Separation of compositionally distinct extracellular fluids is indispensable for epithelia that line the lumen of different organs and is mediated by various tight junctional complexes. In the inner ear, tight junctions between the epithelial cells lining the scala media are responsible for isolating the endolymph (high K^+, low Na^+) from the perilymph (low K^+, high Na^+) that fills the other cochlear compartments. Mutations in *TRIC*, that encodes a tricellular tight junction protein, lead to recessively inherited hearing loss in humans (*DFNB49*). To determine the mechanism of deafness due to loss of tricellulin, we developed and characterized the *Tric* knock-in mouse model. Mice homozygous for the knock-in mutation displayed early onset rapidly progressing hearing loss and were completely deaf by 4 weeks of age. Progression of hearing loss coincided with outer hair cell degeneration, followed by loss of inner hair cells. Although the stria vascularis and vestibular functions were intact, the tricellular tight junctions in the marginal cell layer and vestibular epithelia were structurally abnormal in the homozygous mutant mice. Potassium current measurements indicated that the outer hair cell maturation was normal in the homozygous mutants. Therefore, the organ of Corti degeneration in the *Tric* knock-in mouse suggests compromised barrier function of the reticular lamina, which leads to outer hair cell death due to K^+ leakage from the endolymph. Consistent with this hypothesis, the hair cell loss in tricellulin mutant mice was rescued *in vivo* when the endocochlear potential was eliminated by deleting *Pou3F4*. Finally, comprehensive phenotypic screening showed that the homozygous mutants have a broader phenotype besides hearing loss. Thus, the loss of tricellulin leads to syndromic deafness in mice.

Generation and characterization of *Plp1* dup, a new mouse model of Pelizaeus-Merzbacher Disease with tandem genomic duplication. *G. Hobson[1, 2, 3], K. Clark[1, 2], L. Sakowski[1, 2], K. Sperle[1], L. Banser[1], D. Bessert[4], R. Skoff[4].* 1) Nemours Biomedical Res, A I duPont Hosp Children, Wilmington, DE; 2) Dept Biology, Univ Delaware, Newark, DE; 3) Jefferson Med College, Thomas Jefferson University, Philadelphia, PA; 4) Dept Anatomy and Cell Biology, Wayne State University, Detroit, MI.

Pelizaeus-Merzbacher disease (PMD; MIM #312080) is an X-linked leukodystrophy that most commonly leads to life-long disability. The disorder arises from various lesions in the proteolipid protein 1 gene (*PLP1*; MIM #300401), which encodes proteolipid protein (PLP1), the most abundant protein in myelin. The most common mutation (50–75%) is a tandem, direct duplication of the genomic region encompassing *PLP1* and other flanking genes. Transgenic models carrying 4–7 extra copies of the *Plp1* gene on an autosome have been useful for understanding the consequences of overexpression of *Plp1* on myelination, but they do not recapitulate the genetics of the disease. We have developed a murine strain, *Plp1*dup, with a duplication analogous to human alleles. *Plp1*dup mice carry a stable tandem duplication of the genomic region on the X chromosome including the *Plp1* gene and 5 flanking genes. These mice have progressive CNS myelin degeneration and associated neurological abnormalities (motor skills, gait). The *Plp1*dup mouse will be a useful model for understanding the pathogenesis of PMD and for testing potential therapeutic strategies.

Gtf2i copy number affects the growth of neural progenitors in the developing mouse cortex. *H. Oh[1], L.R. Osborne[1,2,3].* 1) Institute of Medical Sciences, University of Toronto, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Ontario, Canada; 3) Department of Medicine, University of Toronto, Toronto, Ontario, Canada.

Williams-Beuren syndrome (WBS) is a neurodevelopmental disorder caused by the deletion of 26 genes on chromosome 7q11.23. People with WBS exhibit an array of cognitive and behavioral features including intellectual disability, social disinhibition, anxiety, deficits in visuospatial construction and attention deficit hyperactivity disorder, but the neurobiological basis for these symptoms remains unknown. Our lab has generated mouse models with altered gene dosage of two candidate genes from the WBS deletion region, General Transcription Factor 2 I (Gtf2i) and GTF2I Repeat Domain containing protein 1 (Gtf2ird1). These models include mice with hemizygous deletion of Gtf2i (Gtf2i+/−) or of both genes (Gtf2i/Gtf2ird1+/−) and mice with duplication of Gtf2i (Gtf2i+/Dup). We have used these mice to determine whether altered expression of Gtf2i and/or Gtf2ird1 affects neural stem cell growth and neurogenesis, and potentially contributes to the neurological features of WBS. Neuronal precursor cells (NPCs) from the brain cortex of embryonic day 12.5 mice were dissected, dissociated, seeded at equal densities and cultured for between 1 and 3 days in vitro (d.i.v.). We then used cell-specific markers to analyze cell proliferation, apoptosis and differentiation. We initially used pooled litters which we validated using single embryo culture, where we were able to directly compare individual littermates of different genotypes. Our results showed that mice with a hemizygous deletion of Gtf2i and Gtf2ird1 had an overall reduction in the number of NPCs after 1 d.i.v compared to wildtype mice, whereas mice with an additional copy of Gtf2i had an increase in the number of precursors. Similar results were seen for differentiated neurons after 3 d.i.v. No change in either proliferation or apotosis was associated with any genotype. These results indicate that gene copy number of Gtf2i directly affects the growth of the neural stem cell population in the mid-gestation developing mouse cortex. We are now looking to see whether this affect continues into later developmental stages or translates into altered neuronal density in the post-natal or adult cortex. The growth and differentiation of the NPC pool into neurons and the specification of specific neuronal subtype identities are crucial in the proper development of the cortex, and we hypothesize that some of the neurological features of WBS may stem from impairments in these early stages of neuronal development.

2666T

***GPM6A* is duplicated in a patient with learning disability and behavioral anomalies and influences stress response and long-term memory in *Drosophila melanogaster*.** *C. Zweier[1], A. Gregor[1], J. Kramer[2], I. Schanze[1,3], A.B. Ekici[1], A. Schenck[2], A. Reis[1].* 1) Institute of Human Genetics, University Erlangen-Nuremberg, Erlangen, Germany; 2) Department of Human Genetics, Nijmegen Centre for Molecular Life Sciences, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) Institute of Human Genetics, University Hospital Magdeburg, Magdeburg, Germany.

In a 10 year old patient with learning disability and a tested IQ of 75 we detected a de novo copy number gain of 655 kb containing only the *GPM6A* gene with an Affymetrix 6.0 SNP array. This aberration was not observed in 820 healthy controls. The girl additionally presented with behavioral anomalies such as provocative actions, repetitive questions, and problems in interaction with others. Apart from mild obesity and short metacarpalia IV and V she showed no specific dysmorphism or organic anomalies. Expression analysis in blood lymphocytes showed increased *GPM6A* expression in the patient compared to healthy controls. Glycoprotein M6a (GPM6A) is a transmembrane protein of the PLP/DM20 protein family whose expression is restricted to neurons. In rats GPM6A has been implicated in neurite outgrowth, neuronal differentiation and synapse formation. M6a has also been implicated in stress response in different animal models. So far, no association of *GPM6A* defects with cognitive disorders has been reported. Mutational screening of the gene in 284 patients with variable intellectual disability did not reveal any further alteration. We therefore employed *Drosophila melanogaster* as a model organism to further elucidate the role of GPM6A in stress response, synapse formation, and behavior and learning. Using the UAS-Gal4 system we analyzed the function of the Drosophila homologue m6 after tissue specific knockdown and overexpression with different m6 RNAi and m6 overexpressing lines. We found elevated expression levels of m6 in fly brains of L3 larvae and adult flies after heat shock stress treatment, which further increased with heat shock elongation. These findings indicate that m6 expression is also stress responsive in flies. While analyses of neuromuscular junctions in L3 larvae upon knockdown or overexpression of m6 did not reveal any significant alterations in synapse formation, behavioral testing using the courtship conditioning paradigm revealed impairment of long-term memory in both knockdown and overexpression conditions. Our findings in Drosophila indicate a role of m6 in neuronal function, especially in stress response and long-term memory, thus supporting a relevance of the*GPM6A* duplication in our patient for her cognitive and behavioral phenotype.

2667F

FASPS Associated Per3 Mutation Affects Mesenchymal Stem Cell Differentiation. *K. Kaasik[1], C.R Jones[1], Y.H Xu[1], S. Nishino[2], L.J Ptacek[1], Y.H Fu[1].* 1) Univeristy of California San Francisco, San Francisco, CA 1550 4th street, 2922, San Francisco, CA94143; 2) Stanford University.

Circadian clock and sleep homeostasis are tightly regulated. Here we identified double mutation in the circadian co-transcriptional factor Period 3 gene from the human subsets with Familiar Advanced Sleep Phase Syndrome (FASPS) and severe depression phenotype. The Per3 BAC transgenic mouse model recapitulates aspects of human FASPS phenotype. We found increased wakefulness and reduced non-rapid eye movement (REM) sleep during the light phase and quicker recovery of REM sleep after sleep deprivation. This phenotype was not observed in Per3 null mice and Per3 wt BAC mice. Depression-like behavior was released by lorazepam and imipramine treatment. We also observed that transgenic mice have reduced fat mass and increased lean mass compared them wt littermates. We found that fat cell formation from mesenchymal stem cell is inhibited in transgenic mouse model. Here we identified that circadian clock gene Per3 links metabolism to sleep homeostasis.

2668W

Characterization of a novel mitofusin 2 knock-in mouse model. *A. Rebelo[1], A. Strickland[1], F. Zhang[1], J. Price[1], J. Silva[1], R. Wen[1], B. Bolon[2], J. Vance[1], S. Zuchner[1].* 1) HIHG, University of Miami, Miami, FL; 2) College of Veterinary Medicine, Columbus, OH.

Charcot-Marie-Tooth disease (CMT) comprises a group of heterogeneous peripheral neuropathies affecting 1 in 2,500 individuals. While mutations in several genes cause axonal degeneration in CMT, mitofusin 2 (MFN2) variants account for 91% of the most severe cases of the disease; making it the single most important cause of inherited peripheral axonal degeneration. MFN2 is an integral mitochondrial outer membrane protein that plays a major role in mitochondrial fusion and motility, however, the mechanism by which dominant mutations in this protein lead to neurodegeneration is still unknown. In order to investigate the underlying pathophysiology, we have generated a MFN2 knock-in mouse strain containing the R94W mutation originally identified in several CMT families. We have performed behavioral, morphological, cell biological, and biochemical studies to characterize the consequences of this mutation. In mice, homozygous inheritance of this mutation leads to a low birth weight, followed by death within a day. On the other hand, heterozygous inheritance causes no gross behavioral deficits for the duration of the mouse life (up to 1 year of life observed). Heterozygous mice do not differ from their wildtype littermates based on an array of behavioral tests and morphological analyses. Interestingly, heterozygous and homozygous mouse embryonic fibroblasts (MEF) show fragmented instead of elongated mitochondrial morphology compared to wild type mice. Homozygous tissues show both decreased mitochondrial DNA and ATP amounts. The presence of molecular mitochondrial abnormalities in MFN2-R94W mice underlines the usefulness of this model for interrogating the pathophysiology of CMT. In contrast to the human phenotype, the lack of overt behavioral deficits in heterozygous mice is likely attributable to the shorter life span and axon length in rodents. However, molecular studies will benefit from cells and tissues harvested from these mice and information on pathway interactions can be obtained by breeding these mice with other mutant mouse models.

2669T

Triply mouse model of Tay-Sachs disease shows altered brain ganglioside pattern. *V. Seyrantepe, Z. Timur.* Molecular Biology and Genetics, Izmir Institute of Technology, Izmir, Turkey.

Tay-Sachs disease is a severe lysosomal storage disorder caused by mutations in the HEXA gene coding for α subunit of lysosomal β-hexosaminidase A enzyme, which converts GM2 to GM3 ganglioside. HexA-/- mice, depleted of β-hexosaminidase A enzyme, remain asymptomatic to 1 year of age, owing to the ability of these mice to degrade stored GM2 ganglioside via sialidase (s) (sialidases Neu1, Neu2, Neu3 or Neu4) into glycolipid GA2 which further processed by β-hexosaminidase B, thereby completely bypassing the HexA defect. Previously we showed that mouse model with targeted disruption of both HexA and Neu4 genes (HexA-/-Neu4-/-) have epileptic seizures and accumulating GM2 ganglioside in brain tissue. To elucidate whether lysosomal Neu1 sialidase can also contribute to GM2 ganglioside degradation, a triply mouse model has been generated by breeding HexA-/-Neu4-/- mouse model and hypomorph mouse with 8–10% lysosomal Neu1 sialidase activity. Thin layer chromatography analysis of brain tissue gangliosides from affected mice at age of 4–5 and 8–9 months old showed lysosomal Neu1 sialidase deficiency slightly affect brain ganglioside pattern in triply mice suggesting that a mouse model with targeted distruption of Neu1 gene are required to show the involvement of lysosomal Neu1 sialidase in glycolipid degradation in HexA-/- and HexA-/-Neu4-/- mice. In our study, increased expression levels of lysosomal Neu1 and plasma membrane-associated Neu3 sialidases in brain tissue of HexA-/- and HexA-/-Neu4-/- mice also suggest contribution of other sialidases to the metabolic bypass pathway.

Deficiency of *SPECC1L* down-regulates PI3K-AKT signaling in the pathogenesis of Oblique Facial Clefts. *N.R. Wilson[1], A.J. Olm-Shipman[1], L. Pitstick[2], B.C. Bjork[2], I. Saadi[1].* 1) Department of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS; 2) Department of Biochemistry, Midwestern University, Downers Grove, IL.

Orofacial clefts are among the most frequent birth defects, affecting one child in eight hundred, in the U.S. alone. Although the majority of orofacial clefts are limited to the lip and palate, a small subset involve a cleft that extends from the oral cavity to the eye, termed Tessier type IV or Oblique Facial Clefts (ObFCs). Previously, we identified *SPECC1L* (sperm antigen with calponin homology and coiled-coil domains 1-like) as the first gene mutated in ObFCs. SPECC1L is a novel cytoskeletal `crosslinking' protein, which interacts with both the actin and microtubule cytoskeletons. Further, SPECC1L deficiency in *Drosophila*, zebrafish and mammalian cells results in migration and adhesion defects, revealing a potential mechanism underlying ObFCs (Saadi et al., *AJHG* 2011). A critical question is through what signaling pathway(s) SPECC1L regulates these two cytoskeletal systems to control cell migration and cell adhesion. To explore this, we performed expression microarrays and antibody arrays on SPECC1L-deficient cells. Our analyses reveal a down-regulation of the PI3K-AKT signaling pathway, which coordinates extracellular cues relevant to both migration and adhesion. These cues include growth factor responses and Integrin-ECM interactions that culminate in the remodeling of the actin cytoskeleton. Thus, our data suggest that SPECC1L is a novel, craniofacial-specific mediator of PI3K-AKT signaling. Interestingly, SPECC1L-deficient U2OS osteosarcoma cells show a drastic change in cell shape - from an epithelial polygonal to a fibroblast-like elongated shape - *only* upon reaching confluence. These deficient cells also show an increase in F-actin fluorescence. We propose this remarkable change in cell morphology upon cell-cell contact is PI3K-AKT mediated and bears importance for many developmental events critical in craniofacial morphogenesis, including induction of cranial neural crest (CNC) cells as well as coordinate movement of CNC-derived sheets of cells in the facial prominences that fail to fuse in ObFCs. We are now validating our findings *in vivo* and are modulating the PI3K-AKT pathway with small molecule agonists and antagonists to characterize further the function of SPECC1L in the pathogenesis of ObFCs.

Transgenic rescue of BBS phenotypes in Bbs4 null mice. *X. Chamling[1,2], S. Seo[3], K. Bugge[1,2], C.C. Searby[1,2], A.V. Drack[3], K. Rahmouni[4], V.C. Sheffield[1,2].* 1) Pediatrics, University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA; 3) Department of Ophthalmology and Visual Sciences, University of Iowa, Iowa City, IA; 4) Department of Internal Medicine, University of Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a genetically heterogeneous autosomal recessive disorder characterized by obesity, retinal degeneration, polydactyly, hypogenitalism and renal defects. Recent findings have associated the etiology of the disease with cilia, and BBS proteins have been implicated in trafficking various ciliary cargo proteins. To date, 17 different genes have been reported for BBS among which BBS1 is the most common cause of the disease followed by BBS10, and BBS4. A murine model of BBS4 is known to phenocopy most of the human BBS phenotypes, and it is being used as a BBS disease model. To better understand the in vivo localization, cellular function, and interaction of BBS4 with other proteins, we generated a transgenic BBS4 mouse expressing the human BBS4 gene under control of the beta actin promoter. The transgene is expressed in various tissues including brain, eye, testis, heart, kidney, and adipose tissue. These mice were further bred to express the transgene in Bbs4 null mice, and their phenotype was characterized. Here we report that despite tissue specific variable expression of the transgene, human BBS4 was able to complement the deficiency of Bbs4 and rescue all the BBS phenotypes in the Bbs4 null mice. These results provide an encouraging prospective for gene therapy for BBS related phenotypes and potentially for other ciliopathies.

2672T

Overexpression of Rai1 in mouse forebrain neurons is enough to cause most PTLS-like phenotypes. *L. Cao[1], J. Molina[2], P. Carmona-Mora[3], A. Oyarzo[4], J. Young[1,3], K. Walz[1,3,5].*1) Dr. John T. Macdonald Foundation Department of Human Genetics, Miller school of medicine, university of Miami, Miami, FL, USA; 2) Centro de Estudios Científicos, CECS, Valdivia, Chile; 3) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, FL, USA; 4) Cellular Communication Laboratory, Program of Molecular & Cell Biology, ICBM, Medical Faculty, University of Chile, Santiago, Chile; 5) Department of Medicine, Miller School of Medicine, University of Miami, FL, USA.

PTLS (Potocki Lupski Syndrome) is a genomic disorder associated with a duplication in 17p11.2. The clinical features of PTLS include intellectual disability, autistic features and developmental deficits. A PTLS mouse model, Dp(11)17/+, was generated by chromosome engineering, harboring a genomic duplication syntenic to the PTLS region. Many PTLS phenotypes were recapitulated in this mouse model including underweight, low fat content, hyperactivity, impaired memory and learning ability and social deficiencies. Further investigations showed that most of these phenotypes can be rescued by correcting the RAI1 dosage, indicating that RAI1 dosage is directly associated with PTLS phenotypes. Since RAI1 is highly expressed in brain neurons and it seems to be responsible for the neurobehavioral phenotypes in the PTLS mouse model, we wanted to define the specific brain regions that are related to the abnormal phenotype due to RAI1 overexpression. Here we generated a transgenic mouse line carrying transgene encoding Rai1 controlled by a tTa responsive promoter. By crossing this mouse line with camkII-tTa mice which express tTa downstream of CamkII promoter, we obtained bi-transgenic mice (I-Rai1) which over-express Rai1 specifically in mouse forebrain neurons. Surprisingly, I-Rai1 mice showed most of the PTLS-like phenotypes including underweight, lower fat content, hyperactivity, dominant behavior and impaired learning and memory ability. Anxiety is not observed in I-Rai1 mice, indicating that other brain regions might be involved in the development of Rai1-related anxiety behavior. After fear conditioning, we observed less c-fos induction in I-Rai1 mouse hippocampus which might be responsible for the impaired contextual memory ability. Other stress induced immediate early genes (IEG) are also dysregulated in I-Rai1 mouse hippocampus such as Bdnf and Growth hormone. Cell fractionation experiment showed Rai1 protein is mainly bound to the chromatin in neurons, suggesting Rai1 might affect the IEG expression by interacting with chromatin structures. Our results clearly showed that several PTLS phenotypes (body weight, social, memory and learning ability) are centrally governed. Moreover, Rai1 dosage is critical in forebrain neurons, and it affects the regulation of stress induced gene expression. In summary we present here a phenotype-tissue/cell/function specific relationship that will be crucial for advancing in the development of PTLS therapeutic strategies.

A Zebrafish model for Richieri-Costa-Pereira Syndrome: knockdown of eif4a3 gene results in craniofacial development disorder. *L. Alvizi[1,2], A. Weiner[3], F. Favaro[1,2,4], R. Zechi-Ceide[4], A. Richieri-Costa[4], M. Guion-Almeida[4], N. Calcaterra[3], M. Passos-Bueno[1,2].* 1) Genetics and Evolutive Biology, University of São Paulo, São Paulo, Sao Paulo, Brazil; 2) Human Genome Research Center, Institute of Biosciences of University of São Paulo, São Paulo, SP, Brazil; 3) Instituto de Biología Molecular y Celular de Rosario (IBR), CONICET- Área Biología General, Departamento de Ciencias Biológicas, Facultad de Ciencias Bioquímicas y Farmacéuticas, Universidad Nacional de Rosario, Rosario. Argentina; 4) Department of Clinical Genetics, Hospital of Rehabilitation of Craniofacial Anomalies (HRCA), University of São Paulo, SP, Brazil.

Purpose: Richieri-Costa-Pereira Syndrome (RCPS) is a rare acrofacial dysostosis characterized by Robin sequence, cleft mandible, short stature and limb defects. RCPS is inherited in an autosomic recesive fashion, presenting a high rate of consanguinity, increased male mortality and 25% recurrence in sibs among patient's families. Recently, our group has identified a mutation in EIF4A3 gene (Eukariotic Initiation Factor 4A3) in homozygosity in RCPS patients as a putative molecular cause underlying this disorder (Favaro et al., ASHG 2012 submitted). Once zebrafish modeling for human genetic diseases has been emerging as a very informative tool in the developmental field, our objective was to knockdown eif4a3 expression in zebrafish embryos in order to phenocopy RCPS and study the malformation of craniofacial structures during embryonic development. Methods: We injected zebrafish embryos at the two-cells stage with either an eif4a3 translation-blocking or a mismatch control morpholinos (GeneTools). Development was observed at the points of 4, 15, 24 and 48 hours post-fertilization (hpf) and 5 days post-fertilization (dpf). Expression of p53 and p21 were assessed through qRT-PCR using 24 hpf embryos to check morpholino off-target effects and p53 apoptotic pathway activation by p21. For a deeper phenotype characterization, whole-mount RNA in situ hybridization for myoD, sox9b and col2a1 expression were performed. Besides, cartilage and bone formation were analysed by alcian blue and calcein stainings. Finally, by acridine orange staining we detected the apoptosis level assessment. Results/Conclusion: At 24 hpf, 71% of embryos in average treated with eif4a3 translation-blocking morpholino presented severely affected as well as dysmorphic craniofacial structures and a mortality rate of 29%. Forty-eight hpf embryos were smaller in size than controls and also presented craniofacial abnormalities. Larvae at 5 dpf had no mandible development. p53 mediated apoptosis pathway was not overexpressed with morpholino treatment since p53 and p21 expression was not significantly distinct from negative controls, excluding an off-target effect from morpholino. Our results suggest that eif4a3 embryonic expression is essential for normal craniofacial development and its impairment leads to craniofacial dysmorphisms in zebrafish. Besides, eif4a3 knockdown in zebrafish appears to be a good model for future research in Richieri-Costa-Pereira Syndrome. CEPID/FAPESP/CONICET.

Trousseau, Paris, France.

Periventricular nodular heterotopia (PH) is a human brain malformation caused by defective neuronal migration that results in ectopic neuronal nodules lining the lateral ventricles beneath a normal appearing cortex. Most affected patients have seizures and their cognitive level varies from normal to severely impaired. Mutations in the Filamin-A (or FLNA) gene are the main cause of PH, but the underlying pathological mechanism remains unknown. Although two FlnA knockout mouse strains have been generated, none of them showed the presence of ectopic nodules. To recapitulate the loss of FlnA function in the developing rat brain, we used an in utero RNA interference-mediated knockdown approach and successfully reproduced a PH phenotype in rats comparable with that observed in human patients. In FlnA-knockdown rats, we report that PH results from a disruption of the polarized radial glial scaffold in the ventricular zone altering progression of neural progenitors through the cell cycle and impairing migration of neurons into the cortical plate. Similar alterations of radial glia are observed in human PH brains of a 35-week fetus and a 3-month-old child, harboring distinct FLNA mutations not previously reported. Finally, juvenile FlnA-knockdown rats are highly susceptible to seizures, confirming the reliability of this novel animal model of PH. Our findings suggest that the disorganization of radial glia is the leading cause of PH pathogenesis associated with FLNA mutations.

2675T

Mining phenotype and disease models from the Mouse Genome Informatics Resource. *J.T. Eppig, S.M. Bello, H. Dene, A. Anagnostopoulos, H. Onda, R. Babiuk, M.N. Knowlton, M. Tomczuk, C.L. Smith.* Jackson Laboratory, Bar Harbor, ME.

The laboratory mouse is the premier model for studying human biology and disease. Large-scale forward and reverse mutagenesis projects are making available mutations in every gene. The phenotyping of mutant genotypes promises an explosion in analyzing gene function and in discovering and validating new models for human disease.

The Mouse Genome Informatics (MGI, www.informatics.jax.org) database is a treasure trove for biologists and clinicians seeking to correlate mouse and human phenotypes. MGI catalogs all mouse mutant alleles, with key molecular attributes, captures descriptions of phenotypes, and links mouse genotypes experimentally determined to be models of human disease with corresponding disease terms in OMIM. Standardization of nomenclature and application of bio-ontologies, including the Mouse Anatomical (MA) Dictionary and Mammalian Phenotype (MP) Ontology, ensure that data are consistently annotated, making robust searches possible.

Currently >740,000 alleles are cataloged in >20,000 genes. More than 32,000 alleles are propagated in live mice or are available as cryopreserved embryos or sperm; the rest existing only in ES cell lines. The amount of phenotypic data available is very rich, with nearly 44,000 unique genotypes curated with >223,000 MP terms. This substantial data set makes possible mining of MGI to look for phenotype associations (e.g., What phenotypes are found concordantly? What genotypes have similar phenotype profiles?). Such questions can uncover genes in a common pathway, implicate genes with particular functions, or identify relationships between diseases and their underlying genetic defects. User access to mouse phenotype and disease data is achieved in a number of ways from gene, allele, phenotype, or disease perspectives.

MGI will integrate data from the new International Mouse Phenotyping Consortium (IMPC) Centers, which are collecting systematic large-scale phenotyping data from knockouts and conditional-ready knockouts of every mouse gene. These new data, in context of existing phenotypic data, will be an unparalleled opportunity for mining phenotype-genotype-disease correlations and provide a platform for therapeutic discovery. Supported by NIH grant HG000330.

Molecular Genetics and Modeling of a Novel BBS5 Mutation. *M.H. Al-Hamed[1, 2], C.V. Lennep[2], F. Al-Fadhly[3], R.J. Simms[2], B.F. Meyer[1], J.A. Sayer[2].* 1) Genetics Department, King Faisal Specialist Hospital and Research Centre, P. O. Box 3354, Riyadh, Saudi; 2) Institute of Genetic Medicine, Newcastle University, Central Parkway, Newcastle upon Tyne, NE1 3BZ, United Kingdom; 3) Department of Pediatrics, Maternity & Children's Hospital, PO Box 6205,Al Madina Al Munawara, Saudi Arabia.

Bardet-Biedl Syndrome (BBS; OMIM 209900) is an autosomal recessive disorder clinically characterized primarily by obesity, progressive early-onset retinal degeneration, polydactyly, hypogenitalism, cognitive impairment and renal failure. BBS is a ciliopathy, with the multisystem syndrome secondary to defects in ciliary / basal body structure and function. To date, 15 BBS genes have been identified. We investigated a consanguineous family with 3 children presenting with BBS. Firstly, to identify the disease locus within this family, we carried out a genome wide linkage search using Affymetrix GeneChipR Human Mapping 250K Arrays. All three affected children shared one region of homozygosity on chromosome 2. This region of homozygosity contained the known BBS gene, BBS5, which was screened by direct sequencing of the PCR products of all coding regions (12 exons). In exon 12 of the BBS5 gene we found a novel mutation c.967insT (p.A323CfsX55) predicted to cause a frameshift which reaches a stop codon 168 nucleotides downstream. The mutation results in a predicted elongated peptide that has 378 amino acids instead of 341 in the wild type BBS5 protein. The three affected siblings were all homozygous for the mutation, whilst both parents and unaffected son were heterozygous for the mutation. Using zebrafish embryos, morpholino antisense oligonucleotides were used to modify the gene expression of BBS5. Morphant embryos displayed a typical ciliopathy phenotype with body axis curvature, cardiac abnormalities (including situs inversus) and pronephric duct dilatation. HEK293 were transfected with GFP-tagged mutant BBS5 (c.967insT) and wild type BBS5-GFP using Lipofectamine 2000. Mutant BBS5 failed to localize to the basal body in these cells. In conclusion we describe a family with clinical features of BBS, together with a novel mutation in BBS5. Modeling this disease in zebrafish mimics the human disease, and pathogencity of the novel BBS5 mutation is demonstrated by mislocalisation in renal epithelial cells.

Limb differences in muscle dystrophy and gene expression in a murine model of MDC1A suggest possible targets for therapy. *J.S. Benjamin, R. Marx, R.D. Cohn.* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine.

Merosin-deficient congenital muscular dystrophy (MDC1A) is an autosomal recessive congenital muscular dystrophy caused by mutations in the *LAMA2* subunit of the lamanin heterotrimeric extracellular matrix protein. The disease presents neonatally or shortly after birth, shows a range of phenotypes (including general muscle weakness, a delay of normal motor milestones and hypotonia), and currently has no known cures or effective therapies. Several mouse models for the disease exist including laboratory induced mutants in Lama2 as well as a few spontaneous lines. One such spontaneous line, the Dy2j in C57BL/6, contains a deletion in *Lama2* that causes a partial loss of function leading to muscle weakness several weeks after birth. We present an interesting phenotypic finding that while the hind limbs of these mice show weakness and paralysis after several weeks, the forelimb show near normal function until 12 months of age. Histological analysis combined with measurement of the area of fibrosis demonstrate that the hind limb tibialis anterior muscle shows approximately five-fold increase in area of fibrosis compared to the forelimb triceps muscle. Since the forelimb muscle seems to be protected and instead shows a milder muscular dystrophy phenotype when compared to other tissues, we hypothesize that genes differentially expressed between the triceps and tibialis anterior muscles could be responsible. To assess these differences, we ran an Affymetrix Gene 1.0 ST mouse expression array on 3 month old wild type and Dy2j mice for both tibialis anterior and triceps. Interestingly, among the genes most up regulated in the triceps compared to tibialis anterior, we see genes involved with polyamine biosynthesis/metabolism (which has been implicated in cell proliferation and migration) including *Amd1*, *Smox*, and *Zmynd17*, as well as *Spns2* (involved in myocardial precursor migration). Additionally, in the genes most increased in the tibialis anterior compared to triceps we see an increase in *Mgp*, a negative regulator of cell growth. Further functional studies on these genes and other candidates will be necessary to determine if they can play a role in protecting muscle from dystrophy, and can become viable targets for therapy.

