive genetic variation. To better elucidate the biological pathways underlying familial liability of SCZ, we target rare variants via whole exome sequencing of affected families ascertained by the Multiplex-Multigenerational Genetic Investigation (MGI) of Schizophrenia. The MGI families were selected for study on the presence of two or more cases of SCZ or schizoaffective disorder, depressed type (SAD). In addition to clinical evaluations, subjects were tested with a computerized neurocognitive battery that assesses accuracy and efficiency of the following cognitive domains: abstraction and mental flexibility (ABF); attention; verbal, face and spatial memory; language and reasoning; spatial and emotion processing; and sensorimotor dexterity. Exome sequencing was performed on the Illumina HiSeq2000 at 50x coverage. Previous analyses of this data set have revealed significant evidence for linkage to SCZ at chromosome 19q, as well as significant and nominal signals overlapping at chromosome 5q for various neurocognitive measures. Preliminary exome sequence results (n=29 subjects) were examined for these two linkage regions, revealing a number of genome-wide significant associations at chromosome 5q for tests of abstraction and mental flexibility, and attention. For measures of attention, variants from the gene FAM153B are significantly associated with accuracy (rs148943943; P=2.63×10-6) and efficiency (rs148943943; P=7.76×10-6). For ABF, a variant from IL9, a putative candidate gene for SCZ, exhibits significant association with speed (rs1478080; P=3.36×10-6). Previous gene expression analyses have implicated MCAT in ABF performance, with a number of variants from this gene showing evidence of association in our data (best P=1.94 x10-3). Exome sequencing will ultimately be performed on 144 subjects from the MGI samples, with the objective of investigating the influence of exome variants on SCZ and related neurocognitive phenotypes on a genome-wide scale.

2590T

Mining for Rare Genetic Variation underlying Psychiatric Disorders using Family Based Sequencing. *S. McCarthy[1], J. Badner[2], D. Morris[3], M. Ayub[4], M. Kramer[1], D. Blackwood[5], A. Corvin[3], W. Byerley[6], W.R. McCombie[1].* 1) Stanley Institute for Cognitive Genomics, Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, USA; 2) Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL, USA; 3) Department of Psychiatry, Trinity College Dublin, Dublin, Ireland; 4) School of Medicine and Health, University of Durham, Durham, UK; 5) Division of Psychiatry, University of Edinburgh, Edinburgh, UK; 6) Department of Psychiatry, University of California San Francisco, San Francisco, CA, USA.

Interest in the contribution of rare genetic variation to the risk of psychiatric disorders has been revitalized by recent genome wide association and copy number variation surveys of the human genome. Next generation sequencing affords a unique opportunity to explore the impact of rare genetic variation even further at nucleotide resolution. Although targeted and whole genome sequencing provide comprehensive catalogues of rare sequence variation at nucleotide resolution, evaluating which of the thousands of variants may be risk factors for schizophrenia is an arduous and difficult task. Family based strategies such as parent-offspring trios and extended outbred or consanguineous pedigrees are powerful approaches to increase the signal to noise of risk variants for bipolar disorder, major depression and schizophrenia above the background of benign or insignificant genomic variation. Here we shall present the principles and hypotheses of family based sequence analyses, and present our findings from human exome sequencing of parent-offspring trios with schizophrenia as well as findings from whole genome sequencing in extended pedigrees with schizophrenia and consanguineous families with bipolar disorder and major depression. We shall highlight the importance of rare, private de novo or inherited variants in risk of schizophrenia in over 60 schizophrenia trios. In addition we will present our analysis of >15 whole genomes representing two extended pedigrees with schizophrenia and one large consanguineous family with bipolar disorder and major depression. Our findings illustrate the significance of family specific variants with potentially damaging effects in genes with neurobiological function but also highlight the genetic overlap between major psychiatric illnesses. In conclusion our results demonstrate how advancements in next generation sequencing provide the opportunity to disentangle the complex genetics of psychiatric disorders and how family based approaches are a powerful resource to enrich and harrow rare genetic variation contributing to the risk of schizophrenia, bipolar disorder and major depression.

2591F

Identification of the causative gene for SPG27 by Exome capture. *A. Noreau[1], I.A. Meijer[1], S.L. Girard[1], D. Spiegelman[1], A. Szuto[1], P. Cossette[1], P.A. Dion[1,2], G.A. Rouleau[1,3,4].* 1) The Centre of Excellence in Neuroscience, CRCHUM, Montreal, Quebec, Canada; 2) Université de Montréal, Department of pathology and cellular biology, Montreal, Quebec, Canada, H3T 1J4; 3) University of Montreal, Faculty of Medicine, Department of Medicine, Montreal, Quebec, Canada, H3C 3J7; 4) Research Center, CHU Sainte-Justine, Montreal, Quebec, Canada, H3T 1C5.

Hereditary spastic paraplegia (HSP) is a motor neuron disease for which the key symptoms are lower limb spasticity and weakness because of progressive neurodegeneration events. The group of HSP is particularly heterogeneous because different modes of inheritance were observed (dominant, recessive and X-linked) as well as various levels of symptoms complexity; pure and complicated forms were described. To date, over 45 spastic paraplegia locus were identified and 22 genes identified. A previous linkage analysis on an autosomal recessive pure HSP family identified a new locus (SPG27) on the 10q22.1-10q24.1 region; a locus partially overlapping the SPG9 locus. We proposed to perform use an exome capture approach with the Agilent Technology SureSelect Human All Exon Kit (50MB) and proceed to resequencing with ABI SOLID4 DNA sequencer. Four affected individuals, the unaffected-carrier father and another unaffected sibling carrying the same disease-allele as the father will be used. As we may be looking for compound-heterozygote mutations, we will develop an algorithm to determine the parental origin of variants and the more promising mutations will be validated through Sanger sequencing. By this method, it will be possible to cover the 40 genes, find the causative mutation and maybe solve the SPG9 clue.

DEC2 Gene Mutations Associated with distinct Sleep Phenotypes and Sleep length. *R. Pellegrino[1, 2, 3], I.H Kavakli[4, 5], N. Goel[6], C. Cardinale[1], D. Dinges[6], S. Tufik[3], J. Hogenesh[4], A. Pack[2], H. Hakonarson[1].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, USA; 2) Center for Sleep and Circadian Neurobiology, University of Pennsylvania - School of Medicine, PA, USA; 3) Universidade Federal de São Paulo - UNIFESP; 4) Department of Pharmacology, Institute for Translational Medicine and Therapeutics, University of Pennsylvania School of Medicine, PA, USA; 5) Department of Chemical and Biological Engineering, Koc University, Istanbul, Turkey; 6) Division of Sleep and Chronobiology, Department of Psychiatry, School of Medicine, University of Pennsylvania, PA, USA.

Introduction: DEC2 gene is a negative component of the circadian clock by suppressing BMAL1-CLOCK transactivation. It belongs to a basic helix-loop-helix protein family and they dimerize with each other and can affect gene transcription by binding to specific DNA sequences. DEC2 and DEC1 repress Clock/Bmal1-induced transactivation of the Per2 promoters through direct protein-protein interaction and/or competition for E-boxes. DEC2 is probably a component of the mammalian clock system. It has been reported that a mutation in DEC2 is associated with a human short sleep phenotype. Methods: Given the complexity of phenotyping to study sleep homeostasis and genetics, we intend to evaluate differences in the phenotype between monozygotic and dizygotic twins. In addition, we also included unrelated samples and controls. We sequenced 589 (total) individuals for 5 exons covering the DEC2 gene. In order to examine the effect of the mutations on DEC2 transactivation, wild-type (WT) and mutants were used in a luciferase assay to evaluate the activity of Clock/Bmal-Per2-mediated transactivation. Results and discussion: We discovered a new Dec2 mutation (Dec2-Y362H) in a genetically related cohort which associated with a short sleep assessed by actigraphy and polysomnography. Results indicated that both mDec2-Y362H and mDec2-P384R have comparable attenuated repressive activity on BMAL1-CLOCK transactivation compared with wild type mDec2. On the other hand, mDec2-P384Q mutants displayed the opposite effect on BMAL1-CLOCK transactivation where it strongly inhibited BMAL1-CLOCK transactivation on mPer2 promoter. The Y362H and P384R is correlated to a decrease of sleep length and the individuals with P384Q mutations demonstrated normal or increased sleep length. Conclusion: We observed the DEC2 region in exon 5 as a “hot spot” for mutations. This region can be associated with important changes in phenotypes according with the position of the mutation and amino acid substitution. It is remarkable how recent data on the genetics of human sleep and increased knowledge of regulatory mechanisms of sleep quality and quantity will facilitate the development of prospective interventions in situations relating to sleep deprivation.

2593T

Common and rare variants in obsessive-compulsive disorder (OCD) identified by exome and targeted resequencing. *D. Trujillano[1], S. Ossowski[1], P. Alonso[2], C. Tornador[1], J.M. Menchón[2], M. Gratacòs[1].* 1) Genes and Disease, Centre for Genomic Regulation (CRG-UPF), Barcelona, Catalonia, Spain; 2) Psychiatry Department, Bellvitge University Hospital, Barcelona, Catalonia, Spain.

Obsessive-compulsive disorder (OCD) is a mental disease characterized by unwanted and intrusive thoughts, images, or impulses (obsessions) and/or repetitive behaviors or mental acts (compulsions). Although OCD affects 2%–4% of the population worldwide, very little progress has occurred in the elucidation of the underlying risk-conferring genetic variation by means of candidate-gene, linkage, and GWAS. We hypothesize that a wide spectrum of common and rare genetic variants contributes to OCD. In this study, taking advantage of NGS technologies, we have examined the extent to which common and rare variation might play a role in OCD. We used a two-step approach to study OCD. We begun with the screening of the exomes by NGS of 40 extremely well characterized OCD patients (clinical evaluation, course of the disease and MRI) to identify candidate genes affected by deleterious common and/or rare single nucleotide variants (SNV). For this, we used the SureSelect Human All Exon Kit (Agilent) in combination with the Illumina's GAIIx sequencer. Then, we followed this initial screening with association studies of the selected SNVs in a larger cohort of 500 OCD cases and 500 controls to identify statistically significant variants by means of direct genotyping for common SNVs, and NGS targeted resequencing for novel and rare SNVs. From the high depth of sequencing data generated, we selected 436 genes recurrently affected by deleterious novel and rare SNVs across the 40 patients of the discovery set. The resulting list of genes was targeted resequenced in 500 OCD cases and controls. In parallel, we also identified 60 deleterious common SNVs with significantly altered allelic frequencies in our initial sample set when compared to the normal population. Preliminary results of this study have identified a large number of SNVs that show significant different allelic frequencies between OCD cases and control samples. By combining targeted resequencing of genes enriched in novel and rare variants with genotyping of common SNVs, we will provide a comprehensive characterization of the genetic basis of. Coexistence of common and rare SNVs in the same genes and functional predicted consequences should help to prioritize functional studies, and hopefully facilitate to define a set of genes for comprehensive evaluation of OCD risk assessment and fine diagnosis. The knowledge acquired in this project should provide a grounding basis for new treatment strategies for OCD.

2594F

Deep whole genome sequencing in 18 Irish individuals with schizophrenia. *B.T. Webb[1,2], E. Loken[1], T.B. Bigdeli[1], B. Wormley[1,2], F.A. O'Neill[4], D. Walsh[5], K.S. Kendler[1,2], B.P. Riley[1,2,3].* 1) Virginia Institute for Psychiatric and Behavioral Genetics; 2) Departments of Psychiatry and; 3) Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA; 4) Department of Psychiatry, Queens University, Belfast; 5) The Health Research Board, Dublin, Ireland.

Background: Recent evidence supports the involvement of both common and rare variation to the genetic architecture of schizophrenia. We have previously conducted GWAS on the Irish Study of High Density Schizophrenia Families and the Irish Schizophrenia Case Control samples. We now seek to understand the contribution of rare and alternative classes of variation in these samples. Whole genome sequencing can be used to; 1) estimate the frequency of novel or very rare high impact variants, 2) measure mutational load in sporadic versus familial cases, 3) assess additional classes of variation including structural variation and mobile insertion element, 4) potentially discover population specific haplotypes and 5) provide additional Irish specific reference samples for more accurate imputation low frequency and rare variation. Methods/ Results: Sequencing, alignment, variant calling, and annotation of 18 case samples was performed by Complete Genomics. The median amount sequence where both pairs mapped was 162.8 Gb (55.2X) with 0.69, 0 .82, 0.92 of the genome covered at >40, 30, and 20X, respectively. The SNP transition/ transversion ratio for high quality calls was 2.14 and 3.04 for the genome and exome, respectively. Novel SNPs (unobserved in dbSNP132) were rare (0.034) while novel insertions (0.195), deletions (0.229), and substitutions (0.354) were more common. A median of 0.029 of the genome was associated with novel Copy Number Variation (CNV). Each sample had 1548 high quality structural variant junctions on average. A median of 4414 Mobile Element Insertions (MEI) per sample was observed with most MEIs being novel (0.767). Novel high impact variation including nonsense, frameshift, misStart, and splice site disruption was common with 352 candidate events per genome Conclusion: Metrics for Complete Genomics genomes are in agreement with recent reports from the 1000 genomes and NHLBI Exome sequencing projects for measures such as rare functional variation frequency. Further, the addition of population or study specific deep sequenced genomes yields low frequency variation not in current reference panels and therefore can improve imputation. Deep sequencing also offers the opportunity to investigate additional classes of variation that may contribute to the genetic architecture of schizophrenia. Finally, the identification of loci with multiple high impact rare variants can be used to improve pathway and gene-set enrichment analysis of GWAS data.

Background The etiology of intellectual disability (ID) remains elusive in the majority of patients due to the absence of morphological or positional clues and lack of suitable screening methods.

Methods We used exome sequencing in parent-child trios to identify *de novo* variants in 51 individuals with sporadic non-syndromic intellectual disability. Twenty trios were investigated as controls.

Results We defined 88 *de novo* variants in the case group resulting in an exomic mutation rate of 1.73 per individual per generation. The corresponding figures in the control group were 24*de novo* variants and 1.14 events per individual per generation. Most strikingly, a considerably higher number of individuals in the case group had loss-of-function variants (cases= 20/51 versus controls=2/20) indicating their contribution to disease etiology. Evaluation of the single variants revealed that 16 patients carried *de novo* variants in known ID genes with three recurrently mutated genes (STXBP1, SYNGAP1, and SCN2A). Focusing only on loss-of-function variants, we considered at least 7 mutations in 7 novel genes to be disease causing. We further identified several missense alterations with potential pathogenicity. Interestingly, our study revealed no evidence for a sizable contribution of autosomal recessive inheritance.

Conclusions Our results demonstrate that *de novo* point mutations and small indels are a major cause of severe, sporadic non-syndromic ID with high locus heterogeneity. The high number of *de novo* variants in known ID genes is only partially attributable to known unspecific phenotypes. Rather, several patients did not meet the expected syndromic manifestation indicating a strong bias in the current clinical syndrome descriptions.

A spectrum of mutations in 12 PLP1-related disorders patients from SARAH network of rehabilitation hospitals - Brazil. *S.C.L. Santos, D.R. Carvalho, R.I. Takata, C.E. Speck-Martins.* Human Genetics, SARAH Network of Hospitals, Brasília, DF, Brazil.

PLP1-related disorders represent a group of neurological features ranging from Pelizaeus-Merzbacher disease (PMD, MIM# 312080) with severe CNS involvement to the milder spastic paraplegia type 2 (SPG2, MIM# 312920). Mutations in PLP1 gene (MIM# 300401) lead to the arrest of myelination and can be grouped into two main categories: PLP1 gene duplications (60–70%) and intragenic sequence variants (15–20%). Twelve male patients from 11 unrelated families were screened for PLP1 gene duplications using SALSA MLPA kit P022-B1. PLP1 gene sequencing (ABI3130) was performed in negative patients for duplication. PLP1 duplications were identified in 4 (36%) unrelated patients whereas two of them presented duplications in flanking MLPA probes besides PLP1 gene probes. The duplication sizes were confirmed by using aCGH [(arr Xq22.1q22.3(RP3-347M6->RP1-75H8)x3 and arr Xq22.1q22.3(RP3-347M6->RP1-75H8)x3]. Seven different PLP1 intragenic mutations were found in the remaining 8 (64%) patients. So far, 4 out of 7 PLP1 intragenic mutations were not described yet, including two missense mutations (p.Tyr58Cys, p.Lys151Arg) and two microdeletion (c.216_217delC, c.354_355delA) resulting in frameshift (Ile72AlafsX44, Thr118GlyfsX28, respectively). Functional significance of the novel missense mutations was analyzed by the MutPred and SIFT tools. Both tools predicted a potencial deleterious effect for p.Tyr58Cys mutation and a non-deleterious effect for p.Lys151Arg mutation. Further investigation must be applied to confirm these data. All PLP1-duplication patients presented the classical form of PMD, but the patient with the largest PLP1 duplication showed a more severe phenotype presenting microcephaly, a high frequency of epileptic episodes and brain atrophy. Peripheral neuropathy was absent in PLP1-duplications patients, but was present in two patients with intragenic mutations. Our study detected novel intragenic mutations in PLP1-related disorders patients, as well as confirmed some genotype-phenotype correlations in a series of Brazilian patients.

2597F

Association between the NMDA Receptor Subunit 2B Gene (GRIN2B) gene and Alzheimer's Disease. *F. Trecroci, R. Cittadella, M. Liguori, F. Condino, P. Spadafora, E.V. De Marco, G. Di Palma, V. Andreoli.* Institute of Neurological Sciences-National Research Council, Pianolago di Mangone, Cosenza., Italy.

Various mechanisms may contribute to neurodegeneration in Alzheimer's disease (AD), the most common cause of dementia, including glutamate-mediated excitotoxicity. While normal glutamatergic neurotransmission is required for learning, memory and information processing of human brain, excessive glutamatergic activity may cause neuronal dysfunction and eventually degeneration. This excitotoxic effect appears to be mediated, in part, by the N-methyl-D-aspartate receptors (NMDAR). The NMDA receptor subunit 2B (NR2B) has attracted more attention due to its characteristic distribution and selective reduction in AD brain. The human gene encoding this subunit, named GRIN2B (chr 12p12), consists of 13 exons and it is expressed in the hyppocampus, basal ganglia, and cerebral cortex. We hypothesized that GRIN2B represents a candidate gene for AD and we carried out systematic mutation search of the GRIN2B gene in an independent series of Southern Italy samples. Clinical data and blood sample were collected from 270 selected AD patients, after inform consent. All coding exons and exon-intron junctions were amplified using specific primers and a mutational screening was done by DHPLC and DNA direct sequencing. At moment, five single nucleotide polymorphisms (SNPs) were detected. Although these variants are in the coding sequence, they are silent polymorphisms: c.15G>T-Ala5; c.366C>G -Pro122; c.1665C>T-Ser555; c.2514C>T-Cys838; c.3534C>T-His1178. First, we investigated three SNPs, Pro122 in exon 2; Ser555 in exon 8 and His1178 in exon 13 of the GRIN2B gene, in our AD patients and 250 healthy Caucasian age-matched controls. The distribution frequency of neither GRIN2B genotype nor allele (Pro122 P=0.337; Ser555 P=0.142 and His1178 P=0.868) was significantly different between AD patients and normal controls, even when the subjects were stratified by gender, APOE and age of disease onset in AD patients. The results of the Ala5 and Cys838 polymorphisms were omitted because of the low frequencies of the detected alleles. The present study, based on a case-control design, was performed on a cohort of unrelated Italian patients affected with AD. Furthermore, it appears that the GRIN2B polymorphisms analysed here did not show an association with the disease in our sample of AD patients. However, we will continue with a more comprehensive screening of GRIN2B polymorphisms that might be useful to determine the involvement of this gene in AD.

Rare missense variants in *CHRNA5* and *CHRNB3* are associated with increased risk of alcohol and cocaine dependence. *G. Haller[1,2], J. Budde[1,2], M. Kapoor[1,2], A. Agrawal[1], H. Edenberg[3], J. Kramer[4], L. Bierut[1], A. Goate[1,2].* 1) Deparment of Psychiatry, Washington University, Saint Louis, MO; 2) Deparment of Genetics, Washington University, Saint Louis, MO; 3) Deparment of Psychiatry, Indiana University, Indianapolis, IN; 4) Deparment of Psychiatry, University of Iowa, Iowa City, IA.

Previous findings have demonstrated that variants in nicotinic receptor genes are associated with alcohol and cocaine dependence. It is unclear, however, whether this is independent of their effect on nicotine dependence. Recent studies have shown that multiple nicotinic receptor genes harbor rare missense variants associated with reduced risk of nicotine dependence when taken in aggregate. In order to investigate the possible contribution of rare variants to the development of substance dependence, specifically alcohol and cocaine dependence, we undertook pooled sequencing of the coding regions and flanking sequence of the *CHRNA5*, *CHRNA3*, *CHRNB4*, *CHRNA6* and *CHRNB3* genes in 287 African American and 1028 European American individuals from the Collaborative Study of the Genetics of Alcoholism (COGA). All members of families for whom any individual was sequenced (2504 African Americans and 7318 European Americans) were then genotyped for all variants identified by sequencing. For each gene, we then tested for association between carrying at least one rare missense variant and each substance dependence phenotype, incorporating family structure using a kinship matrix. For European Americans, we find increased DSM-IV alcohol dependence symptoms among carriers of missense variants in *CHRNA5* ($p = 0.003$, $\beta = 0.35$) and increased DSM-IV cocaine dependence symptoms among carriers of missense variants in *CHRNA5* ($p = 0.006$, $\beta = 0.28$) and*CHRNB3* ($p = 0.004$, $\beta = 0.24$). Furthermore, these associations remained significant, when the average number of cigarettes smoked per day was included as a covariate, suggesting that these findings are not mediated through the effect of these variants on nicotine consumption alone. African American carriers of missense variants in *CHRNA5* also showed increased DSM-IV alcohol dependence symptoms ($p = 0.007$, $\beta = 1.29$). As a note, carriers of the GWAS significant SNP in *CHRNA5* (rs16969968/D398N) were not included in any analyses so as to insure novel findings. These are the first results to implicate rare variants in *CHRNB3* or *CHRNA5* in risk for alcohol or cocaine dependence and the first results to implicate *CHRNB3* generally in alcohol or cocaine dependence.