***FREM1* Deficiency Causes a Syndromic Form of Congenital Diaphragmatic Hernia in Humans and Mice.** *T.F. Beck[1], O. Shchelochkov[2], Z. Yu[1], B. Kim[1], H. Zaveri[1], B. Lee[1,3], D.W. Stockton[4], M. Justice[1], D.A. Scott[1,5].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Department of Pediatrics, The University of Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute, Houston, TX; 4) Department of Pediatrics, Wayne State University, Detroit, MI; 5) Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX.

Congenital diaphragmatic hernia (CDH) is a life-threatening birth defect that affects approximately one in 4,000 newborns and is a feature of several genetic syndromes. Autosomal recessive mutations in *FREM1* have been shown to cause eye defects and renal anomalies as part of Bifid Nose and Anorectal and Renal malformations (BNAR) and Manitoba-Oculo-Tricho-Anal (MOTA) syndromes, but have not been previously implicated in the development of CDH. However, we recently identified a female patient with a left-sided CDH and features suggestive of BNAR. Copy number and sequence analysis of her *FREM1* gene revealed two mutations, a maternally-inherited, approximately ~86 kb deletion affecting only*FREM1*, and a paternally-inherited point mutation affecting the splice donor site of exon 28. This suggests that the spectrum of phenotypes associated with autosomal recessive *FREM1*mutations includes CDH. We also note that *FREM1* is located in a region of chromosome 9 that is recurrently deleted in individuals with CDH. Further evidence for the role of *FREM1* in the development of CDH comes from our work on a novel mouse strain, termed ***eye2***, which carries a homozygous truncating mutation in *Frem1*. *Frem1*$^{eye2/eye2}$ mice develop eye defects and renal agenesis similar to those seen in BNAR and MOTA syndromes but also develop anterior CDH and lung segmentation defects. CDH in these mice occurs in the muscularized portion of the diaphragm located directly behind the sternum. We confirmed that *Frem1* is expressed in the anterior portion of the developing diaphragm and found that *Frem1*$^{eye2/eye2}$ embryos had decreased levels of cell proliferation in their diaphragms when compared to wild type embryos. The penetrance of CDH in *Frem1*$^{eye2/eye2}$ mice was found to be highly dependent on strain background suggesting the existence of genetic modifiers. We conclude that *FREM1* plays a critical role in the development of the eye, kidney, lung, and diaphragm and that FREM1 deficiency can predispose to the development of a syndromic form of CDH in both humans and mice.

Characterization of visual impairment in a Wfs1 mouse model of Wolfram syndrome. *C. Delettre[1], D. Bonnet-Wersinger[1], Y. Tanizawa[3], G. Lenaers[1], C. Hamel[2].* 1) INSERM U1051, Montpellier, France, PhD; 2) INSERM U1051, Montpellier, France, MD; 3) Department of Bio-Signal Analysis, Yamaguchi University Graduate School of Medicine, Ube, Japan, MD.

Wolfram syndrome is a childhood onset rare genetic disease (1/180,000) featuring diabetes mellitus and optic neuropathy unavoidably progressing towards legal blindness before the age of 20. A Wfs1-/- mouse model has been generated (Ishihara et al, 2004), showing pancreatic beta cell atrophy. Nothing is known about the visual function of Wfs1-/- mouse. We have studied the visual impairment of these mice by electrophysiology and histopathology. Electroretinogram testing (ERG, retinal function) and visual evoked potentials (VEPs, visual pathway) were performed in Wfs1-/- and Wfs1+/+ mice at 3, 6, 9, and 12 months of age. Total nuclei and retinal ganglion cell (RGC) populations of nerve fiber layer were quantified from Brn3a immunolabeling of retinal sections. RGC axonal loss was also quantified by electron microscopy in transversal optic nerve sections. Grating acuity and contrast sensitivity were measured based on the optomotor tracking responses on a virtual apparatus (OptoMotry; Cerebral Mechanics, Lethbride, Alberta, Canada). Both a- and b-wave ERG amplitudes were slightly reduced at 12 months. In contrast, VEPs showed progressive decrease of N+P amplitudes in Wfs1-/- by 30, 40 and 50% at 6, 9 and 12 months, respectively, as compared with controls. Brn3a positive RGC and total nuclei in RGC layer were not significantly lost in Wfs1-/- genotype. Transmission electron microscopy analysis of 10 month-old Wfs1-/- mice determined little reduction in axonal density. Frequency and contrast thresholds of optokinetic tracking reflex remained normal in Wfs1-/- mice. Progressive VEPs alteration with minimal cell loss suggests functional defect of the signal conduction in the optic pathway. However, visual acuity is preserved and immunohistology didn't show any alteration of RGC layer in the retina. We conclude of a mild phenotype in the exon2 Wfs1-/- mice. Compensation, specific murine phenotype or truncated Wfs1 proteins can be assumed to explain this unaltered visual phenotype.

Gene therapy for X-linked retinitis pigmentosa in a knockout mouse model of *RP2*. *S. Mookherjee[1], L. Li[2], A.K. Ghosh[3], N. Khan[3], P. Colosi[1], H. Khanna[2], A. Swaroop[1].* 1) Neurobiology - Neurodegeneration & Repair laboratory, National Eye Institute, National Institutes of Health, Bethesda, MD; 2) Department of Ophthalmology, University of Massachusetts Medical School, Worcester, MA; 3) Department of Ophthalmology and Visual Sciences, University of Michigan, Ann Arbor, MI.

X-linked retinitis pigmentosa (XLRP) is a relatively severe form of retinal degeneration that is characterized by early onset night blindness, progressive loss of peripheral vision and pigmentary retinopathy. Mutations in the *RP2* gene account for 10–20% of XLRP. Though the precise function of this ubiquitously expressed protein is still poorly understood, RP2 may play a role in pericetriolar vesicle transport between Golgi and primary cilium. No specific treatment is available for the patients with XLRP. Gene replacement therapy presents a viable option but, to date, no animal models have been available for efficacy studies. Here we report the generation and characterization of a conditional *Rp2* knockout model that is being used to evaluate gene transfer strategies for the treatment of XLRP disease. We generated an $Rp2^{flox}$ mouse by introducing *loxp* sites flanking exon 2. The $Rp2^{flox}$ mouse was then bred to CAG-Cre (a ubiquitous Cre expressing transgenic line) mice and male progeny was analyzed further for photoreceptor development and function. Immunoblot and immunofluorescence analysis of the mutant retina did not reveal detectable expression of the RP2 protein. Electroretinography (ERG) analysis of $Rp2^{CAG\text{-}Cre/lox}$ mice revealed a progressive loss of cone function starting at around 5 months of age followed by decrease in rod function by 6 months of age. We also detected reduction in the thickness of outer nuclear layer of the retina starting at approximately 4 months of age. Further analysis of retinal whole mounts at 4 months of age showed a decrease in total cone population as well as shortened outer segments and swollen soma, as revealed by staining with peanut agglutinin (PNA). Staining of cryosections of the retina of 4 month old $Rp2^{CAG\text{-}Cre/lox}$ mice showed reduction of M- and S-opsin staining as well as mislocalization of S-opsin in cones. We have performed unilateral subretinal injection of an AAV8 sc RK RP2 vector at 2 months of age. The vector genome has a self-complementary structure and is composed of the rhodopsin kinase promoter, a CMV/b-globin intron, the RP2 cDNA and the beta globin polyadenylation site. Treated mice are being evaluated for therapeutic effect on retinal structure and visual function. Our studies provide the framework for elucidating the mechanism of XLRP-RP2 pathogenesis and development of gene-based therapy for this blinding disease.

Altered splicing of BIN1 muscle-specific exon in human and Great Danes with progressive centronuclear myopathies. *J. Bohm[1], N. Vasli[1], M. Maurer[2], B.S. Cowling[1], W. Kress[3], G.D. Shelton[4], U. Schara[5], J. Anderson[6], R. Herrmann[7], J. Weis[8], L. Tiret[2], J. Laporte[1].* 1) Department of Translational Medicine and Neurogenetics, IGBMC, Illkirch, France; 2) Génétique Fonctionnelle et Médicale, Ecole Nationale Vétérinaire d'Alfort, Maisons-Alfort, France; 3) Department of Human Genetics, Julius-Maximilian University, Würzburg, Germany; 4) Department of Pathology, University of California at San Diego, La Jolla, USA; 5) Department of Paediatric Neurology, University of Essen, Essen, Germany; 6) Institute of Comparative Medicine, University of Glasgow Veterinary School, Glasgow; 7) Department of Paediatrics I, University Hospital Essen, Essen, Germany; 8) The Institute for Neuropathology, Medical Faculty, RWTH Aachen University, Aachen, Germany.

Excitation-contraction coupling (ECC) occurs at the skeletal muscle triad and converts an electrical stimulus into mechanical muscle work. The triad is composed of the sarcoplasmic reticulum and a plasma membrane invagination, called the T-tubule. One of the key factors in muscular membrane remodeling is amphiphysin 2 (BIN1), located at the triad. We identified and characterized BIN1 mutations affecting the splicing of the muscle-specific exon 11 and involving a rapidly progressing myopathy in human and dogs. The impact of both mutations on the AG acceptor splice site was verified by mRNA analysis. The canine muscle disorder is known as IMGD (Inherited Myopathy in Great Danes) and typically starts before 10 months of age and most of the dogs are euthanized before 18 months of age due to severe debilitating muscle weakness. The human patients presented with a disease onset at 3.5 years and a rapidly progressive and fatal myopathy. Mutations in the ubiquitous BIN1 exons have previously been associated with recessive centronuclear myopathy (CNM) in patients with a clinically milder phenotype than described here. In addition, mis-splicing of BIN1 exon 11 was associated to myotonic dystrophies. Human and canine muscle histopathology displayed prominent nuclear internalization, atrophy, and unusual rippled sarcolemma. Ultrastructural analysis confirmed nuclear internalization, mitochondrial accumulations around the nuclei and myofibrillar disarray. Immunolabelling revealed a defective structure of the triad, and myotubes transfected with the exon 11 containing isoform showed massive tubulation, whereas the construct without exon 11 did not have this effect. Taken together, our data suggest that the amphiphysin 2 muscle isoform plays an important role in triad buildup and/or maintenance and that defective excitation-contraction coupling is a primary cause of the progressive human and dog diseases. Our study is the first genetic proof of the direct implication of BIN1 exon 11 in the muscle-specific function of amphiphysin 2. We provide the evidence that an alteration of the physiological function of the membrane-deforming properties of amphiphysin 2 and its alternative splicing-dependant activity is a common mechanism for canine and human myopathies. The identification and characterization of a spontaneous canine model represents a faithful model for preclinical trials. This is of particular interest, as BIN1 null mice are perinatally lethal.

Up-regulation of androgen-binding protein is associated with testicular phenotype in $Smarcal1^{del/del}$ mice. *A. Baradaran-Heravi, C.F. Boerkoel.* Department of Medical Genetics, Child and Family Research Institute, University of British Columbia, Vancouver, BC, Canada.

Schimke immune-osseous dysplasia (SIOD) is a fatal childhood disorder of spondylo-epiphyseal dysplasia and short stature, renal failure, T-cell deficiency, and small testes. SIOD is caused by bi-allelic mutations of *SMARCAL1*, which encodes a DNA annealing helicase and is involved in DNA repair, replication, recombination and transcription. Similar to SIOD patients $Smarcal1^{del/del}$ male mice have small testes characterized by degeneration of seminiferous tubules and a relative increase in interstitial cells. We hypothesized that $Smarcal1^{del/del}$ testis phenotype arises cell autonomously from defective proliferation of germ cells. Using immunohistochemistry and immunofluorescence, we found that Smarcal1 was highly expressed in Sertoli and Leydig cells but not in germ cells. This was confirmed by RT-PCR on the isolated germ cells and Sertoli cells. This finding makes a major role for Smarcal1 in DNA replication or recombination of sperm precursors unlikely. Based on the phenotypic similarity of $Smarcal1^{del/del}$ testes to the ones of aromatase-deficient and androgen-binding protein (ABP) over-expression mice, we looked for expression levels of *Cyp19* (encodes aromatase) and *Shbg* (encodes ABP) genes within $Smarcal1^{del/del}$ testes. We found that similar to ABP over-expression testes, both of these genes were up-regulated in $Smarcal1^{del/del}$ testes particularly around puberty. We are currently investigating whether the pathology in $Smarcal1^{del/del}$ testes is associated with overexpression of ABP. Such a mechanism would fit with SMARCAL1 homologues functioning as modulators of gene expression and disease arising when their deficiency results in alteration of expression beyond a threshold.

2683W

A Mouse Model of *mut*$^{-}$ Methylmalonic Acidemia (MMA). *J.S. Sénac[1], V.H. Aswani[2], J.R. Sysol[1], I. Manoli[1], C.P. Venditti[1].* 1) Genetics and Molecular Biology Branch, National Institute of Health, Bethesda, MD; 2) Marshfield Clinic, Department of Internal Medicine & Pediatrics, Marshfield, WI.

Methylmalonic acidemia (MMA) is caused by mutations of the mitochondrial gene methylmalonyl-CoA (MUT). We have previously studied MMA using a mouse model mimicking the most severe form of the disease (*mut*^{0}) and characterized by a complete absence of Mut. *Mut*$^{-/-}$ mice are fragile, display lethality and subsequently present limited use to study the induction, control, and rapid treatment of some clinical manifestations, such as metabolic strokes, pancreatitis and kidney disease. To overcome these difficulties, we developed tissue specific transgenic mice but these animals restrict the study of MMA to selected organs. In order to circumvent these barriers, we developed a new mouse model with a milder enzymatic phenotype (*mut*$^{-}$). Among the wide spectrum of *mut*$^{-}$ mutations, the mechanism of enzymatic impairment has been defined only for a few, such as p.G717V, documented to be a putative Km mutant. Following expression and kinetic assay of the homologous mouse mutant (G715V) and the wild type (3C) MUT enzymes in yeast, we generated transgenic mice that ubiquitously express the mutant cDNA (*Mut*$^{-/-}$;Tg$^{INS\text{-}CBA\text{-}G715V}$) and transgenic mice that express the wild type cDNA control (*Mut*$^{-/-}$;Tg$^{INS\text{-}CBA\text{-}3C}$). *Mut*$^{-/-}$;Tg$^{INS\text{-}CBA\text{-}G715V}$ mice were born in Mendelian proportions, can be maintained regular diet, and achieve 80–90% of control littermate weight through the first year of life. The p.G715V Mut enzyme is expressed in liver, kidney, brain, and muscle but has a limited activity as measured by the oxidation of 1-^{13}C propionate into $^{13}CO_2$. The *Mut*$^{-/-}$;Tg$^{INS\text{-}CBA\text{-}G715V}$ mice metabolized 46.8±4.3% of the label in 25 min, compared to 63.1±3.1% in *Mut*$^{+/-}$ and 10±1.1% in *Mut*$^{-/-}$. Baseline plasma MMA levels (μM) were 159.4±53.6 in transgenic mice, compared to <5 in controls, which is similar to levels observed in G717V MMA patients. While other MMA mouse models are susceptible to death on an unrestricted diet, *Mut*$^{-/-}$;Tg$^{INS\text{-}CBA\text{-}G715V}$ can tolerate a regular diet and survive a high protein diet challenge despite a significant increase in plasma MMA level, rapid weight loss, and formation of megamitochondria in the liver and kidney. Finally, these mouse model fail to respond to hydroxocobalamin treatment. This novel murine model mimics physiologic and phenotypic observed in mild MMA patients. These mice provide a new inducible platform to study the pathophysiology and treatment of clinical syndromes associated with MMA, such as metabolic strokes, pancreatitis and chronic kidney disease.

2684T

Allelic heterogeneity contributes to variable ocular dysgenesis caused by *Col4a1* and *Col4a2* mutations in mice. *M. Mao[1], DS. Kuo[1], C. Labelle-Dumais[1], M. Jeanne[1], J. Favor[2], DB. Gould[1].* 1) Departments of Ophthalmology and Anatomy, Institute for Human Genetics, UCSF School of Medicine, San Francisco, CA, 94143, USA; 2) Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, Germany, D-85764.

Type IV collagen alpha1 (COL4A1) and alpha2 (COL4A2) are major components of the basement membrane. Mutations in *COL4A1* and *COL4A2* cause a broad spectrum of disorders including cerebrovascular diseases, ocular dysgenesis, renal and muscle defects. Not all patients with *COL4A1* and *COL4A2* mutations have the same disease, and genetic context and allelic heterogeneity are possible explanations for the phenotypic variability. We have previously shown that a splice site mutation, *Col4a1*$^{\Delta ex41/+}$ causes ocular dysgenesis including anterior segment dysgenesis and optic nerve hypoplasia in mice. In addition, we also found that genetic context can modify the severity of both diseases. The purpose of this study was to test if allelic heterogeneity also contributes to a variable ocular dysgenesis. To this end, we bred eight different *Col4a1* mutations and one *Col4a2* mutation into the same genetic background (C57BL/6J) and compared the severity of ocular dysgenesis between these mutations. We found that all mutations caused ocular dysgenesis; however, the pathology differed in penetrance and severity. Molecular analysis revealed variable biosynthetic consequences of these mutations. Most mutations, but not all, showed increased intracellular and decreased extracellular levels of COL4A1 and COL4A2 proteins. Our results demonstrate phenotypic and molecular heterogeneity among *Col4a1* and *Col4a2* mutations. Whether the phenotypic heterogeneity reflects a mechanistic heterogeneity remains to be tested.

2685F

Tmprss3 loss of function impairs cochlear inner hair cell BK channel properties. *B. Delprat[1,2], L. Molina[3], L. Fasquelle[1,2], R. Nouvian[1,2], N. Salvetat[3], H. Scott[4], M. Guipponi[5], F. Molina[3], J.L. Puel[1,2].* 1) Inserm U 1051, Institut des Neurosciences, Hôpital Saint Eloi, 34091 Montpellier, France; 2) Université de Montpellier, 34091 Montpellier, France; 3) SysDiag UMR 3145 CNRS / Bio-Rad, Cap Delta / Parc Euromédecine, 1682 rue de la Valsière, CS 61003, 34184 Montpellier Cedex 4, France; 4) Department of Molecular Pathology, the Institute of Medical and Veterinary Science, SA Pathology and The Centre for Cancer Biology, Box 14 Rundle Mall Post Office, Adelaide, SA 5000 and the School of Medicine University of Adelaide, SA, 5005, Australia; 5) Department of Genetic Medicine and Development, University of Geneva Medical School and University Hospitals of Geneva, 1211 Geneva 4, Switzerland.

Mutations in TMPRSS3 cause human hereditary deafness DFNB8/10. Initial characterization of Tmprss3Y260X-mutant mice reveals that the protein has a critical role in hair cell survival at the onset of hearing. In order to unravel the role of Tmprss3 in cochlear hair cell physiology, we characterized the altered protein network of proteins mutant mice compared to wild-type animals using 2D gels followed by mass spectrometry. This proteomic approach led to the identification of four putative altered pathways highlighted by four hub proteins: potassium BK channels, 14-3-3 β, 14-3-3 ζ and PSD95. Using immunohistochemistry and patch-clamp analysis of inner hair cells (IHCs), we demonstrated that Tmprss3 is essential for the expression of BK channels at the IHC plasma membrane and that the protein modulates the biophysical properties of the remaining BK channels. In conclusion, our data demonstrate, for the first time, that a type II serine protease, Tmprss3, is able to modulate potassium BK channels.

2686W

Interaction with p97/VCP alters the intracellular itinerary of the copper-transporting ATPase, ATP7A. *L. Yi, S.G. Kaler.* Molecular Medicine Program, NICHD/NIH, Bethesda, MD.

ATP7A is a P-type ATPase that regulates cellular copper homeostasis via activity at the trans-Golgi network (TGN) and plasma membrane (PM). Mutations in ATP7A lead to Menkes disease or its variants, occipital horn syndrome, or adult-onset distal motor neuropathy, a newly discovered condition for which the precise mechanism is obscure. Previously, we characterized the two known distal motor neuropathy mutations, T994I and P1386S, and demonstrated subtle defects in intracellular trafficking resulting in increased plasma membrane (PM) localization, as well as abnormal interaction between ATP7A-T994I and p97/VCP, a TGN-resident protein mutated in two autosomal dominant conditions featuring motor neuron degeneration: 1) inclusion body myopathy and 2) amyotrophic lateral sclerosis (Lou Gehrig's disease). Using a series of protein truncation and biochemical methods in combination with cell biological techniques, we identified the p97/VCP and ATP7A interacting binding sites: the N-terminal globular domain of p97/VCP, and two regions in the cytosolic portion of ATP7A. Binding of p97VCP to the first ATP7A binding site, in the middle of the wild type protein near the Actuator domain, was associated with formation of cytosolic ATP7A protein aggregates on confocal microscopy. The second site, found only in the T994I mutant protein, is located in the carboxyl-half of the protein between the 6th and 7th transmembrane segments of ATP7A (amino acid residues 1108–1356). This covert p97/VCP binding site is evidently exposed by changes in ATP7A conformation associated with the nearby T994I mutation. Deletion of the C-terminal tail of ATP7A (residues 1416–1450) results in PM retention of the WT, but not the T994I mutant protein, indicating that the aberrant p97/VCP interaction impairs ATP7A vesicular trafficking. These findings help illuminate the mechanism underlying ATP7A-related distal motor neuropathy and establish a link between p97/VCP and genetically distinct forms of motor neuron degeneration.

JNK phosphorylation is responsible for the greater osteogenic potential of periosteum derived fibroblasts harboring the FGFR2 S252W mutation (Apert Syndrome). *R. Atique[1], E. Yeh[1], H. Matsushita[2], N. Alonso[2], MR. Passos-Bueno[1].* 1) Human Genome Research Center-University of São Paulo, São Paulo, Brazil; 2) Department of Plastic Surgery, School of Medicine, University of São Paulo, São Paulo, Brazil.

Apert syndrome is a syndromic craniosynostosis characterized by premature fusion of the coronal sutures and symmetric syndactyly of the hand and feet. It is caused by one of two possible gain of function mutations in the FGFR2 gene (S252W and P253R). The mutated FGFR2 loses specificity for its ligands leading to its overactivation. Gene expression array studies have shown that one of the main differentially expressed genes in Apert syndrome fibroblast cultures is DUSP2, whose protein is a phosphatase with specificity to the MAPK family of kinases, which includes ERK and JNK. Alterations in JNK phosphorylation have been previously linked to osteogenic differentiation. In this study we aim to evaluate the role of JNK in the augmented osteogenic diferential potential of fibroblasts from the periosteum covering the coronal suture region and if there is any difference in the phosphorylation levels of JNK by activation of the FGFR2 S252W receptor when compared to the wild-type. We first assessed the difference in JNK phosphorylation (P-JNK) levels between FGFR2 S252W fibroblasts and controls, we found no statistically significant differences. We hypothesized that culture condition may have interfered in these results. To test this hypothesis, we compared the JNK expression in starving and non-starving conditions. Starvation increased JNK expression significantly more in S252W cells (1500 %) than in control cells (300%), showing that the JNK signaling regulation is disturbed in the S252W fibroblasts. We then evaluated, through Elisa assay, if the activation of FGFR2 by FGF2 treatment altered JNK phosphorylation. The FGF2 treatment increased the JNK phosphorylation levels in S252W fibroblasts by 25% and decreased them in controls by 15%. Lastly we evaluated the effects of JNK inhibition on osteogenic differentiation by inhibiting the kinase activity of JNK. The complete inhibition of JNK activity reversed the phenotype leading the osteogenic differentiation levels in FGFR2 S252W fibroblasts similar to controls (P<0,05) . In conclusion, we demonstrated that JNK is involved with the greater osteogenic potential in fibroblasts harboring the Apert syndrome mutation (FGFR2 S252W).

Novel p.Leu795Pro INSR mutation with decreased autophosphorylation in a patient with Donohue syndrome. *T. Hovnik[1,2], K. Trebus{{ak}}ak Podkrajs{{ak}}ek[2], J. Kovac{{ak}}[1,2], N. Bratanic{{ak}}[1], T. Battelino[1].* 1) Department of Pediatric Endocrinology, Diabetes and Metabolic Diseases, University Children's Hospital, UMC, Ljubljana, Bohoric{{ak}}eva 20, 1000 Ljubljana, Slovenia; 2) Center for Medical Genetics, University Children's Hospital, UMC, Ljubljana, Vrazov trg 1, 1000 Ljubljana, Slovenia.

Donohue syndrome (leprechaunism; OMIM *246200) is a rare, recessively inherited disorder of extreme insulin resistance due to mutation in the insulin receptor gene (INSR). The pathogenesis of insulin resistance is due to a cellular defect in insulin binding, receptor autophosphorylation and tyrosine kinase activity on insulin-stimulated biological activity. We report a patient with pronounced clinical picture of leprechaunism who developed severe progressive hypertrophic obstructive cardiomyopathy (HOCM) and renal tubular dysfunction which improved on continuous subcutaneous infusion of rhIGF-I. To investigate the molecular basis of insulin resistance, INSR gene molecular analysis and insulin receptor (IR) autophosphorylation on cultured fibroblasts were performed. Sequencing analysis of the 22 exons and intron-exon junctions revealed a homozygous novel missense mutation c.2465T>C located in exon 12, leading to a substitution of the leucine to proline at amino acid position 795 (p.Leu795Pro) at the conserved site in the extracellular domain of the IR β subunit. Insulin-induced autophosphorylation in the patient was reduced by 87.3% when compared to control, and by 86% when compared to his mother's fibroblasts. Functional characterization showed that novel INSR gene mutation in insulin receptor β subunit is causing a syndrome of extreme insulin resistance due to decreased insulin receptor autophosphorylation rather than insulin binding impairment.

2689W

Post-transcriptional regulation of DMD by its 3'UTR. *A. Larsen, M. Howard.* Human Genetics, University of Utah, Salt Lake City, UT.

Mutations in the DMD gene can cause either the severe Duchenne Muscular Dystrophy (DMD) or the milder Becker Muscular Dystrophy (BMD). Mutations that lead to the milder Becker phenotype are generally in-frame deletions that lead to a partially functional dystrophin protein. This observation has led to potential therapeutic strategies, such as exon-skipping, that could be used to treat Duchenne patients by expressing a mini-dystrophin. Although transcriptional regulation of dystrophin has been well characterized, the post-transcriptional regulation of DMD expression is not well understood. Here, we report the identification of highly conserved regions in the DMD 3'UTR that regulate mRNA stability and translation in differentiated C2C12 myotubes. To investigate the role the DMD 3'UTR has on gene expression, we generated Renilla Luciferase constructs containing the full-length DMD 3'UTR and several deletions within the DMD 3'UTR. Using the dual-luciferase reporter assay, we show that deleting an ~80 bp region in the 3'UTR results in ~50% decrease in protein levels with no significant decrease in steady-state RNA levels suggesting that this region acts as a translational enhancer. We also used qPCR to measure RNA levels of C2C12 myoblasts and myotubes treated with Actinomycin D and show that deleting the conserved regions of the DMD 3'UTR results in a modest decrease in mRNA stability.

2690T

NPHP10 (SDCCAG8) interacts with components of the multi-aminoacyl-tRNA synthetase complex. *K. Weihbrecht[1,2], M. Humbert[1,2], V. Sheffield[1,3], S. Seo[2].* 1) Dept. of Pediatrics, Univ. of Iowa, Iowa City, IA; 2) Dept. of Ophthalmology and Visual Sciences, Univ. of Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute.

Nephronophthisis (NPHP) is a recessive kidney disorder that is the leading cause of early onset, end-stage renal failure. Many proteins mutated in cystic kidney disease have been shown to localize to the primary cilia and centrosomes, providing a coalescing mechanism for NPHP-related ciliopathies (NPHP-RC). Aside from renal failure and kidney cysts, retinal degeneration and dysplasia or degeneration of the cerebellum are also seen in many NPHP-RCs. SDCCAG8 is a nephronophthisis gene (NPHP10), with patients exhibiting retinal and renal abnormalities, obesity, and learning disabilities. Mutations in SDCCAG8 were also found in several BBS patients, making SDCCAG8 the 16th BBS gene (BBS16). However, little is known about the molecular functions of NPHP10 and how loss of NPHP10 function leads to the observed phenotypes. Our goal was to gain insight into the function of NPHP10 by determining its interactors. Here, we show that NPHP10 interacts with components of the multi-aminoacyl tRNA synthetase complex (MSC), including 8 out of 9 aminoacyl tRNA synthetases (ARS) as well as aminoacyl-tRNA-synthetase-complex interacting multifunctional protein 2 (AIMP2). We performed tandem affinity purification using stably transfected HEK293T cells expressing FLAG- and S-tagged NPHP10 and isolated its associated proteins. We further determined that among the MSC components, NPHP10 directly interacts with AIMP2. Sucrose gradient ultracentrifugation of WT mouse tissues showed that NPHP10 is associated with the MSC in the kidney, brain, and eye, all affected tissues in NPHP10 patients. Lastly, we show that disruption of the MSC through AIMP2 knockdown significantly reduces ciliogenesis. Altogether, these findings suggest that NPHP10 functions through an MSC-mediated mechanism or vice versa, and that the MSC is an important component for ciliary function.

Effect of the mutations Gly250Val and Leu451Val on the expression of the gene HEXA: disease causing or pseudo-mutations. *L. Peleg[1,3], R. Svirski[3], Y. Lerental[2], M. Karpati[1], A.J. Simon[2].* 1) Genetic Inst, Sheba Medical Ctr, Ramat Gan, 52621, Israel; 2) Cancer Research Center, Sheba Medical Ctr, Ramat Gan, 52621, Israel; 3) Human Molecular Genetics and Biochemistry, Sackler School of Medicine, Tel Aviv University,Tel Aviv, 69978, Israel.

Defects in the alpha-subunit of beta-hexosaminidase A (HexA) are responsible for the various forms of the autosomal recessive Tay-Sachs disease (TSD). The disease is relatively common among Ashkenazi and Moroccan Jews (carrier rate1:29 and 1:110 respectively) and an elevated frequency (1:140) was also found among Iraqi Jews (IJ) (pan-ethnic frequency - 1:280). Two mutations had been identified among the IJ: Gly250Val and Leu451Val (G749T and C1351G, respectively). A reduced HexA activity, in the TSD carrier's range, was found in all heterozygotes and they were identified in 75% of the IJ carriers. Yet, neither homozygotes nor compound heterozygotes with any disease causing mutation have been diagnosed so far. The purpose of this study was to examine the effect of the IJ mutations on the expression and function of the HEXA gene. Using site directed mutagenesis the IJ mutations and a known disease causing mutation (Arg137X) were introduced to pCMV6-vector containing the entire human HexA-alpha polypeptide. The plasmids were sequenced to ensure the presence of those mutations. The level of expression was examined in COS-7 cell cultures by enzyme activity and Western blot analyses. The enzymatic activity was measured with the fluorescence substrate 4-methylumbelliferyl-sulfo-N-acetyl-beta-glucosaminide (4MUGS) (specific to alpha subunit). In cultures baring the Arg137X mutation, as expected, no activity was found. In the case of Leu451Val and Gly250Val, 13% and 1% respectively, of the normal activity (no mutated insert) was measured. For western blot analysis pEGFP fused to alpha chains was used. Analysis of the bands showed a reduction of 95% and 41% of the alpha protein in the presence of Arg137X and Gly250Val mutations (respectively), while only about 12% reduction in the Leu451Val band (not significant). The results of this study might help genetic counseling for prenatal diagnosis of TSD cases. The pregnancies with compound heterozygotes fetuses were as yet terminated.

Identification and biochemical characterization of a novel mutation in DDX11 causing Warsaw Breakage Syndrome. *J. Capo-chichi[1], S. Bhati[2], J.A. Sommers[2], T. Yammine[3], E. Chouery[3], L. Patry[1], G.A. Rouleau[5], M.E. Samuels[1], F.F. Hamdan[1], J.L. Michaud[1], R.M Brosh Jr[2], A. Mégarbane[3,4], Z. Kibar[1,6].* 1) Centre de Recherche du CHU Sainte-Justine, Montréal, Québec, Canada; 2) 2Laboratory of Molecular Gerontology, National Institute on Aging, NIH, NIH Biomedical Research Center, 251 Bayview Blvd, Baltimore, MD 21224, USA; 3) Unité de Génétique Médicale et laboratoire associé Inserm UMR_S910, Université Saint Joseph, Beirut, Lebanon; 4) Institut Jérôme Lejeune, Paris, France; 5) Center of Excellence in Neuroscience of Université de Montréal, CHUM Notre-Dame Hospital Research Center and the Department of Medicine, Montréal, Canada; 6) Department of Obstetrics and Gynecology, Université de Montréal, Montréal, Canada.

Mutations in the gene encoding the iron-sulfur-containing DNA helicase DDX11 (ChlR1) were recently identified as a cause of a new recessive cohesinopathy Warsaw Breakage Syndrome (WABS), in a single patient with severe microcephaly, pre-and postnatal growth retardation, and abnormal skin pigmentation. Here, using homozygosity mapping in a Lebanese consanguineous family followed by exome sequencing, we identified a novel homozygous mutation (c.788G>A [p.R263Q]) in DDX11 in 3 affected siblings with severe intellectual disability (ID) and many of the congenital abnormalities reported in the WABS original case. Cultured lymphocytes from the patients showed increased drug-induced chromosomal breakage, as found in WABS. Biochemical studies of purified recombinant DDX11 indicated that the p.R263Q mutation impaired DDX11 helicase activity by perturbing its DNA binding and DNA-dependent ATP hydrolysis. Our findings thus confirm the involvement of DDX11 in WABS, expand its phenotypical spectrum, and provide novel insight into the structural requirement for DDX11 activity.

2693T

Development of a cell-based reporter assay for the analysis of regulatory interactions between FGF23/KLOTHO/FGFR1, small inhibitors, and downstream targets. *S. Diener[1], B. Lorenz-Depiereux[1], T.M. Strom[1,2].* 1) Institute of Human Genetics, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Bavaria, Germany; 2) Klinikum Rechts der Isar der Technischen Universität München, Institute of Human Genetics, Munich, Bavaria, Germany.

The analysis of rare genetic disorders affecting phosphate homeostasis led to the identification of several proteins essential for the renal regulation of phosphate homeostasis: PHEX (XLH [MIM 307800]), FGF23 (ADHR [MIM 193100]), SLC34A3 (HHRH [MIM 241530]), DMP1 (ARHR1 [MIM 241520]), ENPP1 (ARHR2 [MIM613312]), GALNT3 (FTC [MIM 211900]), and KLOTHO (FTC [MIM 211900]). A key regulator of phosphate homeostasis is the fibroblast growth factor 23 (FGF23). It is mainly secreted from osteocytes, circulates in the blood, and binds to receptor heterodimers composed of FGF receptor 1 (FGFR1) and KLOTHO in the kidney. FGF23 activates KLOTHO/FGFR1 to inhibit renal phosphate reabsorption and to suppress 1,25-dihydroxyvitamin D3 synthesis. As a key signaling pathway mitogen-activated protein kinase (MAPK) pathway is employed. To analyze regulatory interactions between FGF23/KLOTHO/FGFR1, small inhibitory compounds, and further downstream targets, we have developed FGF23-inducible HEK293 cells that stably express KLOTHO (HEK293-KL). Stable cell clones were picked, expanded, and expression of KLOTHO was confirmed by Western blot analysis. By investigating the activation of MAPK pathway we could show that HEK293-KL cells are FGF23-inducible. Moreover, we could inhibit the induction with FGF23 by the use of two small inhibitory molecules: (1) SU5402, an inhibitor of FGFR1, and (2) U0126, an inhibitor of MAPK pathway. Taken together, we have established a potent cell-based reporter assay, which can now be used to investigate FGF23/KLOTHO/FGFR1 receptor signaling and receptor complex inhibition in more detail. By RNA-Seq, which refers to high-throughput sequencing technologies, we will analyze transcriptome-wide changes in expression levels of genes in HEK293-KL cells after the induction with FGF23 in comparison to uninduced cells. Thereby, we will try to identify novel downstream targets which may be candidates for regulatory compounds involved in phosphate homeostasis.

2694F

The most activating calcium-sensing receptor mutation is located in the sixth transmembrane domain and can be corrected with chemical treatments. *AS. Lia-Baldini[1], A. Nizou[1], C. Magdelaine[2], F. Sturtz[1,2], B. Funalot[1,2], A. Liendhard[3].* 1) EA6309 - Maintenance Myélinique et Neuropathies Périphériques, Université de Limoges, Limoges, France; 2) Laboratoire de Biochimie, Centre Hospitalo-Universitaire de Limoges, Limoges, France; 3) Service de Pédiatrie, Centre Hospitalo-Universitaire de Limoges, Limoges, France.

The calcium-sensing receptor (CASR) has an important role in calcium homoeostasis by controlling PTH secretion and renal calcium handling. Gain-of-function mutations of the CASR gene have been identified in patients with sporadic or familial autosomal dominant hypocalcaemia (ADH), while inactivating mutations of the CASR gene cause familial hypocalciuric hypercalcaemia (FHH). We report here two cases of novel CASR mutations localized on the same amino-acid but leading either to ADH or to FHH. The first patient was an 11-year-old girl suffering from ADH, who developed nephrocalcinosis when she was 5 years old. The second patient was a 30-year-old lady presenting a mild hypercalcaemia. Genetics studies were performed by PCR amplification of CASR coding exons and direct sequencing of PCR products. Using the MAPK assay system and transient transfection of wild-type and mutated CASR into COS-7, we studied the ability of these mutated receptors to react to extracellular Ca2+ and to the negative allosteric CASR modulator, NPS2143. We found two heterozygous missense mutations localized in the sixth transmembrane domain of CASR. In vitro analysis of functional properties of the first mutated receptor to react to extracellular calcium did not reveal the classical expected leftward shift in the concentration-response curve for the mutant 1 compared to wild-type receptor, but a constitutive effect of this mutant. The mutated receptor exhibited almost 70% wild-type receptor activity even in the absence of extracellular calcium. We showed that this strong activity can be reduced with NPS2143 treatment. For mutant 2, a typical rightward shift compared to the wild-type receptor was observed. This finding, which has never been described to our knowledge, suggests the importance of this amino acid for the activation of the CASR protein and its critical physiological role in CASR signaling.

Dysregulated pathways in Cornelia de Lange syndrome cells mutated in core cohesin genes. *A. Musio[1], L. Mannini[1], A. Gimigliano[2], I. Bianchi[2], M. A. Deardorff[3], F. Cucco[1], I. D. Krantz[3], L. Bini[2].* 1) Istituto di Ricerca Genetica e Biomedica, CNR, Pisa, Italy; 2) Functional Proteomics Laboratory, Department of Biotechnologies, University of Siena, Siena, Italy; 3) Division of Genetics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, USA.

Cohesin is an evolutionary conserved multiprotein complex responsible for correct chromosome segregation during the cell cycle. Beyond this structural function, increasing data argues non-canonical roles for cohesin, including gene expression regulation. Mutations in cohesin and regulatory cohesin genes have been identified in human disorders, collectively called cohesinopathies, with Cornelia de Lange syndrome being the most frequent. However, the etiopathogenetic mechanisms underlying Cornelia de Lange syndrome are still poorly understood. To define biochemical pathways that are affected in Cornelia de Lange syndrome we analyzed the proteomic profile of Cornelia de Lange syndrome cell lines carrying mutations in the core cohesin genes, SMC1A and SMC3. Dysregulated protein expression was found in Cornelia de Lange syndrome probands compared to controls. The proteomics analysis was able to discriminate among probands harboring mutations in the different domains of the SMC proteins. Differentially expressed protein spots were identified by mass spectrometry and were shown to be involved in important biological processes such as metabolism, cytoskeleton organization, antioxidant and detoxification, cellular and protein fate and RNA processing. The c-MYC gene represents a divergent hub and lies at the center of these pathways and is down-regulated in Cornelia de Lange syndrome cell lines. This study allowed us to highlight, for the first time, specific biochemical pathways that are affected in Cornelia de Lange syndrome providing plausible causal evidence for some of the phenotypic features seen in Cornelia de Lange syndrome. This work was supported by a grant from Tuscany Region to AM.

Conformations of Slipped-DNA Junctions Determine Correct or Mutagenic Repair of CAG/CTG Repeats. *M.M. Slean[1, 2], K. Reddy[1,2], B. Wu[3], K. Nichol Edamura[2], M. Kekis[1], F. Nelissen[3], R. Aspers[3], M. Tessari[3], O.D. Scharer[4], S.S. Wijmenga[3], C.E. Pearson[1,2].* 1) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Program of Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Department of Biophysical Chemistry, Radboud University Nijmegen, Institute of Molecules and Materials, Nijmegen, The Netherlands; 4) Program of Pharmacological Sciences and Chemistry, Stony Brook University, Stony Brook, New York, USA.

Slipped-strand DNAs, formed by out-of-register mispairing of repeat units on complementary strands, are transient intermediates in repeat length mutations causing at least 30 neurodegenerative diseases. Expansions of (CTG)•(CAG) repeated DNAs is the mutagenic cause of 14 neurological diseases, likely arising through the formation and processing of slipped-strand DNAs. The three-way slipped-DNA junction, at which the excess repeats slip-out from the duplex, is a poorly understood feature common to these mutagenic intermediates. Here, we reveal that slipped-junctions can assume various interconverting conformations where the strand opposite the slip-out is either fully-base paired, or has one- or two-unpaired nucleotides. Junction conformation can alter correct nick-directed repair levels. Surprisingly, certain junction conformations are aberrantly repaired to expansion mutations: Mis-direction of repair to the non-nicked strand opposite the slip-out leads to integration of the excess slipped-out repeats rather than their excision. Thus, slipped-junction structure can determine whether repair attempts lead to correction or expansion mutations.

High incidence of *SMAD3* mutations in thoracic aortic aneurysm and/or dissection patients. *H. Morisaki[1, 2], I. Yamanaka[1], A. Yoshida[1, 2], R. Sultana[1], H. Tanaka[3], Y. Iba[3], H. Sasaki[3], H. Matsuda[3], K. Minatoya[3], T. Kosho[4], N. Okamoto[5], A. Kawame[6], T. Morisaki[1, 2, 7].* 1) Dept Bioscience & Genetics, NCVC Res Inst, Suita, Osaka, Japan; 2) Dept Medical Genetics, NCVC, Suita, Osaka, Japan; 3) Dept Cardiovascular Surgery, NCVC, Suita, Osaka, Japan; 4) Dept Medical Genetics, Shinshu U Sch Med, Matsumoto, Nagano, Japan; 5) Dept Medical Genetics, Osaka Med Ctr & Res Inst Maternal & Child Health, Izumi, Osaka, Japan; 6) Nagano Childres's Hosp, Azumino, Nagano, Japan; 7) Dept Mol Pathophysiol, Osaka U Grad Sch Pharm Sci, Suita, Osaka, Japan.

SMAD3, a direct mediator of transcriptional activation by the TGFβ receptor, was identified to be the candidate responsible for aneurysm-osteoarthritis syndrome (AOS), new syndrome featuring thoracic aortic aneurysm and/or dissection (TAAD), arterial tortuosity, mild craniofacial features, skeletal and cutaneous anomalies, and early-onset osteoarthritis. Clinical features of AOS often overlap those of Loeys-Dietz syndrome caused by mutation in *TGFBR* genes, while osteoarthritis is a key feature observed in more than 90% of the reported cases. We screened*SMAD3* gene mutations in 194 Japanese index cases without mutation in *FBN1*, *TGFBR1*, *TGFBR2* and *ACTA2*, consisting of 88 cases suspected of connective tissue disorder with some distinct extravascular features (MFS/LDS-like) and 106 cases with young-onset or familial TAAD without these features (TAAD-only). Nine novel *SMAD3* mutations were identified in 4 cases (4.5%) in MFS/LDS-like and 5 cases (4.7%) in TAAD-only. All mutations were thought to be pathogenic since they were either nonsense-, frameshift-, splicing-mutations or missense-mutations in highly conserved residues with well characterized structural importance. Family history was positive in 4 index cases. Total of 12 patients including family members were examined by clinical geneticists, cardiologists and radiologists. Only 4 presented orthopedic problems, including 2 with a history of bone fractures and other 2 with excessive osteoporosis in the bone X-ray. Mild hypertelorism was observed in two but bifid uvula or cleft palate was not observed in any. Skeletal findings were not distinct except for one family, whose member presented mild scoliosis or dolichostenomelia. Thoracic aortic aneurysm/dissection was observed in all of adult cases, but Valsalva sinus was escaped in 2 cases. Arterial tortuosity was observed only in 2 elderly cases. Aneurysms in branch or intracranial arteries were present in 2 cases. Dural ectasia was observed in 4 cases. In summary, we found *SMAD3* mutations in about 5% not only in MFS/LDS-like group but also in TAAD-only group. The figure was much higher than the previous reports, though it may be due to ascertainment bias since our study group was recruited more broadly in sporadic cases. Because the clinical spectrum of patients with *SMAD3* mutations were very broad, we propose that screening of *SMAD3* gene is important in patients with young or familial TAAD even without early-onset joint abnormalities.

2698W

Clinical Exome Sequencing Leads to the Diagnosis of Timothy Syndrome in a Patient with Prolonged QT, Dysmorphic Features, Seizures, and Intellectual Disability. *W. Zeng[1], K.D. Gonzalez[1], X. Li[1], H.M. Lu[1], H. Lu[1], E.M. Miller[2], S. Ware[2], J.J Wei[1].* 1) Ambry Genetics, Aliso Viejo, CA; 2) The Heart Institute, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Early results from clinical exome sequencing have demonstrated the clinical utility of the technology for diagnostic purposes. Exome sequencing was performed on a 2 year-old male with prolonged QT, hypotonia, joint hypermobility, dysmorphic features, cryptorchidism, seizures, developmental delay and bilateral clinodactyly. The family history was negative for similar phenotypes. Extensive molecular and biochemical testing was uninformative. The patient was heterozygous for a novel missense mutation (c. 3497T>C; p.I1166T) in exon 27 of the *CACNA1C*gene. Co-segregation analysis showed that his mother and father did not carry the mutation, indicating a *de novo* mutation occurrence. The amino acid is completely conserved throughout vertebrates. Mutations in *CACNA1C* lead to Timothy syndrome (TS), a rare arrhythmia disorder with fewer than 20 reported cases associated with congenital heart disease, syndactyly, immune deficiency, and autism. TS was listed among the differential diagnoses for the proband and previous sequencing for the common mutation(s) in TS was negative. The majority of reported mutations in the *CACNA1C* gene have been *de novo*. In addition, the proband's phenotype overlaps with those typically seen in Timothy Syndrome: a rate-corrected QT interval of between 480 ms and 700 ms, patent ductus arteriosos, facial anomalies including a flat nasal bridge and a round face, and neurological symptoms including seizures, intellectual disability, and hypotonia. Overall, diagnostic exome sequencing established a molecular diagnosis for a patient in whom traditional testing methods proved unhelpful. Additionally, the findings further expand the knowledge of the clinical spectrum of patients with mutations in the *CACNA1C* gene.

Mutations in calmodulin cause ventricular tachycardia and sudden cardiac death. *M. Nyegaard[1,7], M.T. Overgaard[2,7], M.T. Søndergaard[2], M. Vranas[1], E.R. Behr[3], L.L. Hildebrandt[2], J. Lund[2], P.L. Hedley[4], A.J. Camm[3], G. Wettrell[5], I. Fosdal[6], M. Christiansen[4], A.D. Børglum[1].* 1) Department of Biomedicine, The Bartholin Building, Aarhus University, DK-8000 Aarhus, Denmark; 2) Department of Biotechnology, Chemistry and Environmental Engineering, Aalborg University, DK-9000 Aalborg, Denmark; 3) The Division of Cardiac and Vascular Sciences, St George's University of London, SW17 0RE London, UK; 4) The Department of Clinical Biochemistry and Immunology, Statens Serum Institut, DK-2300 Copenhagen, Denmark; 5) The Division of Paediatric Cardiology, SE-221 85 Lund University Hospital, Sweden; 6) Department of Paediatrics, Visby Hospital, SE-621 55 Gotland, Sweden; 7) MN and MTO contributed equally.

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is a devastating inherited disorder characterized by episodic syncope and/or sudden cardiac arrest during exercise or acute emotion in individuals without structural cardiac abnormalities. Although rare, CPVT is suspected to cause a substantial part of sudden cardiac deaths in young individuals. Mutations in the cardiac sarcoplasmic calcium channel *RYR2* gene have been identified as causative in approximately half of all dominantly inherited CPVT cases. Applying a genome-wide linkage analysis in a large Swedish family with a severe dominantly inherited form of CPVT-like arrhythmias, we mapped the disease locus to chromosome 14q31–32. Sequencing the *CALM1* gene encoding calmodulin, the quintessential intracellular calcium sensor which exhibits extraordinary evolutionary conservation, revealed a heterozygous missense mutation (Asn53Ile) segregating with the disease. A second, de novo, missense mutation (Asn97Ser) was identified in a CPVT patient of Iraqi origin by screening a collection of 61 arrhythmia samples negative for RYR2 mutations. Both mutations demonstrated compromised calcium binding and the p.Asn97Ser mutation displayed an aberrant interaction with the RYR2 calmodulin binding domain peptide at low calcium concentrations. We conclude that calmodulin mutations can cause severe cardiac arrhythmia. As a consequence of our findings, the calmodulin genes are candidates for genetic screening of patients with idiopathic ventricular tachycardia and unexplained sudden cardiac death.

2700F

Role of SP1-binding site polymorphism of COLIAI gene and a sequence variation 713-8 del C of TGFβ1 polymorphism in osteoporosis in thalassemia major patients. *S. Agarwal, K. Singh, R. Kumar.* Genetics, Sanjay Gandhi Inst Med Sci, Lucknow, India.

Background: Osteoporosis represents an important cause of morbidity in β-thalassemia major though its pathogenesis has not been completely elucidated. Genetic factors play an important role in the pathogenesis of osteoporosis and several candidate gene polymorphisms have been implicated in the regulation of this process. G→T polymorphism in the regulatory region of the collagen type I alpha 1 (COLIAI) gene and deletion of a C in the intron sequence eight base prior to exon 5(713-8 del C) has been targeted with osteoporosis. Aim: To find out the distribution of COLIAI Sp1(G-T) polymorphism and TGF-β1 (713-8delC) sequence variation and its relationship with bone mineral density (BMD) in thalassemia major patients of North India. Material and Methods: One hundred five beta thalassemia major patients attending IPD at Department of Genetics, SGPGIMS, Lucknow for blood transfusion were recruited for the study. TGF beta (713-8delC) gene and COLIA1 Sp1(G-T) polymorphism were analysed by PCR-restriction fragment length polymorphism (PCR-RFLP). Bone mineral density (BMD) was measured by Dual Energy X ray Densitometry (DEXA). Result : Z score of BMD of lumbar spine and hips were -2.39±1.09 and -2.37±0.86. The study indicated 19.8% of β -thalassemia patients as homozygous for wild type G/G (SS), 35.8% as heterozygous for G/T (Ss) and 43.4% as homozygous mutant T/T type (ss). A significant association of COLIA1 gene with Z-score of BMD at hip (p=0.047) and at lumbar spine (p=0.001) region was observed. Out of 105 studied cases, 57 patients had a one base deletion in intronic sequence 8 (713-8delC). However, no association of 713-8delC variant was found with Z score of BMD at lumbar Spine (P value=0.061) and Hips (P value=0.773). We observed Cc genotype of Tgfβ1 as a risk factor (odds ratio=3.3) in low bone density at lumbar spine. Conclusion: Our results raise the possibility that genotyping at the Sp1 site could be of clinical value in identifying chances of osteoporosis (low bone density) at hip and spine regions and patients with ss genotype had lower BMD as compared to SS genotype. While, TGF β sequence variation did not influence the BMD. The sequence variation, 713-8delC, in the TGF-β1 gene is more frequent in thalassemia patients with low bone density as compared to patients with normal bone density (odds ratio=3.3). Hence COLIA1 can be used as genetic marker for accessing osteoporosis in thalassemia patients.

2701W

Loss-of-function mutations in IGSF1 cause a novel X-linked syndrome of TSH deficiency and macroorchidism. *M. Breuning[1], Y. Sun[1], B. Bak[2], N. Schoenmaker[3], A.S.P. van Trotsenburg[4], P. Voshol[3], E. Cambridge[5], J. White[5], P. le Tisser[6,7], S. Mousavy Gharavy[7], J. Martinez-Barbera[7], W. Oostdijk[1], L. Persani[8,12], P. Beck-Peccoz[9,12], T. Davis[10], A. Hokken-Koelega[11], C. Ruivenkamp[1], J. Laros[1], M. Kriek[1], S. Kant[1], J. den Dunnen[1], R. Hennekam[4], K. Chatterjee[3], M. Dattani[7,13], J. Wit[1], D. Bernard[2].* 1) Leiden University Medical Center, Leiden, the Netherlands; 2) McGill University, Montréal, Canada; 3) University of Cambridge, Cambridge, UK; 4) Academic Medical Center, Amsterdam, the Netherlands; 5) The Wellcome Trust Sanger Institute, Hinxton, UK; 6) National Institute for Medical Research, London, UK; 7) UCL institute of Child Health, London, UK; 8) IRCCS intituto Auxologico Italiano, Milan, Italy; 9) Fondazione IRCCS Ca'Granda, MIlan, Italy; 10) The University of Western Australia, Australia; 11) ErasmusMC-Sophia Children's Hospital, Rotterdam, the Netherlands; 12) Università degli Studi di Milano, Milan, Italy; 13) Great Ormond Street Hospital for Children, London, UK.

Congenital central hypothyroidism occurs as component of multiple pituitary deficiencies or as isolated thyroid-stimulating hormone (TSH) deficiency. Deep X-exome sequencing in two male cousins with TSH deficiency, macroorchidism, and delayed testosterone production identified an inframe deletion in IGSF1. Contemporaneously, whole exome sequencing in two male siblings from a second family with congenital TSH deficiency revealed a nonsense mutation in the same gene. Analyses of nine additional families with TSH deficiency, macroorchidism and variable prolactin deficiency, uncovered a further six IGSF1 mutations (including nonsense, missense, frameshift) and two whole gene deletions. The phenotypes of the families highly resemble each other. IGSF1 encodes an integral membrane glycoprotein highly expressed in anterior pituitary gland. Disease-associated IGSF1 mutations impaired plasma membrane trafficking of the IGSF1 protein. Igsf1 deletion in male mice caused significant decreases in intra-pituitary TSH, circulating thyroxine, pituitary TRH receptor expression, and increased body weight and fat mass. These data suggest that loss of function mutations in X-linked IGSF1 cause lifelong TSH deficiency, macroorchidism, and variable prolactin deficiency.

2702T

Hyperphagia, leptin, and brain-derived neurotrophic factor in subjects with Alström syndrome and BMI-Z matched controls. *M.D. Hicks[1], J.D. Marshall[2], P. Maffei[3], A.E. Hanish[1,4], L.A. Hunter[1], S.M. Brady[1], N.M. Sedaka[1], R. Sherafat Kazemzadeh[1], J.W. Tsao[5], G. Milan[3], J. Naggert[2], J.A. Yanovski[1], J.C. Han[1].* 1) Section on Growth and Obesity, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD 20892 USA; 2) The Jackson Laboratory, Bar Harbor, ME 04609 USA; 3) Department of Medicine, Internal Medicine, University Hospital of Padua, Italy; 4) National Institute of Nursing Research, National Institutes of Health, Bethesda, MD 20892 USA; 5) Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

Background: Alström syndrome (AS) is a rare autosomal recessive disorder caused by mutations in ALMS1. AS is a pleiotropic condition, with a wide range of clinical features, including early onset obesity. Recent studies of a mouse model of AS suggest that the Alms1 protein may play an important role in the basal bodies of primary cilia in hypothalamic neurons [1]. Leptin and its downstream mediator, brain-derived neurotrophic factor (BDNF), act within the hypothalamus to decrease appetite [2]. Studies assessing hyperphagia and the leptin pathway have not been previously reported in patients with AS compared with similarly obese, non-syndromic control subjects. Methods: Subjects with AS were matched 1:2 with healthy controls by age, sex, and body mass index Z-score (BMI-Z). Fasting serum leptin and BDNF for all subjects were measured by commercial ELISA. Parents of children ages 4–17 years also completed a hyperphagia questionnaire previously validated for Prader-Willi syndrome [3]. Skewed data were normalized by log transformation. ANCOVAs compared hyperphagia score, leptin, and BDNF (adjusted for age, sex, and BMI-Z). Results: Subjects with AS [n=35] and controls [n=70] were comparable for age (mean± SD for AS vs. controls: 17.5 ± 9.3 vs. 17.9 ± 9.9y, p=0.87), sex (% male: 40% vs. 43%, p=0.84), BMI (34.0 ± 10.7 vs. 31.9 ± 7.6 kg/m2, p=0.25), and BMI-Z (2.14 ± 0.60 vs. 2.07 ± 0.56, p=0.54). Subjects with AS compared with controls had significantly higher hyperphagia score (adjusted mean ± SEM: 24.3 ± 1.1 [n=17] vs. 18.1 ± 1.1 [n=14], p=0.04) and significantly higher leptin (39.5 ± 1.1 [n=32] vs. 23.5 ± 1.1 [n=59] ng/mL, p<0.001). BDNF was similar between groups (18.0 ± 1.2 [n=31] vs. 18.7 ± 0.9 [n=58] ng/mL, p= 0.66), but BDNF/leptin ratio was lower in AS compared with controls (0.5 ± 0.3 [n=30] vs. 1.3 ± 0.2 [n=58], p=0.03). Conclusions: Subjects with AS have greater hyperphagia scores and higher leptin concentrations than expected for their body size, suggesting a dysfunction in leptin-mediated appetite regulation. Negative feedback regulation by leptin on adipocyte-derived leptin production has been described [4]. Thus, the observations that subjects with AS have leptin that is elevated out of proportion with body size and have lower BDNF/leptin ratios are consistent with a potential role for ALMS1 in energy homeostasis within the hypothalamus and that a defect in the leptin signaling pathway may contribute to the pathophysiology of obesity in AS.

The Euro-WABB Registry: differences in molecular genetic confirmation between monogenic Wolfram, Alström, and Bardet-Biedl syndromes. *A. Farmer[1], S. Ayme[2], P. Maffei[3], S. Mccafferty[4], R. Sinnott[4], W. Mlynarski[5], V. Nunes[6], V. Paquis[7], K. Parkinson[8], V. Tillman[9], T. Barrett[10].* 1) Wellcome Trust Clinical Research Facility, Birmingham Children's Hospital, Birmingham, West Midlands, United Kingdom; 2) National Institue of Health and Medical Research (INSERM), INSERM SC11, 102 Rue Didot, Paris, France FR - 75014; 3) Università degli Studi di Padova, Dipartimento di Scienze Mediche e Chirurgiche, Via VIII Febbraio 2 - 35122, Padova, Italy, IT - 35122; 4) University of Glasgow, University Avenue, Glasgow, UK - G12 8QQ, UK; 5) Medical University of Lodz, 4 Kosciuszki Ave, Lodz, PL-90-419, Poland; 6) Fundació Institut Investigació Biomèdica de Bellvitge, Gran via Hospitalet, 199, Hospitalet de Llobregat (Barcelona), ES - 08907, Spain; 7) Centre National de la Recherche Scientifique, CNRS Délégation Côte d'Azur - 250 rue Albert Einstein (LBPG UMR 6267 - INSERM U998 - UNS Faculté de Médecine, 28 avenue de Valombrose 06107 Nice Cedex 2), Valbonne, FR - 06560, France; 8) 49 Southfield Avenue, Paignton, South Devon, TQ3 1LH, UK; 9) Department of Paediatrics, University of Tartu, Lunini 6, Tartu, EE - 501014, Estonia; 10) School of Clinical and Experimental Medicine, College of Medicine and Dentistry, University of Birmingham, Edgbaston, Birmingham B15 2TT, UK.

Objectives. We aimed to develop a registry for the rare genetic diseases Wolfram (WS), Alstrom (AS), Bardet Biedl (BBS) and other diabetes syndromes, containing clinical, genetic diagnostic and outcome data. The purpose is to establish the natural history of these diseases; to assess clinical management; to characterize cohorts for future clinical trials; and to establish genotype phenotype relations. This abstract describes the first 50 patients recruited. Methods. Patients with a confirmed diagnosis (clinical or genetic) were recruited from both within and beyond Europe by their physicians. Information was collected for 42 `core' data fields, reached by consensus to differentiate between syndromes. We analysed prevalence of core clinical symptoms including obesity and diabetes. Results. The age range was 2–44 yrs (interquartile range 6–20yrs). There were 15 patients with WS (median age 18yrs (range 9–44yrs), 16 with AS (14 yrs (2–30yrs), 17 with BBS (8yrs (4–16), 1 with Wolcott-Rollison and 1 with vision and hearing impairment of unknown cause. The prevalences of molecular genetic confirmation were: WS 14/15; AS 14/16; BBS 12/17;p<0.01 for WS and AS combined vs BBS. The prevalences of diabetes and median ages of onset were: WS (14/15; 6yrs); AS (5/16; 13yrs); BBS (2/17; 10 yrs); p<0.01 for ages of onset WS vs AS and BBS combined). Conclusions. The core dataset captured sufficient data to differentiate between diabetes syndromes. Mutations in WFS1 and ALMS1 genes were identified in >95% of patients with WS and AS, but in BBS only 70% of patients had mutations in known BBS genes. The prevalence of diabetes is low in AS and BBS during childhood. Further patient recruitment and longitudinal data collection will use a consensus extended dataset of 400 fields to accurately characterize the phenotypes.