Excess of Rare Variants from Targeted Resequencing of the NKAPL Gene in Schizophrenia. *E.K. Loken[1], D. Brohawn[1], D. Walsh[2], F.A. O'Neill[3], K.S. Kendler[1], B.P. Riley[1].* 1) Virginia Commonwealth University School of Medicine, Richmond, VA; 2) Health Research Board, Dublin, Ireland; 3) Queens University, Belfast, United Kingdom.

Background: The most robust signal observed in genome-wide association studies (GWAS) of schizophrenia is in a region between 27 and 32 Mbp on chromosome 6p22. Although these signals are due to common variants in the population, sequencing GWAS genes or intervals to identify rare, functional and deleterious variation in cases is increasingly important in corroborating associations in specific genes. A GWAS in a Han Chinese sample implicated the NFKB activating protein-like (*NKAPL*) gene as a schizophrenia common variant locus. Through resequencing *NKAPL* in Irish schizophrenia cases and controls we demonstrate validation of variants identified in high-throughput sequencing and novel functional variant detection in a schizophrenia GWAS locus.

Methods: We sequenced 48 cases from the Irish Case-Control Study of Schizophrenia and 44 Irish controls from the Trinity Biobank. We amplified a 10kb region containing the *NKAPL* locus using long range PCR. We then performed multiplexed sequencing on the Ion Torrent PGM. We called variants using SAMtools. We compared the burden of rare variants (minor allele frequency < 5% in cases or controls) between cases and controls using permutation testing.

Results: The associated functional SNP rs1635 from the study in the Han Chinese population in *NKAPL* is rarer in the Irish population, with a 4.2% allele frequency in cases and no alleles in controls. A higher burden of rare variation was observed in the cases with 59 alleles observed in cases and 24 alleles observed in controls. Permutation testing of this difference yielded a p-value = 0.0246, suggesting rare variation across the entire loci may contribute to schizophrenia risk.

Discussion: We demonstrated detection of rare variation in a potential schizophrenia risk loci. There is an emerging pattern of rare variation in the form of rare variants occurring more frequently in schizophrenia cases in the *NKAPL* locus. We are currently sequencing *NKAPL* in a total of 500 Irish cases and 500 ethnically matched controls. Discovering excess functional rare variation in *NKAPL* provides independent evidence implicating this gene as a schizophrenia risk locus containing both common and rare variation contributing to risk.

Exome sequencing of singleton trios and quads to reveal *de novo* mutations in schizophrenia. *A.C. Watts, T. Walsh, M.K. Lee, S. Gulsuner, A.M. Thornton, J. McClellan, MC. King, Genes in Schizophrenia (GENESIS) Consortium.* University of Washington, Seattle, WA.

Schizophrenia is a debilitating neuropsychiatric disorder with a worldwide prevalence of about 1%. Although the heritability of schizophrenia is high, there are many sporadic cases; that is, affected individuals with no family history of mental illness. We are sequencing persons with schizophrenia in the absence of family history of mental illness (probands), their unaffected parents, and whenever possible, an unaffected older sibling, in order to identify *de novo* mutations that may be responsible for the disorder. Our hypothesis is that *de novo* events will be observed in many different genes, and that the functions of the impacted genes will differ between probands and their unaffected siblings. From exome sequence, we filter variants to include only those predicted to be both *de novo* and damaging to the protein product. Next, we validate all candidate variants passing these filters by Sanger sequencing, using diagnostic PCR primers to amplify genomic DNA of probands, siblings, and parents. Results to date suggest that approximately 50% of probands and siblings carry at least one damaging *de novo* mutation. Thus far, every mutation has been found in a different gene. The analysis of pathways in which the genes converge is in progress. Next, we will target these candidate genes and determine their complete variant profiles in 5000 cases and 5000 controls. These results can help us identify critical pathways that are affected in schizophrenia.

Novel Missense Mutations and Partial Deficiency of Collagen VI in Ullrich Congenital Muscular Dystrophy. *J. Yuan[1], I. Higuchi[1], Y. Sakiyama[1], Y. Inamori[1], E. Matsuura[1], Y. Higuchi[1], A. Yoshimura[1], A. Hashiguchi[1], K. Higashi[1], Y. Koreeda[2], K. Arimura[3], H. Takashima[1].* 1) Department of Neurology and Geriatrics, Kagoshima University 8-35-1 Sakuragaoka, Kagoshima City, Kagoshima 890-8520, Japan; 2) Division of Respiratory Medicine, Respiratory and Stress Care Center, Kagoshima University 8-35-1 Sakuragaoka, Kagoshima City, Kagoshima 890-8520, Japan; 3) Division of Neurology, Okatsu Hospital 3-95 Masagohonmachi, Kagoshima, 890-0067, Japan.

Objective To establish a diagnostic procedure and find new molecular mechanism in the patients with early-onset multi-joint contracture/overextension and muscle weakness. Methods A group of 9 patients were selected. Histochemical and immunohistochemical studies with collagen VI, collagen IV, laminin α2, adhalin, dysferlin, dystrophin-C, biglycan, perlecan, and HSP47 were performed on biopsied skeletal muscle. Using a next-generation sequencer (GS Junior platform), all coding regions and flanking intron sequences of 8 candidate genes including COL6A1, COL6A2, COL6A3, COL14A1, COL15A1, SERPINH1, BGN, and FMOD were screened, then suspected mutations were confirmed by Sanger sequencing. Results Histochemical stains indicated dystrophic changes, and no definite abnormality was observed in immunohistochemical stains. The high-throughput pyrosequencing revealed 67 single nucleotide polymorphisms or synonymous variants, and two novel heterozygous missense mutations, c.1499G>A (p.500G>E) in COL6A1 and c.801G>T (p.267K>N) in COL6A2 from patient 1 and 3, respectively. Patient 1, 28-year-old male, was suffered with proximal muscle weekness, atrophy, Achilles tendon contracture, and laxity of the distal joints. Patient 3, 25-year-old male, showed general loss of muscle strength, multiple joint contracture (foot, knee, elbow and wrist), and overextension in distal interphalangeal joints. Using a confocal microscopy, partial deficiency of collagen VI in basal lamina was revealed in double-immunofluorescent staining with collagen VI and IV. Conclusions We suggest high-throughput sequencing for genotyping the patients with early-onset multi-joint contracture/overextension and muscle weakness. We also demonstrated two novel missense mutations in collagen VI genes, and rare partial deficiency of collagen VI on basal lamina in two patients with relatively benign phenotype of Ullrich congenital muscular dystrophy.

Searching for the genes of Tourette's: The Tourette International Collaborative Genetics (TIC Genetics) Study. *G.A. Heiman[1,2], T.V. Fernandez[3], P.J. Hoekstra[4], A. Dietrich[4], R.A. King[3], M.W. State[5], J.A. Tischfield[1,2], the TIC Genetics Team.* 1) Dept. of Genetics, Rutgers University, Piscataway, NJ, USA; 2) Human Genetics Institute of New Jersey, Rutgers University, Piscataway, NJ, USA; 3) Yale Child Study Center, Yale University School of Medicine, New Haven, CT, USA; 4) Department of Psychiatry, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands; 5) Department of Genetics, Yale University School of Medicine, New Haven, CT, USA.

The Tourette's International Collaborate Genetics (TIC Genetics) Study unites a group of highly experienced clinicians specializing in Tourette's disorder (TD) with statistical and molecular geneticists with a strong record of collaboration across the United States, Europe, and South Korea. The goal is to conduct a comprehensive genomics study of TD concentrating on the potential contribution of rare and structural variants. We will ascertain over 1500 individuals over three years, focusing on the identification of TD pedigrees with 3 or more affected members and family-based association trios for pedigree-based gene discovery. Blood for DNA, LCLs and iPSCs are being collected as are PAXgene tubes for eventual RNA analyses. The DNA and cell lines will become part of the National Institute of Mental Health (NIMH) Repository at Rutgers University as an international resource. The samples will be initially analyzed by TIC Genetics Study researchers and later made public by the NIMH to qualified scientists around the world to study how genes cause TD. We will present the structure and clinical assessments of the TIC genetics collaboration. In addition, we will present results of the initial multiplex families using a gene discovery method of first genotyping all members of a family with one million SNP probes, using Illumina HumanOmni1-Quad microarrays, to detect copy number variants and to perform an affected-only parametric linkage analysis. Subsequently, we performed whole-exome sequencing of the two most distantly related affected individuals within a family using Illumina GAIIx to assess for shared disruptive variants within the identified linkage peaks. Variants are analyzed against the RefSeq hg19 gene definitions and determined to be nonsense, missense, splice-site, or indels.

Evidence for involvement of *EIF4G1*, not *VPS35* variations in Parkinson Disease. *J. Vance[1,2,3], K. Nuytemans[1,2], G. Bademci[1,2], V. Inchausti[1,2], S. Zuchner[1,2,3], A. Dressen[1,2], C. Jauregio[1,2], D.D. Kinnamon[1], A. Mehta[1,2], Y. Pasco[1], A. Aviram[1], A. Diaz[1], L. Wang[1,2,3], F. Nahab[2,4], C. Singer[2,4], W. Hulme[1], I. Konidari[1], Y. Edwards[1,2], G. Beecham[1,2,3], E.R. Martin[1,2,3], W.K. Scott[1,2,3].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami Florida, USA; 2) Udall Center, University of Miami, Miami Florida, USA; 3) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami Florida, USA; 4) Department of Neurology, Miller School of Medicine, University of Miami, Miami Florida, USA.

INTRODUCTION: Currently 29 genes are reported to be related to Parkinson Disease (PD) through causal mutations or susceptibility factors. It is important for both clinical diagnosis and research to clarify the mode of action (causal or susceptibility factor for PD) of the individual variants in these genes. Recently, *VPS35* and *EIF4G1* have been suggested to act as causal PD genes. Whole exome sequencing (WES) allows for quick, parallel analysis of multiple genes in a large number of individuals. MATERIAL AND METHODS: We performed WES in 213 PD patients and 272 control individuals. Those variants in *VPS35* and *EIF4G1* with <5% frequency in the exome variant server database and our own control data were considered for analysis. We performed single-variant analysis as well as gene-based joint tests of association in the PD cases and controls. RESULTS: We identified three novel VPS35 missense variations in three PD cases. Two were identified in multiplex families and did not segregate with PD. In *EIF4G1*, we identified 11 rare variants (9 nonsynonymous rare variants (nsRV) and 2 small indels), including the reported causal mutation p.R1205H. This variant p.R1205H segregated in all affected individuals in a large family, but also in one unaffected 86 year old family member, suggesting that its mode of action may not be causal with complete penetrance, but rather a strong risk factor. Several novel nsRV were identified in multiplex families but did not segregate with disease. Considering all rare variants and all rare synonymous variants (<5%) in *EIF4G1*, we found evidence of association between the gene and PD (p=0.06 / p=0.02 respectively). DISCUSSION: No strong evidence for a contribution of *VPS35* variability to PD development could be identified in the patient and control groups. In contrast, we confirmed one variant of*EIF4G1* as a very strong risk factor for PD, but WES in our samples demonstrates that other *EIF4G1* variants cannot be considered as having the same major effect. Further data is needed to strengthen the role of these other *EIF4G1* variants in PD.

2604W

Revealing the complex nature of a monogenic disease: exome sequencing of Rett syndrome. *F. Ariani[1], M.A. Mencarelli[1,2], E. Grillo[1], L. Bianciardi[1], I. Meloni[1], C. Di Marco[1], C. Lo Rizzo[1], F. Mari[1,2], A. Renieri[1,2].* 1) Medical Genetics, Dept Biotechnology, Univ Siena, Siena, Siena, Italy; 2) Medical Genetics, Azienda Ospedaliera Universitaria Senese, Siena, Italy.

Diseases previously thought to be monogenic, may be more complex due to interactions among genes, the contribution of environmental factors, incomplete penetrance and expression variability. Phenotypically discordant patients with the same mutation may be used to test the contribution of expression variability. We used “whole exome sequencing” (Illumina platform) to analyze the functional portion of the genome of two pairs of sisters with Rett syndrome. Although each pair of sisters had the same mutation in MECP2, the gene associated with this syndrome, one pair of sisters could not speak or walk and had a profound intellectual deficit (classical Rett syndrome), while the other pair of sisters could speak and walk and had a moderate intellectual disability (Zappella variant). We show that in addition to the MECP2 mutation each patient had hundreds of “private” variations. Three-hundred of these mutations were predicted to impair protein function. Seventy-six damaging variations were exclusive to the classical girls; many were in genes correlated with ATP synthesis, oxidative stress, myopathy, and intellectual disability and/or autism. Sixty damaging variations were exclusive to the Zappella girls; many were in genes associated with immune system modulation (e.g., interleukin and chemokine receptors). These results suggest that the final phenotype in the patients may be the result of mutations in the main gene (MECP2) in combination with other mutations. Specific arrays of mutations may alter clinical outcomes related to speaking, walking and intellectual capability.

2605T

***De novo* indels in Autism Spectrum Disorders.** *S. Dong[1,2], S. Sanders[1], A.J. Willsey[1], M. Murtha[1], N. DiLullo[1], L. Wei[2], M. State[1].* 1) Program on Neurogenetics, Child Study Center, Department of Psychiatry, Department of Genetics, Yale University School of Medicine, New Haven, CT. USA; 2) Center for Bioinformatics, State Key Laboratory of Protein and Plant Gene Research, College of Life Science, Peking University, Beijing, China.

Autism spectrum disorder (ASD) is a highly heritable syndrome characterized by defects in communication, social interaction, and the presence of a restricted or repetitive range of interests or behaviors. Recent research has demonstrated that *de novo* mutations, including large copy number variations (CNVs) and loss of function single nucleotide variations (SNVs), are strongly associated with ASD. Furthermore, recurrent *de novo* mutations have been used to identify specific risk-associated loci such as 16p11.2 microdeletions/duplications and the gene SCN2A. Small *de novo* insertions and deletions (indels) can be predicted with whole-exome sequencing, however this is more technically demanding process than detecting *de novo* SNVs. Using Dindel (Albers *et al.* 2011) we have developed a pipeline for the reliable detection of such *de novo* indels and confirmed the accuracy of this technique with PCR and Sanger sequencing. We present the use of this pipeline for the comprehensive analysis of indels from whole-exome sequencing of 800 individuals from 200 simplex ASD families with discordant sibling pairs. A higher rate of *de novo* indels was observed in affected individuals compared with their unaffected siblings (1.27 × 10-9 vs. 0.38 × 10-9; OR 3.00 (95% CI: 1.09–8.73); P=0.018). The majority of *de novo*indels observed in affected individuals resulted in a reading frame shift and predicted premature translation termination (17 out of 22). No such difference in the rate of *de novo* indels between probands and siblings was observed for non-coding regions (0.78 × 10-9 vs. 0.62 × 10-9; OR 1.15 (95% CI: 0.37–3.60); P=0.79). A *de novo* frameshift indel was observed in DYRK1A (Dual specificity tyrosine-phosphorylation-regulated kinase 1A), a gene in the Down's syndrome critical region on chr21; this observation, alongside two previously identified *de novo* loss of function mutations in ASD cases suggests that this locus is strongly associated with ASD (P<0.005). In summary, we demonstrate that *de novo* indels, identified through whole-exome sequencing, are associated with ASD and can be used to identify genes mediating ASD risk including DYRK1A.

2606F

Resequencing and promoter methylation analysis of the dopamine D2 receptor gene in schizophrenia. *Y. Chuang[1], M. Cheng[1], C. Lu[2], M. Tsai[3], Y. Shen[4], S. Hsu[1], C. Chen[3,5,6].* 1) Department of Psychiatry, Yuli Veterans Hospital, Hualien, Taiwan; 2) Department of Psychiatry, Hualien Armed Forces General Hospital, Hualien, Taiwan; 3) Division of Mental Health and Addiction Medicine, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan; 4) Department of Psychiatry, Tzu-Chi General Hospital-Hualien, Hualien, Taiwan; 5) Department of Psychiatry, Chang Gung Memorial Hospital at Linkou and Chang Gung University School of Medicine, Taoyuan, Taiwan; 6) Institute of Medical Sciences, Tzu-Chi University, Hualien, Taiwan.

Background: Aberrant dopamine D2 receptor (DRD2) function has been implicated in the pathogenesis of schizophrenia, as all the antipsychotics bind to dopamine D2 receptor. The study aimed to examine whether there are genetic variants in the DRD2 gene associated with schizophrenia. Methods: We resequenced the promoter and all the exons of the DRD2 gene in 560 Han Chinese patients with schizophrenia from Taiwan and conducted a case-control association analysis. We also conducted a methylation analysis of partial promoter region of the DRD2 gene of genomic DNA prepared from peripheral blood lymphocytes in 50 patients with schizophrenia and 50 control subjects using pyrosequencing method. Results: We identified 13 known SNPs in this sample, but SNP-based association analysis did not detect an association of these SNPs with schizophrenia. We also identified a rare variant (g.113346421T>C) that was located at the transcription factor AP-2 binding site of the putative core promoter region of the DRD2 gene in 3 patients and 1 control subject. Reporter gene assay showed that the mutant allele has significantly lower activity than the wild type. In the methylation analysis, we found significantly increased methylation of two CpG residues at the GCF and MAZ transcriptional factor binding sites in 50 schizophrenic patients compared to 50 control subjects. Conclusion: Our study suggests that genetic variants of the DRD2 gene appear not to play a major role in conferring susceptibility to schizophrenia in our population. In contrast, change of methylation status of the promoter of the DRD2 gene in patients with schizophrenia warrants further study.

2607W

A comprehensive genetic analysis of 421 Japanese patients with Charcot-Marie-Tooth disease using DNA microarray chips. *A. Hashiguchi, A. Yoshimura, Y. Higuchi, T. Nakamura, S. Tokunaga, Y. Okamoto, H. Takashima.* Neurology and Geriatrics, Kagoshima University Graduate School of Medical and Dental Science, Kagoshima, Japan.

[Objective] To perform genetic diagnosis in Japanese Charcot-Marie-Tooth disease (CMT) patients, and identify the molecular epidemiology in Japan, we created DNA microarray chips with 28 CMT-causative genes identified until 2004, and performed a genetic test in which CMT-causative genes could be identified fast and at low cost. [Methods] We conducted a genetic test in 421 Japanese patients with CMTfrom April 2005 to the end of 2011. Patients with median nerve motor conduction velocities less than 38 m/s and those with median nerve motor conduction velocities more than 38 m/s were classified into a demyelinating type and an axonal type, respectively. Demyelinating type CMT was conditional on absence of PMP22 gene duplication through the FISH method. Genetic abnormalities detected by a test with DNA microarray chips were confirmed with the Sanger method. When new genetic mutations were detected, they were identified as genes responsible for CMT by a segregation study. [Results and Discussion] Electrophysiologic and genetic classification of the 421 patients before genetic diagnosis showed demyelinating type CMT in 106 patients, axonal type CMT in 198, CMTX in 24, and unclassified type CMT in 93. Because patients with CMT1A due to PMP22 gene duplication among those with demyelinating type CMT were excluded, the number of patients with CMT1B due to MPZ gene mutations was 8, the largest number of patients. In the patients with axonal type CMT, the number of those with CMT2A2 due to MFN2 gene mutations was 17, the largest number of patients, and 9 of the patients with CMTX had GJB1 gene mutations. Some of the patients with demyelinating type CMT and axonal type CMT also showed GJB1 gene mutations. It has become possible to analyze 28 causative genes for CMT within a minimum of two days. The positive rate of genetic diagnosis of CMT is as low as 10 to 20%, and many causative genes other than the 28 genes can be considered to exist. In the future, a comprehensive genetic diagnosis system using next-generation sequencing technology is expected. [Conclusion] An analysis of DNA microarray chips enabled a well-known comprehensive CMT screening test, which led to the confirmation of distribution of genetic abnormalities in Japanese patients with CMT. Further improvement of genetic diagnosis systems is necessary. A comprehensive genetic diagnosis system using next-generation sequencing technology is expected.

2608T

A new frameshif mutation in the dopamine receptor D4 exon III VNTR 7-repeat allele. *D.S.S. Lobo[1, 2], M. Tampakeras[1], N. Freeman[1], J.L. Kennedy[1, 2].* 1) Neuroscience Dept., Neurogenetics Lab., Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Dept. of Psychiatry, University of Toronto, Toronto, Ontario, Canada.