2704W

Biallelic *RFX6* inactivation can cause intestinal atresia with childhood rather than neonatal onset diabetes. *F.H. Sansbury[1, 2], R. Caswell[2], H. Lango Allen[2], S.E. Flanagan[2], B. Kirel[3], S. Ellard[2, 4], A.T. Hattersley[2, 4].* 1) Peninsula Clinical Genetics Service, Royal Devon & Exeter NHS Foundation Trust, Royal Devon & Exeter Hospital (Heavitree), Gladstone Road, Exeter, Devon EX1 2ED, UK; 2) Peninsula College of Medicine and Dentistry, Universities of Exeter and Plymouth, PMS Building, Royal Devon & Exeter Hospital (Wonford), Barrack Road, Exeter, Devon EX2 5DW, UK; 3) Eskisehir Osmangazi University, Faculty of Medicine, Department of Pediatrics, 26480 Eskisehir, Turkey; 4) Royal Devon & Exeter NHS Foundation Trust, Royal Devon & Exeter Hospital (Wonford), Barrack Road, Exeter, Devon EX2 5DW, UK.

Biallelic *RFX6* inactivation is a known cause of intestinal atresia, hepatobiliary abnormalities and NDM (neonatal diabetes mellitus). All the 7 cases to date had NDM, defined as diabetes diagnosed in the first 6 months. We report the first cases without NDM: two double first cousins who presented with intestinal atresia at birth but did not develop diabetes until ages 3 and 6 years.

The proband (born 32/40, 1.65 kg, 42nd centile) was born with duodenal atresia, jejunal web and Meckel's diverticulum. An identical twin with duodenal atresia died aged 1 month. Case 1 then had recurrent gastrointestinal bleeding due to erosive gastritis and duodenal ulceration. She presented aged 3 years with diabetic ketoacidosis. She requires 0.35 units / kg / day of long acting insulin, plus only occasional bolus insulin.

Her cousin (born 34/40, 1.7 kg, 7th centile) was born with duodenal atresia and mid gut malrotation. He has long standing anaemia, and was diagnosed with diabetes aged 6 years.

Both children tested negative for pancreatic auto-antibodies GAD and IA2. Genetic testing showed that both children are compound heterozygotes for the *RFX6* nonsense mutations c.2596C>T (p.Arg866X) and c.2176C>T (p.Arg726X).

This result significantly widens the diabetic phenotype of *RFX6* mutations. Sadly many patients with intestinal atresia die in infancy, before diabetes might present. Clinicians should consider biallelic *RFX6* inactivation as a potential cause of intestinal atresia.

2705T

Identification of a de novo mutation in the thyroid hormone receptor β gene (TRβ;) in a Colombian family with RTH. *M.C. Lozano[1], L. Mejia[2,3], P. Duran[4,5], C. Lattig[1].* 1) Universidad de Los Andes, Bogotá, Colombia; 2) Clínica Valle del Lili, Cali, Colombia; 3) Universidad Libre, Cali, Colombia; 4) Fundación Hospital Cardioinfantil-Instituto de Cardiologia, Bogota, Colombia; 5) Laboratorio de Investigacion Hormonal, Bogota, Colombia.

Resistance to thyroid hormone is an autosomal dominant disorder which affects 1 in every 40,000 births. This disorder is characterized by reduced soft tissue responsiveness to thyroid hormone, with increased levels of T4 and T3 and no inhibition of non-suppressed thyroid hormone (TSH), due to mutations present in the thyroid hormone receptor β gene (TRβ), particularly in its T3 binding domain. The clinical phenotype varies both between different families and between affected family members. Individuals with RTH can have variable resistance in different tissues, as a consequence of mixed features of hypo-and hyperthyroidism. The most common symptoms are goiter, tachycardia, attention deficit disorder, hearing impairment and delayed bone growth. In this study, we performed clinical and molecular characterization of a male patient, who was diagnosed with RTH at 15 months of age. He harbors a new mutation in exon 10 of the TRβ gene, which consists of a deletion of a cytosine at nucleotide 1318 and results in a frameshift that produces a stop codon at position 442. The mutation was not found in neither his parents nor his two healthy sisters, indicating a de novo mutational event. In Colombia, there is only one previously reported mutation associated with RTH (Salguero et. al., 2010), being the present study a second report. It is noteworthy that mutations found in Colombia are unique to our country, which should be taken into account for proper genetic counseling.

2706F

Use of lineage markers to predict founder effect of E180Splice mutation in GHR gene causing Laron syndrome: a witness of Jewish exodus. *F.T. Goncalves[1], C. Fridman[1], E.M. Pinto[10], Z. Laron[2], J. Guevara-Aguirre[3], F.G. Carsola[4], D. Damiani[5], T.S. Lins[6], O. Shevah[2], V. Hwa[7], A.L. Rosembloom[8], R.G. Rosenfeld[9], U.P. Arnhold[10], A.A.L. Jorge[10].* 1) Legal Medicine, Ethics and Occupational Health, Medical School, University of Sao Paulo, Sao Paulo, Brazil; 2) Schneider Childrens' Med Ctr, Petah-Tikva, Israel; 3) Inst for Endocrinology Metabolism and Reproduction, Quito, Ecuador; 4) University of Chile, Santiago, Chile; 5) Instituto da Criança, Medical School, University of Sao Paulo, Sao Paulo, Brazil; 6) Inst Materno Infantil de Pernambuco, Recife, Brazil; 7) Oregon Hlth and Scis University, Portland, OR; 8) University of Florida Coll of Med, Gainesville, FL; 9) Lucile Packard Foundation for Children's Hlth, Palo Alto, CA; 10) Department of Endocrinology, Medical School, University of Sao Paulo, Sao Paulo, Brazil.

Laron syndrome (LS) is a genetic disorder caused by mutations in the Growth Hormone Receptor (GHR) gene leading to severe GH insensitivity. The most prevalent GHR mutation is E180splice which was found only in isolated population of Spanish descent from the Andes (Ecuador); recently it was also found in Israel, Brazil and Chile. A common origin of the E180splice mutation is postulated and it is supported by the presence of common introns haplotype. Herein, to confirm this hypothesis, we analyzed polymorphic markers surround GHR gene (markers from chromosome 5 short arm, intragenic SNPs and GHR exon 3), paternal lineage origin analyzing Y-chromosome STR and maternal lineage investigating mitochondrial DNA haplogroups. We genotyped 20 LS patients from Ecuador, Israel, Brazil and Chile which were homozygous for E180splice mutation and their first degree relatives heterozygous for mutation and compared to 42 normal individuals and 5 LS patients with other mutations. An identical haplotype was identified in all but one of the patients carrying the E180splice mutation: D5S2082: 192/192; D5S665: 150/150; D5S2087: 246/246; rs6179 G/G rs6180 C/C, IVS9 haplotype-I and GHRfl. One patient differed from others by D5S2082 (168/192). Control individuals and LS patients with other mutation showed different haplotypes. This result corroborated that the E180splice-associated haplotype found in all families has not independent origins ($p < 10-8$) and they have a common ancestor. Half of patients showed paternal origin belonging to haplogroup R1b (found in Portugal and Spanish) and 46.6% belonged to haplogroups J and E (typical in the Middle East and in Eastern European Jews). mtDNA analysis showed that 29.4% of patients belonged to Amerindian haplogroup B, 17.6% had European haplogroup J (from Balkan Peninsula), 35.3% presented African haplotypes and the Israeli patient showed subhaplogroup R0 found in Arabia. Jews were expelled from Spain in 1492, but many had converted to the Christian faith. These New Christians emigrated from the Iberian Peninsula to the New World. The founder effect of E180Splice mutation may be explained by this historic event, which we reinforced with strong evidence of co-segregation between several polymorphisms, the germline E180splice mutation and paternal lineage in LS patients from different countries, indicating this mutation originated from a single common ancestor. Supported: FAPESP, LIM25-HCFMUSP, LIM40-HCFMUSP.

Genetics of congenital hypogonadotropic hypogonadism in Denmark. *J. Tommiska[1,2], P. Christiansen[3], N. Jørgensen[3], J. Lawaetz[3], A. Juul[3], T. Raivio[1,2].* 1) Institute of Biomedicine, University of Helsinki, Helsinki, Finland; 2) Children's Hospital, Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Growth and Reproduction, Rigshospitalet, Faculty of Health Sciences. University of Copenhagen, Denmark.

Congenital hypogonadotropic hypogonadism (HH) is a rare disorder characterized by incomplete or absent puberty caused by the lack or deficient number of hypothalamic gonadotropin-releasing hormone (GnRH) neurons, disturbed secretion or action of GnRH, or both. When HH presents with deficient sense of smell (anosmia), the condition is termed Kallmann syndrome (KS). The phenotypic heterogeneity in patients with KS and normosmic HH (nHH) varies from genital hypoplasia and absent puberty to reversal of HH later in life. In the majority of cases, the molecular genetic cause remains unresolved. We examined the genetic background and phenotypic features of HH in Denmark. Thirty eight male patients with congenital HH were screened for mutations in *KAL1*, *FGFR1*, *FGF8*, *PROK2*, *PROKR2*, *GNRHR*, and *KISS1R*. Three KS patients had mutations in *KAL1* (C105VfsX12, C53X, ex5-8del). Five patients had mutations in*FGFR1* (V86M, R209C, R646W, A512V, and a synonymous change c.1614C>T, p.I538I, predicted to affect splicing); they all had severe HH (micropenis and cryptorchidism), and 3 of them also had cleft lip/palate, tooth agenesis, syndactylia, or hearing loss. One KS patient had a *PROK2* mutation (p.I55fsX1) previously identified in autosomal recessive KS, but in a heterozygous state. Among those with nHH, one proband had a homozygous R262Q mutation in *GNRHR*. He had recovered from HH before the age of 32, was without Rx for 30 yrs, and at the age of 60 yrs, presented with signs of late-onset hypogonadism. Three heterozygous R262Q mutations and one Q106R mutation were also found in *GNRHR*, but also in patients with KS, so it is not likely that these mutations contribute to the phenotype, although di/oligogenic inheritance has been suggested in HH. In conclusion, (i) the frequency of *KAL1* and *FGFR1* mutations in this patient series from the largest tertiary centre in Denmark was similar to that recently described in Finland; (ii) the phenotype of the patient with a homozygous *GNRHR* R262Q mutation displayed fascinating age-dependent variation; (iii) although the mutations in *TAC3*, *TACR3*, *KISS1*, *GNRH1*, and *CHD7* have not yet been screened, given the rarity of them in HH patients in all populations, it seems likely that the majority of the HH patients will remain without a molecular genetic diagnosis also in Denmark, implying the existence of hitherto undescribed genes underlying the condition.

2708T

A rare gain-of-function mutation in an inhibitory upstream open reading frame in CDKN1B 5' untranslated region causes MEN4 phenotype. *G. Occhi[1], D. Regazzo[1], G. Trivellin[1,2], F. Boaretto[3], D. Ciato[1], S. Ferasin[1], F. Cetani[4], E. Pardi[4], M. Korbonits[2], N. Pellegata[5], G. Opocher[3], F. Mantero[1], C. Scaroni[1].* 1) Department of Medicine, University of Padova, Padova, Padova, Italy; 2) Department of Endocrinology, Barts and the London School of Medicine, Queen Mary University of London, London, United Kingdom; 3) Veneto Institute of Oncology, Familial Cancer Clinic, Padova, Italy; 4) Department of Endocrinology and Metabolism, Section of Endocrinology and Bone Metabolism, University of Pisa, Pisa, Italy; 5) Institute of Pathology, Helmholtz Zentrum München German Research Center for Environmental Health, Neuherberg, Germany.

The CDKN1B gene encodes for the cyclin-dependent kinase inhibitor p27KIP1 that is a key player in many cell processes including proliferation and differentiation. Impaired p27KIP1 expression and/or localization is often observed in tumor cells, further confirming its central role in regulating the cell cycle. Recently, germline mutations in CDKN1B have been associated with the inherited multiple endocrine neoplasia syndrome type 4 (MEN4, MIM610755). MEN4 is a rare autosomal dominant syndrome characterized by varying combinations of tumors that affect at least two endocrine organs. Aim of present study was to determine the possible causes of multiple endocrine tumors in 24 MEN1-like patients by analyzing the entire CDKN1B gene for point mutations and large rearrangements in germline DNA. A c.-456_-453delCCTT was identified in a regulatory upstream ORF (uORF) in the 5'UTR, in a 62 year old acromegalic patient with a pancreatic endocrine neoplasm. The 4-bp deletion causes the shift of the uORF termination codon with the consequent lengthening of the uORF encoded peptide and the drastic shortening of the intercistronic space. Our functional studies clearly prove a negative influence of such deletion on the translation reinitiation at the CDKN1B starting site. LOH analysis from the pancreatic lesion revealed no loss of the second allele, confirming that p27KIP1 may act as haploinsufficient tumor suppressor. Importantly, our in-silico analyses showed a very high level of inter-species conservation of the uORF within the CDKN1B gene (both at nucleotide and protein level), strongly supporting a physiological role of the uORF-encoded peptide in modulating p27KIP1 translation. Although regulatory uORFs are very common in human and mouse genes, being observed in about half of cases, CDKN1B gene represents the fourth case for which an uORF affecting mutation have been clearly associated to human diseases. In addition, our findings demonstrate for the first time that, besides the already described degradation by the ubiquitin/proteasome pathway and non-covalent sequestration, p27KIP1 activity can also be modulated by an uORF, and that mutations in this region may have deleterious consequences.

2709F

Next generation sequencing to identify cryptic ABCC8 and HADH splice site mutations in patients with congenital hyperinsulinaemic hypoglycaemia. *S. Ellard[1,2], R. Caswell[2], M. Weedon[2], K. Hussain[3], S.E. Flanagan[2].* 1) Molec Gen, Royal Devon & Exeter Hosp, Exeter, United Kingdom; 2) Peninsula Medical School, University of Exeter, United Kingdom; 3) Institute of Child Health, University College London, United Kingdom.

Background Inactivating ABCC8 or KCNJ11 mutations are found by Sanger sequencing in 80% of patients with focal or diffuse forms of diazoxide unresponsive hyperinsulinaemic hypoglycaemia (HH). Some patients with a normal result have partial gene deletions. The mutational mechanism for focal HH suggests all patients will have a ABCC8 or KCNJ11 mutation. Sequence analysis of the exons, intron/exon boundaries, minimal promoter and alternative transcripts previously detected mutations in only 3/6 consanguineous probands with diazoxide-responsive HH who were homozygous across HADH. Objectives To use next generation sequencing (NGS) to search for non-coding ABCC8 mutations in 2 probands with focal HH and non-coding HADH mutations in the 3 consanguineous probands linked to HADH. Methods Long range PCR was used to amplify 117kb genomic DNA encompassing ABCC8/KCNJ11 or 94kb encompassing HADH. The products were sequenced on an Illumina GAIIx. Additional patients were tested by Sanger sequencing for novel mutations, including 23 diazoxide-unresponsive cases (for ABCC8) and 47 consanguineous diazoxide-responsive cases (for HADH). Results We identified a paternal ABCC8 intronic A>G variant in the 2 probands with focal HH and a homozygous HADH G>T mutation in the 3 consanguineous probands. Sanger sequencing detected the ABCC8 mutation in a further 3 and the HADH mutation in 5 additional consanguineous probands. In silico analysis predicts that both variants create cryptic splice donor sites which is likely to result in the incorporation of an out of frame pseudoexon. RNA studies are in progress. Conclusion We identified a novel intronic ABCC8 mutation in 5/25 (20%) probands with diazoxide unresponsive HH and a homozygous intronic HADH mutation in 8/50 (16%) consanguineous probands without a genetic diagnosis. This study highlights the importance of non-coding variants in the aetiology of HH and demonstrates the utility of next generation sequencing to identify these mutations.

2710W

ABCC8 and _KCNJ11_ gene mutational analysis in Slovenian patients with neonatal diabetes and congenital hyperinsulinism. *K. Trebusak Podkrajsek[1], M. Avbelj[1], T. Hovnik[1], N. Bratina[1], N. Bratanic[1], T. Battelino[1,2].* 1) University Children's Hospital, University Medical Centre Ljubljana, Ljubljana, Slovenia; 2) Medical Faculty, University of Ljubljana, Slovenia.

Sulfonylurea receptor 1 (SUR1) encoded by *ABCC8* gene, and inward rectifier KIR6.2 encoded by *KCNJ11* gene, constitute ATP-sensitive K+ channel in pancreatic β-cells responsible for regulation of glucose-induced insulin secretion. Loss of function and activating mutations in respective genes are associated with hyperinsulinism of infancy (HI) and neonatal diabetes (NDM) with/without associated neurological disorder, respectively. The possible implication of *ABCC8* and *KCNJ11* gene mutations in Slovenian patients with the two rare congenital disorders in insulin regulation was evaluated. Five patients with NDM and 3 patients with HI were screened for mutations in *ABCC8* and *KCNJ11* genes by direct sequencing of the whole reading frame and exon-intron boundaries. A novel homozygous *ABCC8* gene mutation p.Gly316Trp was identified in one patient with permanent NDM requiring insulin therapy since the age 2,5 months and otherwise normal development. At the age of 19 years he had well controlled diabetes using only glimepiride. In one of the HI patients a heterozygous *ABCC8* p.Ser1386Phe mutation was identified, inherited from the father diagnosed with type 2 diabetes. The patient had hyperinsulinemic hypoglycemia since neonatal period, developed transient diabetes with insulinopenia at the age of 25 years and suffers from epilepsy, mild to moderate mental retardation and psychiatric disorder marked with aggressiveness and agitation. No other mutations in either ABCC8 or KCNJ11 were detected in this small cohort of patients. The mutations in *ABCC8* and *KCNJ11* do not appear to be a frequent cause of congenital disorders in insulin regulation in Slovenian patients. A novel p.Gly316Trp mutation in *ABCC8* gene in patient with NDM was identified. While p.Ser1386Phe *ABCC8* mutant has been reported previously as an autosomal dominant cause of HI, incomplete penetrance of the disease in our case suggests the heterozygous mutation alone is not sufficient to result in a severe phenotype.

2711T

Severe familial growth hormone deficiency due to defective U12-dependent processing of pituitary developmental genes. *L.A. Perez-Jurado[1], R. Flores[1], G.A. Martos-Moreno[2], I. Cuscó[1], J. Argente[2].* 1) Unitat de Genetica, DCEX, Universitat Pompeu Fabra & Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Barcelona, Spain; 2) Department of Endocrinology, Hospital Infantil Universitario Niño Jesús, Department of Pediatrics, Universidad Autónoma de Madrid & Centro de Investigación Biomédica en Red Fisiopatología de la Obesidad y Nutrición (CIBEROBN), Madrid, Spain.

The minor spliceosome, a ribonucleoprotein complex of proteins and small nuclear RNAs, catalyzes U12-dependent RNA splicing of a small proportion (<1%) of human genes. Mutations in the U4atac snRNA component of the minor spliceosome have been recently found in the early lethal malformation syndrome microcephalic osteodysplastic primordial dwarfism type 1 (MOPD1). We have studied a family with three sisters affected with severe postnatal growth retardation (height around -6 SDS at diagnosis) and otherwise normal development. Growth hormone (GH) levels were undetectable after standard stimuli, while prolactin levels were in the low-normal range and the remaining pituitary hormones were normal. Brain MRI scans revealed hypoplasia of the anterior hypophysis in all three sisters and the therapeutic response to GH replacement has been excellent to date, suggesting a diagnosis of familial (autosomal recessive) isolated GH deficiency with associated pituitary hypoplasia. Mutational and segregation analyses discarded involvement of all known genes of the GH axis. Exome analysis revealed biallelic mutations in the *RNPC3* gene, coding for the 65 kDa protein of the minor splicesome that binds to the 3'-stem-loop of m(7)G-capped U12 snRNA and regulates pre-mRNA minor splicing. We selected candidate genes undergoing U12 processing for expression analysis in lymphoblastoid cell lines of affected individuals. Defective U12 transcripts with the alternative utilization of U2-dependent processing sites were observed in two genes *ARPC5L* and *MAPK8*, predicting the generation of shorter proteins in both cases. *ARPC5L* encodes the subunit 5-like of the actin related protein 2/3 complex involved in regulation of actin polymerization and formation of branched actin networks. *MAPK8* encodes a ubiquitously expressed serine/threonine-protein kinase involved in various developmental processes such as cell proliferation, differentiation, migration, transformation and programmed cell death. Interestingly, *ARPC5L* is differentially expressed in the developing pituitary, being an excellent candidate for the tissue-specific phenotype observed in this family. Our findings provide novel insights into the molecular basis of familial growth hormone deficiency and demonstrate a crucial role of the minor spliceosome component RNPC3 in pituitary development and growth regulation.

2712F

Impaired energy homeostasis and arrested maturation underlie neutrophil dysfunction in glycogen storage disease type Ib. *H.S. Jun[1], D.A. Weinstein[2], Y.M. Lee[1], B.C. Mansfield[1], J.Y. Chou[1].* 1) SCD, PDEGEN, NICHD, NIH, Bethesda, MD; 2) Dept Pediatrics, Glycogen Storage Disease Program, Division of Pediatric Endocrinology, University of Florida, Gainesville, FL.

Glycogen storage disease type Ib (GSD-Ib) is caused by a deficiency in a ubiquitously expressed glucose-6-phosphate (G6P) transporter (G6PT) that translocates G6P from the cytoplasm into the lumen of the endoplasmic reticulum. Inside the lumen, G6P is hydrolyzed by a glucose-6-phosphatase (G6Pase) to glucose and phosphate. A functional G6PT/G6Pase-α complex maintains interprandial blood glucose homeostasis while a functional G6PT/G6Pase-β complex maintains neutrophil homeostasis and function. In GSD-Ib patients the non-functional G6PT/G6Pase complexes results in impaired glucose homeostasis, neutropenia, and neutrophil dysfunction. The loss of glucose homeostasis in GSD-Ib is well understood and recent studies reveal that inactivation of either G6PT or G6Pase-β results in enhanced neutrophil apoptosis that leads to neutropenia seen in both disorders. However, the underlying cause of neutrophil dysfunction remains unknown. The bone marrow in some GSD-Ib patients exhibits neutrophil maturation arrest which may contribute to neutrophil dysfunction observed clinically. We have recently shown that impaired energy homeostasis underlies neutrophil dysfunction in a related disease, G6Pase-β deficiency. In this study, we show that the levels of immature blood in the majority (12 of 13) of GSD-Ib patients are significantly higher than those in normal subjects and neutrophils from all 13 patients are dysfunctional. Since G6PT and G6Pase-β are functionally coupled, we hypothesized that as with G6Pase-β deficiency, impaired neutrophil energy homeostasis might also underlie neutrophil dysfunction in GSD-Ib. Indeed, neutrophils from GSD-Ib patients have a lower glucose uptake, and lower levels of G6P, lactate, and ATP than neutrophils from normal subjects. In parallel, the expression and membrane translocation of NADPH oxidase subunit $p47^{phox}$ are down-regulated. Together, the results show that GSD-Ib neutrophils exhibit impaired energy homeostasis. Previous studies suggested that G-CSF failed to delay apoptosis of cultured GSD-Ib neutrophils. We now show that G-CSF improves the survival of cultured neutrophils from both GSD-Ib and control subjects although GSD-Ib neutrophils still exhibit enhanced apoptosis. The results establish that the G6PT-mediated G6P/glucose cycling is essential for neutrophil survival and energy homeostasis and a deficiency leads to neutropenia and neutrophil dysfunction.

2713W

A Novel Mutation in _PSTPIP1_ is Responsible For PAPA Syndrome in a Jordanian Child. *H. El-Shanti[1,3], F. Al-Amri[2], B. Fathalla[2], S. Al-Dosari[1], M. Al-Mutawa[1], M. Kambouris[1,4].* 1) Shafallah Med Gen Cen, Doha, Qatar; 2) Hamad Medical Corporation, Doha, Qatar; 3) University of Iowa, Pediatrics, Iowa City, IA, USA; 4) 3Yale University School of Medicine, Genetics, New Haven, CT, USA.

Pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome (OMIM #604410) is an autosomal dominant auto-inflammatory disease caused by mutations in the proline-serine-threonine phosphatase-interacting protein 1 *PSTPIP1*. The produced protein is a cytoskeleton-associated adaptor protein that modulates T-cell activation, cytoskeletal organization, and IL-1βrelease. The only two mutations described so far, A230T and E250Q, have been found in patients and families, but other variations were described without clear relation with the phenotype. The two mutations are thought to disrupt the binding of PSTPIP1 with PTP-PEST, a regulatory phosphatase, and increase its avidity for pyrin in the cytosol, thereby dysregulating IL-1βproduction. PAPA syndrome typically presents with recurrent sterile, erosive arthritis in childhood, occurring spontaneously or after minor trauma, occasionally resulting in significant joint destruction. By puberty, joint problems tend to subside and cutaneous symptoms increase. Cutaneous manifestations include pathergy, frequently with abscesses at the sites of injections, severe cystic acne, and recurrent nonhealing sterile ulcers, often diagnosed as pyoderma gangrenosum. We describe a 4 year old boy with recurrent sterile arthritis and history of skin abscesses, but no pyoderma gangrenosum. The sequencing of the coding region of *PSTPIP1* and flanking intronic regions revealed two variations, p.Gln219His (Q219H) and p.Asp246Asn (D246N). Both variants are predicted to be probably damaging by Polyphen, but as tolerated by SIFT. The first is present in the father who is completely asymptomatic, but the second is a de novo variation only present in the child. We anticipate that the mutation p.Asp246Asn is the cause of the symptoms in this child since it falls within the coiled coil domain that harbors all the previously described mutations, a fact that casts suspicion that the PTP-PEST interaction is mediated through this domain. Since the E250Q and A230T variants of PSTPIP1 were shown to severely abrogate binding to PTP-PEST in yeast two hybrid and co-immunoprecipitation experiments, we will assess its function experimentally using similar techniques.

Prevalence of ααα anti3.7 triplication in beta-thalassemia carriers in south of Iran. *G. Shariati[1,2], M. Hamid[3], A.H. Saberi[1,2], B. Sharififard[1], B. Keikhaei[4], M. Pedram[4].* 1) Ahvaz Jundishapur University of Medical Sciences, Ahvaz, Iran; 2) Narges Medical Genetics & PND Laboratory, No. 18, East Mihan Ave, Kianpars, Ahvaz, Iran; 3) Molecular Medicine Dept., Biotechnology Research Center, Pasteur Institute of Iran, Tehran, Iran; 4) Research Center for Thalassemia and Hemoglobinopathy, Ahvaz Jundishapur University of Medical Sciences, Ahvaz-Iran.

There are no any studies investigated alpha globin gene triplication in beta-thalassemia carrier in Irania population, which was the aim of this study. The prevalence of alpha gene triplication in beta thalassemia carriers was studied in 2600 unrelated individuals in south of Iran, Ahvaz city. The association of heterozygous beta thalassemia with gene triplication was found in 30 patients (1.15%). The present result emphasizes that there is need to investigate systematically the ααα anti3.7 triplication in all hemoglobinopathies carriers in south of Iran.

Mutational analysis of Korean patients with Diamond-Blackfan anemia. *H. Chae[1,3], J. Park[1,3], M. Kim[1,3], A. Kwon[3], S. Lee[1,3], Y. Kim[1,3], J.W. Lee[2], N.G. Chung[2], B. Cho[2], D.C. Jeong[2].* 1) Department of Laboratory Medicine, The Catholic University of korea, Seoul, Korea; 2) Department of Pediatrics, The Catholic University of Korea, Seoul, Korea; 3) Catholic Genetic Laboratory Center, The Catholic University of Korea, Seroul, Korea.

Background Diamond-Blackfan anemia (DBA) is a congenital bone marrow failure syndrome characterized by hypoproliferative anemia, associated physical malformations, and a predisposition to cancer. DBA has been associated with mutations and deletions in the large and small ribosomal protein (RP) genes, and genetic aberrations are detected in approximately 50%–60% of patients. Methods Nine Korean DBA patients were screened for mutations in 8 known DBA genes, RPS19, RPS24, RPS17, RPS10, RPS26, RPL35A, RPL5, and RPL11, using the direct sequencing method. For mutation negative cases, array-CGH was performed to identify copy number variations. Genotype-phenotype correlations were evaluated. Results Mutations in RPS19, RPS26 and RPS17 were detected in 4, 2 and 1 patients respectively, and among RPS19 mutations 2 were novel (c.26T>A, c.357-2A>G). No mutations were detected in RPS24, RPS10, RPL35A, RPL5, and RPL11. No deletions involving the known DBA gene regions were identified on array-CGH. Genotype-phenotype correlation of RPS19 aberrations was not evident with respect to malformation status and treatment response. Conclusion Mutations in known DBA genes accounted for 78% of Korean DBA patients, and 44% were RPS19 mutations. We also report 2 novel RPS19 mutations. Our data suggests that Korean DBA patients are more susceptible to RP gene mutation than the Japanese or western DBA cohort.

Apoptosis is responsible for neutropenia in Cohen syndrome. *L. Duplomb[1,2], L. Faivre[1,2,3], A. Hammann[4], G. Jego[4], N. Droin[5], E. Lopez[1], B. Aral[1,2], N. Gigot[1,2], S. El Chehadeh[1,3], F. Huet[1,2], P. Callier[1,2], J. Thevenon[1,2], V. Carmignac[1], C. Capron[6], MA. Gougerot-Pocidalo[7], F. Girodon[2], JN. Bastie[2,4], L. Delva[4], C. Thauvin-Robinet[1,2,3].* 1) Génétique des Anomalies du Développement, Dijon, France; 2) CHU, Dijon, France; 3) Centre de Génétique et Centre de Référence “Anomalies du Développement et Syndromes Malformatifs”; 4) Université de Bourgogne, Inserm UMR 866, Dijon, France; 5) Institut Gustave Roussy, Inserm UMR 1009, Villejuif, France; 6) Institut Cochin, Inserm UMR 1016, Paris, France; 7) Univeristé Paris VII, Inserm UMR 773, Paris, France.

Cohen syndrome (CS) is a rare autosomal recessive disorder, characterized by typical facial appearance, microcephaly, truncal obesity, retinal dystrophy and intermittent neutropenia. The gene responsible for Cohen syndrome is VPS13B (COH1) which encodes a large protein of 4022 amino acids. Recently, VPS13B has been characterized as a peripheral membrane protein of the Golgi complex, with a crucial role for Golgi integrity. Neutropenia is one of major characteristics of CS but this neutropenia is usually intermittent and does not lead to severe infections. However, the exact role of the protein as well as the mechanisms involved in CS neutropenia are still unknown. The mechanisms responsible for neutropenia in other syndromic or non syndromic congenital neutropenia secondary to diverse genes (LEF-1, ELA2, HAX1, AK2,G6PC3...) include maturation arrest in neutrophil differentiation or enhanced apoptosis of mature neutrophils associated or not with endoplasmic reticulum stress. We first showed that CS neutrophils display normal generation of reactive oxygen species, chemotaxis, phagocytosis and morphology. However, when observed by transmission electron microscopy, the Golgi apparatus of neutrophil precursors from CS patients showed a disrupted morphology . In order to understand the mechanisms leading to neutropenia in CS patients, we have isolated CD16+ neutrophils from CS patients and healthy donors and showed by Annexin V-propidium iodide staining that CS neutrophils had an exaggerate apoptosis rate compared to healthy donors after 4h of culture. Expression of related endoplasmic reticulum stress-proteins, Bip and CHOP, were normal in CS neutrophils. For most of the patients, GM-CSF had no protector effect on CS neutrophils despite normal GM-CSF serum level, GM-CSF receptor mRNA expression and GM-CSF signaling (phospho-erk). We also showed that VPS13B mRNA expression dramatically decreased with the spontaneous apoptosis of neutrophils from healthy donors whereas mRNA expressions of 4 other genes (ELA2, HPN3, MPO and LYZ) were stable, confirming the correlation between VPS13B and apoptosis. Our work suggests that CS neutropenia is due to an increased apoptosis rate of circulating neutrophils and these results can be a clue for understanding other features of CS.

A novel pig model of SCID; A tool for cancer and immune research. *N.M. Ellinwood[1,2], E.H. Waide[1], D.M. Thekkoot[1], N. Boddicker[1], R.R.R. Rowland[3], E.M. Snella[1], J.K. Jens[1], C.R. Wyatt[3], J.W. Ross[1], D. Troyer[4], C.K. Tuggle[1], J.C.M. Dekkers[1].* 1) Dept Animal Sci, Iowa State Univ, Ames, IA; 2) Dept Vet Clin Sci, Iowa State Univ, Ames, IA; 3) Dept of Diag Med and Pathobio, Kansas State Univ; 4) Dept of Anat and Physio, Kansas State Univ.

Severe combined immunodeficiency (SCID) is an inherited trait identified in humans, horses and dogs, and artificially created in rodents. SCID mice have been used extensively to study immunity and cancer progression and treatment. We recently reported the first discovery of an autosomal recessive SCID in pigs based on the postmortem of 4 related piglets, which showed severely deficient immune systems, later characterized as being devoid of B and T cells. Objectives herein were to demonstrate the utility of this model in biomedical research, identify the genetic basis of the defect, and show that bone marrow transfer (BMT) was curative. Standard protocols were used for subcutaneous injection of human cancer cells into ears of SCID and normal pigs, and immunohistochemistry to detect human proteins. Genotyping was performed using an Illumina Porcine Beadchip. SNP association analysis was performed using the dfam option of PLINK. Homozygous affected piglets were injected intravenously with unfractionated bone marrow cells harvested from euthanized fully MHC-matched littermates at 16 days of age. Matings of known carriers produced 6 litters with confirmed SCID piglets at approximately 25% frequency. Affected piglets (n=3) were unable to prevent growth of human melanoma (A375SM) and pancreatic carcinoma (PANC-1) cells; human origin was verified by human mitochondrial protein staining of tumors. To identify the genomic region associated with this defect, 20 affected piglets, 50 unaffected littermates, the 6 parents, and 96 normal ancestors were genotyped. Association testing identified a 5.6 Mb region associated with the defect (P = 2.7×10- 7). Sequencing of the region is underway to identify the causative mutation. BMT was conducted on 3 SCID piglets. One developed graft versus host disease at 10 days post-transplant and was euthanized due to immunosuppressive therapy complications. The remaining two transplants have been clinically normal and free of any clincal infectious disease. We have documented engraftment in the recipients based on flow cytometry, and recipients are now 4 months of age. These novel findings are important as SCID pigs will be a valuable large animal model for basic and translational infectious disease, immune, and cancer research. The BMT treated SCID pigs will ensure efficient production of additional SCID animals.

2718F

Polymorphism in the HMOX-1 gene is associated with high levels of HbF in Brazilian patients with sickle cell anemia. *M.B. Melo[1], G.P. Gil[1], G. Ananina[1], M.B. Oliveira[1], M.J. Silva[1], M.N.N. Santos[2], M.A.C. Bezerra[3], B.L.D. Hatzlhofer[3], A.S. Araujo[3], F.F. Costa[4].* 1) CBMEG, Univ Campinas, Campinas SP, Brazil; 2) Department of Pathology, Univ Campinas, Campinas SP, Brazil; 3) Fundação Hemope, Recife, PE, Brazil; 4) Hemocentro, Univ Campinas, Campinas SP, Brazil.

Despite the fact that SCA is caused by a single mutation, the clinical course of these patients is extremely variable; the severity of the symptoms can vary from mild to very severe. The increase of fetal hemoglobin (HbF) has an important role in modulating the clinical status of sickle cell anemia (SCA), once it reduces the tendency of Hb polymerization inside the red cell, exerting an inhibitory role on the sickling process and reducing the severity of clinical manifestations. This phenomenon may result from rare mutations inside the β-globin gene cluster, from mutations in the promoter of the γ-globin gene or from some loci not linked to the β-globin locus. Studies have shown that oxidative stress is very elevated in patients with sickle cell anemia. The increased oxidative stress in SCA occurs due to the generation of free radicals during some events such as deoxygenation of red blood cells, ischemia-reperfusion and vaso-occlusive events. The goal of this study was to investigate the association of three polymorphisms involved in the oxidative stress pathway with the levels of HbF in patients with sickle cell anemia in a Brazilian population. One hundred and nine patients with sickle cell anemia were recruited for peripheral blood collection and for genomic DNA extraction. The epidemiological and clinical data including levels of HbF, sex and age were evaluated. Three polymorphisms, C242T and -930 A/G in the Cytochrome b (-245) Alpha Subunit (CYBA) gene and -413 A/T in the Heme Oxigenase-1 (HMOX1) gene were genotyped through direct sequencing. For statistical analysis the linear regression model from the transformed values of HbF was used. The HbF levels were not significantly associated with sex and age. When the levels of HbF were compared with the polymorphisms, the C242T and -930 A/G did not show significant association, but the TT genotype of the -413 A/T HMOX1 polymorphism showed statistically significant association with increased levels of HbF (p-value = 0.0307). We observed an association between the TT genotype of the -413 A/T polymorphism, present in the promoter of the HMOX1 gene with increased levels of HbF, which indicates the presence of a new marker related to HbF levels in SCA Brazilian patients.

Beta-Thalassemia in The Aegan Region Of Turkey: Identification of A Novel Deletion Mutation. *F. Ozkinay[1,2], H. Onay[2], E. Karaca[2], E. Arslan[2], A. Ece[2], B. Erturk[2], M. Tekin[2], O. Cogulu[1,2], Y. Aydinok[1], C. Vergin[3].* 1) Dept Pediatrics, Ege Univ, Izmir, Turkey; 2) Dept Medica Genetics, Ege Univ, Izmir, Turkey; 3) Dept Pediatrics, Dr. Behcet Uz Hospital, Izmir, Turkey.

OBJECTIVE: To investigate the characteristics of the couples counseled for beta thalassemia and to investigate molecular spectrum of beta thalassemia in the the Aegan Region of Turkey METHODS: Medical records of 438 beta thalassemia related consultations provided at a reference hospital in the Aegan Region of Turkey between 2004–2011 were investigated retrospectively. Between 2004–2011, total 1410 (1166 postnatal and 244 prenatal) molecular tests for beta thalassemia were performed at this center. There were 964 unrelated alleles among the group tested. Either a polymerase chain reaction (PCR)-based reverse dot-blot including 22 mutations or beta globin gene sequencing methods were performed to detect mutations. RESULTS: In 238 of 438 beta thalassemia related consultations, couples were identified to be carriers during premarital screenings. In 46, couples were found to be thalassemia carriers during pregnancy. In 85, couples had a previous child with thalassemia major. Majority of remaining cases were unmarried carriers. Two hundred forty four prenatal diagnosis 244 pnatal diagnosis were performed for thalassemia between 2004–2011 and 60 fetuses were found to be affected. Except 2 cases all couples chose to terminate the pregnancy. Molecular analysis of 964 unrelated chromosomes revealed 28 different genetic mutations in beta-thalassaemia gene among which 7 mutations accounted for 78% of the total beta-thalassaemia genes identified. The most common mutation was IVS1-110 with a frequency of 40% and followed by IVS-1-1 (8%), Codon 8 (7%), IVS-2.745 (7%), IVS2.1 (7%), IVS1.6 (5%), Codon 39 (4%) and Codon 6 (3%). A novel deletion mutation, c.206-212delTCGGTGC was detected in one of the carriers. This study provides important genetic information on beta thalassemia and is useful for genetic counseling in this region.

Development of a Diagnostic Panel for Genetic Immunodeficiencies using Next Generation Sequencing. *E.M. Coonrod[1], J. Durtschi[1], A. Kumanovics[1,2], R.L. Margraf[1], H.R. Hill[1,2,3,4], K.V. Voelkerding[1,2].* 1) R& D, ARUP Laboratories, Salt Lake City, UT; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT; 3) Department of Medicine, University of Utah School of Medicine, Salt Lake City, UT; 4) Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT.

Common Variable Immunodeficiency (CVID), X-linked and Autosomal Recessive Agammaglobulinemias, Hyper-IgM syndrome, and Severe Combined Immunodeficiency (SCID) are genetic immunodeficiencies that predispose to recurrent infections that can be severe and life threatening. Diagnosis can be costly and time consuming because of genetic and phenotypic heterogeneity of these disorders and because other conditions must first be excluded. There are currently 35 genes with variants known to cause these genetic disorders, however, in the case of CVID, only ~15% of cases are associated with a variant in one of the known genes. This suggests that causative variants in additional genes will likely be discovered. An improvement in molecular diagnostic testing for these disorders would incorporate lower costs with a faster turn-around time and the flexibility to add targets as additional genes are discovered. Here we compare custom capture methods for a 35 gene panel to an exome sequencing approach with the goal of developing an accurate and flexible molecular diagnostic test for genetic immunodeficiencies. Custom capture designs with Agilent's HaloPlex and Ion Torrent's AmpliSeq platforms were analyzed in silico. The custom capture designs varied in their theoretical capture of the genes of interest. For example, the TNFRSF13b (TACI) gene, which causes 8–12% of CVID cases, is predicted to be captured at 100% and 74.6% based on the Haloplex and Ion Torrent designs, respectively. Exome data from samples sequenced at our facility were used to determine the capture efficiency and resulting sequencing read coverage for the set of 35 genes along with an additional ~1,050 genes with known roles in immune system function that could be added to the panel in the future. Exomes were prepared using Nimblegen's SeqCap EZ Exome v3.0 kit and one exome was run per lane on the Illumina HiSeq 2000. Initial analyses show that 99.4% of coding sequences contain capture probes within 100 base pairs of the target region. The mean read coverage of the coding sequences in these data sets was 113 fold and 96% of the coding regions were covered by a median of 15 reads. Additional analyses will compare the in silico custom capture designs with our exome sequencing data to determine the most cost effective, comprehensive, and flexible approach to developing a molecular diagnostic test for genetic immunodeficiencies.

2721F

Spectrum of gene mutations in Chinese patients with refractory human herpes viruses associated disease. *H. Liu, F. Wang, Y. Zhang, Y. Wang, W. Teng, L. Guo, C. Tong, T. Wu, Y. Zhao, J. Gu, D. Lu.* Molecular Diagnosis Center, Beijing Daopei Hospital, Beijing, China.

We aimed to investigate the PRF1, UNC13D, STX11, STXBP2, SH2D1A and XIAP gene mutations in Chinese refractory herpes viruses (HHV) associated disease patients. Hemophagocytic Lymphohistocytosis (HLH), X-linked Lymphoproliferative Disease (XLP), chronic active EBV infection (CAEBV) and lymphoma patients were diagnosed according to international criteria. HHV1-8 was screened by PCR. Full length of coding region and splicing donor and receptor of all the 6 genes were sequenced and analyzed. We find that: 1) 43 patients infected with EBV, one of which only EBV positive in tonsils and lymph nodes biopsy specimens but negative in peripheral blood. 3 patients infected with HHV7 and 2 with CMV, 1 with HHV6, 1 with HSV1 and 1 with HSV2. 3 patients were simultaneously positive for 2 or 3 kinds of HHV viruses. 2) 10 cases carrying PRF1 mutations, the median age was 6.5(1–19) years. Totally 10 kinds of PRF1 mutation were detected. All of the 8 biallelic mutations carriers were all diagnosed as FHL2, and the other 2 monoallelic mutation carrier were both diagnosed as CAEBV. 3) 18 cases carrying UNC13D mutation, the median age was 6(0.8–14) years. There were 5 cases carrying biallelic mutations and 13 carrying monoallelic mutations. Totally 19 kinds of UNC13D mutation were detected. 7 cases were diagnosed as FHL3, 8 were diagnosed as CAEBV, 2 were diagnosed as Hodgkin lymphoma (HL). 4) Only one 10 years old female patient carrying a monoallelic STX11 F281 mutation and was diagnosed as EBV associated liver T-cell lymphoma. 5) 11 cases carrying STXBP2 mutations. The median age was 2(1–19) years. Totally 11 kinds of mutations were detected. The 3 biallelic mutations carriers were all diagnosed as FHL5, and the other 8 monoallelic mutations carrier were all diagnosed as CAEBV. 6) 5 male patients carrying SH2D1A mutations and diagnosed as XLP1. 7) 3 male patients carrying XIAP mutations and diagnosed as XLP2. By analysis the spectrum of disease and gene mutations in 47 Chinese patients, we reported that NK cell dysfunction mutations are important reason in Chinese refractory HHV associated disease, including FHL, XLP, CAEBV and lymphoma. The most common infected virus is EBV, and then HHV7, CMV. The most common mutated gene is UNC13D, and then STXBP2, PRF1.

2722W

Exome sequencing identifies missense IRF2BP2 mutation in a family with autosomal dominant common variable immunodeficiency (CVID). *L. Tian[1], D. Li[1], M. Keller[2], K. Cecilia[1], E. Frackelton[1], F. Otieno[1], H. Hakonarson[1,3,6], J.S. Orange[4,5,6].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) Division of Immunology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, USA; 3) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania, USA; 4) Center for Human Immunobiology, Texas Children's Hospital, Houston, Texas, USA; 5) Department of Pediatrics, Baylor College of Medicine, Houston, Texas, USA; 6) These authors contributed equally.

Common variable immunodeficiency (CVID) is a clinically and genetically heterogeneous group of disorders characterized by hypogammaglobulinemia, recurrent infections, and an inability to mount specific antibody responses to antigen. CVID can be multifactorial, or inherited in an autosomal dominant or autosomal recessive manner. Using whole-exome sequencing, we searched for the pathogenic mutation in a family with autosomal dominant CVID. The proband is a young woman who experienced recurrent sinopulmonary infections beginning in early adolescence. Her family history is notable for common variable immunodeficiency in both the proband's father as well as her older brother. Her brother was also diagnosed with type I diabetes. She has no history of autoimmune disease. Four family members were sequenced, of which three are affected (father and 2 children) and one is unaffected (mother). Genomic DNA was isolated from blood samples using standard methods. Whole-exomes were captured using the Agilent SureSelect Human All Exon 50Mb kit and subsequently sequenced with Illumina HiSeq2000 to an effective mean coverage of 80 fold. Paired-end reads (2×101 bp) were aligned to the reference human genome (UCSC hg19) using Burrows-Wheeler alignment (BWA). SNPs and indels were identified using the Genome Analysis Tool Kit. ANNOVAR and SnpEff were used to annotate the variants. We selected variants present in the affected and missing from the unaffected individuals. We narrowed our search by excluding variants that are homozygous in all patients since we are searching for a dominant mutation. The variants were filtered against the 1000 Genomes Project, and 5400 exomes from NHLBI GO Exome Sequencing Project. A missense mutation in IRF2BP2 was identified to be the most probable disease causing mutation. Sanger sequencing of DNA from all available individuals were performed and the IRF2BP2 mutation co-segregated with the disease phenotype. IRF2BP2 encodes an interferon regulatory factor-2 (IRF2) binding protein that interacts with the C-terminal transcriptional repression domain of IRF2. Detailed functional analysis of the IRF2BP2 mutation will be presented at the conference.

2723T

C-terminal frameshift truncation and extension mutation in POU3F4. *W. Park[1], B. Choi[2], D. Kim[1], A. Kim[2].* 1) Biomedical Sciences, Seoul National University College of Medicine, Seoul, South Korea; 2) Department of Otolaryngology, Seoul National University Bundang Hospital, Seongnam.

X-linked nonsyndromic hearing loss can be caused by various mutations of the POU domain, class 3, transcription factor 4 (POU3F4) gene. In Korean patients, we found five novel missense and frameshift truncation and extension mutations. Two missense mutations (p.Thr211Met and p.Gln229Arg) in the POU-specific domain could disturb transcriptional activity in in vitro assay and structure simulation. Two frameshift extension mutations (p.Thr354GlnfsX115 and p.X362ArgextX113) were located outside of POU domain and nuclear localization signal at the C-terminus. Those mutant POU3F4 proteins showed low expression levels, but could be rescued by MG132, a proteasome inhibitor in vitro. Mutant POU3F4 proteins were also localized to the cytoplasm and did not have transcriptional activity. Frameshift mutation (p.Leu317PhefsX12) in POU3F4 leads to the truncation of the C-terminal 44 amino acids including POU domain and nuclear localization signal. This frameshift truncation mutant protein was localized in nucleus and cytoplasm. This frameshift mutant was predicted to encode a protein that would not bind properly to DNA, which was confirmed by a luciferase assay even in presence of MG132. Our results suggested that frameshift truncation and extension mutations in the C-terminus of POU3F4 gene could lead to cytoplasmic localization and subsequent proteosomal degradation due to the structural aberration, which caused transcriptional inactivity, and thus nonsyndromic hearing loss.

2724F

Dominant allele of *DFNM1* suppresses *DFNB26* associated recessive hearing loss. *R. Yousaf[1,2], Z.M. Ahmed[1,3], G. Nayak[1], R.J. Morell[4], S. Sumanas[5], E.R. Wilcox[4], S. Riazuddin[6], T.B. Friedman[4], S. Riazuddin[1,2,3].* 1) Division of Pediatric Otolaryngology Head & Neck Surgery, Cincinnati Children's Hospital Research Foundation, and Department of Otolaryngology, College of Medicine, University of Cincinnati, Ohio 45229, USA; 2) National Center of Excellence in Molecular Biology, University of the Punjab, Lahore, 53700, Pakistan; 3) Division of Pediatric Ophthalmology, Cincinnati Children's Hospital Medical Center, and Department of Ophthalmology, College of Medicine, University of Cincinnati, Ohio 45229, USA; 4) Laboratory of Molecular Genetics, National Institute on Deafness and Other Communication Disorders, Rockville, Maryland 20850, USA; 5) Division of Developmental Biology, Cincinnati Children's Hospital Research Foundation, and Department of Pediatrics, University of Cincinnati, Ohio 45229, USA; 6) Allama Iqbal Medical Research Center, Allama Iqbal Medical College, Lahore, 53700, Pakistan.

We previously reported mapping of nonsyndromc deafness locus *DFNB26*, in a large consanguineous family with eight affected individuals. Interestingly, seven individuals in this family, despite being homozygous for the *DFNB26* linked haplotype, had normal hearing, thus were non-penetrant for the *DFNB26* mutation (Riazuddin et al, 2000, Nature Genetics, 26(4), 431–434). We will discuss in detail the identification of *DFNB26* and *DFNM1* genes at the ASHG 2012 Annual Meeting. The *DFNB26* missense mutation significantly impaired phosphoinositide binding ability and plasma membrane localization of the mutant protein. We used zebrafish embryos to study the effect of *dfnb26* gene knockdown, followed by rescue experiments with wild type and mutant human *DFNB26* and *DFNM1* mRNAs. In the mouse inner ear, *Dfnb26* and *Dfnm1* encoded proteins are localized in the neurons, which innervate both inner and outer hair cells. In lymphoblastoid cells of individuals homozygous for *DFNB26* mutation, several genes of the HGF signaling pathway are dysregulated. Since, the *DFNB26* gene is involved in a wide variety of signaling pathways, deciphering the mechanism of suppression of the hearing loss phenotype by a dominant modifier allele of *DFNM1* may have future clinical relevance beyond addressing *DFNB26* hearing loss.

2725W

Phenome-wide, cross-species comparisons identify novel disease genes with high accuracy. *D.P. Smedley[1], C.J. Mungall[2], S.C. Doelken[3,4], S. Köehler[3,5], B.J. Ruef[6], M. Westerfield[6], P.N. Robinson[3,4,5], S.E. Lewis[2], W.C. Skarnes[1], members of the Mouse Genetics Project.* 1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 2) Genomics Division, Lawrence Berkeley National Laboratory, Berkeley, CA; 3) Institute for Medical and Human Genetics, Charité-Universitätsmedizin, Berlin, Germany; 4) Max Planck Institute for Molecular Genetics, Berlin, Germany; 5) Berlin Center for Regenerative Therapies (BCRT), Charité-Universitätsmedizin, Berlin, Germany; 6) ZFIN University of Oregon, Eugene, OR.

Despite numerous recent successes in identifying causative mutations for genetic disorders, an associated gene has yet to be identified for many diseases and for the others, rarer molecular associations remain to be discovered. Systematic sequencing of genes in linkage regions or exome sequencing approaches are routinely applied to the problem but in both cases 10–100's of candidate genes have to be analysed. Here we describe how semantic phenotypic comparisons of human disease and model organism phenotypic data can be used for prioritization and validation of these disease sequencing efforts. Despite the incomplete coverage of mouse and zebrafish phenotype data, up to 73% of known disease genes can be rediscovered and at stringent levels where on average single candidates are identified for each disease locus, 70% of predictions are correct and 26% of known genes recalled. To uncover novel disease genes, we applied our approach to diseases with a mapped locus but no known molecular association as reported by OMIM and identified candidates for 72 and 22 records using mouse and zebrafish data respectively. We then pursued a validation strategy of reviewing the literature for recently published associations, contacting researchers in each disease area to establish if they have tested our predictions and pursuing collaborative sequencing studies. We have now collected evidence for almost half the predictions based on mouse phenotypic similarities and genomic location. 25% have been confirmed as associated mutations have now been detected in the predicted gene with another 31% having very strong evidence for association. 28% have been screened without success for coding variation but the possibility of non-coding or structural rearrangements remains and, finally, the remaining 14% have been excluded as a mutation in another gene has been found. In conclusion, we find that cross-species phenotypic comparisons are an invaluable tool for the identification of both disease genes and existing animal models for biological characterisation of disease mechanism. This approach will become increasingly powerful as high quality phenotypic annotations of mouse and zebrafish models are generated for all protein coding genes through the efforts of the International Mouse Phenotyping Consortium (www.mousephenotype.org) and Zebrafish Mutation Project (http://www.sanger.ac.uk/Projects/D_rerio/zmp). Our latest predictions are available at http://www.sanger.ac.uk/mouseportal.

2726T

Mutation Screening in *CYP1B1* in Glaucoma Cases from North India. *A. Bhardwaj, V. Vanita.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: We aimed to analyze the disease causing mutations in *CYP1B1* in glaucoma patients from North India. Material and Methods: The present study included 142 glaucoma patients recruited from Dr. Daljit Singh Eye Hospital, Amritsar. Out of these, 109 cases were with primary glaucoma, of which 60 were of primary open angle glaucoma (POAG), 37 primary angle closure glaucoma (PACG) and 12 primary congenital glaucoma (PCG) and rest 33 cases had secondary glaucoma. Detailed ophthalmic evaluation in these cases included visual acuity, tonometry, gonioscopy, slit lamp examination, fundus examination, optical coherence tomography (OCT) and pachymetry. Measurements regarding intraocular pressure, corneal thickness, cup:disk (C/D) ratio, and refractory error were also recorded. Mutation screening in the candidate gene *CYP1B1* was performed by bi-directional sequence analysis of the amplified products. Results: A previously known mutation i.e. p.Arg368His in exon 3 of *CYP1B1* was identified in patients with PACG. In addition, three previously reported polymorphisms (p.Val432Leu, p.Asp449Asp, p.Asn453Ser) were also detected in cases with juvenile open angle glaucoma, primary congenital glaucoma and in angle closure glaucoma phenotypes. Conclusions: We report p.Arg368His as recurrent mutation in *CYP1B1* in our analyzed PACG patients. Three identified polymorphisms in present study have also been previously reported for identical phenotypes. These findings suggest a strong phenotype-genotype correlation of different types of glaucoma with identified substitutions in *CYP1B1*.

Waardenburg syndrome (WS) is a rare auditory-pigmentary disorder that exhibits varying combinations of sensorineural hearing loss and pigmentation defects. Four subtypes are clinically defined based on the presence or absence of additional symptoms. WS type II (WS2) can result from mutations within the MITF or SOX10 genes; however, 70% of WS2 cases remain unexplained at the molecular level, suggesting that other genes might be involved and/or that mutations within the known genes escaped previous screenings. The recent identification of a deletion encompassing three of the SOX10 regulatory elements in a patient presenting with another WS subtype, WS4, defined by its association with Hirschsprung's disease, led us to search for deletions and point mutations within the MITF and SOX10 regulatory elements in 28 yet unexplained WS2 cases. Two nucleotide variations were identified: one in close proximity to the MITF distal enhancer (MDE) and one within the U1 SOX10 enhancer. Despite the fact that each of these variations could potentially create or alter transcription factor binding sites, the results of in vitro functional analysis as well as familial segregation analysis argued in favour of a non-causative effect of the variations identified. Altogether, our results still leave about 70% of WS2 cases unexplained at the molecular level, suggesting that mutations within regulatory elements of WS genes are not a major cause of this neurocristopathy.

Utilization of gene mapping and candidate gene mutation screening for diagnosing clinically equivocal conditions. *V. Chini[1], D. Stambouli[2], F. M. Nedelea[2], G. A. Filipescu[3], D. Mina[4], H. El-Shanti[1, 4], M. Kambouris[1, 5].* 1) Molecular Genetics, Shafallah Medical Genetics Center, Doha, Qatar; 2) Cytogenomic Medical Laboratory, Bucharest, Romania; 3) Elias University Emergency Hospital, Bucharest, Romania; 4) University of Iowa, Pediatrics, Iowa City, IA, USA; 5) Yale University, School of Medicine, Genetics, New Haven CT, USA.

A pregnant female requested prenatal diagnosis for a congenital and complex eye disease segregating in her family. The three-generation pedigree of Romanian ethnic origin was suggestive of an X-linked inheritance, due to exclusively affected males and no father to son transmission. Affected individuals had bilateral optic nerve atrophy, microphthalmia, nystagmus, leukocoria, cataract, retinal detachment, eye tumors reported as retinoblastomas, moderate mental and motor retardation, and seizures. All efforts to obtain the detailed medical records of affected individuals were fruitless. The disease locus was mapped utilizing 78 microsatellite markers that span the X-chromosome at ≈2 Mb intervals. Affected individuals share a ≈10Mb region between DXS1056 and GATA160B08 at Xp11.23–11.4. Candidate genes in this linkage interval included BCOR and NDP. Mutation screening identified a c.C267A p.F89L mutation in the NPD gene in all affected individuals, previously described in a single unrelated Dutch family and speculated as causing Norrie disease (Nikopoulos et al, Human Mutation 31:656–666, 2010) In retrospect clinical symptomatology fits the Norrie disease phenotype. The reported retinoblastomas were most likely pseudogliomas characteristic of Norrie disease. Detection of the c.C267A p.F89L mutation in a second unrelated family confirms the pathogenic nature of the mutation for Norrie disease. Utilization of gene mapping through linkage analyses and candidate gene screening previously utilized exclusively for research applications, were applied at a diagnostic setting and were essential in deciphering the offending molecular defect and diagnosing a disease which due to lack of medical records and poor and misleading clinical history would have no chance of being diagnosed correctly. Clinical diagnosis and mutation identification were essential prerequisites for providing proper genetic counseling and prenatal diagnosis in this family.

Search for a new gene responsible for non-syndromic craniosynostosis. *S. El Chehadeh-Djebbar[1], F. Di Rocco[2], C. Collet[3], M. Le Merrer[3], J. Puechberty[4], G. Lefort[4], B. Aral[5], S. Lambert[6], N. Gigot[5], M. Payet[6], C. Ragon[6], N. Marle[6], A-L. Mosca-Boidron[6], J-R. Teyssier[5], F. Mugneret[6], C. Thauvin-Robinet[1], P. Sarda[4], L. Faivre[1], P. Callier[6].* 1) Centre de Génétique et Centre de Référence Anomalies du Développement et Syndromes Malformatifs, Hôpital d'Enfants, CHU de Dijon, France; 2) Centre de référence des dysostoses craniofaciales, Hopital Necker, Paris, France; 3) Centre de référence des maladies osseuses constitutionnelles, Hopital Necker, Paris, France; 4) Laboratoire de Cytogénétique, CHU Arnaud de Villeneuve, Montpellier, France; 5) Laboratoire de Génétique Moléculaire, Plateau Technique de Biologie, CHU de Dijon, France; 6) Laboratoire de Cytogénétique, Plateau Technique de Biologie, CHU de Dijon, France.

Background: Craniosynostoses are rare heterogeneous condition characterized by premature fusion of one or more of the cranial sutures and comprise two main groups, non-syndromic craniosynostoses, the most frequent (85%), and syndromic craniosynostoses (15%). In certain cases, the latter can be associated with a microdeletion on the short arm of chromosome 7 (CRS1 region, located in 7p21.1), which is responsible for Saethre-Chotzen syndrome. A chromosome 7p14.3–15.1 CRS2 region has been suspected in a small number of patients with craniosynostosis and who had no anomaly in 7p21.1. Objectives: To confirm the existence of the CRS2 locus, and to determine the implication of the PLEKHA8 gene in the etiopathogenesis of craniosynostoses. Method: This study was conducted in two steps. The first comprised a clinical and molecular cytogenetic characterization of two patients with syndromic craniosynostosis and a 7p deletion containing the CRS2 region, as well as two relatives with non-syndromic craniosynostosis who carried a familial balanced translocation involving the 7p15.1 region. The translocation breakpoints were cloned. The second step consisted in sequencing the candidate gene interrupted by the translocation in a cohort of 37 patients with familial (14) and non-familial (23) non-syndromic scaphocephaly, negative for TWIST, FGFR1, FGFR2 and FGFR3 sequencing. Results: We confirmed and further defined the existence of a CRS2 3.6 Mb locus in 7p. The PLEKHA8 (OMIM 608639) gene was interrupted by the 7p translocation breakpoints. PLEKHA8 is involved in Trans Golgi Network to plasma membrane transport and in the formation of post-Golgi constitutive carriers. Interestingly, the PLEKHM1 gene, from the same family, is implicated in osteopetrosis, with a putative critical function in vesicular transport in the osteoclast. However, direct sequencing of this gene in a cohort of 37 patients with non-syndromic craniosynostosis revealed no pathogenic variants. Conclusions: The results of this study, associated with data in the literature, confirm the existence of a second candidate region located in 7p and called CRS2 in etiopathogenesis of craniosynostoses. However, we did not confirm the involvement of the PLEKHA8 gene.