A 48bp VNTR in exon III of the DRD4 gene has been implicated as an important genetic factor in psychiatric disorders. Several studies, including LaHoste et al.(1996), have shown a significant association between the 7-repeat allele (7R) and attention-deficit hyperactivity disorder (ADHD). Previously, studies have reported substantial sequence variation within the exon III VNTR repeat motif and across the various alleles characterized on the basis of length (Lichter et al 1994, Ding et al. 2002). In a recent study of DRD4 exon III VNTR sequence variation in subjects with ADHD, Tovo-Rodrigues et al.(2012) found that the 7R allele had significantly more sequence variation than the 4-repeat allele (4R), and suggested that the DRD4 VNTR region be routinely examined for both size polymorphisms and sequence variants in studies of ADHD and other impulse control disorders. Our objective was to sequence the DRD4 exon III VNTR region for new sequence variants and to investigate which of the previously reported variations within the 48-bp motif were present in a sample of impulsive subjects diagnosed with pathological gambling. Methods: We sequenced 156 individuals who were previously genotyped as 2R(N=4), 4R(N=141) or 7R(N=11) homozygotes to assess the amount of sequence variation in this region using standard Sanger sequencing. Results: Sequencing the DRD4 region in our sample yielded similar results to Ding et al.(2002) and Tovo-Rodrigues et al.(2012); individuals homozygous for the number of repeat motifs showed sequence variation within motifs and in the arrangement of the motifs within alleles characterized previously by the number of repeats. Of particular interest was a 1bp heterozygous deletion observed in 2 subjects homozygous for the 7R allele. In the first subject the 21st bp of the 1st repeat motif was deleted. In the second subject the 21st bp of the 3rd repeat motif was deleted. In both cases the deleted nucleotide was an adenine. Although the deletions are located in 2 different repeat units, both deletions occur at the same position within the repeat units. In silico analysis showed that this deletion causes a premature stop codon and truncated predicted amino acid sequence. No deletions were found in 2R or 4R homozygotes. The high frequency of this frameshift mutation in 7R homozygotes (2/22 alleles= 9%) is noteworthy and may explain, at least in part, conflicting results in the association of this particular allele with impulse control disorders.

SPG4 mutations in Brazilian patients with hereditary spastic paraplegia. *I. Lopes-Cendes[1], D.B. Dogini[1], C. Cartaxo[4], S. Raskin[4], H.A.G Teive[4], J. Saute[3,6], L.B. Jardim[3,5,6], M.C. França Jr[2].* 1) Department Medical Genetics, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, SP, BRAZIL; 2) Department of Neurology, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, SP, BRAZIL; 3) Post-graduation program in Medical Sciences, Universidade Federal do Rio Grande do Sul, RS, BRAZIL; 4) Department of Internal Medicine,Universidade Federal do Paraná, Curitiba, PR, BRAZIL; 5) Department of Internal Medicine, Universiade Federal do Rio Grande do Sul. Porto Alegre, RG, BRAZIL; 6) Medical Genetics Service, Hospital de Clinicas de Porto Alegre, RS, BRAZIL.

Hereditary spastic paraplegia (HSP) belongs to a group of neurodegenerative diseases that represent a significant number of patient visits to a neurogenetics clinic. With a prevalence of 3.8 cases:100,000. HSP has a predominant manifestation of progressive weakness associated with spasticity in the lower limbs and a strong genetic substrate. The pattern of inheritance may be autosomal dominant (AD), autosomal recessive (AR) or X-linked. The objective of this study is to determine the frequency of SPG4-HSP among Brazilian patients with AD-HSP and to identify mutations associated with the disease in this population. We recruited 34 families with AD-HSP at the neurogenetics clinics of three university hospitals; patients underwent a complete clinical evaluation as well as detailed family history. Genomic DNA was extracted from lymphocytes and used in PCR reactions with primers designed to cover the 17 exons of the SPG4 gene. Mutation screening was performed by automatic sequencing and MLPA. We found five potential deleterious mutations in SPG4: c.1413 +5 G> A (splicing-site mutation), c.1255G> T (nonsense), c.1267G> T (missense), c.1849T> G (nonsense) and c.839delA (frameshift). Each variant was found in only one single family. Among the variants found, the mutation c.1255G> T, is reported here for the first time. We found SPG4 mutations in approximately 15% of the families with AD-HSP studied; this represents a smaller proportion compared to the frequency reported in Europe and the USA.

2610W

Changes in the Human Transcriptome Caused by LMNB1 Duplication in a Case of Autosomal Dominant Leukodystrophy: An RNASeq study. *P. Cherukuri[1], D. Simeonov[1], K.V. Fuentes-Fajardo[1], P. Zumbo[2], C. Mason[2], S. Lin[3], Y.H. Fu[3], C. Boerkoel[1], T. Markello[1], W. Gahl[1], C. Toro[1].* 1) Undiagnosed Diseases Program, NHGRI / NIH, Bethesda, MD; 2) Department of Physiology and Biophysics, Weill Medical College, Cornell University, New York, NY; 3) Department of Neurology, University of California, San Francisco, San Francisco, California.

Autosomal dominant leukodystrophy (ADLD) is a rare, progressive, adult-onset demyelinating disorder caused by duplications of the nuclear lamina gene, lamin B1 (LMNB1). LMNB1 is part of the stable fibrous meshwork of intermediate filaments (IFs) that underlie the nuclear membrane, forming the lamina. In addition, LMNB1 is tethered to chromatin at lamina-associated domains and has a role in the regulation of gene expression and gene silencing. In this study, we investigated the global impact of LMNB1 locus duplication on the expression profile of the poly-adenylated RNA fraction of the human transcriptome using massively parallel sequencing (RNASeq). 100ng of high-quality total RNA (RIN>0.8) for each experimental condition was isolated from primary fibroblast cell lines, and cDNA was prepared with the TruSeq mRNA prep kit (v2). Multiplexed cDNA libraries for each triplicate sample (2 samples (1 case & 1 normal); 6 datasets) were sequenced to 50×50 bp on the Illumina HiSeq2000, and post-processed with CASAVA (v1.8.2). Raw data were filtered for high-median quality (Q-value > 20) and then a total of 426 million paired-end (PE) reads (~71 million PE reads per-replicate) were processed on a High Performance Computing (HPC) cluster (SGE) through different RNASeq analysis pipelines (PPBS and ERANGE). Gene expression was quantified as reads-per-kilobase-per-million (RPKM). To test for dysregulation or disruption of gene-expression profiles of clusters of genes in genomic neighborhoods, we developed a computational approach to detect movement of genes' transcription outside of a stable boundary condition. Using this approach, we found that ~80 highly reproducible gene-clusters were significantly dysregulated. These clusters were significantly enriched (P-value=4.7e-29; hypergeometric distribution) for chromatin regions associated with interaction with the lamina. We are pursuing exploring the mechanism underlying these alterations in expression and evaluating genes within these boundaries for robustness of differential expression. This study presents a hypothesis for the mechanism underlying the neurodegeneration.

Exome sequencing of young onset sporadic amyotrophic lateral sclerosis trios. *A.E. Renton[1], J.R. Gibbs[1], J.O. Johnson[1], M.A. Nalls[1], C. Sassi[1], Y. Abramzon[1], C. Edsall[1], G. Restagno[2], M. Sabatelli[3], A. Chiò[4], B.J. Traynor[1].* 1) Neuromuscular Diseases Research Unit, Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD; 2) Molecular Genetics Unit, Department of Clinical Pathology, A.S.O. O.I.R.M.-S. Anna, Turin, Italy; 3) Institute of Neurology, Catholic University of the Sacred Heart, Rome, Italy; 4) Department of Neuroscience, University of Turin, Turin, Italy.

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease. Known pathogenic mutations explain ~65% of familial ALS (FALS) and ~10% of sporadic ALS (SALS). In order to identify *de novo* and recessive mutations putatively underlying SALS, we undertook exome and dideoxy sequencing in a cohort of 19 disease trios from Italy. Each trio consisted of two unaffected parents and one offspring diagnosed with young onset SALS. Gene validation was performed using exome and dideoxy sequence data from 146 unrelated FALS probands. All novel variants were filtered against 1000 Genomes, 150 in-house population exome controls, and 5600 population controls obtained from the Exome Sequencing Project cohort. We confirmed eleven *de novo* and eight recessive non-synonymous mutations in nine trios. Almost all of these were single base alterations, and seven trios carried multiple changes. Two genes exhibiting single *de novo* mutations each harboured two heterozygous non-synonymous mutations in two FALS cases. These findings suggest that we have identified one or more novel ALS genes, and demonstrate the power of the trio-exome paradigm for elucidating the genomic architecture of complex disorders.

2612F

PRRT2 gene missense mutations account for both paroxysmal kinesigenic dyskinesia and infantile convulsions in a Chinese pedigree. *C. Cai[1], W.D. Li[2].* 1) Department of Surgery, Tianjin Children's Hospital, Tianjin, Tianjin, China; 2) Center of Basic Medical Sciences, Tianjin Medical University, Tianjin, China.

Paroxysmal kinesigenic dyskinesia is an autosomal dominant dystonia induced by sudden voluntary movements. Recently, proline-rich transmembrane protein 2 gene mutations, especially frameshift mutations, were described for PKD. Methods: A three-generation paroxysmal kinesigenic dyskinesia -infantile convulsions pedigree was collected in Tianjin, North China. The symptoms of six patients varied; age of onset decreased in each generation. Mutations in the proline-rich transmembrane protein 2 gene in nine PKD family members were screened by PCR sequencing of genomic DNA samples. Results: Missense mutations of the proline-rich transmembrane protein 2 gene were found in all four PKD patients and two children with infantile convulsions. All six individuals carried heterozygous codon 138 (Pro/Ala) and codon 306 (Ala/Asp) mutations. Conclusions: Mild mutations of the proline-rich transmembrane protein 2 gene other than truncate and frameshift mutations were account for PKD and/or infantile convulsions. Age of onset and symptoms were not necessarily associated with proline-rich transmembrane protein 2 mutations.

2613W

Whole-exome sequencing and homozygosity analysis to dissect autism, a complex genetic disorder. *M.H. Chahrour[1,2,3,4,5], T.W. Yu[1,2,3,4,5,6], E.T. Lim[5,7,8], B. Ataman[9], M.E. Coulter[1], R.S. Hill[1,2,3], C.R. Stevens[5], C.R. Schubert[1,2,3,4,5], ARRA. Autism Sequencing Collaboratio[10], M.E. Greenberg[9], S.B. Gabriel[5], C.A. Walsh[1,2,3,4,5,6].* 1) Division of Genetics, Department of Medicine, Children's Hospital Boston, Harvard Medical School, Boston, MA; 2) Manton Center for Orphan Disease Research, Children's Hospital Boston, Boston, MA; 3) Howard Hughes Medical Institute; 4) Department of Pediatrics, Harvard Medical School, Boston, MA; 5) Program in Medical and Population Genetics, Broad Institute of Massachusetts Institute of Technology and Harvard University, Cambridge, MA; 6) Department of Neurology, Harvard Medical School, Boston, MA; 7) Biological and Biomedical Sciences Program, Harvard University, Boston, MA; 8) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 9) Department of Neurobiology, Harvard Medical School, Boston, MA; 10) The ARRA Autism Sequencing Consortium.

Autism is a neurodevelopmental disorder characterized by impaired communication skills, social behavior abnormalities, and stereotypies. Despite the clear genetic component of autism, extreme genetic heterogeneity has made it difficult to identify causative genes. We quantified runs of homozygosity in probands from 1000 families from the Autism Genetic Research Exchange (AGRE) collection, in order to identify those with potential recessive mutations due to distant shared ancestry. Whole-exome sequencing of the top sixteen probands with the highest percent of homozygosity (~1–9%) in their genomes revealed homozygous, potentially pathogenic recessive mutations in four families. The mutations were extremely rare (absent from the 1000 Genomes project, dbSNP130, NHLBI ESP, and a database of 831 exomes), validated, and segregated perfectly with disease. We screened our candidate genes in a larger independent cohort of whole exome data from 418 autism cases and 371 controls, sequenced as part of the ARRA Autism Sequencing Consortium, and identified a modest excess of rare recessive variants (homozygous or compound heterozygous) in cases (24/418, 5.7%) versus controls (11/371, 3.0%) (P = 0.042, Fisher's exact test, one-tailed). The novel candidate genes (*UBE3B*, *CLTCL1*, *NCKAP5L*, *ZNF18*) encode proteins involved in proteolysis, GTPase-mediated signaling, cytoskeletal organization, and other pathways. We show that the transcription of these genes is regulated by neuronal depolarization, suggesting potential activity-dependent roles in neurons. One of the identified mutations is a homozygous missense change in the HECT domain of UBE3B, ubiquitin protein ligase E3B, a member of the E3 ubiquitin-conjugating enzyme family that is highly expressed in the brain. Its paralog *UBE3A* is disrupted in Angelman syndrome, a neurodevelopmental disorder characterized by intellectual disability, movement or balance problems, abnormal behaviors, and speech and language impairment. Our strategy of combining homozygosity analysis with whole-exome sequence data identifies candidate recessive mutations in autism, and may have broader applicability to other complex, heterogeneous disorders.

Gene-Based Rare Variant Analyses Reveal Loci Associated with Autism Spectrum Disorder. *N. Dueker[1], E.R. Martin[1,2], A.J. Griswold[1], H.N. Cukier[1], S. Slifer[1], J. Jaworski[1], I. Konidari[1], P.L. Whitehead[1], M. Schmidt[1], D.J. Hedges[1,2], D. Martinez[1], S. Clarke[1], M.L. Cuccaro[1,2], J.R. Gilbert[1,2], J.L Haines[3], M.A. Pericak-Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL, USA; 3) Vanderbilt University School of Medicine, Vanderbilt University, Nashville, TN, USA.

Background: Autism spectrum disorder (ASD) is a developmental disorder characterized by social, communicative and behavioral impairments leading to average yearly medical costs that are 4.1–6.2 times higher for those with an ASD compared to those without. Despite demonstrating high heritability estimates, only a small proportion of the genetic risk for ASD is explained. Rare variants are hypothesized to have large effect sizes and may contribute to ASD risk. Therefore, we analyzed rare variant data to identify loci associated with ASD. Methods: Participants were drawn from a large, family-based study of ASD and included 944 unrelated cases and 467 controls that were genotyped using the Illumina HumanExome-12v1 Array. This array includes coding region variants across the genome, with a majority of variants (88%) being rare (MAF <5%). We performed gene-based analyses where we tested autosomal genes genotyped on the Array for association with ASD. The sequence kernel association test (SKAT) was used for these analyses, with covariate adjustment for the first three principal components. We also tested 21 pathways previously associated with ASD in copy number variant (CNV) analyses, for association in our study using SKAT. Results: Study participants were primarily male (73.1%) and of self-reported White race (87.4% of cases and 82.4% of controls). Mean age between cases and controls was similar (16.0y for cases and 15.4y for controls). Of the 16,906 genes analyzed, 15 showed p-values <0.001 in the total sample analyses. Two of these genes fall within pathways associated with ASD in CNV analyses, *PODN*(p=0.0002) and *GPSM3* (p=0.0003). In race-stratified analyses, 19 genes showed p-values <0.001 among Whites and 31 genes showed p-values <0.001 among Blacks. None of the 21 tested were associated with ASD. Discussion: Autism spectrum disorders are complex traits, known to be influenced by several genes. Rare variants are thought to exert large influences on disease risk therefore making their study of great importance. In our analysis of rare variants, we identified several genes of interest. Two moderately associated genes fall within two pathways associated with ASD in CNV analyses;*PODN* which falls within a cell motion pathway (GO:0006928) and *GPSM3* which falls within a GTPase activator activity pathway (GO:0005096). These results suggest that rare variants play a role in ASD.

2615F

Data sharing in the genomic age: Genome Variant Database for Neuromuscular Diseases. *M. Gonzalez, R.F. Acosta Lebrigio, S. Zuchner.* John P. Hussman Institute for Human Genetics and Genomics, Unviersity of Miami Miller School of Medicine, Miami, FL.

Many rare neuromuscular diseases (NMDs) show an impressive Mendelian locus and allelic heterogeneity. Yet, known genes still explain only a fraction of many phenotypes. New genomic approaches, such as exome sequencing have significantly increased our ability to identify the remaining, often very rare genes. To further facilitate the study of rare genes we have identified the need for a data-sharing platform for exome/ genome sequencing results. Such a platform requires: 1) ease of access to allow the participation of a wide range of investigators (geneticists, biologists, physician scientists), 2) data protection to prevent non-intended mass downloads and genetic profiling, 3) central data processing under a standard pipeline to guarantee high data quality, and 4) openness to the participation of multiple investigators. We have developed the Genome Variant Database for Neuromuscular Diseases (GVD-NMD), which represents an online public database containing thoroughly annotated de-identified whole exome data from a number of neuromuscular disorders. Our current focus is on inherited disorders of the longest neuronal axons, which are clinically categorized under hereditary spastic paraplegias (HSP) and inherited peripheral neuropathies, also known as Charcot-Marie-Tooth disease (CMT). Currently, GVD-NMD contains 245 samples and hopes to encompass 500–750 exomes by the end of 2012. A conservative set of filters has been applied to limit the number of rare variants to those of interest to the majority of rare variant Mendelian studies. Current filters are as follows: minor allele frequency in NHLBI EVS <1%, minor allele frequency in GVD-NMD <5%, GERP score > 0 OR PhastCons score > 0.3, GATK quality scores (DP ≥ 10, QUAL ≥150, GQ ≥75), and segregation in available families. To date GVD-NMD contains 77,238 variants (SNVs and indels) in 14,926 genes, which represent 51,812 unique variants (48,783 SNVs, 3,029 indels). We see three principle uses of GVD-NMD: 1) human geneticists discover rare variants that further support their top candidate genes, 2) basic scientists identify disease associated variants in genes of functional interest, and 3) physician scientists and medical geneticists identify rare alleles in known genes not yet reported. We believe that sharing of genome-scale data in innovative ways will foster collaborations and lead to more efficient identification of novel disease alleles and genes.

X-linked Charcot-Marie-Tooth disease type 1 in Japan: genetic, clinical, and electrophysiological study of 33 cases. *Y. Higuchi, A. Yoshimura, T. Nakamura, S. Tokunaga, A. Hashiguchi, Y. Okamoto, H. Takashima.* Department of Neurology and Geriatrics, Kagoshima University Graduate School of Medical and Dental Science, Kagoshima City, Kagoshima, Japan.

Objective: To investigate the clinical heterogeneity of X-linked Charcot-Marie-Tooth disease type 1 (CMTX1), which is caused by various mutations in the gap junction beta 1 (*GJB1*) gene.**Methods**: Thirty-three Japanese patients with CMTX1 were genetically, clinically, and electrophysiologically examined. All *GJB1* mutations were screened by an originally designed microarray resequencing DNA chip and confirmed by Sanger sequencing. **Results**: Thirty-three patients showed mutations in GJB1. The mutations included 14 missense mutations, one nonsense mutation, four deletions, and one insertion. Six mutations were not reported previously: N2T, S42C, L76R, K103N, S138R, and V192D. Heterozygous female were asymptomatic or less severely affected than male. The severity of the CMT clinical phenotype did not correlate with the location and type of mutation in GJB1. A distinct phenotypic variability was observed even among patients with the same genotype (e.g., R22Q). In addition to peripheral neuropathy, nine patients had symptoms and signs of central nervous system involvement, presenting with hearing loss, transient episodes of hemiparesis, ataxia, and dysarthria. One patient had chronic inflammatory demyelinating polyneuropathy. Electrophysiological study of 27 patients revealed that 14 showed demyelinating neuropathies, six showed intermediate, and seven showed axonal neuropathies. **Conclusion**: We identified six novel mutations in GJB1. The clinical phenotype of CMTX1 was variable, and significant genotype-phenotype correlation was not possible. These findings suggest that not only loss of function of GJB1 but also some gain of function may be related to the pathogenesis of CMTX1.

Autism spectrum disorders (ASD) are a group of neurodevelopmental conditions characterized by impaired social interaction and communication and by restricted and repetitive behaviors. The latest statistics from the Center for Disease Control indicate one in 88 children in the United States is diagnosed with ASD with worldwide data showing similar trends. Genetic variation contributes an important role in the etiology of ASD, and both de novo and inherited variations have now been identified affecting ASD risk. Recent estimates place the number of susceptibility genes for ASD in the hundreds, and discovering these genes is an urgent goal in the field. We have initiated an international endeavor called the Autism Genome 10K-Project, which aims to sequence the genomes from 10,000 individuals belonging to 2,000 ASD families from Autism Speaks Autism Genetic Resource Exchange (AGRE) and 1000 Chinese ASD families. In an initial pilot study, whole genome sequencing (WGS) was performed in 33 father-mother-ASD child trios of European ancestry (99 individuals), and in a second phase in 33 father-mother-ASD child trios of Chinese ancestry (99 individuals). All ASD subjects were diagnosed using gold standard tools, Autism Diagnostic Interview Revised and Autism Diagnostic Observation Schedule. WGS was performed at BGI using Illumina HiSeq technology yielding ~30X coverage used for the initial analyses. For the first 33 families of European ancestry our first pass analysis used the GATK program to detect SNP and INDEL variants. For each individual, ~4.2M putative SNPs and ~0.89M putative INDELs were identified, of which 1% were annotated in exonic intervals of the genome. The analysis of copy number variants is in progress. We detected roughly 1 de novo SNP in the exome of the individuals with ASD, findings consistent with other (mainly exome sequencing) studies. By scanning across the genome we can infer 400 candidate de novo SNPs, on average, in each trio (we expect this number to be diminished by additional filtering, which is in progress). We are currently experimentally validating all de novo exonic variants and interesting rare inherited variants affecting relevant coding and non-coding segments of the genome. A comparative genome analysis of Caucasian and Chinese ASD families is planned. We will present our complete data analysis from this pilot phase of project, as well as additional progress in the Autism Genome 10K-Project.