Mutation screening in *CNGA1* in an Autosomal Recessive Retinitis Pigmentosa (ARRP) family. *S. Goyal, V. Vanita.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: The aim of present study was to perform mutation screening in gene for Cyclic nucleotide gated channel alpha 1 (*CNGA1*) in an ARRP family of Indian origin. Material and Methods: We came across a large four generation ARRP family at the Dr. Daljit Singh Eye Hospital, Amritsar, with five affected individuals and parents of the proband being first cousins. Age of onset of the disease in this family was from 16 to 22 years. Ophthalmic examinations that included visual acuity, fundus testing and fundus photography after pupil dilation confirmed the status of the five individuals being affected by non-syndromic typical RP. The *CNGA1* that encodes the alpha subunit of the rod photoreceptor cyclic nucleotide gated channel (CNG) and mediates visual transduction in retinal rods and which is linked with ARRP, was selected for mutation screening. Bi-directional sequence analysis of amplified products of all the exons (III, IV, V, VI and VII, IX, XA, XB, XC, XD, XE) and exon-intron boundaries of *CNGA1* was performed in this family. Results: No disease linked mutation was detected in *CNGA1* in the analyzed ARRP family. Conclusions: No any disease linked mutation could be detected in *CNGA1* for non-syndromic typical RP in the tested autosomal recessive family. Present findings suggest the role of some other gene for retinitis pigmentosa in present family.

A novel mutation of the Nicastrin (NCSTN) gene in a large Indian family with autosomal dominant Hidradenitis suppurativa (or Acne inversa). *D. Jhala[1], U. Ratnamala[2], T.Y Mehta[3], F.M.S Al-Ali[4], M. Raveendrababu[1], S.S Chettiar[1], M.V Rao[1], S. Nair[5], J.J Sheth[6], M.R Kuracha[7], S.K Nath[8], U. Radhakrishna[9,10].* 1) Department of Zoology, School of Sciences, Gujarat University, Ahmedabad, Gujarat, India; 2) Department of Pharmacology, Creighton University, Omaha, NE, USA; 3) Samarpan Medical & Research Organization on Skin, Modasa, India; 4) Dermatology Department, Rashid Hospital, Department of Health and Medical Services (DOHMS), Dubai, United Arab Emirates; 5) Department of Fetal Medicine, Lifeline Genetics and Research Centre, Lifeline Hospital, Adoor, Kerala, India; 6) Foundation for Research in Genetics and Endocrinology, Ahmedabad, India; 7) Department of Surgery, Creighton University, Omaha, NE, USA; 8) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, US; 9) Department of Surgery-Transplant, Nebraska Medical Center Omaha, NE, USA; 10) Green Cross Blood Bank, Ahmedabad, India.

Hidradenitis Suppurativa (HS), also known as `Acne Inversa' is a chronic-inflammatory and scarring disease that usually presents after puberty. It is characterized by swollen or inflamed lesions on the groin, anogenital parts, buttocks, thighs, scalp, neck, nipples and armpits, with subsequent scarring and chronic seepage. The prevalence of HS appears to be 1% of the general population and is 4–5 times greater in women than in men. Genetic predisposition plays a key role in HS and considerable progress has been made recently in identifying genes that are responsible for HS predisposition. Recently, mutations of NCSTN, PSEN1 and PSENEN genes on chromosomal regions 1q23.3, 19q13.12 and 14q24.2, respectively, have been found in sporadic and familial HS patients, suggesting that these genes play an important role in HS development. Here, we report a novel mutation of NCSTN in a large seven-generation Indian family (N = 211) with an isolated non-syndromic HS in which 31 members affected by HS with different phenotypic expression including typical characteristics of HS. The other findings were four women with hirsutism and two deaths due to squamous cell carcinoma, in this family. Mutation search in exons and splice junctions of above three candidate genes identified a frameshift mutation, c.687insCC (p.Cys230ProfsX31), which is predicted to terminate at codon 261 after the addition of 31 novel amino acids within exon 6 of NCSTN. It is known that NCSTN is subunit of the gamma-secretase complex, an endoprotease complex that catalyzes the intramembrane cleavage of integral membrane proteins such as Notch receptors and APP (beta-amyloid precursor protein). We did not detect a pathogenic or predisposing variant in any of the three candidate genes in another multigenerational HS family of Arab origin analyzed, demonstrating genetic heterogeneity of HS. Identification of present mutation expands NCSTN gene mutation spectrum associated with HS phenotype.

A Systematic Approach to Identifying Disease Genes in Mullerian Aplasia. *HG. Kim[1], HK. Nishimoto[1], R. Ullmann[2], JA. Phillips III[3], Y. Shen[4], RH. Reindollar[5], HH. Ropers[2], VM. Kalscheuer[2], LC. Layman[1].* 1) Section of Reproductive Endocrinology, Infertility, & Genetics, Dept OB/GYN, Georgia Health Sciences University, Augusta, GA; 2) Department of Human Molecular Genetics, Max Planck Institute for Molecular Genetics, Ihnestrasse 63–73, 14195 Berlin, Germany; 3) Dept of Pediatrics, Vanderbilt University, Nashville, TN 37212, USA; 4) Dept of Neurology, Children's Hospital, Harvard Medical School, Waltham, MA 02453, USA; 5) Dept Ob/Gyn, Dartmouth College, Lebanon, NH 03756, USA;.

Developmental abnormalities of the uterus and vagina occur in ~7–10% of women and result in a wide range of reproductive dysfunction. Mullerian aplasia (MA), also known as congenital absence of the uterus and vagina (CAUV) and Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome, represents the most drastic developmental aberration of the Mullerian system since reproduction is essentially arrested. MA occurs in 10% of women with primary amenorrhea, but associated anomalies (renal agenesis, skeletal abnormalities, cardiac anomalies, and deafness) may also be present. The molecular basis for most MA remains unknown as WNT4 point mutations have only been found in a subset of MA patients. A critical barrier to progress in the identification of new MA genes is the lack of realistic candidate genes and familial cases. Molecular mapping of chromosome translocation breakpoints in isolated patients offers an opportunity to identify novel disease genes that are disrupted or dysregulated by the chromosome rearrangement. Even a single balanced chromosome translocation has the potential to lead to the localization and cloning of the disease-causing gene through molecular analysis of the breakpoints. Small Copy Number Variation (CNV) also may pinpoint genomic regions containing only a couple of positional candidate genes. Here we applied positional cloning through both breakpoint mapping in a balanced translocation and array CGH for the identification of small CNVs in MA patients to discover new causative genes in MA. Additionally, we adopted whole exome sequencing in trios of MA families to identify de novo mutations in new MA genes. Our cohort of MA patients with chromosomal abnormalities includes: 1) a de novo balanced translocation 46,XX,t(3;16)(p21;p13.3)dn; 2) a 1.3 Mb deletion at 17q12; and 3) 9 trios (MA patient and healthy parents), as well as additional MA patients. Utilizing these three parallel techniques, we took advantage of the opportunity to locate disease genes of Mullerian aplasia by using our unique cohort of MA patients. We have identified four candidate genes (HNF1B, CTNNA3, KIAA1680, and CHSY3), all of which have intragenic duplications or deletions. Our long-term goal is to identify new disease genes and the biochemical pathways important in human Mullerian development.

2733F

Linkage analysis in an Autosomal Recessive Retinitis Pigmentosa (ARRP) Family. *Vanita. Kumar, S. Saini.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: The aim of present study was to perform linkage analysis in an ARRP family of Indian origin to identify the disease linked gene. Material and Methods: We came across an ARRP family at the Dr. Daljit Singh Eye Hospital, Amritsar, with three affected siblings and their parents being first degree cousins. Ophthalmic examinations that included visual acuity, fundus testing and fundus photography after pupil dilation confirmed three sibs to be affected with non-syndromic retinitis pigmentosa. Linkage analysis was carried out using over 110 highly polymorphic fluorescently labeled microsatellite markers for already known candidate gene regions for autosomal recessive as well as autosomal dominant RP. Genotyping was carried out on a DNA sequencer ABI-377, data collected and analyzed by GENESCAN version 3.1.2, and genotyping was done using GENOTYPER 2.5.1 software. 2-point and multipoint linkage analysis were performed by means of the program packages linkage v.5.2 and Genehunter v.2.1. Results: Linkage analysis was carried out with nine genomic DNA samples from three affected and six unaffected members including parents and four of their unaffected sibs. Two-point lod score values of less than -2.0 at theta = 0.001 were obtained with the analyzed markers at already known candidate gene loci thus excluding these to be linked with ARRP in this family. Multipoint lod score analysis further confirmed the 2-point lod score data. Conclusions: We excluded all the candidate gene loci known to be linked with autosomal recessive as well as autosomal dominant RP in an ARRP family of Indian origin having three members affected with non-syndromic RP. These findings indicate the role of a novel gene for ARRP in present analyzed family. Further, these findings highlight the inherent genetic heterogeneity for non-syndromic RP.

Homozygosity Mapping and Mutation Profile of the *MYO7A* Gene in Saudi patients with Usher Syndrome. *K. Ramzan[1], M. Al-Owain[2], K. Taibah[3], G. Bin-Khamis[4], R. Allam[1], A. Al-Mostafa[1], S. Al-Hazza[5], F. Imtiaz[1].* 1) Department of Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Riyadh, Saudi Arabia; 2) Department of Medical Genetics, KFSHRC, Riyadh, Saudi Arabia; 3) ENT Medical Centre, KFSHRC, Riyadh, Saudi Arabia; 4) Department of Otolaryngology, KFSHRC, Riyadh, Saudi Arabia; 5) Department of Ophthalmology, KFSHRC, Riyadh, Saudi Arabia.

Usher syndrome deafness-blindness disorder, is a clinically and genetically heterogeneous disorder. Three clinical subtypes of Usher syndrome have been identified, with mutations in different set of genes. Usher syndrome type 1 (USH1) is the most severe form of Usher syndrome. The *MYO7A* gene is responsible for USH1B, the most common subtype. Homozygosity mapping is a robust approach that is highly suited for genetically heterogeneous autosomal recessive disorders in populations where consanguinity is prevalent. For genotyping, DNA samples were processed on Gene Chip Human Mapping 250K Arrays (Affymetrix, Santa Clara, CA) following the instructions provided by the manufacturer. Homozygosity mapping was carried out using CNAG software that uses SNP genotypes generated by a DM algorithm for the detection of copy number changes and blocks of homozygosity. For affected individuals where the homozygosity blocks were identified on chromosome 11q13.5 harboring *MYO7A*, direct sequencing was performed for the entire coding and flanking intronic regions. Because of the high frequency of consanguinity in our patients this approach allowed us to quickly identify eleven *MYO7A* mutations in twenty families with Usher Syndrome. Though many different mutations in this gene have been identified worldwide, the purpose of this study was to document the *MYO7A* variants present in the Saudi population.

2735T

Mutation Analysis in an Autosomal Recessive Retinitis Pigmentosa Family. *S. Saini[1], J.R. Singh[2], V. Vanita[1].* 1) Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India; 2) Central University of Punjab, Bathinda, India.

Purpose: To do mutation screening in an autosomal recessive retinitis pigmentosa (arRP) family of Indian origin in candidate genes; cyclic nucleotide gated channel alpha-1 (*CNGA1*), elongation of very long fatty acid 4 (*ELOVL4*), rhodopsin (*RHO*) and retinal degeneration slow (*RDS*)/*Peripherin*. Methods: A detailed family history and clinical data including visual acuity test, fundus examination and optical coherence tomography were recorded. Mutation screening in four candidate genes known for autosomal recessive RP (*CNGA1*, *ELOVL4*, *RHO* and*RDS/Peripherin*) was performed by bi-directional sequence analysis of the amplified products. Results: Mutation screening in the four candidate genes in an arRP family revealed a novel c.205G>T change in heterozygous form in *RDS/Peripherin* resulting in p.Val69Leu substitution in the proband and his unaffected mother. This substitution was absent in proband's unaffected father, his other unaffected siblings and 50 ethnically matched controls. Amino acid conservation analysis revealed valine to be highly conserved at codon 69 of *RDS/Peripherin*. Three already known polymorphisms (p.Gln304Glu, p.Arg310Lys and p.Asp338Lys) were also detected in *RDS/Peripherin* in the present family in affected as well as unaffected members. Further, mutation analysis in *RHO* indicated a novel polymorphism i.e. c.163A>T in heterozygous form leading to p.Asn55Tyr in the proband and his unaffected parents while his unaffected sister had both wild type alleles. Conclusions: We identified previously unreported substitution i.e. p.Val69Leu in *RDS/Peripherin* in an arRP family. Mutations in RDS/Peripherin have not yet been reported with arRP although it has been linked with autosomal recessive central areolar choroidal dystrophy type 2 (CACD2. There is a possibility that in present analyzed family the disease is either being carried in autosomal recessive pattern with pseudodominance or p.Val69Leu substitution in *RDS/Peripherin* in association with polymorphism (p.Asn55Tyr) in RHO, both in heterozygous state, may lead to RP in the proband. Another possibility is that another mutation in compound heterozygous state in some other gene segregating with the mutation p.Val69Leu in *RDS/Peripherin* may lead to RP in present family.

2736F

The role of APCS and RBP4 genes as modifiers of age-at-onset in Familial Amyloid Polyneuropathy (FAP ATTRV30M). *D. Santos[1], T. Coelho[2], J.L. Neto[1,3], J.P. Basto[1,3], J. Sequeiros[1,3], I. Alonso[1,3], C. Lemos[1,3], A. Sousa[1,3].* 1) UnIGENe, IBMC, Porto, Portugal; 2) Unidade Clínica de Paramiloidose, Centro Hospitalar do Porto (CHP), Porto, Portugal; 3) ICBAS, Instituto Ciências Biomédicas Abel Salazar, Univ. Porto, Portugal.

Familial amyloid polyneuropathy (FAP ATTRV30M) is an autosomal dominant inherited disease, due to a point mutation in the TTR gene (chr18q11.2-q12.1). Remarkable differences in mean age-at-onset (AO) have been described in different clusters, including within Portuguese population. Among Portuguese families, FAP shows a wide variation in AO (17–82 yrs) and asymptomatic carriers aged 95 can be found; this variation is also often observed between generations. A previous study in Portuguese patients (Soares et al., 2005) found a modifier effect in AO for APCS gene and RBP4 gene, when comparing classic and late-onset patients with controls. However variation between generations was not taken into account. Our aim was to investigate if these two candidate-genes have a modifier effect in AO variation from parent to offspring in FAPATTRV30M families. We collected a sample of 36 FAP families with at least 2 generations affected. We selected 5 tagging SNPs through the degree of linkage disequilibrium (LD) existing between SNPs and also the 5 SNPs previously described. These SNPs were analysed by SNaPshot and RFLP, respectively. Samples' genotyping is currently underway and results are being analyzed with the GeneMapper™ v.4.0 software. Preliminary results in 5 FAP families showed that although for RBP4 gene we found different genotype's frequencies in patients for rs7079946 and rs17484721 from HapMap, no striking differences were found between generations in the families analyzed for the two genes. In the total sample of Portuguese families ascertained, we expect to find or exclude the potential role of these candidate-genes as modifiers of FAP ATTRV30M AO. The study of genetic modifiers is crucial to understand the mechanisms involved in AO variability within and between families and may have an important impact in genetic counselling.

2737W

Linkage Analysis in Families with Autosomal Dominant Corneal Dystrophies. *D. Singh[1], V. Vanita[2].* 1) Dr. Daljit Singh Eye Hospital, Sheranwala Gate, Amritsar, Punjab, India; 2) Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: To perform linkage analysis in two autosomal dominant corneal dystrophy families of Indian origin so as to identify the disease linked gene. Material and Methods: We came across two autosomal dominant corneal dystrophy families at the Dr. Daljit Singh Eye Hospital, Amritsar. In one family in 4-generations 17 members were found to be affected with Reis Bucklers type and in the second family 15 members in 3-generations had granular type corneal dystrophy. Linkage analysis was carried out using highly polymorphic fluorescently labeled microsatellite markers for already known candidate gene regions for corneal dystrophies. Genotyping was carried out on a DNA sequencer ABI-377, data collected and analyzed by GENESCAN version 3.1.2, and genotyping was done using GENOTYPER 2.5.1 software. 2-point and multipoint linkage analysis were performed by using the program packages linkage v.5.2 and Genehunter v.2.1. Mutation screening in the potential candidate gene at the mapped interval was carried out by bi-directional sequence analysis of the amplified products. Results: In two-point and multipoint lod score analysis we obtained significant positive lod scores indicative of linkage with markers at chromosome 5q31 in these two autosomal dominant corneal dystrophy families. Mutation screening in all the exonic regions of the candidate gene i.e. transforming growth factor beta-induced gene TGFBI) at the mapped interval revealed segregation of Arg124Cys mutation in all the affected members of family with Reis Bucklers corneal dystrophy and in none of the unaffected members of this family. Second family with granular type corneal dystrophy showed the segregation of Arg555Trp change in all the tested affected members and in none of the unaffected individuals. Conclusions: Present findings depict the co-segregation of two mutations Arg124Cys and Arg555Trp in gene for TGFBI in two large families of Indian origin with Reis Bucklers and granular type corneal dystrophy respectively. These findings substantiate the role of TGFBI for corneal dystrophy. Further, present findings suggest a strong phenotype-genotype correlation of Reis Bucklers and granular type corneal dystrophy with these two identified mutations.

2738T

A novel chromosomal locus in a family with primary ciliary dyskinesia. *R. Parvari[1,2], M. Mazor[1], S. Alkrinawi[3], V.C. Sheffield[4], M. Aviram[3].* 1) Dept of Virology& Dev. Genetics, Ben Gurion Univ of the Negev, Beer Sheva, Israel; 2) National Institute of Biotechnology in the Negev, Ben Gurion University of the Negev, Beer Sheva, Israel; 3) Division of Pediatrics, Soroka University Medical Center, Beer-Sheva, Israel; 4) Department of Pediatrics - Division of Medical Genetics, Howard Hughes Medical Institute, University of Iowa, Iowa City, IA.

Motile cilia are essential for fertilization, respiratory clearance, cerebrospinal fluid circulation and establishing laterality. Cilia motility defects cause primary ciliary dyskinesia (PCD, MIM244400), a disorder affecting 1:15,000–30,000 births. In a consanguineous Bedouin family with 2 affected and 6 healthy siblings we have searched for the mutation causing the disease. Assuming disease by homozygosity of a mutation from a common ancestor, linkage to the DNAH5 and DNAI1 genes was excluded by the finding of heterozygosity of alleles at known polymorphic markers adjacent to these genes. We further searched for homozygous regions consistent with linkage by genotyping the patients and both parents with the Affymetrix (Santa Clara, CA) GeneChip® Human Mapping 250K Sty arrays. Five homozygous regions larger than 18cM were identified using the KinSNP program. To determine linkage to a single region, all family members were tested with both known polymorphic microsatellite markers and with additional markers developed for this purpose. Linkage was identified to a chromosomal locus on chromosome 18p11.1-q13.3. The multipoint Lod score calculated was 3.0, using the Pedtool server assuming recessive inheritance with 99% penetrance and an incidence of 0.01 or 0.001 for the disease allele in the population. The region contains 10 genes encoding ciliary proteins, a putative mutation causing PCD was not identified in any of these.

2739F

Polymorphism of VEGF +674 gene as potential risk factor for age related macular degeneration (AMD) in Indian patients. *D. Gupta[1], V. Gupta[2], S. Chawla[3], S. R. Phadke[1].*1) Department of Medical Genetics, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, Uttar Pradesh, India; 2) Department of Physiology, Chhatrapati Sahuji Maharaj Medical University Chowk, Lucknow Uttar Pradesh, India; 3) Prakash Netra Kendra, Gomti Nagar Lucknow, Uttar Pradesh, India.

Age related macular degeneration (AMD) is a degenerative disease of the retina that causes progressive impairment of central vision and is the leading cause of irreversible vision loss in elderly people. Vascular endothelial growth factor (VEGF)+674 gene (rs1413711) found on chromosome 6p12 has been determined to be strongly associated with AMD and a major player in the control of angiogenesis. We studied the VEGF +674 (rs1413711) polymorphism in VEGF gene as potential risk factor for AMD in Indian patients. Hundred patients and controls were genotyped for the C-to-T polymorphism in Intron1, 1695 bp downstream from the start of Exon1 of the VEGF gene by Amplification refractory mutation system polymerase chain reaction (ARMS PCR). Genotyping analysis of VEGF gene of 100 AMD patients shows that, 27% homozygous (CC); 19% mutant (TT); and 54% samples had heterozygous (CT) genotype. Whereas in Control samples 45% (CC); 14% (TT); and 41% (TC). The odds ratio of VEGF (rs1413711) gene for development of AMD in carriers of mutant allele (T) vs (C) wild allele is 2.59, homozygosity for the genotype (TT) increased likelihood for AMD 2.5 fold (p-value 0.036 with 95%; CI). +674CC genotype is a potential risk factor for AMD and that carriage of the T allele is potentially protective. While heterozygosity for genotype of VEGF +674 gene CT increased likelihood 2.0 fold which indicate that significant contribution of VEGF gene C>T polymorphisms. Identification of such would not only increase our understanding of the biology of the disease but might also allow a prediction of those `at risk' in the general population. KEY WORDS: Indian, Age related macular degeneration (AMD), Age related maculopathy (ARM), Vascular Endothelial Growth Factor (VEGF), Amplification refractory mutation system polymerase Chain Reaction (ARMS PCR).

Whole genome analysis identifies mutations in inositol polyphosphate phosphatase-like 1 (INPPL1) as the cause of opsismodysplasia. *J.E. Below[1], D. Earl[2,3], K.M. Bofferding[3], M.J. McMillin[3], J. Smith[1], E. Turner[1], M. Stephan[3], L.I. Al-Gazali[4], J. Hertecant[4], D.H. Cohn[5], D.A. Krakow[6], D.A. Nickerson[1], M.J. Bamshad[3].* 1) Genome Sciences, Univ Washington, Seattle, WA; 2) Medical Genetics, Seattle Children's Hospital, Seattle, WA; 3) Department of Pediatrics, Univ Washington, Seattle, WA; 4) Department of Pediatrics, United Arab Emirates Univ, Al Ain, UAE; 5) Department of Molecular, Cell and Developmental Biology, Univ of California Los Angeles, Los Angeles, CA; 6) Department of Human Genetics, Univ of California Los Angeles, Los Angeles, CA.

Opsismodysplasia is a rare chondrodysplasia characterized by micromelia, platyspondyly, delayed skeletal ossification, metaphyseal cupping, and in some individuals severe phosphate wasting. Based on the occurrence of multiple affected siblings born to consanguineous parents, opsismodysplasia is hypothesized to segregate in an autosomal recessive pattern. We performed whole genome sequencing on a parent-child trio of a consanguineous family with two siblings with opsismodysplasia and phosphate wasting. Using linkage analysis we identified regions of homozygosity in the proband. The whole genome sequence data revealed homozygous mutations in several high priority candidate genes within these regions, only one of which, INPPL1, is involved in phosphate metabolism. Sanger sequencing of INPPL1 confirmed homozygosity for a missense mutation, p.Pro659Leu, in both siblings. In a validation cohort of an additional 12 unrelated families with opsismodysplasia, homozygosity or compound heterozygosity for INPPL1 missense, nonsense or splicing mutations was found in 5 families. Thus mutations in INPPL1 that are predicted to result in loss of enzymatic function were found in 6/13 or (~45%) of opsismodysplasia families. INPPL1 encodes an SH2-containing inositol polyphosphate-5 phosphatase. These membrane-bound signaling molecules regulate cell proliferation and survival, and are involved in cytoskeletal reorganization and vesicular trafficking through recruitment of effector proteins to the cell surface. Loss of function mutations in other members of the 5-phosphatase family cause Lowe oculocerebrorenal syndrome, which is, among other findings, characterized by vitamin D-resistant rickets. Comparison of INPPL1 mutation negative and mutation positive families provided insights into the relationship between opsismodysplasia with and without phosphate wasting. These discoveries enable direct genetic testing of individuals in whom the diagnosis of opsismodysplasia is considered They also will facilitate more accurate predictions about the natural history and outcome of individuals with opsismodysplasia, and provide a starting point for exploring the molecular and developmental mechanism underlying opsismodysplasia.

Novel Loci for Autosomal Dominant Nocturnal Frontal Lobe Epilepsy. *S.E. Heron[1], M. Bahlo[2,3], K.R. Smith[2,4], P. Hickey[2], C. Bromhead[2], C.P. Derry[5], J.S. Duncan[6], S. Howell[7], S.F. Berkovic[5], I.E. Scheffer[5,8], L.M. Dibbens[1].* 1) Epilepsy Research Program, School of Pharmacy and Medical Sciences, University of South Australia, Adelaide, South Australia, Australia; 2) Bioinformatics Division, The Walter and Eliza Hall Institute of Medical Research, Melbourne, Victoria, Australia; 3) Department of Mathematics and Statistics, The University of Melbourne, Melbourne, Victoria, Australia; 4) Department of Medical Biology, The University of Melbourne, Melbourne, Victoria, Australia; 5) Epilepsy Research Centre, Department of Medicine, University of Melbourne, Melbourne, Victoria, Australia; 6) Department of Clinical and Experimental Epilepsy, Institute of Neurology, University College London, Queens Square, London, United Kingdom; 7) Department of Neurology, Royal Hallamshire Hospital, Sheffield, United Kingdom; 8) Centre for Neuroscience and Melbourne Brain Centre, Florey Neuroscience Institute, University of Melbourne, Melbourne, Victoria, Australia.

Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) is a seizure disorder characterized by violent motor seizures arising during sleep. Approximately 10% of cases are caused by mutations in the nicotinic acetylcholine receptor genes (nAchR) CHRNA4, CHRNB2 and, in rare cases, CHRNA2. The genetic basis of the majority of cases remains unknown. We ascertained two families with severe ADNFLE accompanied by psychiatric features and intellectual disability. No nAchR mutations were found in either family and linkage to the known loci was excluded, suggesting that both families had mutations at a novel locus. We genotyped the members of both families using Affymetrix or Illumina SNP arrays and performed genome-wide linkage analysis using MERLIN. Linkage for Family A was found to a single locus at chromosome 9q34.2. Linkage for Family B was found to two loci with identical LOD scores: a locus at chromosome 8q22.1–24.13 and a locus at chromosome 15q25.1–26.1. Both the chromosome 8 and chromosome 9 linkage intervals represent new loci for ADNFLE. The chromosome 15 locus has been previously described. The chromosome 8 and 15 loci contain 131 and 73 genes respectively. The chromosome 9 locus contains 99 genes. The identification of the causative genes at these loci will reveal new pathways in the pathogenesis of ADNFLE.

2742F

Identification of a new gene for X-linked Charcot-Marie-Tooth neuropathy using linkage and exome analysis. *M. Kennerson[1,2,3], E. Yiu[4,5], D. Chuang[6], S-C. Tso[6], C. Ly[1], A. Kidambi[1], G. Perez Siles[1], M. Ryan[4,5], G. Nicholson[1,2,3].* 1) Northcott Neuroscience, ANZAC Res Inst, Concord, Australia; 2) Molecular Medicine Laboratory, Concord Hospital, Concord, NSW Australia; 3) Sydney Medical School, University of Sydney, NSW Australia; 4) Children's Neuroscience Centre, Royal Children's Hospital, Victoria, Australia; 5) Murdoch Childrens Research Institute, Victoria, Australia; 6) UT Southwestern Medical Center, Dallas, Texas, USA.

Charcot Marie Tooth neuropathy (CMT) is a clinically and heterogeneous group of disorders characterized by chronic motor and sensory polyneuropathy. It is the most common hereditary neuromuscular disorder presenting in neurogenetics clinics and affects approximately 1 in 2,500 population. X-linked Charcot-Marie-Tooth (CMTX) disease accounts for 10–15% of all CMT. To date, there are five loci reported (CMTX1, CMTX2, CMTX3, CMTX4 Cowchock and CMTX5) and two genes Connexin 32 (Cx32) and phosphoribosyl pyrophosphate synthetase (PRPS1) have been identified for CMTX1 and CMTX5 respectively. We have identified a large family with probable X-linked dominant axonal motor and sensory polyneuropathy. The affected male proband presented at 9 years of age with foot deformity and gait abnormalities. Clinical findings included bilateral pes cavus, clawed toes, distal wasting and weakness and absent ankle jerks. There is no male to male inheritance and carrier females have very mild clinical features. We have screened the Cx32 gene in the proband (coding, UTR and promoter) and have excluded pathogenic mutations. Using traditional linkage analysis we mapped a new locus for X-linked dominant CMT to a 1.6-Mb interval on Xp11.1-p21.3. Whole exome sequencing of family members (2 affected males and one normal male) identified a non-synonymous exonic variant that maps within the established linkage region. The variant fully segregates with the affected phenotype and has been excluded in 1200 ethnically matched control chromosomes. The variant occurs in a highly conserved amino acid residue of the protein and is predicted to be pathogenic. Genetic validation and functional studies supporting pathogenicity of the variant will be presented. The combination of linkage analysis and exome sequencing continues to be a powerful approach for inherited peripheral neuropathy gene discovery.

2743W

A novel splice site Mutation in Erlin2 gene causes complicated form of Hereditary Spastic Paraplegia in a Saudi Family. *S. Majid[1], S. Bohlega[3], S. Hagos[1], H. Dossari[1], K. Ramzan[1], Z. Hassnan[2].* 1) Department of Genetics; 2) Department of Medical Genetics; 3) Department of Neurosciences,King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia.

Hereditary Spastic paraplegias (HSP) encompass clinically and genetically heterogeneous group of neurodegenerative disorders characterized by insidiously progressive weakness and spasticity of the lower extremities. We describe a consanguineous family segregating a complicated form of hereditary spastic paraplegia in autosomal recessive pattern. The 2 affected siblings have spasticity of the lower extremities, speech delay, and mild intellectual disability. Their upper extremities were mildly hypertonic. An intronic splice acceptor site mutation in the Erlin 2 gene was found to be responsible for causing this disorder. Erlin-2 protein is a mediator of Endoplamic Recticulum Degradation Pathway (ERAD) which helps to remove the aberrant proteins. An ERAD pathway targets certain proteins which are needed to maintain cellular homeostasis in tightly regulated level. Our results, in concurrence with previous studies of Erlin-2 suggest that alteration in Erlin-2 gene is a common cause of Complicated HSP thereby increasing the spectrum of mutations in SPG18 locus.