Analysis of low-frequency, protein altering variation in 13,000 individuals from a Swedish schizophrenia cohort on the exome array. *B.M. Neale[1,2,3], J. Goldstein[1,2], C. O'Dushlaine[3], M. Fromer[1,3,4], G. Genovese[3], J.L. Moran[3], K. Chambert[3], C.M. Hultman[5], P. Sklar[4], S. Purcell[1,2,3,6], M.J. Daly[1,2], P.F. Sullivan[7], S. McCarroll[3,8].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Program in Medical and Population Genetics, the Broad Institute of Harvard and MIT, Cambridge, MA; 3) Stanley Center for Psychiatric Research, the Broad Institute of Harvard and MIT, Cambridge, MA; 4) Division of Psychiatric Genomics, Mount Sinai School of Medicine, New York, NY; 5) Department of Medical Epidemiology, Karolinska Institutet, Stockholm, Sweden; 6) Deparment of Psychiatry, Harvard Medical School, Boston, MA; 7) Department of Genetics, Psychiatry, and Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill,; 8) Deparment of Genetics, Harvard, Boston, MA.

The recently developed exome chip array enables the assessment of low-frequency coding variation. Containing approximately 250,000 variants drawn from whole genome and exome sequencing of 12,000 individuals, this array enables assessment of ~200,000 missense, ~5,500 nonsense, and ~10,000 splice site mutations. Consequently, we assess the role of coding variation in a large population derived sample of schizophrenia. We genotyped over 13,000 individuals drawn from the Swedish Schizophrenia Study on the Illumina Infinium HumanExome BeadChip. Using a subset of samples for whom exome sequencing and exome chip genotype data are available, we designed zCall to improve low-frequency variant genotyping. Based on comparisons with sequencing, ~99% of variants with a singleton on the chip (i.e. only one heterozygote observed) in 947 individuals were called with a single heterozygote in the correct individual. Similarly, approximately 75% of the coding variation within an individual was captured. The overwhelming majority of the variation on the assay is low-frequency, with ~46% of the sites invariant and another ~25% variable sites having fewer than 10 copies. We identified a significant subset of the sample of apparent Finnish ancestry enabling the identification of low-frequency functional variation significantly increased in Finland due to the limited founder population. We present single SNP association analysis using both logistic regression with principal components and a mixed model incorporating genome-wide similarity. Beyond single locus association, we also describe regional association analyses, combining evidence for association across a gene, testing for recessive disease models, and critically evaluating loss of function alleles. While our analysis is provisional as of the date of submission of this abstract, the results to date suggests that at most a few (and possibly no) protein-altering alleles influence schizophrenia in Sweden with an effect size that makes them detectable at genome-wide significance in a cohort of 13,000. The exome array allows large scale analysis of functional variation. The data generated here demonstrate that this assay performs well and captures most of an individual's variation. Furthermore, these results bound how much standing coding variation influences schizophrenia in Sweden and provide context for previously reported genome-wide association results, partly addressing the question of synthetic association.

Search for rare-variant risks of Parkinson's disease by sequencing of candidate genes and exome sequencing. *W. Satake[1], Y. Suzuki[2], Y. Ando[1], T. Nishioka[1], K. Syoji[1], H. Tomiyama[3], M. Yamamoto[4], M. Murata[5], N. Hattori[3], S. Sugano[2], T. Toda[1].* 1) Div of Neurology, Kobe Univ Grad Sch Med, Kobe, Japan; 2) Dept of Med Genome Sci, the Univ of Tokyo, Japan; 3) Dept of Neurology, Juntendo Univ Sch Med, Tokyo, Japan; 4) Dept of Neurology, Kagawa Pref Cent Hosp, Takamatsu, Japan; 5) Dept of Neurology, Natl Cent Hosp of Neurology and Psychiatry, Kodaira, Japan.

Parkinson's disease is one of the most common neurodegenerative diseases worldwide, mainly manifesting motor impairment due to degeneration of dopamigenic neurons. Heterozygous mutations in the GBA gene, whose homozygous mutations cause one of lysosomal disorders Gaucher's disease, have been reported as strong risk factors for Parkinson's disease. In addition, some patients with Gaucher's disease have been reported to manifest parkinsonism as a part of Gaucher's symptoms. Here, we examined whether other causative genes for lysosomal diseases or diseases showing parkinsonism can be genetic risks for Parkinson's disease. We selected 13 genes as candidates of genetic risks for Parkinson's disease; 8 lysosomal disease (GM1-gangliosidosis, GLB1; Tay Sacks, HEXA; Sandhoff, HEXB; Fabry, GLA; Metachromatic leukodystrophy, ARSA; Krabbe, GALC; Niemann-Pick, NPC1; Adrenoleukodystrophy, ABCD1) and 5 diseases with parkinsonism in part of the symptoms (Wilson, ATP7B; Creutzfeldt-Jacob, PRNP; FTDP-17, MAPT; Hallervorden-Spatz, PANK2; Choreacanthocytosis, CHAC). We further selected 34 exons from these 13 genes, which have major and high-frequent causative mutations for each disease, including 714 known causative mutations and variants, and re-sequenced them by Sanger method using DNA samples of 541 Parkinson's disease cases (500 sporadic and 41 familial cases). In our patients' sample, the mutations and variants were detected in 7 genes; HEXB, GLA, ARSA, GALC, ATP7B, PRNP, and MAPT. We tested allele frequencies between cases and controls by x2 statistics; however no significant association was obtained in each SNV; P= 0.934, 0.808, 0.359, 0.097, 0.059, 0.502, and 0.154 respectively. Moreover, we tested exome-sequensing for a pair of an affected sibling in order to extract candidate SNVs as Parkinson's disease-risks. We extracted 50Mb exome by Agilent Sureselect and performed massive parallel sequencing using Hiseq2000. After BWA mapping, GATK SNV calling, and dbSNPs filtering, we detected novel 690 and 694 SNVs in each case sample. Of these, 321 SNVs were matched in the sibling, which may contain candidates for risk variants for PD. Furthermore, to identify rare-variant risks, we are now performing exome-sequencing of several hundreds of Parkinson's disease cases.

Rare combination of inherited mutations in a large multigenerational pedigree with autism spectrum disorder (ASD) and co-morbid neurodevelopmental disorders. *P. Szatmari[1], O. Migita[2], I. O'Connor[1], A. Prasad[2], D. Sato[2], S. Walker[2], A. Thompson[1], S.W. Scherer[2], D. Pinto[2,3].* 1) Dept Psychiatry, Chedoke Site, McMaster Univ, Hamilton, ON, Canada; 2) The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada; 3) Departments of Psychiatry, and Genetics and Genome Sciences, Mount Sinai School of Medicine, NY, USA.

Autism spectrum disorders (ASD) are a heterogeneous group of neurodevelopmental disorders with a complex inheritance pattern. Rare copy number variations (CNVs) and sequence-level mutations have been identified as etiologic factors in ASD. Here we report the genetic analyses of a large multigenerational family composed of an index case presenting autism, low functioning and epilepsy. Initial whole-genome SNP array and whole-exome resequencing analyses found that the index case carries two inherited rare variants in keeping with the `multiple-hit model' for ASD: a maternally inherited *NRXN1* premature stop mutation not seen in dbSNP, 1000GP and 6,000 unrelated controls, and a paternally inherited 15q11.2 (BP1-BP2) deletion. Neither of these rare variants was seen in the two unaffected siblings. The *NRXN1* gene encodes an adhesion protein important in synapse development/function, and has been associated with neurodevelopmental disorders. The 15q11.2 deleted region has been associated with a number of neurological disorders, including epilepsy, and contains the *CYFIP1* gene that codes for a protein that binds FMRP, the protein missing in fragile X syndrome. Clinical history and phenotype assessment are being collected for both maternal and paternal sides of the extended family. At least 8 additional nuclear pedigrees with autism across four-generations have already been identified. On the father's side, there are also two kinships with epilepsy and a kinship with Tourette syndrome. To evaluate the segregation of these rare variants in the extended family, we further genotyped nuclear families with affected children with Illumina 1M or 2.5M arrays, and whole-genome sequencing is planned for two kinships. We expect that integration of the various genetic analyses coupled with deep phenotyping will aid in establishing genotype-phenotype correlations.

2621F

Resequencing of 17 genes in the N-methyl-D-aspartate (NMDA) glutamate system to identify rare variants affecting risk of substance dependence. *P. Xie[1,4], H.R. Kranzler[5], J.H. Krystal[2,4], L.A. Farrer[6], H. Zhao[1,3], J. Gelernter[1,2,4].* 1) Departments of Genetics, Yale University School of Medicine, New Haven, CT; 2) Departments of Psychiatry, Yale University School of Medicine, New Haven, CT; 3) Department of Epidemiology and Public health, Yale University School of Medicine, New Haven, CT; 4) VA CT Healthcare Center, West Haven, CT; 5) Department of Psychiatry, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; VISN 4 MIRECC, Philadelphia VAMC, Philadelphia, PA; 6) Departments of Medicine (Biomedical Genetics), Neurology, Ophthalmology, Genetics and Genomics, Epidemiology, and Biostatistics, Boston University School of Medicine and Public Health, Boston, MA.

As for most common traits, common variants found by association studies explain only a small fraction of the heritability of substance dependence (SD) risk. In this study, we aimed to identify rare variants in genes important in the NMDA glutamate receptor system, and explore their possible relationship to alcohol, cocaine and opioid dependence (AD, CD, and OD). Glutamate is the major excitatory neurotransmitter in the brain. NMDA receptors are known to play important roles in SD. We selected 17 genes involved in the system: three NMDAR subunit genes (*GRIN1*, *GRIN2A*, and *GRIN2B*), ten genes encoding protein kinases, phosphatase and palmitoyltransferase that perform post-translational modifications of NMDAR (*FYN*, *SRC*,*PRKCG*, *PTPN5*, *PPP1CA*, *PPP1CB*, *PPP1CC*, *PPP1R1B*, *PPP1R9B*, and *ZDHHC3*), and four genes encoding proteins that regulate NMDAR function (*DISC1*, *NRG1*, *DAOA*, and *DTNBP1*). We used a pooled sequencing design (20 subjects of the same sex and population and with phenotypes of AD, OD, and CD in each pool; Illumina HiSeq), and sequenced the coding regions and the flanking intronic regions with high coverage in 760 cases with all three substance dependence diagnoses and 760 healthy controls. A total of 454 variants, including 380 rare variants (minor allele frequency ≤ 1% in both EAs and AAs) were identified. The transition/transversion ratio was 3.50, consistent with results from the 1000 Genomes Exon Pilot Project, indicating likely low false-positive variant identification. Based on case-control allele count differences, we selected 17 exonic rare variants and genotyped them using the TaqMan method in 6751 subjects for follow-up and the 1520 subjects from the sequencing stage for validation. The 17 rare variants were found in at least three more case pools than control pools, or vice versa. Eleven of them were successfully genotyped, and all variants called in the sequencing stage were validated. Using the Sequence Kernel Association Test (SKAT; Wu M.C., *et al.* 2011) in the 8271 subjects, we found a statistically significant cumulative association between the 11 rare variants and OD in AAs (P=0.00080). Results from gene-based association tests showed that the association signal derived mostly from *DISC1* (P= 0.0010) and *GRIN2B* (P=0.00085). The three *DISC1* rare variants investigated were largely limited to AAs. We conclude that rare variation in the set of genes we selected contributes significantly to OD risk in AAs and potentially in other populations.

Widespread novel RNA editing in human brain tissue, identified by RNA-Seq. *L. Hou[1], N. Akula[1], J. Wendland[1], D.T. Chen[1], X. Jiang[1], K. Choi[2], B.K. Lipska[3], J.E. Kleinman[3], F.J. McMahon[1].* 1) Human Genetics Branch, National Institute of Mental Health Intramural Research Program, National Institutes of Health, US Dept. of Health and Human Services, Bethesda, MD USA; 2) Department of Psychiatry, Uniformed Services University of the Health Sciences, Bethesda, MD USA; 3) Section on Neuropathology, Clinical Brain Disorders Branch, NIMH-IRP, National Institutes of Health, US Dept of Health and Human Services, Bethesda, MD USA.

RNA editing is a post-transcriptional process that alters the sequence of primary RNA transcripts. Previous studies have shown that RNA editing occurs in the brain and may be a key regulator of neural development. Dysregulation of RNA editing might also be associated with some psychiatric disorders. Recent advances in high-throughput sequencing technology have made it possible to study RNA editing on a genome-wide scale. In this study, poly(A)$^+$ RNA extracted from postmortem dorsolateral prefrontal cortex of 11 unaffected controls and 10 individuals with bipolar disorder (BP) was sequenced on an Illumina GA-IIx or HiSeq 2000 platform. Paired-end reads were aligned to the reference human genome (hg19) by GSNAP, with all known splice sites provided (based on RefSeq Genes). Single nucleotide variants (SNVs) were called with GATK Unified Genotyper. To reduce false positive calls from paralogous sequences, only uniquely mapped reads were used. Additionally, a series of filters based on read depth, strand bias, mapping quality, and read position were used to remove false positive calls stemming from mapping or sequencing errors. The remaining SNVs were filtered against known variants in dbSNP135, the 1000 Genomes Project, and the NHLBI Exome Sequencing Project. The mRNA levels of the adenosine deaminase encoding genes, ADAR1, ADAR2, and ADAR3, were quantified by Cufflinks. On average, 9516 ± 248 RNA editing sites were identified in each individual, about 10% of which could be found in the DAtabase of RNa EDiting (DARNED). Most of the putative RNA editing sites were canonical A-to-I editing sites, and were located in 3'-UTR, consistent with known RNA editing sites. Individuals with BP did not differ in the total number of RNA editing sites or in the proportion of identified sites in DARNED. Overall, the proportion of edited reads was lower in individuals with BP. Consistent with this, we observed decreased expression of ADAR2 in brain tissue from individuals with BP (p=0.008 and p=0.038 in the GA-IIx and HiSeq data, respectively). This study shows that RNA-seq data can be used to identify RNA editing sites in postmortem brain, these sites appear to be widespread across the genome, and many are novel. Very stringent data analysis methods are required to avoid false calls, especially when as in this study DNA sequencing data are not available. Decreased ADAR2 expression, if replicated, suggests that RNA editing might be involved in BP.

2623T

Association of the polymorphisms of ITPK1 gene in inositol metabolic pathways with NTDs. *Z. Guan, JH. Wang, J. Guo, F. Wang, XW. Wang, GN. Li, Q. Xie, X. Han, B. Niu, T. Zhang.* Department of biotechnology, Capital Institute of Pediatrics, beijing, CH., China.

Neural tube defects (NTDs) are common and severe malformations that is multifactorial, involving the combined action of both genetic and environmental factors. Maternal nutritional status(myo-inositol) is associated with the occurrence of NTDs. Myo-inositol and related genetic factors are suggested to be implicated in the etiology of NTDs. Inositol, 1,3,4-trisphosphate 5/6-kinase(ITPK1) is a very important enzyme in inositol metabolism. To investigate the role of genetic variants in ITPK1 and NTDs risk, a case-control study of women with NTD-affected pregnancies (n=200) and controls (n=328) from a high-risk area for NTDs in China was carried out. The study protocol was reviewed and approved by the ethic evaluation committee of Capital Institute of Pediatrics, Beijing, China, and we obtained written informed consent from all participants. DNA of maternal peripheral blood was extracted. The 13 Snps of ITPK1 were genotyped by the Sequenom MassArray system, and EMSA(Electrophoretic mobility shift assay) was applied to verify the binding activity between wild and mutated oligonucleotides probes. We found that 4 SNPs (rs4586354, rs2236131, rs3783903, rs170689) were statistically associated with NTDs occurrence (p<0.05). After stratifying participants by NTD phenotypes, the significant association only existed in cases with spina bifida. The result of the EMSA showed a different allelic binding capacity of activator protein-1 in the intron region of the ITPK1 gene, which is affected by an A→G exchange at rs3783903 (OR=2.72, 95% CI=1.33–5.54, p<0.005). The results suggested that the polymorphism in ITPK1 may be a genetic risk factor for NTDs in a high-risk area of China. Zhen Guan, Jian-Hua Wang, contributed equally to this manuscript.

High apolipoprotein E4 allele frequency in FXTAS patients. *M. Mila[1,2,3], F. Silva[1,4], I. Madrigal[1,2], MI. Alvarez-Mora[1,2], R. Oliva[1,3,5], L. Rodriguez-Revenga[1,2].* 1) Hospital Clinic, Barcelona, Spain; 2) CIBER de Enfermidades Raras (CIBERER), Barcelona, Spain; 3) IDIBAPS (Institut d'Investigacions Biomediques August Pi I Sunyer), Barcelona, Spain; 4) Fundacio Clinic per a la Recerca Biomedica, Barcelona, Spain; 5) Faculty of Medicine. University of Barcelona, Barcelona, Spain.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a late-onset neurodegenerative disorder that occurs in *FMR1* premutation carriers. I it is well known that the ApoE ε4 allele is a risk factor for neurodegenerative disease. The main goal of this work was to evaluate the ApoE genotypes and allelic distribution among FXTAS patients. A total of 44 unrelated *FMR1*premutation carriers (22 presenting with FXTAS and 22 non-FXTAS) have been genotyped. All the ApoE ε4/4 genotype carriers detected (100%) and 6 out of the 7 ApoE ε4/3 genotype carriers (85.7%) are patients presenting with FXTAS symptoms, while only 40% of the ApoE ε3/3 genotype carriers belong to the FXTAS group. The results showed that the frequency of the ApoE ε4 allele in the FXTAS group is statistically significant when comparing with non-FXTAS group (P = 0.023). On the basis of these results, we conclude that the presence of at least one ApoE ε4 allele might act as a genetic factor predisposing to develop FXTAS.Acknowledgments We would like to thank the Fragile X families, the “Associació Catalana Síndrome X fràgil”, and the Federación Española del Síndrome X Frágil for their cooperation. This work was supported by FIS (PS09/00413) from Instituto de Salud Carlos III, AGAUR SGR1337 from Generalitat de Catalunya and Fondo Europeo de Desarrollo Regional (Fondos FEDER) and FSE (SFRH/BD/81271/2011). Generation and characterization of induced Pluripotent Stem (iPS) cells from patients with the autosomal dominant disorder Spinocerebellar Ataxia Type 1 (SCA1). *N. Mollema[1], A. Shanmugam[2], E. Leathley[1], D. Kaufman[2], H.T. Orr[1].* 1) Institute for Translational Neuroscience, University of Minnesota, Minneapolis, MN; 2) Stem Cell Institute, University of Minnesota, Minneapolis, MN.

Generation of induced Pluripotent Stem (iPS) cells is a viable way to study human disease processes in an *in vitro* culture system, and iPS cells have been created from a variety of neurodegenerative disease patients. Spinocerebellar Ataxia Type 1 (SCA1) is a neurodegenerative disease that results from a polyglutamine expansion in the gene *ATXN1*. The expanded protein is inherited in an autosomal dominant manner, and results in late-onset degeneration of cerebellar Purkinje cells. Mutant ATXN1 protein is stabilized by phosphorylation at location S776, and must enter the nucleus to cause disease. We set out to generate iPS cells from SCA1 patients for the long-term goal of utilizing these cells in the drug screening for inhibitors of ATXN1 expression, and gene expression studies. In these studies, human dermal fibroblasts from SCA1 patients and unaffected controls were infected with a lentivrial vector containing the four classic transcriptional reprogramming factors (*OCT4*, *SOX2*, *C-MYC*, *KLF-4*). The infected cells were cultured in fibroblast media for six days and then transferred to mouse fibroblast feeder layers in iPS cell media. Colonies emerged after approximately 26 days in culture and were manually selected. Cells were assessed by immunohistochemistry, and karyotyping. Human embryonic stem (hES) cells (NIH approved line H9) were used as controls for these experiments. hES and iPS cells were differentiated to a mitotic population of neural epithelial cells, and these cells were maintained in culture for further differentiation. SCA1 patient and control iPS lines showed hallmark morphology of stem cells, and stained for markers of pluripotency. Mutant protein did not appear to inhibit the reprogramming process, although some variations in *ATXN1* repeat length were noted after cellular reprograming. We determined that ATXN1 is not expressed in hES, iPS cells, or subsequently differentiated neuroepithelial cells. We are in the process of differentiating human ES- and iPS-generated neuroepithelial cells along a ventral/midbrain pathway, to generate cell types where ATXN1 is normally expressed *in vivo*. These studies will allow us to determine when ATXN1 expression turns on during the process of differentiation from stem cell to neuron, and identifying when the protein is phosphorylated.

Quality of Life in Machado-Joseph Disease/Spinocerebellar Ataxia Type 3 (MJD/SCA3) is related to depressive and extracerebellar disease features. *J.A. Saute[1,2], R. D Ávila[2], R.M. Castilhos[2], T.L. Monte[3], A.F.S. Schuh[4], K.C. Donis[2], G.N. Souza[2], A.D. Russo[2], T.C. Gheno[4], G.V. Furtado[4], M.L. Saraiva-Pereira[2,4,5], C.R.M. Rieder[1,3], L.B. Jardim[1,2,4,6].* 1) Post-Graduate Program in Medical Sciences - UFRGS, Porto Alegre, Rio Grande do Sul, Brazil; 2) Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Rio Grande do Sul Brazil; 3) Neurology Service, Hospital de Clínicas de Porto Alegre, Rio Grande do Sul Brazil; 4) Post-Graduate Program in Molecular Biology and Genetics - UFRGS, Porto Alegre, Rio Grande do Sul, Brazil; 5) Biochemistry Department - UFRGS, Porto Alegre, Rio Grande do Sul, Brazil; 6) Internal Medicine Department - UFRGS, Porto Alegre, Rio Grande do Sul, Brazil.

MJD/SCA3, caused by a CAG repeat expansion (CAGn) at ATXN3 gene, is an untreatable condition characterized by a relentless deterioration of cerebellar and other neurological functions. Few studies have explored the quality of life (QoL) of MJD/SCA3 patients. Aim: to describe the main factors influencing patient's QoL through the WHOQoL-Bref questionnaire. Methods: molecularly diagnosed MJD/SCA3 patients were recruited from our Neurogenetics Outpatient Clinic in South Brazil. WHOQoL-Bref and Barthel score (both with higher scores indicating better performance); Neurological Examination Score for Spinocerebellar Ataxia (NESSCA), Scale for the Assessment and Rating of Ataxia (SARA) and Beck Depression Inventory (BDI) - all crescent in severity - were applied. Results: 62 patients (30 males) were included, with the following characteristics (m±sd): 40.5±9 years of age; age at disease onset (AO) of 34.4±8.8 years; disease duration (DD) of 6±2.5 years; CAGn of 75.4±3; NESSCA of 14.3±4.7; SARA of 10.8±4; Barthel index of 94.2±8; BDI of 12.3±9; and WHOQol-Bref - total score of 68.3±10.5. WHOQol-Bref total score and its four sub-scores were not associated with DD, AO, CAGn or SARA scores. WHOQol-Bref total score was correlated to NESSCA (R=-0.323, p=0.01). NESSCA was then divided in its cerebellar (up to 14 points) and extra-cerebellar items (up to 26 points): the correlation with WHOQol-Bref was maintained only by the extra-cerebellar items (R=-0.35, p=0.005). When WHOQol-Bref subdomains were analyzed, the association with extra-cerebellar items of NESSCA was evidenced with physical health (R=-0.36, p=0.005) and environment domains (R=-0.30, p=0.016). WHOQol-Bref total score was strongly associated to BDI (R=-0.71, p=0.0001), specially its psychological domain. Finally, the physical health domain of WHOQol-Bref was associated with severity of gait ataxia (R=-0.282, p=0.02) and with Barthel index (R=-0.284, p=0.02) Discussion: As expected, quality of life is reduced in MJD/SCA3, even in early stages of disease. The losses seemed to be mainly related to depressive manifestations and to extra-cerebellar dysfunctions as measured by NESSCA, with only a minor role for ataxic features. These findings point to the importance of depressive and extra-cerebellar manifestations of this disease. Acknowledgments: FIPE-HCPA, FAPERGS, CNPq, INAGEMP.

A health non penetrant pedigree derives from a late onset Parkinsonism founder index case with SCA2 and SCA8 expansions. *V. Volpini, H. San Nicolas, J. Corral, L. De Jorge, B. Campos.* Center For Molecular Genetics Diagnosis (CDGM), Idibell, L' Hospitalet De Llobregat, Barcelona, Spain.

Late onset cerebellar ataxias are a group of severe neurodegenerative disorders with an estimated prevalence in our population of 1 in 100,000. Ataxia with progressive course is the most characteristic sign of these disorders. Age at onset varies from 5 to 70 years, but it usually begins around 30 to 40y. Spinocerebellar ataxia type 2 (SCA2) is characterized by progressive cerebellar ataxia, including nystagmus, slow saccadic eye movements and, in some individuals, ophthalmoparesis or Parkinsonism. Pyramidal findings are present; deep tendon reflexes are brisk early on and are absent later in the course. Age of onset is typically in the fourth decade with 10 - to 15 - year disease duration. SCA2 expanded alleles with moderate size presenting CAA interruptions are associated with late onset Parkinsonism. Is generally known that SCA2 expanded alleles without CAA interruptions are associated with pathological development of the disease and that the interruptions would prevent elongation of the expanded sequence. Spinocerebellar ataxia type 8 (SCA8) is caused by CAG/CTG repeat expansion, but SCA8 diagnosis is not clear due to reduced penetrance of some expanded alleles present in asymptomatic cases. In this study we show one pedigree in which segregate SCA2 expanded alleles with CAA interruptions coexisting with SCA8 expanded alleles in several members. The index and founder case shows a SCA2 interrupted expanded allele of 38 CAG repeats coexisting with an SCA8 allele of 89 repeats. He presents late onset essential tremor and cerebellar atrophy. No mutations were found in LRRK2 and Parkin genes associated with Parkinson's disease to explain his etiology. One of his sons and two of his grandchild's share the same expanded interrupted SCA2 allele, coexisting with SCA8 expansions from 78 to 84 repeats, and all of them remain asymptomatic. In conclusion, SCA2 expanded alleles in pathological range with CAA interruptions could be associated with late onset Parkinsonism with uncertain penetrance. The role of SCA8 expansion coexisting with SCA2 expanded alleles remains unknown.

Impaired TFEB signaling accounts for autophagy pathway dysfunction in the neurodegenerative proteinopathy X-linked spinal & bulbar muscular atrophy. *C. Cortes[1], Y. Batlevi[1], J.E. Young[2], H. Frankowski[1], B.L. Sopher[3], G.A. Garden[3], A.R. La Spada[1,2,4].* 1) Pediatrics, University of California, San Diego, San Diego, CA; 2) Cellular & Molecular Medicine, University of California, San Diego, San Diego, CA; 3) Neurology, University of Washington, Seattle, WA; 4) Neurosciences, University of California, San Diego, San Diego, CA.

Autophagy is a highly conserved pathway of cellular macromolecule and organelle turnover, with a recently defined role in degrading aggregate-prone proteins. Autophagy dysfunction occurs in many neurodegenerative disorders, but its role in polyglutamine (polyQ) disease remains unclear. To address this, we studied autophagy in the neurodegenerative proteinopathy X-linked spinal & bulbar muscular atrophy (SBMA), a rare motor neuron disorder caused by a polyQ repeat expansion in the Androgen Receptor (AR). We found that primary neurons expressing AR-polyQ displayed altered lysosomal staining, but maintained robust induction of autophagy. Biochemically, we observed a significant decrease in the levels of cathepsin D, a key lysosomal enzyme, and a concomitant decrease in long-term protein turnover and lysosomal function in MN-1 AR66 cells (a classic in vitro SBMA model). Expression of full-length AR led to impaired autophagosome maturation, and defects in autophagosomal turnover were detected. Ultrastructural analysis of lumbar spinal cord sections from SBMA transgenic mice revealed that upregulation of functional autophagy in motor neurons correlated with maintenance of normal neural function (during the presymptomatic stage). However, emergence of disease in these mice was associated with a block in autophagy pathway progression. To determine the basis of autophagy pathway dysregulation in SBMA, we considered a role for Transcription Factor E-B (TFEB), a glutamine-tract containing master regulator of lysosomal function and autophagy. We found an interaction between AR and TFEB by co-immunoprecipitation, and observed AR polyQ length-dependent repression of a TFEB response element (4X CLEAR) promoter-reporter in cell co-transfection assays. This effect was not due to impaired trafficking of TFEB into the nucleus, but rather occurred after both transcription factors were activated and translocated into the nucleus. Overexpression of TFEB rescued impaired autophagic flux in AR66 cells, and restored 4X CLEAR transactivation in the face of lysosomal stress. Our results thus implicate AR-mediated TFEB transcriptionopathy in autophagy pathway dysregulation in SBMA, and pinpoint altered CLEAR signaling pathway function as a pathological turning point in SBMA and potentially in other related neurodegenerative proteinopathies.

The histone demethylase *KDM5C* gene is a direct target of the ARX homeobox transcription factor. *L. Poeta[1,2], F. Fusco[1], D. Drongitis[1], C. Shoubridge[3,4], G. Manganelli[1,5], A. Padula[1], S. Filosa[1,5], M. Courtney[6,7], P. Collombat[6,7], M.B. Lioi[2], J. Gecz[3,4], M.V. Ursini[1], M.G. Miano[1].* 1) Institute of Genetics and Biophysics "Adriano Buzzati Traverso", CNR, Naples 80131, Italy; 2) University of Basilicata, Potenza 85100, Italy; 3) Department of Paediatrics, University of Adelaide, Australia, South Australia 5006, Australia; 4) Department of Genetics and Molecular Pathology, SA, Pathology, Adelaide, Australia; 5) IRCCS, Neuromed, Pozzilli 86077, Italy; 6) Universitè de Nice-Sophia Antipolis, FR-06108, Nice, France; 7) Inserm U1091, IBV, Diabetes Genetics Team, FR-06108 Nice, France.

Intellectual Disability (ID) and Epilepsy often occur together with a dramatic impact on the development and quality of life of the affected children. Mutations of the *Aristaless-related homeobox* gene (ARX) cause a spectrum of X-chromosome phenotypes with ID (XLID) and various forms of malignant pediatric epilepsy, including infantile spasms. Located at Xp22.13,*ARX* is a homeobox gene encoding a paired-type-HomeoDomain transcription factor of crucial significance for brain ontogenesis. We show that *lysine (K)-specific demethylase 5C*(*KDM5C/JARID1C/SMCX*), a known XLID gene involved in chromatin remodeling, is regulated by ARX. By in vitro assays, we demonstrate that ARX directly regulates and binds the 5' region of the *KDM5C* gene. We studied ARX mutant proteins carrying various PolyAlanine expansion mutations, identified in XLID/Epilepsy patients. They are in frame duplications affecting two out of the four ARX PolyAlanine amino acid tracts and represent disease hot spot sites with a strong tendency to add coding trinucleotide repeats. We prove that the changes in the repeat units in the PolyAlanine tracts cause hypomorphic *ARX* mutations, which exhibit a decreased trans-activating activity and a reduced binding to the *KDM5C* regulatory region. Furthermore, the altered functioning of the ARX PolyAlanine mutants tested seems to correlate with the degree of XLID/Epilepsy severity. We found a down-regulation of the *Kdm5C* mRNA and protein levels in the murine Arx KO neuron-oriented ES cells. Additionally, we observed that *Arx* KO produced an increase of the Kdm5C-mediated levels of H3K4me3, potentially due to a compromised activity of Kdm5C. In summary, we discover a new ARX-dependent disease path and suggest that the molecular pathogenesis of the *ARX* PolyAlanine mutations may be in part caused by an aberrant histone demethylation as a result of the KDM5C defect. Even though many other ARX targets could have important roles in the expansion phenotype, a further development of our findings could open up the possibility of additional studies aimed to elucidate the symptoms associated with the *ARX* PolyAlanine-related neurophenotypes.

15q11.2 microdeletion and *FMR1* premutation in a family with intellectual disabilities and autism. *L. Rodriguez-Revenga[1,2], I. Madrigal[1,2], M. Mila[1,2,3].* 1) Hospital Clinic, Barcelona, Spain; 2) CIBER de Enfermedades Raras (CIBERER), Barcelona, Spain; 3) IDIBAPS (Institut d'Investigacions Biomèdiques August Pi i Sunyer). Barcelona, Spain.

Genomic rearrangements of chromosome 15q11-q13 are responsible for diverse phenotypes including intellectual disabilities and autism. 15q11.2 deletion, implicating common PWS/AS breakpoints BP1–BP2, has been described in patients with delayed motor and speech development and behavioural problems. Here we report the clinical and molecular characterization of a maternally inherited BP1–BP2 deletion in two siblings with intellectual, motor and speech delay, autistic syndrome disorder and several dysmorphic features. One of the patients was also a carrier of an *FMR1* allele in the low premutation range. The four genes within the deletion were underexpressed in all deletion carriers but *FMR1* mRNA levels remained normal. Our results suggest that BP1–BP2 deletion could be considered as a risk factor for neuropsychological phenotypes and that it presents with variable clinical expressivity. FRAXE molecular diagnosis in individuals referred for FRAXA screening. *A. Javed[1], G. Ali[1], L. Caicedo[1], I. Marques[2], R. Santos[2], P. Jorge[2].* 1) R& D, Gene Link, Inc, Hawthorne, NY; 2) UI&D, Centro de Genetica Medica Dr. Jacinto de Magalhaes - Porto, Instituto Nacional de Saude Dr. Ricardo Jorge, INSA I.P., Porto, Portugal.

FRAXE mental retardation is a form of mild to moderate intellectual disability generally associated with learning difficulties, communication deficits, attention problems, hyperactivity and autistic behavior. FRAXE (AFF2/FMR2 gene) a folate-sensitive fragile site in Xq28 ~600 kb distal to the FRAXA (FMR1 gene) site is the most common form of inherited mental retardation. Molecular characterization revealed that individuals expressing FRAXE had amplifications of a CCG repeat adjacent to a CpG island. Normal individuals showed 4–39 copies of the polymorphic FRAXE CCG repeat, while individuals expressing the fragile site had >200 copies and their CpG island was fully methylated. These findings are similar to those found for folate-sensitive fragile X site FRAXA. Reports of FRAXE full expansions and pre-mutations are rarely documented. In this respect, it has been very difficult to determine to what extent the alleles, with CCG repeats in the range of 36 and 199, have a pathogenic effect. Intellectually disabled individuals are primarily referred for FRAXA screening and individuals who are negative for FRAXA are possible candidates for FRAXE screening. Traditionally in some laboratories AFF2 molecular analysis is performed by PCR, it is known that CCG repeats in the range of ~80 and above are not reliably amplified. We embarked on an effort to supplement our PCR analysis by Southern blot and cloned a segment of the AFF2 gene that can be used by appropriate labeling as a probe to determine expansion of the CCG repeats in the AFF2 gene. We have developed a probe to be used for Southern blot analysis that reliably detects the AFF2 CCG triple repeat amplification. We present data of AFF2 molecular analysis in a subpopulation of 5,000 individuals referred for FRAXA screening. The presence of pre-mutated and fully expanded alleles in either gender, were confirmed by Southern blot analysis, which also enabled exclusion of methylation or repeat number mosaics as well as PCR failure. We recommend the use of this probe as suitable for genotyping of pre-mutations, full mutations, and mosaics specifically for individuals presented for FRAXA screening with negative results to determine FRAXE status.

An isogenic, epi-isoautosomal fibroblast model to investigate *FMR1* premutation-associated cellular dysfunction. *K.A. Koscielska, S. Roenspie, P.J. Hagerman.* Department of Biochemistry and Molecular Medicine, University of California, Davis, School of Medicine, Davis, CA.

The *FMR1* gene contains a CGG trinucleotide repeat in its 5' UTR. The premutation alleles of the gene (55–200 repeats) give rise to several different human disorders, including primary ovarian insufficiency (POI) and the late-onset neurodegenerative disorder, fragile X-associated tremor ataxia syndrome (FXTAS). The molecular mechanism of premutation-induced cellular dysregulation is not well understood, but is a consequence of the elevated levels of the CGG-containing *FMR1* mRNA, while FMRP protein levels remain close to the normal range. Cellular dysregulation has been observed in human and mouse neurons, as well as in human skin fibroblasts, the latter readily obtained from premutation carriers.

To better understand the cellular phenotype in humans, cloned female fibroblasts were generated to establish a case-control model of the premutation in an isogenic, epi-isoautosomal (differing active X chromosomes) genetic background. Each clonal line expresses exclusively either a normal or an expanded CGG repeat, depending on whether the maternal or the paternal X chromosome is active. In addition, fibroblasts from a mosaic male patient were cloned, in order to established an isogenic cell culture model with differing CGG repeats. The CGG repeat size was shown to be stable throughout long-term cell culture, and was also unchanged by the iPSC reprogramming and neuronal differentiation. The cloned fibroblast cell lines were characterized with respect to their *FMR1* mRNA and FMRP levels, and are a promising human cell culture model for the study of premutation disorders.

Formation of an R-loop at the *FMR1* 5'UTR: Unraveling the extra thread of *FMR1* expression. *E.W. Loomis[1], F.L. Chédin[2], P.J. Hagerman[1].* 1) Department of Biochemistry and Molecular Medicine, UC Davis School of Medicine, Davis, CA; 2) Department of Molecular and Cellular Biology, UC Davis, Davis, CA.

The $(CGG)_n$ trinucleotide repeat in the 5' untranslated region (5'UTR) of the *FMR1* gene is responsible for a number of heritable disorders, albeit by remarkably distinct pathogenic mechanisms: gene silencing for fragile X syndrome; RNA toxicity for FXTAS. In our studies of expression in the "premutation" repeat range (55–200 CGG repeats), we have discovered that long, three stranded, R-loop structures form during transcription through the guanine-rich sequences within the 5'UTR region. The G-rich transcribed mRNA forms a stable RNA/DNA hybrid with the template DNA strand, displacing the coding DNA strand. Recent research demonstrates that R-loops form throughout the human genome at a majority of CpG island promoters, including *FMR1*, and play an important role in the genome. However, the consequences of CGG repeat expansion on R-loop formation have not been considered previously.

To better understand the relationship between R-loop formation and CGG-repeat size, we have begun to characterize R-loop formation in human fibroblast cell lines containing alleles across the range of transcribed expanded *FMR1* CGG repeats. Immunoprecipitation with an RNA/DNA hybrid-specific antibody (DRIP) of genomic DNA from cultured human skin fibroblasts with both normal (CGG ≈ 30) and premutation (55 < CGG > 200) repeat alleles demonstrates a significant enrichment of *FMR1* over background, indicative of R-loop formation. Additionally, non-denaturing bisulfite mapping of the RNA-displaced single-stranded DNA spanning the 5'UTR and the CGG repeats in genomic DNA reveals clear differences in secondary structure within the displaced (G-rich) DNA strand. R-loop formation through expanded CGG repeat alleles is a previously uncharacterized phenomenon at *FMR1* that is likely to be involved in the complex molecular pathology observed in association with repeat expansion.

2634W

The role of AGG interruptions, alternative splicing and bidirectional transcription in the stability and function of the *FMR1* gene. *C.M. Yrigollen[1], H. Tang[1], E. Loomis[1], G. Filippova[2], P.J. Hagerman[1, 3], F. Tassone[1,3].* 1) Biochemistry and Molecular Medicine, University of California Davis, School of Medicine, Davis, CA, United States; 2) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA, United States; 3) MIND Institute, University of California Davis, Sacramento, CA, United States.

The CGG repeat element in the 5'UTR of the *FMR1* gene normally contains 2–3 AGG interruptions, although this number decreases in expanded alleles. We have determined that the presence and number of AGG `interruptions' strongly influences the likelihood of generating a full mutation allele in a premutation mother-to-offspring transmission. This observation will have an important impact on genetic counseling of carrier women who are contemplating the risk of having a child with fragile X syndrome. In our study of 267 maternal premutation alleles, considering the number and positions of AGG interruptions, and the length of pure and total CGG repeats, we found that the presence of AGG interruptions significantly reduces the risk of transmission of a full mutation for a maternal premutation allele of fewer than ~100 CGG repeats. Additionally, alternative splicing in the coding region of the *FMR1* gene together with alternative start and polyadenylation site usage gives arise to multiple transcripts, which generate multiple protein isoforms whose altered distribution in the premutation range may have profound biological consequences. Our preliminary quantitative RT-PCR (real time PCR) and sequencing (single molecule real time (SMRT) sequencing) data indicate that some isoforms are differentially overexpressed with increasing CGG repeat number and show specific tissue expression. Finally, the antisense FMR1 mRNA (ASFMR1 mRNA) has been reported to be similarly overexpressed in premutation carriers and silenced in full mutations. We further observed that the levels of ASFMR1 mRNA are also elevated in gray zone alleles and that altered ASFMR1 splicing/expression might play a role in Fragile X associated tremor ataxia syndrome (FXTAS). Indeed, we show that the expression of a splice isoform in the ASFMR1 transcript, located near the ASFMR1 promoter is elevated in those with a premutation and particularly in those with FXTAS. This absent/minor splice isoform in normal *FMR1* alleles may represent an important outcome measure associated with FXTAS. These molecular mechanisms contribute to cell dysfunction and to the variable phenotypes associated with the *FMR1* gene particularly for alleles in the premutation range.

MutLα is required to repair short slipped-DNAs of trinucleotide repeats. *G. Panigrahi[1], M. Slean[1, 2], J. Simard[1], C. Pearson[1, 2].* 1) Dept Genetics & Genomic Biol, Hosp Sick Children, TMDT Building 101 College St., 15th Floor, Room 15–312 East Tower, Toronto, Ontario, CanadaM5G 1L7; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

Mismatch repair is required for proper maintenance of the genome by protecting against mutations, as well as for driving certain mutations, including disease-associated trinucleotide repeat instability. We recently revealed a role of hMutSβ in the repair of short slip-outs containing a single CTG repeat units (Panigrahi et al., 2010, PNAS, 107(28)12593–12598). The involvement of other MMR proteins in short slip-out repair is unknown. Here we show that hMutLα is required for the highly efficient in vitro repair of single CTG repeat slip-outs. HEK293T cell extracts, deficient in hMLH1, are unable to process single-repeat slip-outs, but are functional when complemented with hMutLα. The MMR-deficient hMLH1-mutant, T117M, with a point mutation proximal to the ATP-binding domain, was defective in slip-out repair; further supporting a requirement for hMLH1 in processing of short slip-outs and possibly the involvement of hMHL1 ATPase activity. The hPMS2-deficient HEC-1-A cell extracts, cells express hMLH1, hMLH3 and hPMS1, are only functional when complemented with hMutLα, indicating that neither hMutLβnor hMutLγ are sufficient to repair short slip-outs. Furthermore, clustered slip-outs are poorly repaired, and this low level of repair (<15%) appears to depend upon the presence of a functional hMutLα in addition to hMutSβ.

Regional alterations of transcriptome-wide AGO:miRNA binding profiles in Huntington's disease patient brains. *R.L. Boudreau[1], P. Jiang[2], B.L. Gilmore[1], Y. Xing[2], B.L. Davidson[1].* 1) Internal Medicine, University of Iowa, Iowa City, IA; 2) Biostatistics, University of Iowa, Iowa City, IA.