Clinical and genetic study of a new form of familial multiple keratoakanthoma in a Tunisian family: The palmoplantar familial multiple keratoacanthoma. *O. Mamaï[1], L. BoussofaraARA[2], L. Adala[1], I. Ben Charfeddine[1], S. Bouraoui[1], A. Amara[1], R. Nouira[2], M. Denguezli[2], B. Sriha[3], M. Gribaa[1], A. Saad[1].* 1) Laboratory of Human Cytogenetics, Molecular Geneti, Farhat Hached University Hospital, Sousse, Sousse, Tunisia; 2) Departement of Dermatology and Venerology, Farhat Hached University Hospital, Street Ibn El Jazzar, 4000 Sousse, Tunisia; 3) Department of Pathology and Cytology, Farhat Hached University Hospital, Street Ibn El Jazzar, 4000 Sousse, Tunisia.

Keratoacanthoma (KA) is a benign, self-healing epithelial neoplasm; it is characterized by rapid growth and spontaneous regression with residual scarring. It is considered benign growth but evidence is accumulating in favor of a low grade squamous cell carcinoma (SCC). There is tree form of familial multiple keratoacanthoma (FMKA). We investigated a five generation Tunisian family in which 13 members were affected by FMKA and seemed to be Ferguson Smith types transmitted as an autosomal dominant pattern with ulcerate lesions. This disease has been linked to 9q22.3–31 locus, and caused by specific mutations in TFGBR1gene. A detailed disease history with particular attention about the age of onset, distribution, and clinical course of their skin lesions were noted. The whole family was genotyped for this locus; karyotype and the fragility test were performed for all affected persons. After this study a genome wide scan genotyping by Human660W-Quad BeadChip Illumina SNP array was performed. We found particular palmoplantar localization for the lesion with conjuntival keratoacanthoma association and an early age of onset. Haplotype analysis, for 9q22.3–31 locus, did not found any common haplotype linked to FMKA in this family and no mutation was detected in the TGFB11 gene. All patients had a normal karyotype with absence of chromatin fragility. After SNP array analysis we found a delineated single candidate locus of 10 Mb on chromosome 17. We suggested a new form of FMKA named as: the Palmoplantar Familial Multiple Keratoacanthoma (PPFMKA) linked to this new locus that we project to sequence and identify the causative mutation.

2745F

FBLN5 mutation as the cause of HMSN I in a Czech family -usefulness of combination of SNP linkage and exome sequencing analysis. *D. Brožková, P. Laššuthová, J. Lisoňová, M. Krůtová, P. Seeman.* DNA laboratory, Department, University hospital Motol, Prague, Czech Republic.

Hereditary motor and sensory neuropathy is genetically very heterogeneous and can be caused by mutations in more than 40 genes. Sometimes it is difficult to find the causal mutation even in the families with more affected members. A Czech family with an autosomal dominant type of demyelinating HMSN was initially tested in 2001 for the most common causes of HMSN I: CMT1A/HNPP, GJB1, MPZ, PMP22 mutations. Later linkage analysis and additionally exome sequencing were performed. The disease onset is between 30–50 years. Two sisters 57 and 61 old show muscle atrophies below knees, unsecure walking and extremely reduced vibration sense on lower limbs. In three of their sons HMSN I was diagnosed mainly by slow nerve conduction velocity in the second decade, one other son is healthy. Genomewide SNP genotyping was performed on 8 persons with 10k Affymetrix chips. The linkage analysis revealed 20 regions with the LOD score 1.204. The regions with linkage comprised 2 HMSN associated genes - MFN2 and RAB7, but no mutation was detected by sequencing in them. Other HMSN genes and regions were excluded by the linkage, therefore we expected a new not yet known form of the HMSN. Exome sequencing of the 2 patients was performed on Illumina platform and over 18 000 variants were detected in each. The filtering criteria for candidate variants were as follows: common heterozygous variants, coding, not present in db SNP. The criteria fulfilled 357 variants, but after applying of linkage intervals only 5 of them remained. Two of the variants have lower in silico predictions to be a pathogenic. Sanger sequencing confirmed the segregation of the remained 3 variants in all affected patients, but only variant p.R373C in FBLN5 gene seemed most likely to be causal for HMSN I in family. Recently a paper about FBLN5 as a novel gene associated with demyelinating HMSN was published by another group reporting a family with AD HMSNI from Austria with the same p.R373C mutation. Since the Czech family originates from a region close to the Austria, we expect the common origin of this mutation in both families. We conclude that the mutation p.R373C in FBLN5 is causal for HMSN I in our family and we did not observed any apparent signs of macular degeneration or carpal tunel syndrome in any of the patients yet as reported in the Austrian family. Our family seems to by only the second family reported worldwide with FBLN5 mutation and classical HMSN I phenotype. Support- IGA MHCZ NT 11521/4.

Expansion of a repeat motif in the 5' untranslated region of EIF4A3 causes craniofacial and limb defects (Richieri-Costa-Pereira syndrome). *F. Favaro[1,2,3], RM. Zechi-Ceide[1], L. Alvizi[2,3], J. Souza[4], TM. Felix[5], SRF. Twigg[6], SJ. McGowan[6], AOM. Wilkie[6], A. Richieri-Costa[1], ML. Guion-Almeida[1], MR. Passos-Bueno[2, 3].* 1) Department of Clinical Genetics, Hospital of Rehabilitation of Craniofacial Anomalies (HRCA), University of São Paulo, SP, Brazil; 2) Department of Genetic, Institute of Biosciences of University of São Paulo, São Paulo, SP, Brazil; 3) Human Genome Research Center, Institute of Biosciences of University of São Paulo, São Paulo, SP, Brazil; 4) Assistance Center for Cleft Lip and Palate (CAIF), Curitiba-PR, Brazil; 5) Division of Medical Genetics, Hospital of Porto Alegre, Brazil; 6) Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, England.

Richieri-Costa-Pereira syndrome (RCPS; OMIM 268305) is an autosomal recessive acrofacial dysostosis comprising Robin sequence, cleft mandible and limb defects. Despite previous efforts, no causative genetic mechanism for RCPS has been identified. We conducted the present study to identify the pathogenic mechanism of RCPS. We included DNA samples of 20 affected individuals ascertained in a geographic isolate and their non-affected relatives whenever possible. We conducted linkage analysis using SNP microarray 50K in 8 affected individuals and in 3 non-affected sibs. The best homozygous candidate region was at chromosome 17q25 (physical position: 68465456bp–80253028bp). Segregation analysis with markers mapped at this region in all the affected patients and non-affected relatives (n=70) supported linkage between markers rs2289534 and rs3829612, spanning 128.5kb. Neither Sanger sequencing (SS) nor Exome sequencing (ES) revealed any obvious pathogenic mutation in the coding regions of the 4 genes mapped in the 17q25 region or in the rest of the genome. Resequencing of exon 1 of one of the candidate genes revealed that the affected individuals have 16 repeats of a 20 nucleotide (nt) region at the 5'UTR of the EIF4A3 gene. We next verified that homozygosity of the 16 repeats were exclusively present among the affected individuals and not found in the parents or non-affected sibs or in 520 Brazilian controls. We also verified that the 20 nt repeat motif is transcribed in only one of the 2 EIF4A3 isoforms and through qRT PCR, we observed that the 16 repeat-isoform is associated with very low transcription levels (P=0,039) of the EIF4A3. We also found that 3 other Brazilian RCPS patients ascertained elsewhere were also homozygous for the 16 repeats at the 5' UTR of the EIF4A3. Homozygous mutations in EIF4A3 are very likely the cause of RCPS. Exome sequencing did not detect this alteration possibly because it is a CG rich region and have many repetitions. Of the 4 genes in this candidate region EIF4A3 is also the best functional gene. It is involved in splicing processes of many types of RNA, adding RCPS to the list of craniofacial syndromes caused by mutations in genes involved in RNA processing and translation. Reduction in EIF4A3 is possibly interfering in important molecular events during early development, as supported by knockdown studies in zebrafish (Alvizi et al 2012 submitted to ASHG). CEPID/FAPESP, CNPq.

2747T

A recurrent mutation of keratin 4 gene causing white sponge nevus in a Japanese family. *M. Kimura[1], T. Nagao[1,2], J. Machida[1,3], S. Yamaguchi[1], A. Shibata[1], G. Takeuchi[1,2], H. Miyachi[1], K. Shimozato[1], Y. Tokita[4].* 1) Maxillofacial Surgery, Aichi-Gakuin University School of Dentistry, Nagoya, Japan; 2) Department of Oral and Maxillofacial Surgery, Okazaki City Hospital, Okazaki, Japan; 3) Department of Oral and Maxillofacial Surgery, Toyota Memorial Hospital, Toyota, Japan; 4) Perinatology, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan.

White sponge nevus (WSN;OMIM 193900) is a rare autosomal dominant disorder characterized by painless, white, and `spongy' plaques of the oral mucosa. Less frequently, nasal, esophageal, laryngeal, vaginal and anal mucosa may also be affected. Although it is a pathologically benign lesion, there is no effective therapy so far. Mutations in keratin 4 (*KRT4*) and 13 (*KRT13*) genes have been reported as responsible genes of WSN. The purpose of this study is to identify pathogenic mutations of *KRT4* or *KRT13* in a Japanese family with three generations affected by WSN, and to reveal its dysfunction. Proband in this family was a 38-year-old female and four individuals of the family were affected by WSN. Mutation search was performed using DNA from peripheral blood lymphocyte and functional analysis was carried out using HEK293 cells. A heterozygous 3bp deletion (N160Del) was found in the helix-initiation motif at the beginning of alpha-helical domain 1A of *KRT4*. In addition, this mutation was found to lead the disruption of the keratin filament network. From the results of the study, we conclude that the amino acid residue of asparagine in position 160 of *KRT4* is functionally important for keratin filament network formation.

Molecular analysis of benign familial neonatal-infantile convulsion in a Japanese family. *Y. Yamada[1], K. Yamada[1], D. Fukushi[1], K. Miura[2], N. Nomura[1], A. Yamano[1], T. Kumagai[3], N. Wakamatsu[1].* 1) Dept Gen, Inst Dev Res, Aichi Human Service Ctr, Kasugai Aichi, Japan; 2) Dept Pediatrics, Nagoya Univ Sch Med, Nagoya, Japan; 3) Ctrl Hosp, Aichi Human Service Ctr, Kasugai Aichi, Japan.

Benign familial neonatal-infantile convulsion (BNFC) is an autosomal dominant disorder in which afebrile seizures occur in clusters during the first year of life, without neurologic sequelae. As the gene responsible for BNFC, sodium channel and potassium channel genes have been reported. Focusing on a large family including 8 patients with benign spasm, we investigated to define the genetic mutation causing BNFC and establish a method for the simple detection of the mutation. Linkage analysis of the family pathogenesis narrowed down the gene locus to the region between D2S335 and D2S142 (Lodscore 2.1 maximum). Some sodium channel genes (*SCN1A, SCN2A, SCN3A, SCN7A*) were located in this chromosome 2q23-2 domain. Firstly, we analyzed the nucleotide sequences in all exons and adjacent splice sites of *SCN2A* likely to be the causative gene, but no responsible mutations were detected. In the analysis of *SCN1A* and*SCN3A*, we also could not identify any mutations. However, we identified a single nucleotide substitution (IVS18+7A>G) in a new candidate gene, *SCN7A*. As the identified mutation was located at the 5'-end region in intron 18 as the splice-donor site, it is suggested that the mutation caused abnormal splicing of *SCN7A* mRNA. Then, we analyzed the mRNA using the cultured B-lymphoblast from patients in the family, but have not been able to confirm the expression of abnormal mRNA. Next, we constrated a mini chimeric gene containing a part of patients' intron 18, transfected HEK293 cells with it, and analyzed the *SCN7A* mRNA. However, these studies have not proved that the substitution IVS18+7A>G causes splice error. Most recently, the IVS18+7A>G has been reported as a rare single nucleotide polymorphism (SNP, A:0.992, G:0.008). Therefore, we performed array CGH analysis considering the posibility of gene deletion, but chromosome abnormalities causing BFNC have not been identified. Exome analysis of all genes of the affected and non-affected individuals in the family are now in progress.

A Newly Identified Locus for Benign Adult Familial Myoclonic Epilepsy on Chromosome 3q26.32-3q28. *P. Yeetong[1,2,3], S. Ausavarat[2,3], R. Bhidayasiri[4], K. Piravej[5], N. Pasutharnchat[4], T. Desudchit[6], C. Chunharas[4], J. Loplumlert[4], C. Limotai[4], K. Suphapeetiporn[2,3], V. Shotelersuk[2,3].* 1) Inter-Department Program of Biomedical Sciences, Faculty of Graduate School, Chulalongkorn University; 2) Center of Excellence for Medical Genetics, Department of Pediatrics, Faculty of Medicine, Chulalongkorn University; 3) Excellence Center for Medical Genetics, King Chulalongkorn Memorial Hospital, Thai Red Cross; 4) Division of Neurology, Department of Medicine, Faculty of Medicine, Chulalongkorn University; 5) Department of Rehabilitation Medicine, Faculty of Medicine, Chulalongkorn University; 6) 6Division of Neurology, Department of Pediatrics, Faculty of Medicine, Chulalongkorn University, Bangkok, 10330, Thailand.

Benign Adult Familial Myoclonic Epilepsy (BAFME) is an autosomal dominant disorder characterized by adult-onset cortical tremor or action myoclonus predominantly in the upper limbs, and generalized seizures. We investigated a Thai BAFME family. Clinical and electrophysiological studies revealed that 13 were affected with BAFME. There were a total of 24 individuals studied. Genetic analysis by genome-wide linkage study (GWLS) was performed using 400 microsatellite markers and excluded linkage of the previous BAFME loci, 8q23.3-q24.1, and 2p11.1-q12.2. GWLS showed that the disease-associated region in our Thai family was linked to a newly identified locus on chromosome 3q26.32-3q28. Next-generation sequencing was used to sequence the whole critical region of 18 Mb. In addition, array comparative genomic hybridization was performed to identify copy number variations. Even with both advanced assays, the etiologic gene remains elusive. Discovery of the fourth BAFME chromosomal region will facilitate the identification of the responsible gene. This may provide further understanding into the molecular basis of epilepsy and better insight into the disease mechanism leading to more effective treatment of this disorder.

2750T

Calpain-5 causes autoimmune uveitis, retinal neovascularization and photoreceptor degeneration. *V.B. Mahajan[1], J.M. Skeie[1], A.G. Bassuk[2,3], J.H. Fingert[1], T.A. Braun[1,4], H.T. Daggett[1], J.C. Folk[1], V.C. Sheffield[1,2,5], E.M. Stone[1,5].* 1) Department of Ophthalmology and Visual Sciences, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA, United States; 3) Department of Neurology, University of Iowa, Iowa City, IA, United States; 4) Department of Biomedical Engineering, University of Iowa, Iowa City, IA, United States; 5) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA, United States.

Background: Autosomal dominant neovascular inflammatory vitreoretinopathy (ADNIV) is an autoimmune condition that sequentially mimics uveitis, retinitis pigmentosa, and proliferative diabetic retinopathy as it relentlessly progresses from a relatively subtle onset to complete blindness over five decades. The purpose of this study was to identify the disease-causing gene and to understand how a single gene could cause this wide range of clinical findings.

Methods: Eye examinations were performed in three different kindreds. High-density genotyping narrowed the disease interval, and exome sequencing of two individuals from the largest kindred identified the disease-causing gene. Sanger DNA sequencing was used to confirm the disease-causing mutation and to identify the mutations in the other two families. Immunohistochemistry, structural modeling, and heterologous cell expression of the mutant alleles were performed to investigate the pathophysiology.

Results: Two different missense mutations were identified on chromosome 11q13 in exon 6 of the *CAPN5* gene, which encodes the calcium-activated cysteine protease calpain-5. Structural modeling revealed that both mutations lie within a putative regulatory domain near the active site. Calpain-5 is expressed in retinal photoreceptor cells. Both mutations cause mislocalization from the cell membrane to the cytosol in vitro.

Conclusions: This is the first report of a specific molecular cause autoimmune eye disease. *CAPN5* is only the second member of a large protease gene family to cause a human Mendelian disorder. Further investigation of these mutations is likely to provide new insight into the pathophysiologic mechanisms of common eye diseases ranging from autoimmune disorders to diabetic retinopathy.

2751F

Soluble ICAM-1 levels are associated to a protective prognosis in sickle cell retinopathy. *P.R.S. Cruz[1], T.R. Zaccarioto[2], F.N. Mitsuuchi[3], S.A.C. Pereira Filho[3], R.P.C. Lira[3], I. Meyer[4], M.A.C. Bezerra[5], K.Y. Fertrin[6], F.F. Costa[6], M.B. Melo[1].* 1) Laboratory of Human Molecular Genetics, Center of Molecular Biology and Genetic Engineering (CBMEG), University of Campinas - UNICAMP, Campinas, São Paulo, Brazil; 2) Department of Clinical Pathology, School of Medical Sciences, State University of Campinas-UNICAMP, Campinas, São Paulo, Brazil; 3) Department of Ophthalmology, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, São Paulo, Brazil; 4) Eyes Instute of Recife - IOR, Recife, Pernambuco, Brazil; 5) Center of Hematology and Hemotherapy of Pernambuco - HEMOPE, Recife, Pernambuco, Brazil; 6) -Hemotherapy Center, Department of Clinical Medicine, University of Campinas - UNICAMP, Campinas, São Paulo, Brazil.

Hemoglobinopathies are among the most common inherited diseases globally. The HbS and HbC variants of the beta globin gene lead to sickle cell anemia (HbSS) and SC hemoglobinopathy (HbSC). Sickled red blood cells are more likely to adhere to the vascular endothelium, resulting in vascular obstruction and ischemia. Sickle cell retinopathy is an ocular condition derived from vaso-occlusion in the microvasculature of the retina leading to hypoxia, neovascularization and eventually to blindness. The reasons for HbSC patients being more likely to exhibit ocular manifestations than patients with HbSS are not clear. A possible relation to the rate of sickling, hematocrit and blood viscosity is postulated. These facts combined to endothelium activation and altered expression of adhesion molecules such as P-selectin, E-selectin, intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) offer a more feasible view of the vaso-occlusion process in retinopathy development. There is also evidence of angiogenesis regulation molecules participation, namely angiopoetin-1 (Ang-1), angiopoetin-2 (Ang-2), pigment epithelium-derived factor (PEDF) and vascular endothelial growth factor (VEGF). In order to evaluate the involvement of these factors, the plasmatic Ang-1, Ang-2, sVCAM-1 and sICAM-1 levels were quantified by ELISA in 37 Brazilian sickle cell retinopathy patients (13 HbSS and 24 HbSC) which were compared to 34 Brazilian sickle cell patients without retinopathy (19 HbSS and 15 HbSC), along with healthy sex and age-matched individuals (n=10). Moreover, two polymorphisms (-358G/A and -790T/C) in the PEDF gene promoter region were analyzed in 92 patients (32 HbSC e 60 HbSS) by direct sequencing. It was observed that soluble ICAM-1 is elevated in the HbSC non-retinopathy group compared to the affected HbSC group ($p=0.012$). Furthermore Ang-1 and Ang-2 levels were altered in SCD compared to healthy controls ($p=0.001$ and $p<0.001$, respectively). Ang-2 levels were also heightened in HbSS in comparison to HbSC individuals ($p<0.001$). Ang-2 levels were negatively correlated to hematocrit in both HbSC (Pearson's correlation coefficient, $r = -0.719$, $p< 0.001$) and HbSS patients ($r = -0.438$, $p = 0.046$). However, sVCAM-1, sE-selectin, sP-selectin, VEGF and PEDF analysis exhibited no statistical significant differences among groups. These results underline the importance of carefully analyzing sickle cell disease different genotypes separately.

2752W

X-linked CHARGE-like Abruzzo-Erickson syndrome and classic cleft palate with ankyloglossia result from TBX22 splicing mutations. *P. Stanier[1], E. Pauws[1], E. Peskett[1], C. Boissin[1], K. Mengrelis[1], E. Carta[1], M.A. Abruzzo[2], M. Lees[1,3], G.E. Moore[1], R.P. Erickson[4].* 1) UCL Institute of Child Health, 30 Guilford Street, London, WC1N 1EH, UK; 2) Dept. of Biology, California State University, Chico, CA, 95929-0515, USA; 3) Great Ormond Street Hospital, London, WC1N 3JH, UK; 4) Dept. of Pediatrics, University of Arizona Health Science Center, Tucson, AZ, 85724-5073, USA.

X-linked cleft palate (CPX) is caused by mutations in the gene encoding the TBX22 transcription factor and is known to exhibit phenotypic variability, usually involving either a complete, partial or submucous cleft palate, with or without ankyloglossia. This study hypothesized a possible involvement of TBX22 in a family with X-linked, CHARGE-like Abruzzo-Erickson syndrome, of unknown etiology. The phenotype extends to additional features including sensorineural deafness and coloboma, which are suggested by the Tbx22 developmental expression pattern but not previously associated in CPX patients. A novel TBX22 splice acceptor mutation (c.593-5T>A) was identified that tracked with the phenotype in this family. A novel splice donor variant (c.767+5G>A) and a known canonical splice donor mutation (c.767+1G>A) affecting the same exon were identified in patients with classic CPX phenotypes and were comparatively analyzed using both in silico and in vitro splicing studies. All three variants were predicted to abolish normal mRNA splicing while the in vitro assay indicated that use of alternative splice sites was a likely outcome. Collectively, the data demonstrated the functional effect of several novel splice site variants but most importantly confirms that TBX22 is the gene underlying Abruzzo-Erickson syndrome, expanding the phenotypic spectrum of CPX.

Enlarged vestibular aqueduct syndrome - characterization of three new mutations. *E. Prera, S. Arndt, A. Aschendorff, R. Birkenhäger.* Otorhinolaryngology H&N Surg, Univ Med Ctr Freiburg, Freiburg, Germany.

Introduction: Enlarged vestibular aqueduct (EVA) syndrome is a congenital autosomal recessive anomaly, characterised for a progressive bilateral sensorineural hearing impairment, with temporal bone abnormalities (enlarged vestibular aqueduct). In combination with a euthyroid goiter it is called a Pendred syndrome. 40% of affected individuals have a mutation in the SLC26A4 gene. The gene product Pendrin is expressed in the inner ear, thyroid gland and kidney. This gene product is an iodide/chloride transporter. Here we describe the identification of three new mutations, which in combination with an already known mutation lead to an enlarged vestibular aqueduct syndrome. Patients and Methods: In this analysis four members of two different families were included. Complementary to the audiologic and radiologic diagnosis complete molecular-genetic analyses were performed with all family members. Sensorineural hearing impairment occurred on one of the involved members at the age of 22 years and on the second family on one member at the age of 12 years. All intron transitions and exons from the SLC26A4 gene were sequenced directly. Results: Two loss of function mutations (c.1353_1354insGCT;IVS7-2T>C) and two missense-mutations (c.412G>T, p.V138F; c.1238A>G, p.E413R) were identified. Conclusion: The discovery of these new mutations can derive to a better understanding of the phenotype variability of EVA and Pendred syndrome, and leading to a better understanding of phenotype-genotype correlation.

2754F

A Novel Molecular Basis for Carpenter Syndrome. *S. Movva, U. Kotecha, R. Puri, I.C. Verma.* Center of Medical Genetics, Sir Ganga Ram Hospital, New Delhi, India.

Carpenter syndrome (OMIM:201000) is a rare autosomal recessive disorder characterized by craniosynostosis, obesity, polydactyly and soft-tissue syndactyly. The gene for Carpenter syndrome (RAB23), was identified in 2007, following which there have been three reports describing different types of mutations in the gene, although the spectrum of identified mutations in has been limited. In the present report we describe a novel homozygous mutation in an Asian Indian patient. A non-consanguineously married woman from Punjab was referred during her third conception. Her first child had died within 24 hrs of life, and had an abnormal shape of the skull with ambiguous genitalia. The second born is a healthy girl. In the current pregnancy antenatal ultrasound study at 31 weeks of gestation showed polyamnios, clover leaf skull, polydactyly in both lower and one upper limb. In view of the previous history, possibility of an autosomal recessive disorder was entertained. Examination of the neonate after delivery, along with radiographs, CT scan of the brain with bone window 3D reconstruction was recommended. A male baby was born at 32 weeks and succumbed within 2 hrs of life. As the family was from another state and the newborn could not be examined by us, the attending pediatrician took photographs with blood sample for karyotyping and DNA studies. Three years later the family came for preconception counseling. The neonatal photographs were reviewed and a diagnosis of Carpenter syndrome was strongly suspected. RAB23 gene was sequenced using the stored DNA of the baby. We identified a novel mutation which converted the stop codon into a coding one, resulting in formation of a lengthened protein. The Stop238E causes an open reading frame of the coding sequence in the exon 7 of the gene up to nucleotide no. 918 followed by a subsequent stop codon sequence at nucleotide nos.919–921. This results predictably in an additional 69 amino acid residue sequence leading to a longer mutated Rab23 protein containing 307 amino acids in contrast to the wild type protein containing 237 amino acid residues. The present study identified a novel molecular basis for the Carpenter syndrome due to a stop codon mutation in the RAB23 gene adding to the spectrum of reported mutations. The case also highlights the importance of clinical history, taking photographs and storing the DNA, all of which helped to establish the diagnosis.

De novo activating mutations in Phosphatidylserine Synthase 1 cause a rare mental retardation-multiple congenital anomalies syndrome. *S.B. Sousa[1,2], D. Jenkins[3], E. Chanudet[4], A. Barnicoat[5], K. Chrzanowska[6], J. Sá[2], J. Saraiva[2], R. Scott[5], D. Wattanasirichaigoon[7], G. Anderson[8], G. Tasseva[9], J. Vance[9], P. Beales[3], G.E. Moore[1].* 1) Clinical and Molecular Genetics Unit, UCL Institute of Child Health, London, United Kingdom; 2) Serviço de Genética Médica, Hospital Pediátrico de Coimbra, Coimbra, Portugal; 3) Molecular Medicine Unit, UCL Institute of Child Health, London, UK; 4) GOSgene, UCL Institute of Child Health, London, UK; 5) Clinical Genetics Department, Great Ormond Street Hospital, London; 6) Department of Medical Genetics, The Children's Memorial Health Institute, Warsaw, Poland; 7) Department of Pediatrics, Faculty of Medicine, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 8) Histopathology Department, Great Ormond Street Hospital for Children, London; 9) Group on the Molecular and Cell Biology of Lipids, Department of Medicine, University of Alberta,Edmonton, Canada.

Phosphatidylserine is a component of mammalian cell membranes, usually representing 2–10% of total phospholipids. Phosphatidylserine is known to play important roles in biological processes such as apoptosis and cell signalling. We collected clinical information and DNA/tissue samples from four unrelated patients with a rare syndrome characterized by mental retardation and multiple congenital anomalies, including facial dysmorphology and skeletal abnormalities. Affected individuals of both sexes have been identified on several ethnic backgrounds, but no familial cases are known and parental consanguinity has not been reported. We therefore hypothesized that the disease is caused by a dominant de novo mutation in affected individuals. We performed whole exome sequencing in the four unrelated affected patients, and identified novel heterozygous missense mutations in the Phosphatidylserine Synthase 1 gene (PTDSS1) in all affected individuals. These mutations were validated by Sanger sequencing, were not present in the available control databases, affected conserved residues and were confirmed de novo in 2/2 cases where parental samples were available, further suggesting pathogenicity. The structure of the enzyme Phosphatidylserine Synthase 1 is not known in detail, but the identified missense mutations are both located in transmembrane domains. The reported PTDSS1 null-mutant mice were normal, suggesting a gain-of-function mechanism. This was supported by measuring PTDSS1 enzymatic activity in primary fibroblasts, which was strongly increased in patient samples compared to controls. Furthermore, expression of the corresponding missense mutant versions of human PTDSS1 in zebrafish embryos caused severe defects of the craniofacial skeleton that were not observed in embryos expressing the wild-type form. Ongoing studies aim to clarify the physiopathology of these mutations. In summary, we report the first human mutations affecting the phosphatidylserine pathway, which emphasize its importance and give insights into its role in neural and skeletal development.

Exome sequencing of a consanguineous Palestinian kindred with syndromic cleft palate. *H. Shahin[1], U. Sharaha[1], M. Lee[2], S. Saed[4], J. van Aalst[3], MC. King[2], T. Walsh[2].* 1) Life Sciences Department, Bethlehem University, Bethlehem, Palestinian Territory; 2) Department of Medical Genetics, University of Washington, Seattle, WA, USA; 3) Plastic & Reconstructive Surgery, University of North Carolina, Chapel Hill, NC, USA; 4) Palestinian Cleft Society, Palestine.

Cleft lip and cleft palate (CLP) are among the most common birth defects worldwide and confer lifelong morbidity on affected individuals. The trait is highly heterogeneous both phenotypically and genetically. We are studying a 4-generation consanguineous Palestinian kindred including seven affected relatives. The participants in the present project are three siblings (two male, one female), ages 23, 21, and 12 years, and their unaffected first-cousin parents. All three siblings have complete clefting of the soft palate, incomplete bilateral clefting of the hard palate, severe velopharyngeal insufficiency, and moderate to severe bilateral hearing loss. One male has retarded growth. Vision and cognitive development are normal in all siblings. The sibship also includes four unaffected brothers, two unaffected sisters, and a fourth affected child who is deceased. Exome sequencing of genomic DNA of the three affected siblings, followed by filtering for rare potentially damaging variants, yielded exactly one exome variant homozygous in all three affected siblings: COL2A1 c.2563G>A (p.G855S). COL2A1 is a collagen of cartilage. Glycine is conserved at this site in all sequenced vertebrates, and p.G855S is predicted to be damaging by all bioinformatics tools. Both parents were heterozygous and unaffected and 3 of 320 controls from the same region of the West Bank were also heterozygous and unaffected. Severe heterozygous mutations in COL2A1 are responsible for multiple human disorders, including achrondrogenesis, chrondrodysplasia, early onset osteoarthritis, Stickler syndrome type I, and spondyloepiphyseal dysplasia congenita (SEDC). Many disease-associated mutations in COL2A1 are missenses at glycine residues in the collagen triple helix repeats. The glycine at residue 855 lies between the first (aa 513–571) and second (aa 969–1016) collagen triple helix repeats. We speculate that although p.G855 and neighboring residues are highly conserved throughout vertebrates, p.G855S may be less severe than mutations in the triple helix repeats themselves, so that homozygosity for p.G855S is compatible with life. We are presently sequencing COL2A1 in other Palestinian families with cleft palate to determine if COL2A1-associated phenotypes may be more frequently recessive than previously appreciated.

2757F

Mutations in the DOCK6 gene in Adams-Oliver syndrome. *W. Wuyts[1], A. Laureys[1], E. Van Hul[1], M. De Smedt[2], K. Storm[1], N. Van der Aa[1].* 1) Dept Med Gen, Univ Antwerp, Edegem, Belgium; 2) Dept Med Genet, Leuven University Hospital, Leuven, Belgium.