MicroRNAs (miRNAs) are small RNAs which regulate gene expression and play important roles in development and disease. Mammalian genomes encode hundreds of miRNAs which, in conglomerate, regulate up to one-third of the transcriptome. miRNAs are excised from larger stem-loop containing transcripts and incorporated into Argonaute (AGO) proteins, the core component of the RNA Induced Silencing Complex (RISC), producing functional entities capable of silencing target transcripts via sequence complementarity, often by as few as 6–7 base-pairs. To better understand the biological function of miRNAs and their contributions to disease pathogenesis, target identification is of paramount importance. Although bioinformatic prediction and wet-lab validations have identified hundreds of individual miRNA:target interactions, this represents a limited scope considering the complex nature of the miRNA regulatory network. To address this, recent efforts have focused on high-throughput mapping of transcriptome-wide miRNA binding sites. Researchers have employed a crosslinking immunoprecipitation protocol coupled with high-throughput sequence analysis (CLIP-seq) to map AGO:miRNA binding sites to specific regions within target mRNAs. Here, we utilized AGO-CLIP-seq to investigate the pathogenic role of miRNAs in Huntington's disease (HD), a dominantly-inherited late-onset neurodegenerative disease. Prior data support that mRNAs and miRNAs are dysregulated in HD patient brains, and we hypothesized that complementary AGO-CLIP-seq data would facilitate the interpretation of these changes and assist with identifying novel pathogenic mechanisms. We performed AGO-CLIP-seq on control and HD patient brain samples isolated from either primary motor cortex or cingulate gyrus, regions with transcriptional changes implicated in HD phenotypes. We have sequenced and mapped over one million unique reads in each sample, and our preliminary evaluation reveals an abundance of brain-enriched miRNAs and thousands of miRNA binding sites throughout the brain transcriptome. Our immediate near-term goal is to perform a thorough bioinformatic comparison to identify disease- and regional-associated changes in miRNA expression and mRNA targeting. These data represent the first AGO-CLIP-seq study performed in post-mortem human brain tissue, and this innovative approach may serve to elucidate new therapeutic targets for HD and other human ailments with disease-associated transcriptional changes.

Large repeat expansions in the *C9ORF72* gene contribute to a spectrum of neurodegenerative disorders including Alzheimer disease. *M.A. Kohli[1], K. John-Williams[1], R. Rajbhandary[1], A. Naj[1], P. Whitehead[1], K. Hamilton[1], R.M. Carney[1], C. Wright[2], E. Crocco[3], H.E. Gwirtzman[4], R. Lang[5], G. Beecham[1,6], E.R. Martin[1,6], J. Gilbert[1,6], M. Benatar[2], G.W. Small[7], D. Mash[2], G. Byrd[5], J.L. Haines[4], M.A. Pericak-Vance[1,6], S. Züchner[1,6].* 1) University of Miami, Miller School of Medicine, John P. Hussman Institute for Human Genomics, Miami, FL, USA; 2) University of Miami, Miller School of Medicine, Department of Neurology, FL, USA; 3) University of Miami, Miller School of Medicine, Department of Psychiatry and Behavioral Science, FL, USA; 4) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN, USA; 5) North Carolina Agricultural and Technical State University, Department of Biology, Greensboro, NC, USA; 6) University of Miami, Miller School of Medicine, Dr. John T. Macdonald Foundation Department of Human Genetics, Miami, FL, USA; 7) David Geffen School of Medicine at UCLA, Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, USA.

Progressive neurodegenerative diseases comprise clinically and genetically highly heterogeneous phenotypes. For instance, *PSEN1 and 2*, *MAPT* and *GRN* mutations are associated with clinical characteristics typical of Alzheimer disease (AD), frontotemporal dementia (FTD) and/or Parkinson disease (PD). These data point towards molecular, but also clinical, commonalities, which are important for our understanding of some of the most common neurodegenerative diseases of older age. Recently, an intronic hexanucleotide $(GGGGCC)_n$ repeat expansion in the*C9ORF72* gene has been identified to account for up to 50% of FTD/ALS families, 7% - 12% of FTD families, and 2% - 5% of sporadic FTD cases in Caucasians. Given the clinical, pathological and genetic overlap between FTD and AD, we hypothesized that *C9ORF72* expansions may also confer risk to AD. We analyzed 1,268 and 292 cases with a clinical and/or pathological diagnosis of AD and 1,039 and 620 neurologically healthy controls aged over 60 from European and African American ancestry, respectively. In Caucasians, we found *C9ORF72*expansions in the pathogenic range of FTD/ALS (>30 repeats) at a rate of 0.9% in AD cases versus zero in controls (p=0.0014, 1,268 cases, 1,039 controls). This case-control association became stronger in a subsequent meta-analysis comprising 2,177 AD cases and 6,441 neurologically healthy controls from literature (p=7.5E-05). In contrast, no large expansions were detected in individuals of African-American ethnicity (292 cases, 620 controls). Moreover, in the range of normal variation of *C9ORF72* expansions (0–23 repeat copies), we detected significant differences in distribution and mean repeat counts between Caucasians and African-Americans. These differences were unexpected, but likely reflect ancient haplotype distributions, including haplotypes at risk for a repeat expansion. *C9ORF72* expansions in the normal range did not significantly confer risk to AD in either ethnicity when compared to elderly controls. Most relevant, evaluation of AD cases with large *C9ORF72* repeat expansions revealed a phenotypic spectrum in affected families that includes ALS, FTD and classic AD, with autopsy confirmed diagnoses. Thus, these data support the hypothesis that *C9ORF72* expansions contribute to a broad phenotypic spectrum of neurodegenerative diseases and will be a key factor to further decipher the underlying molecular pathology of AD.

2638T

C9ORF72 repeat expansions are a genetic cause of parkinsonism. *S. Lesage[1], I. Le Ber[1,2], C. Condroyer[1], E. Broussolle[4], A. Gabelle[5], S. Thobois[4], A. Durr[1,3], A. Brice[1,3], Parkinson's Disease Genetics Study Group.* 1) Université Pierre et Marie Curie-Paris6, Centre de Recherche de l'Institut du Cerveau et de la Moelle épinière, UMR-S975; Inserm, U975, Cnrs, UMR 7225, Paris, France; 2) Centre national de référence des démences rares, Paris, France; 3) Département de Génétique et Cytogénétique, Hôpital de la Pitié-Salpêtrière, Paris, France; 4) Université Lyon I; Centre de Neurosciences Cognitives, CNRS UMR5229; Service de Neurologie C, Hôpital Neurologique Pierre Wertheimer, Lyon, France; 5) Département de neurologie, CHU Gui de hauliac, Montpellier, France.

BACKGROUND: The recently identified C9ORF72 gene accounts for a large proportion of amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degenerations (FTLD). Since several forms of these disorders are associated with parkinsonism, we hypothesized that some patients with Parkinson's disease (PD) or other forms of parkinsonism might carry pathogenic C9OFR72 expansions. AIM: To evaluate C9ORF72 repeat expansions in 1,446 parkinsonian patients. PATIENTS AND METHODS: The study included a total of 1,446 unrelated patients: 1,225 clinically diagnosed with PD, 123 with progressive supranuclear palsy (PSP), 21 with corticobasal degeneration syndrome (CBDS), 43 with Lewy body dementia (LBD) and 25 with multiple system atrophy-parkinsonism (MSA-P). Of the 1,225 PD patients, 40% reported family histories of typical PD and 4% had family histories of other neurodegenerative disorders. The GGGGCC repeat expansions in the first intron of C9ORF72 were searched for, using the repeat primed PCR. RESULTS: Five of the 1,446 patients with parkinsonism had C9ORF72 repeat expansions. In the subgroup of the 1,225 PD patients, 3 carriers of C9ORF72 repeat expansions (0.2%) had isolated parkinsonian symptoms at onset (ages at onset: 29–64 years). Two cases had long disease durations of typical PD (5 to 8 years) before cognitive deficit or dementia developed; one case had no cognitive deficit, 12 years after PD onset. Although these 3 patients were clinically diagnosed with typical PD, they all had family histories of atypical PD, degenerative dementias or ALS. We also identified C9ORF72 repeat expansions in a patient with CBDS and another with PSP. No expansion was found in patients with MSA-P or LBD. CONCLUSION: This study shows that although rare, C9ORF72 repeat expansions may be associated with clinically typical PD, but also with PSP and CBDS. In several patients, the parkinsonism was levodopa-responsive and, like PD, remained pure, without associated cognitive deficit or dementia, for more than 10 years. Interestingly, all C9ORF72 mutation carriers had positive family histories of parkinsonism, degenerative dementias or ALS. The present study, therefore, suggests that patients with PD or other parkinsonian syndromes, particularly when a family history of other neurodegenerative disorders is present, should be screened for C9ORF72 expansions. This provides the tools for identifying potential carriers with important consequences for genetic counseling.

2639F

Autosomal dominant family history is a highly sensitive but not exclusive indicator of pathogenic C9ORF72 expansions in frontotemporal dementia and amyotrophic lateral sclerosis. *J.C. Fong[1], S.J. Sha[1], L. Takada[1], K.J. Rankin[1], J.S. Yokoyama[1], N.J. Rutherford[2], A.M. Karydas[1], B.K. Khan[1], M.C. Baker[2], M. DeJesus-Hernandez[2], M. Pribadi[3], G. Coppola[3], D.H. Geschwind[3], R. Rademakers[3], A.L. Boxer[1], B.L. Miller[1].* 1) Dept of Neurology, UCSF Memory and Aging Center, San Francisco, CA; 2) Dept of Neuroscience, Mayo Clinic Florida, Jacksonville, FL; 3) Depts of Psychiatry and Neurology, UCLA, Los Angeles, CA.

Background: Diagnosis of frontotemporal dementia (FTD) is complicated by overlap with other conditions. A related but distinct disorder, amyotrophic lateral sclerosis (ALS) co-occurs in 15% of behavioral-variant FTD (bvFTD) patients. 50% of ALS patients have frontal lobe deficits. Expansion of a hexanucleotide repeat in a noncoding region of C9ORF72 was identified as the cause of chromosome 9-associated FTD and ALS. C9ORF72 analysis offers definitive molecular diagnosis in patients with FTD, ALS or both, but the challenge is how best to identify who benefits from testing. Family history is a useful tool to identify disease risk. The practical utility of family history of neurodegenerative and psychiatric disease to predict C9ORF72-associated disease remains to be clarified. **Methods:** 384 subjects with a FTD-spectrum disorder were screened by a 2-step process for pathogenic C9ORF72 expansions. PCR products with a unique electrophoresis stutter pattern provided evidence of a mutation. Pedigrees from 92 unrelated subjects underwent blinded review. Family history assessment of neurodegenerative disease followed published criteria (Goldman score or GS 1–4). Positive psychiatric family history meant ≥1 1st-/2nd-degree relative with schizophrenia, bipolar disorder, substance abuse, personality change or death by suicide. **Results:** 23 unrelated subjects carried a C9ORF72 expansion, C9+ (C9- matched controls): 12 bvFTD (47), 3 ALS (6), 8 FTD/ALS (16). An autosomal dominant (ADo) family history of neurodegenerative disease (GS 1) had 100% sensitivity (95%CI, 60–100%) to identify expansions in 7 subjects. Familial aggregation not meeting ADo criteria (GS 2) had 29% sensitivity (8–64%), 82% specificity (72–89%), and 13% positive predictive value (PPV) (4–36%) to identify expansions among remaining C9+ subjects. Diagnosis of FTD/ALS with positive psychiatric family history had 56% sensitivity (27–81%), 80% specificity (55–93%), and 63% PPV (31–86%). 43% C9+ subjects had a noncontributory/unknown family history (GS 4).**Conclusions:** An ADo family history of FTD, ALS or both is indicative of a C9ORF72 mutation. High specificity reflects high penetrance of the expansion. Poor predictive value of GS 2 reflects subjective family history reporting. Family history of psychiatric disease should be carefully assessed in FTD/ALS patients, as this may predict an expansion. Presence of expansions among patients with GS 4 supports gene testing among sporadic FTD or ALS cases.

2640W

Walking down the molecular pathogenic road of ARX polyalanine tract expansions: where do they part? *C. Shoubridge[1, 2], K.P.Y Lee[1], T. Mattiske[1], J. Gécz[1, 2].* 1) Genetics & Molec Pathology, SA Pathology, Adelaide, South Australia, Australia; 2) Dept of Paediatrics, University of Adelaide, Adelaide, South Australia, Australia.

Intellectual disability (ID) is a highly prevalent disorder that affects 1–3% of the population, with a number of causative genes mapped to the X-chromosome. The Aristaless-related homeobox gene (*ARX*) encodes a transcription factor characterised by a homeodomain and four polyalanine (PolyA) tracts. ARX is indispensable for proper forebrain and testis development and is a frequently mutated X-Linked ID gene. Expanded PolyA tracts account for over half of all mutations in *ARX* and clinically give rise to ID with or without epilepsy. Mice modelling the human PolyA expansions ($Arx^{(GCG)7}$) recapitulate many of the clinical features seen in humans, including learning impairment and a predisposition to epileptic seizures[1]. To dissect the molecular basis of different PolyA expansions *in vivo*, we have analysed mice modelling the two most frequent PolyA expansion mutations ($Arx^{(GCG)7}$ and $Arx^{432–455dup24}$) (Kindly provided by K Kitamura)[1]. Given that *Arx* is expressed in the mouse brain from 9.5 dpc, we initiated our analysis from 12.5 dpc to capture early consequence(s) of PolyA mutations. Interestingly, we did not observe protein aggregation in cells expressing Arx in contrast to our, and others, in vitro studies. We confirmed that the marked reduction in Arx protein abundance noted at 14.5 dpc[1] is present in both strains at 12.5 dpc. This reduction could not be accounted for by a loss of cell mass or expression of *Arx* transcripts in either mouse models. We are currently investigating if this reduction in protein level is due to translation efficiency or differences in protein stability. To better dissect the mechanism underpinning the phenotypic differences due to PolyA expansions, we have assessed the transcriptional consequences of mutations in these mouse models. Our data indicate a selective effect of these mutations impacting on some but not all Arx downstream targets. Since Arx is essential for interneuron development, establishing the i*n vivo* distribution of interneuron subpopulations in the two mouse models is underway. This study provides further evidence that protein dynamics can be different between *in vitro* and in vivo systems. We demonstrate that in mice, PolyA expansion mutations lead to a marked reduction of Arx protein during early brain development, and identify affected gene targets that potentially contribute to the manifestation of clinical features of the associated disease. [1](Kitamura et al. Hum Mol Genet 18:3708–3724, 2009).

Copy number variation of the neuronal glucose transporter 3 and age of onset in Huntington's disease. *A. Vittori[1,2], C. Breda[2], M. Repici[2], T.F. Outeiro[1,3,4], F. Giorgini[2], E.J. Hollox[2], the REGISTRY investigators of the EHDN.* 1) Instituto de Medicina Molecular, Cellular and Molecular Neuroscience Unit, Instituto de Fisiologia, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal; 2) Department of Genetics, University of Leicester, Leicester, UK; 3) Instituto de Fisiologia, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal; 4) Department of NeuroDegeneration and Restaurative Research, University Medizin Gottingen, Gottingen, Germany.

Huntington's disease (HD) is a neurodegenerative disease caused by an expanded triplet repeat within the *HTT* gene. The length of this repeat is inversely correlated with the age of onset (AO) of the disease, which ranges from ~2 to 80 years old. The length of this repeat explains ~50–70% of the variance of AO with the remaining variation due to environmental and other genetic factors. We investigated copy number variation (CNV) which may affect AO in HD. Decreased expression of *SLC2A3*, which encodes the neuronal glucose transporter Glut3, in the caudate of the brain is prodromal to significant neurodegeneration in HD patients and a study in a fly (*Drosophila melanogaster*) HD model has shown that overexpression of the *SLC2A-3*functional homolog is protective against neurodegeneration. We thus analyzed copy number variation of the human SLC2A3 gene as a candidate genetic modifier of the AO in HD, as the*SLC2A3* diploid copy number can vary in the population from one to three copies, possibly affecting expression levels of the gene. We genotyped *SLC2A3* CNV in 989 HD patients from the European Huntington's Disease Network (EHDN) cohort using the paralog ratio test (PRT), a comparative PCR-based method. We found that deletions and duplications of *SLC2A3* are rare (1% and 3% respectively), consistent with the frequencies found in healthy Europeans, and a weak but significant association of copy number with AO in HD (ANOVAIII test, p value = 0.030). Individuals with three copies show a delay in the AO of ~3 years compared to individuals with one or two copies. To investigate the functional basis for this effect, we have constructed lines showing over- or under-expression of the functional homolog of *SLC2A3* in a fly model of HD. We are currently analysing several disease-relevant metrics, including neurodegeneration of the photoreceptors, longevity and locomotor activity, in order to elucidate how different expression levels of the neuronal glucose transporter modulate severity of the HD phenotype in vivo.

The frequency of SCAs in diverse populations is not well known, as well as the reason for the clinical heterogeneity in each disorder. Aims: to describe the proportion of SCA1, 2, 3(MJD), 6, 7, 10, 12, 17 in families from different regions of Brazil; and to study the effect of the expanded CAG repeat (eCAGn) of SCA1,2,3,6 and 7 as well as the normal CAG repeats (nCAGn) in age at onset (AO) and neurological characteristics of SCAs. Methods: patients with an adult onset, autosomal dominant ataxia were recruited in university hospitals of 12 Brazilian cities, distant up to 3,800 km. DNA samples were sent to the central laboratory, to target analysis of the related genes. Results: 502 patients (336 families) were recruited. SCA3/MJD was the most frequent (210 or 63.3% of all families), specially in South (Rio Grande do Sul, 79%, p<0,05). The following were SCA2 (25 or 7,3% of all families; but more frequent in São Paulo, 16,4%, than in other regions, p<0,05), SCA7 (15 or 4,5% overall; but more frequent in São Paulo and Rio de Janeiro, 22,6% and 10,9%, than in other regions, p<0,05), and SCA10 (11 families or 3%). 6 SCA1 and 5 SCA6 families were also detected. 62 families or 18,6% had these diagnoses excluded; this rate was higher in the Northeast Brazil (64,3%). SCA12, 17 and DRPLA were not identified. There were no differences in the nCAGn distribution of CAG loci with respect to geographical origin, this distribution being unrelated to the different frequencies of SCAs. AO was associated to the eCAGn in SCA2 (r=-0,77), SCA3/MJD (r=-0,54), and SCA7 (r=-0,93) (p<0.0001). AO were older in SCA6 (m±sd of 55±10 years) and younger in SCA2 and SCA7 patients (29±11 and 24±12 years) than the SCAs in general (33±12, p=0,005). The nCAGn of ATXN2, 3, 7 and CACNA1A did not influence AO in SCA2, SCA3/MJD and SCA7 (ns, linear regression). In SCA3/MJD, the finding of eyelid retraction, absent reflexes, rigidity and bradykinesia were associated to large nCAGn of the CACNAIA; and ophthalmoparesis was associated to large nCAGn of ATXN2 gene (p=0.05, logistic regression). Discussion: SCA3/MJD is the most frequent SCA in Brazil. The high frequency of SCA without diagnosis in Northeast Brazil points to the presence of other, non-studied SCA in those populations. Whereas the effect of eCAGn in the AO of each specific disease was confirmed, our results suggest that the normal alleles at ATXN2 and CACNA1A genes might modify the phenotype of SCA3/MJD.

Comprehensive haplotype analysis of the Huntington's disease gene. *J. Lee[1, 2], H. Li[3], J.C. Roach[3], N. Goodman[3], L. Hood[3, 4], J.A. Kaye[5], H. Zayed[5], I.H. Kratter[5], A.C. Daub[5], S. Finkbeiner[5], R.H. Myers[6], M.E. MacDonald[1,2], J.F. Gusella[1,2].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA 02114, USA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, MA 02142, USA; 3) Institute for Systems Biology, Seattle, WA 98109, USA; 4) Luxembourg Center for Systems Biomedicine, University of Luxembourg, Luxembourg, Luxembourg; 5) Gladstone Institute of Neurological Disease, San Francisco, CA 94158, USA; 6) Department of Neurology, Boston University School of Medicine, Boston, MA 02118, USA.

Huntington's disease (HD) is a dominantly inherited neurodegenerative disease in which the same type of genetic alteration is responsible for all cases of the disease, an expansion of huntingtin (HTT) CAG repeat. In HD, HTT CAG repeat lengths greater than 35 cause characteristic symptoms including involuntary movements, cognitive decline and psychiatric disturbances. Importantly, the length of the CAG repeat also determines the age at onset of neurological symptoms as ~65% of the variance in age at onset of motor symptoms is explained by the CAG repeat length. Previously, we discovered based upon common SNP-based haplotype analysis that common HTT haplotypes on HD chromosomes do not differ in their CAG repeat length distribution or for the associated age at onset of motor symptoms. Here, we expand our haplotype analysis to understand individual haplotype composition. The top 10 most frequent haplotypes on HD chromosomes (i.e., mutation-bearing chromosomes) and on normal chromosomes accounted for 89.4% and 77.7%, respectively. The union of these (i.e., 14 haplotypes) made up 90% and 82.3% of HD expanded chromosomes and normal chromosomes, respectively. Individually, HD subjects with the most common HTT expanded haplotype and the most common normal chromosome haplotype account for 10.4% of all HD subjects. In addition, approximately 90% of all HD subjects carried two different HTT haplotypes, suggesting that the vast majority of HD subjects could be eligible for HTT expanded allele-specific gene silencing approaches. Furthermore, we obtained high resolution haplotypes by whole-genome sequencing of pedigrees. Among eight HD pedigrees, four carry the most common HTT haplotype, two carry a less common haplotype, and other pedigrees carry different haplotypes. Pedigrees with same haplotype can be further stratified by rare variants. Haplotype analysis based on the sequence data confirmed the common SNP-based haplotypes and further analysis of the haplotypes at the high resolution revealed novel genetic variants that differed between HTT expanded and normal haplotypes. Together, our haplotype analysis results demonstrate the power of integrated approaches of combining population-targeted and individual-targeted analysis to understand HTT haplotype structure. The novel variants discovered may be important for delineating the history of HTT haplotypes, understanding their effects on the disease process and developing allele-specific gene silencing strategies.

Brain-specific junctophilins: Function and role in neurodegeneration. *X. Sun, M. Bhat, C. Zhang, W. Zheng, R.L. Margolis, D.D. Rudnicki.* Johns Hopkins, Baltimore, MD.

The junctophilin family of proteins, characterized by C-terminal endoplasmic/sarcoplasmic reticulum (ER/SR) transmembrane domains and N-terminal MORN motifs that specifically bind with plasma membrane (PM), participate in the formation of junctional membrane complexes linking ER/SR and PM. Muscle-specific JPH1 and JPH2 are involved in calcium-induced calcium release (CICR) in cardiac and skeletal myocytes through physiological coupling between cell surface and intracellular channels; mutations in JPH2 cause hypertrophic caridomyopathy. Our laboratory has identified a CTG repeat expansion mutation in the brain-specific junctophilin JPH3 that causes the neurodegeneration disorder Huntington's Disease-like 2 (HDL2). The pathogenic mechanism appears to involved both a loss of JPH3 protein expression and toxic properties of the expanded CUG tract in the mutant JPH3 transcript. While the physiological function of JPH3 and the other brain-specific junctophilin, JPH4, is less clear, mouse knock-out models indicate that they play a role in neuronal plasticity and motor function. Using expression analysis, knockout mouse models and proteomic techniques, our data suggests that loss of JPH3 expression increases neuronal vulnerability to multiple insults, including RNA toxicity. In addition, the subcellular distribution of the JPH3 and JPH4 protein products, and their protein interacting partners, suggest that each may have functions beyond modulation of calcium flux.

Repeat associated non-AUG translation in repeat expansion disorders. *T. Zu[1], B. Gibbens[2], L.P.W. Ranum[1].* 1) Center for NeuroGenetics, Dept. Mol. Genetics & Microbiology, Univ Florida, Gainesville, FL; 2) Univ Minnesota, Minneapolis, MN.

A variety of neurodegenerative diseases, including myotonic dystrophy type 1 (DM1) and spinocerebellar ataxia type 8 (SCA8), are caused by expansion of unstable repeats. We discovered that the canonical rules of translation do not apply for CAG•CTG expansions and that in the absence of AUG or other known alternative start codons, expanded CAG and CTG trinucleotide repeats express homopolymeric expansion proteins in all three frames. This Repeat-Associated Non-AUG (RAN) translation occurs in mammalian tissue culture and in lentiviral-vector transduced cells and tissues. We also show that RAN translation across human spinocerebellar ataxia type 8 (SCA8) and myotonic dystrophy type 1 (DM1) CAG-expansion transcripts results in the accumulation of SCA8 polyAla ($SCA8_{GCA-Ala}$) and DM1 polyGln ($DM1_{CAG-Gln}$) expansion proteins in multiple organ systems in affected patients and mice. Experiments to understand the mechanisms of RAN translation show this process is repeat length-dependent and occurs across a variety of hairpin-forming repeat tracts. We have now performed additional cell-culture studies to characterize the RNAs capable of undergoing RAN translation and the cellular factors and conditions that favor this process. We show RAN translation occurs in two or more frames across a variety of triplet and tetranucleotide repeat motifs including the DM2 CCTG•CAGG repeat expansion motif. Analysis of RAN translation in different cell types shows that robust expression of polyGln, polyAla and polySer in HEK293T, HeLa and T98 cells but not in several other cell lines, suggesting the influence of specific cellular factors on RAN translation. Additionally we show that overexpression of the MBNL1 protein, which has been shown to sequester CUG expansion RNAs in the nucleus decreases RAN translation. RAN translation is also modulated in mouse embryonic fibroblasts generated from a series of knockout mice lacking Mbnl1, Mbnl2, and Mbnl3. In summary, the efficiency of RAN translation is affected by repeat length, repeat motif and cellular factors and the accumulation of the homopolymeric proteins appears to contribute to a large category of repeat expansion disorders.

MicroRNA Expression in Alzheimer's Disease: An Exploratory Investigation. *L.M. Bekris[1, 2], F. Lutz[1, 2], T.J. Montine[3, 7], C.E. Yu[1, 2], E.R. Peskind[3, 4], J.B. Leverenz[4, 5, 6, 7].* 1) Geriatric Research, Education, and Clinical Center (GRECC), VA Puget Sound Health Care System, Seattle, WA; 2) Department of Medicine, University of Washington, Seattle, WA; 3) Pathology, University of Washington, Seattle, WA, USA; 4) Northwest Network VISN-20 Mental Illness Research, Education and Clinical Center (MIRECC), VA Puget Sound Health Care System, Seattle, WA; 5) Psychiatry and Behavioral Sciences, University of Washington School of Medicine; 6) Department of Neurology, University of Washington School of Medicine, Seattle, WA; 7) Northwest Network VISN-20 Parkinson's Disease Research, Education and Clinical Center (PADRECC).

MicroRNA (miRNA) play an essential role in gene regulation in the brain. However, little is known about their role in neurodegenerative diseases, such as late-onset Alzheimer's disease (AD). Characterizing expression profiles of miRNA in AD brain may help elucidate the role of miRNA in the pathophysiology of AD and may lead to identification of AD specific biomarkers. The aim of this exploratory investigation was to determine if miRNAs are differentially expressed according to tissue type, disease status, neuritic plaque or Braak stage. In the first phase, a post-mortem brain sample set was pooled to measure multiple miRNA (n=377) using miRNA arrays. In the second phase, individual post-mortem brain AD and control samples from this sample set, were used in qRT-PCR assays to further explore differences in miRNA levels according to neuritic plaque score or Braak stage. In the third phase, hippocampus, cerebellum, cerebrospinal fluid and plasma miRNA found positive in the first and second phase were measured in a small independent sample set. Finally, in silico analyses were performed to predict target genes for differentially expressed miRNAs. Many miRNA were not detected in our brain sample and some were not detected in both the cerebellum and hippocampus leaving 247 miRNA for further analysis. MiRNA differentially expressed in AD hippocampus compared to control hippocampus were chosen for qRT-PCR validation (n=21). Five qRT-PCR validated miRNA showed significant sensitivity and specificity for disease status, plaque score or Braak stage. Most of these 5 miRNA were detected in CSF, plasma and human neuronal and astrocyte cell lines. Plasma miRNA-15a was found to be associated with plaque score in this small independent sample. In conclusion, this investigation demonstrates that miRNA represent potential biomarkers of AD, neuritic plaque score and Braak stage. MiRNA identified in this exploratory study are predicted to target AD relevant genes and thus may warrant further investigation into their functional impact on expression and their utility as biomarkers of neurodegenerative disease.

Behavioral abnormalities of knockout mice of *Grm3*, a candidate gene for schizophrenia susceptibility. *Y. Fukumaki[1], R. Fujioka[1], T. Nii[1], A. Iwaki[1], A. Shibata[1], I. Ito[2], K. Kitaichi[3,4], M. Nomura[5], S. Hattori[6], K. Takao[6], T. Miyakawa[6].* 1) Div. of Human Molecular Genetics, Medical Institute of Bioregulation, Kyushu Univ., Fukuoka, Japan; 2) Dept. of Biology, Faculty of Science, Kyushu Univ., Fukuoka, Japan; 3) Dept. of Pharmacology, Nagasaki International Univ., Nagasaki, Japan; 4) Dept. of Pharmacy, Gifu University Hospital, Gifu, Japan; 5) Graduate School of Medical Science, Kyushu Univ., Fukuoka, Japan; 6) Div. of Systems Medical Science, Institute for Comprehensive Medical Science, Fujita Health Univ., Toyoake, Japan.

On the basis of glutamatergic dysfunction hypothesis of schizophrenia pathogenesis, we previously performed systematic association studies of glutamate receptor gene family members with schizophrenia and found an association of *GRM3* (a gene of metabotropic glutamate receptor 3: mGluR3) with the disorder. To explore the physiological role of *GRM3* in brain functions and functional roles in schizophrenia pathogenesis, we have conducted comprehensive behavioral analyses of mGluR3 knockout (KO) mice. The KO mice showed hyperactivity in the open field and light/dark transition tests, impaired reference memory for stressful events in the Porsolt forced swim test and impaired working memory in the T-Maze forced alternation task. The hyperactivity and impaired working memory are known as endophenotypes of schizophrenia. Regarding memory impairments, we examined short- and long-term synaptic plasticities by assessing the paired-pulse facilitation (PPF) and long-term potentiation (LTP), respectively, in the CA1 region of the hippocampus of the 12–14 weeks old mice. We observed PPF in KO and WT mice, but detected no differences in the amplitude of PPF between the two genotypes. In the LTP assay, the EPSP slope at 40 min after tetanus was normalized using the mean slope before stimulation. There were no statistically significant differences in the LTP between two genotypes, suggesting that mGluR3 is not essential for LTP in the CA1 region of the hippocampus of mice. As hyperactivity is typically associated with increased dopaminergic transmission, we performed *in vivo* microdialysis measurements of extracellular dopamine in the central nervous system of the KO and WT mice. We observed enhancement of methamphetamine-induced release of dopamine in the nucleus accumbens of the KO mice, indicating the altered dopaminergic transmission in the KO mice. These results suggest that interaction of dopaminergic and glutamatergic systems is involved in pathophysiology of the schizophrenia-like behavior.

Repeat Expansion in C9ORF72 in Alzheimer's Disease. *E. Majounie[1], Y. Abramzon[1], AE. Renton[1], R. Perry[2], SS. Bassett[3], O. Pletnikova[3], JC. Troncoso[3], J. Hardy[4], AB. Singleton[1], BJ. Traynor[1].* 1) National Institute on Aging, Bethesda, MD; 2) University of Alabama at Birmingham, Birmingham, AL; 3) Johns Hopkins University, Baltimore, MD; 4) University College London Institute of Neurology, London, United Kingdom.

Alzheimer's disease is the most common progressive neurodegenerative disorder, with a prevalence of 35 million worldwide. Our understanding of the genetic etiology of the disease is still largely incomplete, and only the common genetic variant (E4) in the apolipoprotein E gene is widely accepted as risk factor for sporadic Alzheimer's disease. We recently demonstrated that a hexanucleotide repeat expansion (GGGGCC) within gene C9ORF72 accounts for approximately 40% of cases of familial amyotrophic lateral sclerosis and 30% of cases of frontotemporal dementia. Given the clinical and pathological overlap between frontotemporal dementia and Alzheimer's disease, we tested the hypothesis that the C9ORF72 hexanucleotide expansion may also be associated with susceptibility to Alzheimer's disease. We screened 342 late-onset Alzheimer's disease families using a repeat-primed PCR method. The cohort consisted of 771 cases who had received a probable diagnosis of Alzheimer's disease (on the basis of criteria of the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association) and 223 siblings who were assessed as being unaffected at the time of collection. We showed that the pathogenic C9ORF72 repeat expansions was present in 3 of 342 families (<1%) apparently affected with Alzheimer's disease. Postmortem analyses of two affected sisters showed neuropathological findings consistent with a primary diagnosis of frontotemporal dementia with ubiquitin-positive, tau-negative neuronal inclusions. These findings support the possibility that the subjects carrying the C9ORF72 repeat expansion had amnestic frontotemporal dementia that was misdiagnosed as probable Alzheimer's disease. As postmortem studies estimate the diagnostic accuracy of clinical Alzheimer's disease to be 83%, the availability of a test for the C9ORF72 repeat expansion may provide an opportunity to correct the misclassification of frontotemporal dementia as Alzheimer's disease in current and future patients.

Oxr1 Is Essential for Protection against Oxidative Stress-Induced Neurodegeneration. *P.L. Oliver, M.J. Finelli, K. Liu, B. Edwards, E. Bitoun, E.B. Becker, K.E. Davies.* MRC Functional Genomics Unit, Department of Phsiology Anatomy and Genetics, University of Oxford, Oxford, UK.

Oxidative stress is a common etiological feature of neurological disorders, although the pathways that govern defence against reactive oxygen species (ROS) in neurodegeneration remain unclear. We have identified the role of oxidation resistance 1 (Oxr1) as a vital protein that controls the sensitivity of neuronal cells to oxidative stress; mice lacking Oxr1 display cerebellar neurodegeneration, and neurons are less susceptible to exogenous stress when the gene is over-expressed. A conserved short isoform of Oxr1 is also sufficient to confer this neuroprotective property both *in vitro* and *in vivo*. In addition, biochemical assays indicate that Oxr1 itself is susceptible to cysteine-mediated oxidation. Finally we show up-regulation of Oxr1 in both human amyotrophic lateral sclerosis (ALS) as well as over-expression at the pre-symtomatic stage in several mouse models of neurodegeneration. These data suggest that Oxr1 is a novel early marker for stress in neurons and potentially a new neuroprotective factor in neurodegenerative disease.

Joint SNP analysis identifies multiple signals underlying association between *CHRNB3-CHRNA6* and nicotine dependence. *B. Sadler[1,2], E. Johnson[3], N. Saccone[2], L. Bierut[2], A. Goate[2].* 1) Arizona State University, Tempe, AZ; 2) Washington University, St. Louis, MO; 3) Research Triangle Institute, Research Triangle Park, NC.

Today, tobacco use and related traits are the number one cause of preventable deaths in the United States. The loci identified by GWAS to be associated with nicotine addiction mainly include genes encoding neuronal cholinergic nicotinic receptors *(CHRNs)* in two gene clusters, one on chromosome 15 containing *CHRNA5*, *CHRNA3* and *CHRNB4* and one on chromosome 8 containing *CHRNB3* and *CHRNA6*. The strongest association with nicotine addiction is a non-synonymous change (rs16969968) in *CHRNA5*. This strong association has been replicated and validated across several studies and populations, yet does not explain a large percentage of the overall heritability of nicotine dependence, accounting for less than 5% of the variance. Variants within the gene cluster on chromosome 8 were found to affect nicotine consumption in several GWAS, but the region has not been fine-mapped nor has a causal variant been found. Using imputed data from a GWAS of nicotine dependence including 2055 European Americans (1062 ND cases and 993 controls), haplotype and conditional analyses were run for the region on chromosome 8 encompassing the *B3-A6* nicotinic receptor subunits. Of the 558 SNPs in the region, only SNPs with a MAF >5% and imputation allelic R^2 values of >0.8 were considered in the conditional analyses (179 SNPs). To determine whether there was evidence for multiple functional variants at the locus contributing to risk for nicotine dependence, the most significant SNP in the region was added to the model as a covariate in a stepwise manner for three rounds of analysis (rs7017612, $p=3.15^{-5}$; rs13263434, $p=8.28^{-4}$; rs9298628, $p=8.43^{-3}$). Examination of LD in the region confirms that the r-squared values between these SNPs are sufficiently low so as to be representative of different association signals (r^2 range 0.43–0.64). These SNPs were then used in three-locus haplotype analyses. Six haplotypes were observed although 3 had a frequency below 2%. Three broad categories of risk were associated with these haplotypes: the most common haplotype (74.5%) increased risk (OR= 1.18, p=0.029); a second haplotype with a frequency of 2.57% was neutral and 2 additional haplotypes of low frequency were strongly protective (OR=0.324, $p=9.20^{-5}$; OR=0.442, p=0.002). These data strongly suggest that the *CHRNA6/B3* locus contains multiple alleles affecting risk for nicotine dependence. We are genotyping key imputed SNPs to confirm these associations.

2651F

Variation in Gene Expression Related to Schizophrenia-Associated Neurocognitive Endophenotypes. *E.E. Quillen[1], M.A. Carless[1], J. Neary[1], M.Z. Kos[1], R.C. Gur[2], M.F. Pogue-Geile[3], K. Prasad[4], J. Blangero[1], H.H.H. Göring[1], V.L. Nimgaonkar[4], R.E. Gur[2], L. Almasy[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Departments of Psychiatry, Neurology and Radiology, University of Pennsylvania Medical Center, Philadelphia, PA; 3) Department of Psychology, University of Pittsburgh, Pittsburgh, PA; 4) Department of Psychiatry and Human Genetics, University of Pittsburgh Medical Center, Pittsburgh, PA.

The Multiplex-Multigenerational Genetic Investigation (MGI) of Schizophrenia is a family-based study of schizophrenia (SCZ) and related endophenotypes including measures of disordered cognition, a hallmark of SCZ. Scores on these neurocognitive tests are heritable and genetically correlated with SCZ (ρ_G = -0.27 to -0.56), suggesting overlapping genetic influences on these endophenotypes and SCZ. MGI families were ascertained on the basis of two affected probands and all family members over age 16 were invited to participate. A Computerized Neurocognitive Battery was utilized to assess abstraction and mental flexibility, verbal memory, face memory, spatial memory, spatial processing, sensorimotor dexterity, and emotion processing. For each domain, efficiency was calculated as the ratio of accuracy to speed and shown to differ among affected individuals, unaffected relatives, and healthy controls. For genetic analysis, the endophenotypes were prioritized using the Endophenotype Ranking Value. RNA was extracted from lymphoblastoid cell lines and genome-wide transcriptional profiling was completed for 587 individuals using Illumina HT-12 Expression BeadChips. 26,358 variably expressed transcripts were normalized and measured transcript association analysis was performed in SOLAR to assess the age- and sex-adjusted relationship between expression and response efficiency for the top endophenotypes while controlling for pedigree structure (N = 320). Diminished abstraction and mental flexibility (h^2 = 0.33) is associated with decreased expression of mitochondrial gene *MCAT* ($p <$ 5e-5 for all associations). Increased expression of*RAP1GDS1*, a gene known to be expressed in the mouse brain, with high activity in the hippocampus (functionally similar to the human frontal cortex), is associated with worse performance on attention (h^2 = 0.45). Poor sensorimotor skills (h^2 = 0.60) are associated with increased *MRPS12* and decreased *FAM108C1*, *TEK*, and *TOX2* expression. Bivariate polygenic analysis indicates a shared genetic basis between sensorimotor skills and *FAM108C1* (ρ_G = 0.21) and *MRPS12* (ρ_G = -0.31) and between attention and *RAP1GDS1* (ρ_G = -0.57). In humans, *TOX2*, a transcription factor, is expressed across many regions of the brain and *MRPS12* exhibits decreased expression while *FAM108C1* and *TEK* exhibit increased expression in the frontal cortex. These results suggest a mechanism for the observed increase in frontal lobe abnormalities among individuals with SCZ.

A genome-wide epigenetic analysis in monozygotic twins discordant for schizophrenia. *F. Nishimura[1], A. Yoshikawa[1], S. Nanko[2], A. Imamura[3], Y. Okazaki[4], K. Iwamoto[5,6], T. Kato[6], T. Sasaki[7], K. Kasai[1], C. Kakiuchi[1,6].* 1) Department of Neuropsychiatry, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 2) Department of Psychiatry, Teikyo University School of Medicine, Tokyo, Japan; 3) Department of Neuropsychiatry, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 4) Tokyo Metropolitan Matsuzawa Hospital, Tokyo, Japan; 5) Department of Molecular Psychiatry, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 6) Laboratory for Molecular Dynamics of Mental Disorders, RIKEN Brain Science Institute, Saitama, Japan; 7) Office for Mental Health Support and Graduate School of Education, University of Tokyo, Tokyo, Japan.

Introduction: Schizophrenia is one of the major mental disorders with approximately 1% prevalence rate. The family, twin and adoption studies have established that the genetics play a significant role in the etiology of schizophrenia. Disease concordance rate of schizophrenia within monozygotic twin is about 50% and on the other hand, disease concordance rate of schizophrenia within dizygotic twin is about 15%. This suggests the development of schizophrenia has a strong genetic determinant and concurrently non-genetic factors, epigenetic changes, are also important. We previously used DNA microarray analysis to examine the mRNA expression patterns in the lymphoblastoid cells derived from two pairs of monozygotic twins discordant for schizophrenia. We found the expression changes of the ADM, SEPX1, and CD200. The up-regulation of ADM and SEPX1 were previously reported and this indicated that there are some kinds of biological differences which make the mRNA expression differences within monozygotic twin discordant for schizophrenia. In this study, we reported the DNA methylation differences that may be directly involved in etiology of schizophrenia. Method: We performed a genome-wide DNA methylation analysis on peripheral blood obtained from two twin pairs discordant for schizophrenia using Illumina Infinium HumanMethylation450 BeadChip. The objective of this study was clearly explained and written informed consent was obtained from all subjects. The study was approved by the Ethical Committee of the Faculty of Medicine, the University of Tokyo. Results: The methylation status of 485,512 individual CpGs was detected from two twin pairs. We found 59 differentially methylated CpGs from one pair and 740 CpGs from another twin pair. A number of common differentially methylated CpGs between two twin pairs is 10 sites. Conclusion: We have undertaken the genome-wide methylation analysis in monozygotic twins discordant for schizophrenia and identified new potential susceptibility genes for schizophrenia.

MicroRNA-9 and -206 expression profile in human amyotrophic lateral sclerosis. *D. Dogini[1], A. Nucci[2], I. Lopes-Cendes[1], M. França Jr[2].* 1) Dept of Medical Genetics, FCM - UNICAMP, Campinas, Sao Paulo, Brazil; 2) Dept of Neurology, FCM - UNICAMP, Campinas, Sao Paulo, Brazil.

MiRNAs are a new class of small RNA molecules (21–24 nucleotide-long) that negatively regulate gene expression either by translational repression or target mRNA degradation. MiRNAs are involved in many important biological processes including cell differentiation, central nervous system development and neurodegenerative diseases. Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease that specifically affects upper and lower motor neurons, leading to progressive paralysis and death. Recent data indicate that miR-9 and miR-206 are abnormally expressed in animal models of ALS. The main goal of this study is to investigate the expression pattern of the neuronal microRNA (miRNA) miR-9 and the muscle-specific miRNA, miR-206 in patients with ALS. Total RNA was isolated from skeletal muscle tissue of 7 patients with ALS and 5 healthy controls for comparison. Each patient fulfilled El Escorial diagnostic criteria for probable or definite ALS. RNA samples were used in real-time PCR reactions with TaqMan™ microRNA assays (Applied Biosystems) to quantify miR-9 and miR-206. MiR-9 and miR-206 were both over expressed in patients when compared to controls (5-fold and 3-fold, respectively). We have identified abnormal expression of miR-9 and miR-206 in human ALS, which may indicate a tight down regulation of genes regulated by these miRNAs in ALS. Our results should be explored in additional studies to find and validate possible gene targets that improve understanding of miRNA regulation in ALS and investigate miRNAs that can be used as biomarkers for early diagnosis of ALS disease.

2654F

Altered cell growth and mTOR signaling in idiopathic autism spectrum disorders. *A.M. Suzuki[1], C.O.F. Machado[2], K.G. Oliveira[1], E. Vadasz[3], M.R. Passos-Bueno[1], A.L. Sertie[2].* 1) Departamento de Genética e Biologia Evolutiva, Universidade de São Paulo, São Paulo, Brazil; 2) Hospital Israelita Albert Einstein, Instituto de Ensino e Pesquisa, São Paulo, Brazil; 3) Instituto de Psiquiatria, Faculdade de Medicina, Universidade de São Paulo, São Paulo, Brazil.

Autism Spectrum Disorders (ASD) are common neurodevelopmental conditions with high phenotypic and genetic heterogeneity. Although the genetic cause is mostly unknown, evidences support the hypothesis that common pathogenic pathways may be shared by ASD. The molecular mechanisms underlying the neurological defects in genetically defined syndromes with increased prevalence of ASD, such as Fragile-X and Tuberous sclerosis syndromes, may provide important clues for such common pathways. Currently, it is well known that these monogenic disorders present dysregulated mTOR signaling, which controls several biological processes, such as cell growth and protein synthesis. Therefore, the present study was undertaken to investigate whether altered mTOR signaling is also a feature of subjects with idiopathic ASD. Firstly, we compared the proliferative response of dental pulp stem cells (DPSCs) derived from 6 autistic male patients and 5 matched controls to different fetal bovine serum (FBS) concentrations. Interestingly, all patient-derived DPSCs showed significant increased or decreased mitogenic response to FBS compared to controls. Next, to investigate whether these responses were due to altered mTOR signaling, we evaluated by western blot the pattern of phosphorylation of pAktS473, pmTORS2448, and pS6S235/236 proteins in an expanded sample of 13 patients and 8 controls DPSCs after 48hr of starvation period followed or not by stimulation with 20% FBS for 30min. Under these conditions, 2 patient-derived cells, in which proliferative response to FBS was higher than in the controls, showed increased phosphorylation of components of the mTOR cascade compared to controls: in relation to FBS-starved condition, 1 patient showed 23.5-fold increase in pAkt, 9.8-fold increase in pmTOR, and 10.4-fold increase in pS6, and the other showed 6.9-fold increase in pS6; whereas controls had lower activation values: mean 3.8-fold (SD 2.7) for pAkt, mean 1.8-fold (SD 1.3) for pmTOR, and mean 3.1-fold (SD 1.1) for pS6. Our data suggest that dysregulation of mTOR pathway may play an important role in the pathogenesis of at least a subgroup of idiopathic ASD cases. In addition, our findings suggest that other pathways may also be involved in the altered cell proliferation phenotype observed in patient-derived cells. Collectively, these data support an important contributory role for pathways involved in cell growth and protein synthesis in the pathophysiology of ASD. FAPESP, CNPq.

BACKGROUND: Wistar audiogenic rat (WAR) is a genetic epilepsy model susceptible to audiogenic seizures, after high-intensity sound stimulation. Another genetic model we have recently identified is the generalized epilepsy with absence seizures (GEAS) rat. The aim of the present study was to characterize and compare the genetic profile of these two strains using gene expression analysis. METHODS: We obtained total RNA from five susceptible WAR (hippocampus and corpora quadrigemina), and two resistant WAR, as well as from hippocampus of three GEAS rats and three control Wistar. Gene expression analysis was performed using the GeneChip® Rat Genome 230 2.0 Array (Affymetrix™), and analyzed in R environment using the Affy and RankProd packages from Bioconductor. Overrepresented gene ontology categories were identified with DAVID software, and gene interactions and correlation networks were identified with Ingenuity Pathways Analysis software. RESULTS: Enriched gene ontology identified in WAR was involved in neuronal development and differentiation, regulation of synaptic transmission and neuron projection, as well as cell-cell signaling. The most active signaling pathways were development of the cochlear duct (Neurod1 up-regulated), and calcium and GABA receptor signaling (Gabra6 up-regulated). The main genes with differential expression and a possible biological role in epileptogenesis were, Apbb1 and Scn1A. In the GEAS rats we found differential expression of genes related to central nervous system development, activation of MAPK transcription factors, neuronal migration and apoptosis, such as Nrsn1, Hspb1, Fos, Twist1 and Krt18. The top enriched gene ontology categories included signal peptide, extracellular region and antigen processing and presentation. Among the most activated signaling pathways was neurosystem development. CONCLUSION: Our results clearly show a different molecular signature in the two genetic rat models analyzed. This study may help to clarify the underlying molecular mechanism that leads to the predisposition to seizures in these animals. SUPPORTED: FAPESP-FAPEMIG.

Effects of oral L-carnitine administration in narcolepsy patients. *T. Miyagawa[1], H. Kawamura[2], M. Obuchi[2], A. Ikesaki[2], A. Ozaki[3], K. Tokunaga[1], Y. Inoue[4, 5], M. Honda[4, 6].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Clinical Trial Operations Division, Site Support Institute Co., Ltd. (SSI), Tokyo, Japan; 3) School of Nursing, Faculty of Nursing, Toho University, Tokyo, Japan; 4) Japan Somnology Center, Neuropsychiatric Research Institute, Tokyo, Japan; 5) Department of Somnology, Tokyo Medical University, Tokyo, Japan; 6) Sleep Disorders Project, Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan.

Narcolepsy is a sleep disorder characterized by excessive daytime sleepiness, cataplexy, and rapid eye movement (REM) sleep abnormalities. A genome-wide association study identified a novel narcolepsy-related SNP rs5770917, which is located adjacent to the carnitine palmitoyltransferase 1B (*CPT1B*) gene encoding an enzyme involved in β-oxidation of long-chain fatty acids. The mRNA expression levels of *CPT1B* were associated with SNP rs5770917. In addition, we recently reported that acylcarnitine levels were abnormally low in narcolepsy patients. To assess the efficacy of oral L-carnitine for the treatment of narcolepsy, we performed a clinical trial administering L-carnitine (510 mg/day) to patients with the disease. The study design was a randomized, double-blind, cross-over and placebo-controlled trial. Thirty narcolepsy patients were enrolled in our study. Two patients were withdrawn and 28 patients were included in the statistical analysis (15 males and 13 females, all with *HLA-DQB1*06:02*). L-carnitine treatment significantly improved the total time for dozing off during the daytime, calculated from the sleep logs, compared with that of the placebo period (P=0.048). L-carnitine efficiently increased serum acylcarnitine levels, and reduced serum triglycerides concentration. Differences in the Japanese version of the Epworth Sleepiness Scale (ESS) and the Medical Outcomes Study 36-Item Short-Form Health Survey (SF-36) vitality and mental health subscales did not reach statistical significance between L-carnitine and placebo. However, the JESS scores and SF-36 subscale scores showed a tendency to improve in the L-carnitine period from the baseline. Although we examined the possible association of SNP rs5770917 with the clinical efficacy data, no significant associations were observed for any of the parameters. This study suggests that oral L-carnitine can be effective in reducing excessive daytime sleepiness in narcolepsy patients.

Discovery of genetic syndromes in patients manifesting with primary neuropsychiatric disorders. *J. So, J.L. Kennedy.* Neurogenetics Section, Neuroscience Research, Centre for Addiction and Mental Health, Toronto, ON, Canada.

Background: Many genetic syndromes are known to present with psychiatric features. Significantly, many syndromes require surveillance for other, sometimes preventable or treatable, clinical manifestations. Additionally, many metabolic conditions are treatable by dietary adjustments, medication and/or enzyme replacement therapy. However, many patients being treated for psychiatric symptoms are not routinely referred for genetic assessment, despite the presence of comorbidities that may suggest a genetic diagnosis. The goal of this study is to determine the role of hidden genetic conditions in patients with psychiatric features and comorbidities. By defining the prevalence of genetic syndromes within this population, we aim to increase awareness of potential genetic diagnoses in psychiatric patients, thereby potentially revolutionizing the standard of care, management and treatment of selected individuals with psychiatric impairment.**Methods**: Patients recruited are age 16 years and older with psychiatric features and at least one of 1) neurologic abnormality, 2) developmental delay (DD), autism spectrum disorder (ASD) or pervasive developmental disorder (PDD), 3) dysmorphic features, 4) congenital anomalies or 5) family history of DD, ASD or PDD. A database of phenotypic correlates will aid in determining the highest-yield data that lead to the most effective and efficient diagnosis of genetic syndromes in patients with neuropsychiatric disorders. Additionally, novel adult phenotypes in genes associated with known genetic syndromes can be delineated. If a diagnosis cannot be achieved by clinical means, samples from recruited patients are investigated for the presence of alterations and CNVs in high-priority candidate genes and for novel variants by high-resolution SNP array. **Results**: We present examples of genetic syndromes and variants identified in the patient cohort to date, including an unusual presentation of Fragile X syndrome in a female. Patient recruitment and sample analysis are ongoing. **Discussion**: This study will contribute to identifying genetic syndromes that can mimic or contribute to psychiatric illness, as well as determining the prevalence of these syndromes in psychiatric populations. It will facilitate education of primary care physicians, patients and families about, as well as establishment of standardized protocols for, the surveillance, management and treatment of genetic diagnoses in psychiatric patients with comorbidities.

Genomic and bioinformatic analyses of sex differences in autism spectrum disorder. *D.M. Werling[1], J.K. Lowe[2,3,4], V. Chandran[2], R.M. Cantor[4,5], D.H. Geschwind[2,3,4], ACE Genetics Consortium.* 1) Interdepartmental PhD Program in Neuroscience, Brain Research Institute, University of California, Los Angeles, Los Angeles, CA; 2) Program in Neurogenetics, Department of Neurology, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA; 3) Center for Autism Research and Treatment, Semel Institute, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA; 4) Center for Neurobehavioral Genetics, Semel Institute, University of California, Los Angeles, Los Angeles, CA; 5) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA.

Males are four times more likely to be affected by autism spectrum disorder (ASD) than females, an unexplained feature of ASDs likely to provide important pathophysiological clues. To investigate this sex difference, two methods, an unbiased genetic approach and a supervised bio-informatic analysis, were employed to identify new sex-specific genetic loci for ASD and examine known ASD-associated genes for evidence of sex-specific regulation. We first stratified multiplex families from the Autism Genetic Resource Exchange (AGRE) into two groups: those with affected male children only (male only, MO), and those with at least one affected female child (female containing, FC). Within each group, genome-wide SNP data were tested for association with ASD and 57,929 SNPs pruned for $r^2 \leq 0.1$ were used for nonparametric linkage analyses. Peak LOD scores were used to define genomic regions of interest, and haplotypes and imputed SNPs were tested for association with ASD within these regions. No genome-wide significant association was observed. However, significant linkage was observed in the MO group at chr1p31.3 (LOD 3.04; rs7521242). The strongest single-marker association signals within a 1-LOD interval around this peak (4.9Mb, 16 genes) were in *INADL*, a gene related to tight junctions, which is implicated in retinal degeneration, and interacts with the tuberous sclerosis complex. The strongest linkage signal in the FC group was at chr8p21.2 (LOD 2.51; rs10111167); association signals within a 1-LOD interval around this peak (3.3 Mb, 23 genes) implicate *EBF2*, a transcription factor involved in cerebellum development. For the second strategy, we used the JASPAR database of experimentally-validated transcription factor binding sites to assess transcription factor binding site enrichment in two sets of ASD-associated genes drawn from the literature. Compared with selected background sequences, the upstream regions (1 kb) of ASD candidate genes were enriched for binding site sequences for SRY, a chrY transcription factor best known for its critical role in sex determination of the gonads. This finding suggests that SRY-driven sex-specific transcriptional regulation of ASD-associated genes may play a role in males' greater vulnerability to ASDs. These complementary strategies, linkage and analysis of sex-specific gene regulation, show significant promise in identifying novel genetic loci and potential mechanisms that may contribute to the unexplained sex bias in ASD.

Analysis of RBFOX1 gene expression in lymphoblastoid cell lines of discordant ASD sibpairs. *C. Zusi, P. Prandini, G. Malerba, A. Marostica, E. Trabetti, P.F. Pigatti, The Italian Autism Network (ITAN).* Department of Life and Reproduction Sciences, University of Verona, Verona, Verona, Italy.

Several line of evidence suggest that 16p region is associated with ASDs (Autism Spectrum Disorders) and gene expression network studies of autistic brain vs controls show underexpression of genes related to neuronal marker RBFOX1 (Voineagu I et al, Nature 2011), a key specific alternative splicing regulator in neural cells. Here, we report on RBFOX1 gene expression in discordant ASD sibpairs using specimens which are more accessible than brain samples, i.e. lymphocytes from peripheral blood and lymphoblastoid cell lines (LCLs). Ten male sibpairs aged between eight and fifteen years (mean=10,8 years, SD 1.99) were selected from ITAN cohort. After RNA isolation from each sample, expression of RBFOX1 and housekeeping genes (DECR, FPGS, and TRAP1) was measured by semiquantitative RT-PCR using TaqMan assays. RBFOX1 gene expression was detected in LCLs but not in lymphocytes. No significant differences between ASD and non affected brothers were found in LCLs. Although LCLs are generally considered a valid approximation of in-brain expression, we were not able to confirm in ASD LCLs the previously reported gene expression dowregulation of RBFOX1. This maybe due to the fact that differences in RBFOX1 gene expression in brain samples are more pronounced than in LCLs.

Sinai Hospital, Toronto, Ontario, Canada; 6) New York University Abu Dhabi, United Arab Emirates.

Autism spectrum disorder (ASD) is a psychiatric disorder with a strong genetic component. A large number of functionally diverse genes have been shown to play a role in ASD. We investigated ASD from a systems biology perspective by experimentally constructing a protein-protein interaction (PPI) network that involves 191 candidate genes. Using stringent yeast-two-hybrid system we screened 420 brain-expressed splice isoforms of these genes for interactions against human ORFeome (~15,000 clones) and built Autism-centered Interactome Network (ACIN). In addition, by screening splice isoforms for interactions against themselves, we built a unique autism "splice" interactome. High quality of ACIN was confirmed in an independent assay in mammalian system (MAPPIT) and further verified by integrating publically available annotations for interacting protein pairs. Significant enrichment of co-expressed, co-regulated and co-GO annotated pairs was observed in ACIN as compared to control. Moreover, ACIN preys (binding partners of ASD candidates) demonstrated increased interconnectivity and significant enrichment in CNV membership, suggesting their potential relevance to disease. Subsequent grouping of ACIN nodes based on CNV membership produced highly connected autism CNV-CNV network. For the first time, this network revealed direct functional connections between different autism-relevant CNVs. Additional analysis of recent exome sequencing data mapped to ACIN showed that ACIN preys were not enriched in genes hit by damaging *de novo* mutations. Integration of brain expression data (from *Voineagu et al, Nature, 2011*) with ACIN PPIs revealed that ACIN is significantly enriched in genes differentially expressed in ASD cases *vs.* controls (P=4.5×10-5). Analysis of isoform interaction network showed strong influence of alternative splicing on PPIs, introducing an additional layer of network complexity. Testing splice isoforms for interactions proved useful, as exemplified by *BZRAP1* isoforms that connects autism genes from functionally diverse pathways into a single component. In summary, our results corroborate autism relevance of previously known genes (eg.*FOXP2*, *STX1A*, *BZRAP1*) and identify new players in autism pathways that were previously unrelated or weakly related to ASD (eg.*PIAS2*, *NAPB*, *TCF4*). Moreover, the unique "splice" interactome provides a more complete view of connectivity among ASD genes, CNVs and pathways, representing a valuable resource for future studies.

Transcriptome analysis of brain-related diseases in whole blood by RNA sequencing. *S. de Jong[1], T. Wang[1], A.P.S. Ori[1], M. Wiedau-Pazos[2], E. Strengman[3], N. Tran[4], J. DeYoung[1], R.S. Kahn[5], M.P.M. Boks[5], S. Horvath[6,7], R.A. Ophoff[1,5,7].* 1) Center for Neurobehavioral Genetics, University of California Los Angeles, Los Angeles, CA; 2) Department of Neurology, David Geffen School of Medicine at UCLA, Los Angeles, California, USA; 3) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, the Netherlands; 4) Informatics Center for Neurogenetics and Neurogenomics, University of California Los Angeles, Los Angeles, California, USA; 5) Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, Utrecht, the Netherlands; 6) Department of Biostatistics, School of Public Health, University of California Los Angeles, Los Angeles, California, USA; 7) Department of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, California, USA.

Neuropsychiatric and neurological disorders are prevalent in the population. They can severely disrupt daily life of patients and their families and bear a huge societal and economic burden. Genetic studies have identified a number of susceptibility loci but these do not nearly explain the high heritability estimates for these disorders, most likely due to extensive clinical and genetic heterogeneity. Efforts have been made to develop biomarkers using array-based gene expression profiles from peripheral blood of patients but results remain equivocal. In order to comprehensively study trait-specific gene expression profiles in blood we performed a RNA sequencing (RNA-seq) experiment with 192 subjects representing three different brain-related diseases. Transcriptome analysis by RNAseq allows for in-depth study of gene expression while the inclusion of patients with different disease types will provide insights into the specificity of these expression profiles distinguishing different brain-related disorders. We included four groups of subjects (each n=48): patients with diagnosis of (i) schizophrenia, (ii) severe bipolar disorder, (iii) amyotrophic lateral sclerosis, and (iv) healthy controls. RNA was collected from whole blood using PAXgene tubes and sequencing was performed using the Illumina TruSeq sample kits and HiSeq2000 technology. In addition to standard case-control comparisons, we will also present comparisons of gene expression signatures between these disorders. We use systems biology methods to reconstruct weighted co-expression networks and perform expression QTL analysis. Our study design with RNA-seq data of 192 subjects provides an unique opportunity for detailed analysis of gene-expression differences including allele-specific expression and alternative splicing in the context of psychiatric and neurologic diseases.

The role of GTF2IRD1 in the auditory pathology of Williams-Beuren syndrome. *CP. Canales[1], ACY. Wong[2], GD. Housley[2], PW. Gunning[1], EC. Hardeman[1], SJ. Palmer[1].* 1) Cellular and Genetic Medicine Unit, School of Medical Sciences, University of New South Wales, Sydney, Australia; 2) Translational Neuroscience Facility, School of Medical Sciences, University of New South Wales, Sydney, Australia.

Williams-Beuren Syndrome (WBS) is an autosomal dominant condition associated with multisystemic developmental abnormalities caused by a hemizygous deletion of a 1.55 Mb WBS critical region (WBSCR) on chromosome 7q11.23, involving up to 28 genes. The auditory impact has been widely studied because of reports of higher musical ability and phonophobia in WBS patients. Children are typically reported as having hyperacusis (high sensitivity to sound) or auditory allodynia (aversion to certain sounds not normally found aversive). However, high-frequency sensorineural hearing loss (SNHL) is common in individuals with WBS at all ages. In addition, patients who have “normal” hearing, as defined by behavioural thresholds, can show sub-clinical impairments or undetected cochlear pathology. Most reports suggest that although hearing capacity is reduced in WBS patients, the perception of sound is somehow amplified. Atypical smaller deletions of the WBSCR have implicated the genes *GTF2I* and *GTF2IRD1* as the prime candidates for the cause of specific cognitive and behavioural defects that result in the distinctive WBS personality profile. However, the SNHL has not yet been genetically mapped. In this study, we aimed to investigate the role of GTF2IRD1 in the causation of hearing loss using a targeted *Gtf2ird1* null mouse that blocks normal GTF2IRD1 protein production. GTF2IRD1 protein is a transcription factor that is broadly expressed during development and in adult neuronal tissues, but its cellular role is not completely understood. However, Gtf2ird1 null mice have shown some intriguing parallels with WBS, including craniofacial abnormalities and behavioural changes. We have examined hearing capacity by auditory brainstem response (ABR), which measures sound-evoked auditory neurotransmission from the cochlear nerve to the auditory midbrain, and by distortion product otoacoustic emissions (DPOAE) to analyse the amplifying function of the outer hair cells. Our results indicate that *Gtf2ird1* null mice have impaired cochlear sound transduction, as manifested by higher auditory thresholds in the DPOAE analysis and compromised auditory neurotransmission, as determined by the ABR analysis. Analysis of *Gtf2ird1* expression in the organ of corti has revealed transcription in the outer hair cells and very strong expression in the cochlear spiral ganglion cell bodies. These data indicate that GTF2IRD1 plays an important role in the WBS hearing phenotype.