Introduction Adams-Oliver syndrome (AOS)is a rare genetic disorder characterized by aplasia cutis congenita (ACC) and terminal transverse limb defects. Mutations in the ARHGAP31 gene have been described as a cause of autosomal dominant AOS while mutations in the DOCK6 gene were shown to be responsible for an autosomal recessive form of AOS. To investigate the contribution of both genes to the AOS phenotype we performed mutation analysis of ARHGAP31 and DOCK6 genes in a cohort of AOS patients. **Materials and Methods** A cohort of 20 patients with clinical characteristics of AOS were included in the study, including familial and sporadic cases. Mutation analysis of the ARHGAP31 gene was performed by sequence analysis of the terminal exon 12. Mutation analysis of the DOCK6 gene was performed by sequence analysis of all coding exons. **Results and discussion** For 12 patients potential recessive inherritance was suspected based on observed inherritance pattern or known or suspected consanguinity of the parents. Mutation analysis of all DOCK6 coding exons revealed the presence of homozygous inactivating mutations in 3 patients, including a nonsene mutation, a frameshift mutation and a multi-exon deletion. Mutation analysis of the ARHGAP31 terminal exon (exon 12) did not reveal a mutation in any of the patients analyzed. Our results confirm the involvement of the DOCK6 gene in Adams-Oliver syndrome. However, as the majority of patients in our cohort did not show a DOCK6 or ARHGAP31 mutation, further genetic heterogeneity is supected for AOS.

2758W

Novel mutations of the FGD1 gene in 16 patients with Aarskog-Scott syndrome. *T. Kaname[1], K. Yanagi[1], N. Okamoto[2], K. Kurosawa[3], Y. Izumikawa[1], Y. Fukushima[4], Y. Makita[5], M. Tsukahara[6], A. Altincik[7], S. Mizuno[8], K. Naritomi[1].* 1) Dept Med Gen, Univ Ryukyus, Nishihara, Japan; 2) Dept Dev Med, Osaka Med Centr Res Inst Maternal and Child Health, Izumi, Japan; 3) Div Med Genet, Clin Res Inst, Kanagawa Child Med Centr, Kanagawa, Japan; 4) Dept Med Genet, Shinshu Univ, Matsumoto, Japan; 5) Edu Centr, Asahikawa Med Univ, Asahikawa, Japan; 6) Faclt Health Sci, Yamaguchi Univ, Ube, Japan; 7) Faclt Med, Dokuz Eylul Univ, Turkey; 8) Dept Pediatr, Cent Hosp, Aichi Hum Serv Centr, Aichi, Japan.

Faciogenital dysplasia 1 (FGD1) gene was identified as a responsible gene for Aarskog-Scott syndrome (AAS) or facio-digito-genital dysplasia (MIM#305400), which is an X-linked disorder characterized by genital and skeletal abnormalities. To date, more than 25 mutations have been reported. However, neither phenotype/genotype correlations nor phenotypic features on patients with FGD1 mutation have been cleared. We identified nine mutations of the FGD1 gene in 16 Japanese or Turkish patients with clinical AAS. Of nine mutations, five are missense mutations, two are splice site mutations, and two are deletion mutations. In addition, we found two synonymous variations in the patients by PCR-HRM analysis. All mutations were not found in 200 controls, suggesting that the mutations would be pathogenic. Although the evidence for phenotype/genotype correlations between the type of mutations and clinical features was not found, many clinical features met the primary diagnostic criteria for AAS in the patients with mutations in the FGD1 gene.

2759T

Exome Sequencing Identifies an *IFIH1* Mutation Causing Singleton-Merten Syndrome by Dysregulation of the Innate Immune Response. *F. Rutsch[1], M. MacDougall[2], C. Lu[2], Y. Nitschke[1], I. Buers[1], O. Mamaeva[2], D.K. Crossman[2], J. Dong[2], C. Müller[1], H.G. Kehl[3], J. Kleinheinz[4], P. Barth[5], K. Barczyk[6], D. Bazin[7], J. Altmüller[8], H. Thiele[8], P. Nürnberg[8], W. Höhne[9], A.S. Feigenbaum[10], R. Hennekam[11].* 1) Department of General Pediatrics, University Children's Hospital, Münster, Germany; 2) Institute of Oral Health Research, University of Alabama Medical School, Birmingham, AL, USA; 3) Department of Pediatric Cardiology, University Children's Hospital, Münster, Germany; 4) Department of Cranio-Maxillofacial Surgery, Münster University Hospital, Münster, Germany; 5) Gerhard-Domagk Institute of Pathology, Münster University Hospital, Münster, Germany; 6) Institute of Immunology, Münster University Hospital, Münster, Germany; 7) Laboratoire de Physiques des Solides, Paris Sud University, Orsay, France; 8) Cologne Center for Genomics, University of Cologne, Cologne, Germany; 9) Department of Biochemistry, Charité University Medicine, Berlin, Germany; 10) Department of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Canada; 11) Department of Pediatrics, Academic Medical Center, Amsterdam University, Amsterdam, The Netherlands.

Singleton-Merten Syndrome (SMS; MIM 182250) is a rare autosomal-dominant disorder characterized by calcification of the ascending aorta and cardiac valves leading to premature death with psoriasis, dentin dysplasia, delayed tooth eruption, early loss of permanent teeth through root resorption and widened medullary cavities of the phalanges with focal osteoporosis. To identify the underlying disease gene, whole exome sequencing was performed on four SMS patients from three families. We identified the same heterozygous missense mutation segregating with the disease in all four patients in *IFIH1*, encoding for melanoma differentiation associated protein 5 (MDA5), not present in the Single Nucleotide Polymorphism or the 1000 Genomes databases. MDA5 regulates inflammatory signals belonging to the RIG-I-like receptor family of sensors for cytoplasmic double-stranded RNA and initiates antiviral responses by producing type I and type II interferons. Genome wide association studies have linked MDA5 SNPs with type I diabetes and psoriasis. The identified p.R822Q MDA5 mutation is at a highly conserved amino acid in the helicase domain. Structural analysis of this region revealed a positive surface potential for RNA orientation during unwinding that is changed, altering the potential affinity and/or activity of the helicase. Expression analysis (qRT-PCR and immunohistochemistry) showed MDA5 expression in heart tissue, skin, alveolar bone and tooth ameloblasts (enamel producing), odontoblasts (dentin producing) and the periodontal apparatus; all disease targeted tissues. Osteogenic array analysis of dental mineralizing SMS versus control cells showed ~55% of the gene tested were dysregulated. Ingenuity pathway analysis of Affymetrix GeneChip expression profiles revealed that inflammatory response/immunity networks and interferon and type I diabetes mellitus signalling pathways were the most significantly dysregulated. Transient and stable transfection of HEK 293 cells with wildtype, SMS-MDA5 and corrected SMS-MDA5 (corSMS-MDA5) vectors showed enhanced (dominant) cytokine production of INF-β and TNF-α associated with the SMS MDA5 mutation that was recovered to baseline levels with the corSMS-MDA5 construct. These data suggest that the deficient dental structure formation, abnormal root resorption, localized osteoporosis, cardiac calcification and psoriatic skin changes seen in SMS result from the p.R822Q MDA5 mutation by modulation of the innate immune response.

The presence of hair and teeth anomalies, alopecia, and partial syndactyly of the fingers and/or toes defines the ectodermal dysplasia-syndactyly syndrome (EDSS1; OMIM #613573), a rare autosomal recessive disorder so far reported in no more than five families worldwide. Its disease-causative gene is PVRL4, encoding nectin-4, an immunoglobulin superfamily cell adhesion molecule implicated in the formation of cadherin-based adherens junctions. Nectin-4 function is closely related to its ability to form heterodimers with nectin-1, encoded by the paralog PVRL1, whose mutations are responsible for the autosomal recessive cleft lip/palate-ectodermal dysplasia syndrome (CLPED; OMIM #225000) also showing variable syndactyly. Here we describe two novel patients with EDSS in which we have identified two novel homozygous mutations in PVRL4. A third patient with abnormalities in hair, teeth and cutaneous syndactyly without cleft lip/palate, initially diagnosed with EDSS, was found mutated in PVRL1. The first family is a consanguineous Lebanese family with two members affected by EDSS, in which sequence analysis revealed a novel PVRL4 homozygous nonsense mutation. In the second family, the EDSS proband is the single child of healthy unrelated Danish parents. He has a large biallelic exonic deletion involving one PVRL4 exon, confirmed in his heterozygous parents by quantitative real-time PCR. Interestingly, a large 1.8 Mb homozygous region involving the PVRL4 locus at 1q23 was identified, arguing for a possible founder effect in the Danish population. In the third patient from Germany, no mutations in the PVRL4 gene were identified, while a novel nonsense mutation truncated the coding sequence of PVRL1. Notably this is the third patient mutated in PVRL1 and the first without oral defects. Our results define "nectinopathies" as clinically overlapping ED syndromes caused by defective nectins-1 and 4, two molecules essential for correct ectodermal derivatives and limb development.

2761W

ELN Mutations in Autosomal Dominant Cutis Laxa. *E. Lawrence[1], M. McGowan[1], C. Su[1], M. Mac Neal[1], K. Levine[1], A. Zaenglein[2], M. Bodzioch[3], A. Kiss[4], Z. Urban[1].* 1) Department of Human Genetics University of Pittsburgh; 2) Dept. of Dermatology Penn State Milton S. Hersey Medical Center; 3) Jagiellonian University Medical College; 4) Dept. of Clinical Genetics Universidade Federale de Ciencias de Porto Alegre.

Cutis laxa (CL) is an inherited skin disease with remarkable locus heterogeneity. Mutations in the elastin gene (ELN) cause autosomal dominant cutis laxa (ADCL). We have sequenced the last 5 exons of ELN in 63 consecutive probands with CL. Mutations were identified in 4 probands. Two had a previously published c.2296delA mutation in exon 32 and one had an earlier reported mutation in exon 30 (c.2177delC). Finally, one proband carried a novel mutation in exon 34 (c.2351delG). Examination of the origin of the mutations was possible in 3 families, 1 showing inherited, and 2 de novo mutations. In addition to CL, 3/5 affected individuals had mild-moderate obstructive pulmonary disease and one had a mild aortic root dilatation. Immunoblotting showed elevated canonical, but unaffected non-canonical transforming growth factor-beta signaling in fibroblasts from patients with ELN mutations. We conclude that ELN-positive CL explains approximately 6% of cutis laxa cases and elevated transforming growth factor-beta signaling is a disease mechanism in ADCL shared with other connective tissue diseases.

2762T

***RIPK4* mutations explain a portion of *IRF6*-negative popliteal pterygium cases.** *E.J. Leslie[1], S. Goudy[2], M. Cunningham[3], J.C. Murray[1].* 1) Department of Pediatrics, University of Iowa, Iowa City, IA; 2) Department of Otolaryngology, Vanderbilt University, Nashville, TN; 3) Department of Pediatrics, University of Washington, Seattle, WA.

Van der Woude syndrome (VWS) and popliteal pterygium syndrome (PPS) are two allelic, autosomal dominant cleft lip/palate disorders caused by heterozygous mutations in *IRF6*. However, mutations have not been detected in approximately 30% of VWS and 3% of PPS patients. There is substantial clinical overlap between PPS and the recessive pterygia syndrome Bartsocas-Papas syndrome (BPS), which has recently been determined to be caused by mutations in *RIPK4*. *Irf6*$^{-/-}$ and *Ripk4*$^{-/-}$ mice have nearly identical phenotypes and both genes are transcriptional targets of p63. Given these data, we hypothesized that mutations in *RIPK4* could explain a portion of PPS or VWS patients that have no detectable mutation in *IRF6*. We sequenced *RIPK4*in 27 VWS and 3 PPS patients without mutations in *IRF6*. We identified novel homozygous mutations in two PPS patients. The first, A448P, was present in a patient with bilateral cleft lip and palate, oral synechia, bilateral popliteal pterygia, and syndactyly. This patient, from consanguineous parents, also had a dorsal-ventral patterning defect of the hands and feet. The second mutation, R618H, was found in a patient with bilateral cleft lip and palate, lip pits, oral synechia, and popliteal pterygium from healthy, non-consanguineous parents. The mutation was carried by the mother, but not by the father. No deletion was detected in the patient or father by array CGH. SNP genotyping demonstrated maternal isodisomy of chromosome 21, where *RIPK4* is located. Our results show RIPK4 mutations may explain a significant portion of PPS cases that are *IRF6* mutation negative, demonstrate phenotypic overlap for mutations in the *RIPK4* gene, and have important implications for genetic counseling given the differing patterns of inheritance for PPS caused by *IRF6* as opposed to *RIPK4*. Finally, the results suggest a common biological pathway uniting *IRF6* and *RIPK4*. It remains possible that non-coding mutations in *RIPK4* or other members of this pathway could explain the remaining causes of VWS.

2763F

Sacsin-related ataxia caused by the novel missense mutation Arg272His in a patient from Southern-Italy. *F. Cavalcanti[1], A. Nicoletti[2], G. Annesi[1], P. Tarantino[1], M. Gagliardi[1,3], G. Mostile[2], V. Dibilio[2], A. Quattrone[4,5], A. Gambardella[1], M. Zappia[2].* 1) Inst. of Neurological Sciences, National Research Council, Mangone (CS), CS, Italy; 2) Department of Neurosciences, University of Catania, Catania, Italy; 3) University of Magna Graecia, Catanzaro, Italy; 4) Institute of Neurology, Department of Medical Sciences, University of Magna Graecia-Catanzaro, Italy; 5) Neuroimaging Research Unit, National Research Council, Catanzaro, Italy.

Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) is an early-onset cerebellar ataxia with spasticity, amyotrophy, nystagmus, dysarthria, and peripheral neuropathy. SACS is the only gene known to be associated with the ARSACS phenotype. The gene was initially reported to be encoded by a single gigantic exon. Recently eight additional exons were identified upstream of the giant exon. The SACS protein product, sacsin, is believed to integrate the ubiquitin-proteasome system and Hsp70 chaperone machimery. Recent studies indicates a role for sacsin in regulation of mitochondrial dynamics. To date, more than 70 different mutations, predominantly located in the giant exon, have been identified worldwide; of these only seven, exclusively located in the giant exon, were identified in Italian patients. The authors identified a novel homozygous variation c.815G>A, which results in the missense mutation p.Arg272His (R272H) in a patient from Southern-Italy. This mutation was present in heterozygosis in both unaffected parents as in one unaffected sibling and in several unaffected relatives. The phenotype of our patient closely resembled the classic phenotype. R272H missense mutation falls in the seventh coding exon of the SACS gene, hence not in the carboxyterminal giant coding exon which contains most reported sacsin mutations. R272H represents the first described Italian mutation located upstream of the giant exon of the SACS gene. The residue is completely conserved in evolution. The missense mutation R272H was not detected among 200 control chromosomes. Although it is also in a well-conserved region of the protein, no functional domain is defined for this region.

SCA36 molecular analysis in patients with spinocerebellar ataxia. *D. Di Bella, E. Sarto, C. Mariotti, C. Gellera, S. Magri, F. Taroni.* Genet Neurodeg & Metab Dis, IRCCS Istituto Neurologico C Besta, Milan, Italy.

Autosomal dominant spinocerebellar ataxias (SCA) are a heterogeneous group of neurological disorders characterized by cerebellar dysfunction mostly due to Purkinje cell degeneration. Recently, a novel form of spinocerebellar ataxia (SCA36) with motor neuron involvement was described in Japanese and Galician patients. It is caused by a GGCCTG repeat expansion in intron 1 of NOP56 gene. This gene encodes a component of the ribonucleoprotein complex and plays a role in transcription and splicing. We screened a large cohort of Italian unrelated patients with familiar (n=102) or sporadic (n=94) spinocerebellar ataxia for GGCCTG repeat expansion in NOP56 intron 1. All patients were negative for the common SCA1 and SCA2 mutations. The NOP56 repeat was analysed by fluorescent triplet repeat-primed PCR (TP-PCR) analysis, using three primers including one fluorescent-dye-conjugated forward primer, a first reverse primer consisting of 4 repeat units and a 5' anchor tail, and a second reverse anchor primer. NOP56 intron1 repeat expansion was detected in 4 probands from 4 different unrelated Italian families with dominant ataxia. No expansions were identified in sporadic patients. Normal alleles in the SCA population ranged from 6 to 14 repeats, with the 9-repeat allele being the most frequent. Clinically, mutated patients presented with late-onset (range 40–65 yrs), slow-progressing spinocerebellar ataxia characterized by pyramidal signs and eye movement abnormalities. Interestingly, all probands originated from a relatively small area in central Italy, suggesting a common ancestor and a founder effect for this mutation. In conclusion, SCA36 accounts for approximately 4% of Italian autosomal dominant SCA families negative for the common SCA mutations, a frequency lower than that (6.9%) observed in Galician patients but similar to that (3.6%) found in the Japanese population. Clinically, SCA36 is characterized by slow progressive gait ataxia with upper motor neuron involvement. Neuroimaging revealed prominent cerebellar atrophy affecting the vermis, with minor involvement of cerebellar hemispheres and brainstem [Supported in part by Telethon-Italia grant GGP09301].

2765T

Germline CAG repeat instability causes extreme CAG repeat expansion with infantile onset of spinocerebellar ataxia type 2 in offspring. *J. Ek[1], T. Vinther-Jensen[2,3], M. Dunoe[1], F. Skovby[1], L.E. Hjermind[2,3], J.E. Nielsen[2,3], T.T. Nielsen[2,3].* 1) Molecular Genetic Laboratory, Copenhagen University Hospital, Copenhagen, Denmark; 2) Memory Disorders Research Group, Neurogenetics Clinic, Department of Neurology, Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark; 3) Department of Cellular and Molecular Medicine, Section of Neurogenetics, The Panum Institute, University of Copenhagen, Denmark.

The spinocerebellar ataxias (SCA) are a genetically and clinically heterogeneous group of diseases, characterized by dominant inheritance, progressive cerebellar ataxia and diverse extracerebellar symptoms. Mutations in 26 different genes are known to cause autosomal dominant inherited SCA, and a subgroup of the ataxias is caused by unstable CAG repeat expansions in their respective genes leading to pathogenic expansions of polyglutamine stretches in the encoded proteins. They belong to the CAG repeat disorders, which share a tendency of anticipation, implying that the CAG repeat is unstable and tends to expand further in successive generations resulting in earlier onset and more severe symptoms. In general, unstable CAG repeats have an uninterrupted CAG repeat whereas stable CAG repeats are either short or interrupted by CAA codons, which - like CAG codons - code for glutamine. Here we report a family in which infantile-onset SCA2 was diagnosed in a girl several years post-mortem, after presentation of the disease in her father. The girl presented with an atypical clinical phenotype with delayed motor milestones and epilepsy. She had myoclonic jerks and athetoid movements, and the only features indicative of a cerebellar disorder were uncoordinated eye movements and subtle findings on an MRI scan. Molecular genetic analysis revealed that the girl had a CAG repeat length in *ATXN2* of at least 124 repeats. Her father had a 45 CAG repeat allele. Surprisingly, the expanded allele of the father was an interrupted CAG repeat sequence. Furthermore, analyses of single spermatozoa from the father showed a high frequency of paternal germ line instability in the SCA2 locus. In conclusion, this study shows a high degree of germline instability in the SCA2 locus in spite of a CAA interruption in the CAG repeat. Our observations question the general assumption that instability is primarily limited to pure CAG repeats. Finally, this study highlights the importance of considering rare genetic disorders during diagnosis of infants and children even without known neurodegenerative disorders in the family.

Genetic Aspects of Dravet Syndrome in Southern Italy. *M. Gagliardi[1,2], P. Tarantino[1], F. Cavalcanti[1], M. Sesta[5], P. Conti[5], D. Galeone[5], G. Tortorella[3], A. Labate[4], M. Caracciolo[1], T. Mirante[1], A. Bagala[1], A. Quattrone[4], A. Gambardella[1], G. Annesi[1].* 1) Institute of Neurological Sciences, National Research Council, Mangone, Cosenza, Italy; 2) University Magna Graecia, Catanzaro, Italy; 3) Departement of Neurosciences, Psychiatry and Anaesthesiology University of Messina, Messina, Italy; 4) Institute of Neurology, University Magna Graecia Catanzaro and Neuroimaging Research Unit, National Research Council, Germaneto, Italy; 5) Departement of Neurosciences, Psychiatry and Anaesthesiolog Department of Neurology, Pediatric Hospital, Bari, Italy.

Dravet syndrome (DS), or severe myoclonic epilepsy of infancy (SMEI) is a genetically determined encephalopathy mainly caused by de novo mutations in the SCN1A gene. A small percentage of female patients with a DS-like phenotype might carry in the gene encoding protocadherin-19 (PCDH19) who were negative for mutations in the SCN1A gene. The aim of this study was to investigate the frequency of SCN1A mutations in 70 SMEI patients with epileptic encephalophathy of infancy (EEI) from southern Italy and to investigate the frequency of PCDH19 mutations in female patients who resulted negative for SCN1A mutations. All patients had seizures onset before 12 months of age, mild to severe mental retardation with poor language development, with or without ataxia. Genomic DNA from the patients was analysed by direct sequencing of the SCN1A and PCDH19 genes on an ABI 3130XL Avant automated sequencer. The genomic anomalies of the SCN1A gene were screened using MLPA and confirmed by real-time PCR. We identified 13 different heterozygous mutations of SCN1A gene in 13/70 patients with SMEI (18,57%) (Lys1246fsX1268, Phe807Leu, Arg1636X, p.1502del, Glu1021X, IV242A-G, Arg1886Gly, Thr1289Ile, IVS7+4delA, 3840insT, Ser1505X, del. ex 1–25, Tyr1460X). Thirty-one/70 female with genetic test negative for SCN1A mutations were analyzed for the PCDH19 gene. This analysis revealed three different heterozygous novel mutations (9,67%) (Ile508ProfsX59, Arg550Pro, Ser856Cys). We found 13 patients carrying different SCN1A mutations, thus confirming the high genetic heterogeneity related to DS. The proportion of patients with SCN1A mutations in our population is 18,57%. Previous studies a higly variable rate of SCN1A mutations, ranging from 30% to 80%. These discrepancies may be due to the sizes of the series, the use of different clinical criteria, or the inclusion of broader epileptic phenotypes. Also the results of this study indicate that PCDH19 mutations are a relatively frequent cause of EEI in Southern Italy. This frequency (9,67%) is comparable to that reported in previous studies.

2767W

Vacuolar-type H+-ATPase V1A subunit is a molecular partner of Wolfram syndrome 1 (WFS1) protein, which regulates its stability and expression. *S. Gharanei[1], M. Zatyka[1], D. Astuti[1], J. Fenton[1], E. Rabai[2], A. Sik[3], Z. Nagy[2], T. Barrett[1].* 1) School of Clinical and Experimental Medicine, University of Birmingham, Birmingham, United Kingdom; 2) Department of Pharmacology, School of Clinical and Experimental Medicine, University of Birmingham, Birmingham, United Kingdom; 3) Department of Neurophysiology, School of Clinical and Experimental Medicine, University of Birmingham, Birmingham, United Kingdom.

Wolfram syndrome is an autosomal recessive disorder characterised by neurodegeneration and diabetes mellitus. The gene responsible for the syndrome (WFS1) encodes an endoplasmic reticulum (ER) resident transmembrane protein, that also localises to secretory granules in pancreatic beta cells. Although its precise functions are unknown, WFS1 protein deficiency affects the unfolded protein response, intracellular ion homeostasis, cell cycle progression, and granular acidification. In this study, immunofluorescent and electron-microscopy analyses confirmed that WFS1 also localizes to secretory granules in human neuroblastoma cells. We demonstrated a novel interaction between WFS1 and the V1A subunit of the vacuolar-type H+-ATPase (proton pump) by co-immunoprecipitation in HEK293 cells, and with endogenous protein in human neuroblastoma cells. We mapped the interaction to the WFS1-N terminal, but not the C-terminal domain. V1A subunit expression was reduced in WFS1 stably and transiently depleted human neuroblastoma cells and depleted NT2 cells. This reduced expression was not restored by adenoviral over-expression of BiP to correct the ER stress. Protein stability assays demonstrated that the V1A subunit was degraded more rapidly in WFS1 depleted neuroblastoma cells compared with wild type. We conclude that WFS1 has a specific interaction with the V1A subunit of H+-ATPase; this interaction may be important both for pump assembly in the ER; and for granular acidification.

Altered expression of carbonic anhydrase-related protein XI in neuronal cells expressing mutant ataxin-3. *M. Hsieh[1], W.H. Chang[1], C.F. Hsu[1], C.L. Kuo[2], I. Nishimori[3], T. Minakuchi[3], N. Nukina[4].* 1) Department of Life Science, Tunghai University, Taichung 407, Taiwan, Republic of China; 2) Department of Biomedical Science, Chung-Shan Medical University, Taichung 402, Taiwan, Republic of China; 3) Department of Gastroenterology and Hepatology, Kochi Medical School, Nankoku, Kochi 783-8505, Japan; 4) Laboratory for Structural Neuropathology, RIKEN Brain Science Institute, RIKEN, Wako-shi, Japan.

Spinocerebellar ataxia type 3/Machado-Joseph disease (SCA3/MJD) is a late-onset neurodegenerative disorder caused by the expansion of a polyglutamine tract within the gene product, ataxin-3. Microarray analysis revealed a dramatic differential expression of carbonic anhydrase-related protein XI (CA-RPXI/CA11) in the presence or absence of mutant ataxin-3. Therefore, we examined the expression and distribution of all three CA-RPs (CA8, 10 and 11) in human neuronal cells stably expressing mutant ataxin-3. The protein expression of CA8 and CA11 is significantly increased in human neuroblastoma cells harboring mutant ataxin-3, compared to cells containing normal ataxin-3. Semi-quantitative RT-PCR demonstrated that all three CA-RPs exhibited significantly higher transcript levels in neuronal cells expressing mutant ataxin-3. Interestingly, CA11 is distributed not only in the cytoplasm but also translocated within the nuclei of the stably transfected mutant cells, compared to the sole cytoplasmic distribution in cells containing normal ataxin-3. In addition, results from transient transfection assays in SK-N-SH and Neuro2a cells also confirmed the nuclear localization of CA11 in the presence of truncated ataxin-3. Most importantly, immunohistochemical staining of the MJD transgenic mice and postmortem MJD human brain also revealed that CA11 highly expresses in both cytoplasm and nuclei of the brain cells. Recruitment of CA11 into nuclear inclusions containing mutant ataxin-3 revealed a possible correlation between CA11 and disease progression. Although the exact function of CA-RPs is still undefined in the central nervous system, our findings suggest that CA-RPs, especially CA11, may play specific roles in the pathogenesis of Machado-Joseph disease.

2769F

Alterations in RNA Splicing Underlie Development of Ataxia in SCA1 Mice. *M.A.C. Ingram[1], P. Bergmann[2], H. Kang[3], H.Y. Zoghbi[3,4], H.T. Orr[1].* 1) Institute for Translational Neuroscience, University of Minnesota, Minneapolis, MN; 2) Foresight Logic, Inc. St. Paul, MN; 3) Department of Molecular and Human Genetics, and; 4) Department of Pediatrics, and the Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX.

SCA1, a late onset neurodegenerative disease, is caused by a CAG polyglutamine expansion in the Ataxin-1 (ATXN1) protein. Evidence indicates that ATXN1 normally interacts with regulators of transcription and RNA splicing. Previous work showed that domains other than the polyQ tract, notably a serine residue at site 776, mediate mutant ATXN1 toxicity. A wild type ATXN1[30Q] with phosphomimetic Asp at 776 triggers disease initiation and development of ataxia as seen in mice expressing mutant ATXN1[82Q]. Towards identification of cellular pathways critical for development of SCA1 we performed RNA-seq to examine gene expression and RNA splicing patterns in ATXN1[82Q], ATXN1[30Q]-D776, and wild type FVB cerebella at 12 weeks of age. Gene expression analysis indicated 2500–4000 of significant gene changes (q-value <0.05) occur in ATXN1[82Q] and ATXN1[30Q]-D776 in reference to FVB, 2240 significant gene changes when compared to each other. However, while 5000–6000 significant splicing changes are identified in comparison to FVB, only one splicing change is identified between ATXN1[82Q] and ATXN1[30Q]-D776. Additionally, previous biochemical evidence showed ATXN1[30Q]-D776 increases interaction with the splicing factor RBM17 to the level of ATXN1[82Q]. We propose, ATXN1[82Q] and ATXN1[30Q]-D776 interact with RBM17 to the same extent, resulting in a splicing pattern that leads to the development of ataxia in SCA1.

Non-progressive congenital ataxias (NPCA) with or without intellectual disability (ID) are clinically and genetically heterogeneous conditions. As a consequence, the identification of the genes responsible for these phenotypes remained limited. Using high resolution microarrays, we identified intragenic copy number variations in the CG-1 domain of the Calmodulin-binding Transcription Activator 1 (CAMTA1) gene, segregating with autosomal dominant ID with NPCA in two unrelated families, and a de novo deletion located in the same domain in a child presenting with NPCA. In the ID patients, the deletion led to a frameshift, producing a truncated protein, while the deletion was in frame in the patient with isolated childhood ataxia. Brain MRI of the patients revealed a pattern of progressive atrophy of cerebellum medium lobes and superior vermis, parietal lobes and hippocampi. Although DNA sequencing of the CG-1 domain in 197 patients with sporadic or familial non-syndromic intellectual deficiency, extended to full DNA sequencing in 50 patients with ID and 47 additional patients with childhood ataxia, identified no pathogenic mutation, there is considerable evidence that CAMTA1 rearrangements are being disease causing. Indeed, CAMTA1 is a brain specific calcium responsive transcription factor expressed in the brain and cerebellum during development and later implicated in memory processes; intragenic rearrangements are concentrated in a highly conserved functional domain with transcription regulation ability and nuclear trafficking functions; CAMTA1 transcriptional studies have shown upregulation of genes already implicated in intellectual disability and autism spectrum disorder. Altogether, we show that CAMTA1 loss-of-function is responsible for NPCA with or without ID.

Analysis of Human Mitochondrial Aminoacyl-tRNA Synthetase complexes in patients with MARS2 mutations. *I. Thiffault, F. Sasarman, T. Nishimura, E.A. Shoubridge.* Lab Neurogenetics, 676, McGill Montreal Neurological Hosp, Montreal, PQ, Canada.

In the past few years mutations in at least 10 of the human mitochondrial aminoacyl-tRNA synthetases (ARSs) have been reported. Mutations in these ARSs are associated with a strikingly broad range of gene-specific clinical phenotypes, the molecular basis for which remains unknown. Many of the cytoplasmic ARSs are organized into a supramolecular complex that is coordinated by two proteins not directly involved in translation; but little is known about the organization of the mitochondrial ARSs. Here, we show that at least some of the mitochondrial ARSs exist in high molecular weight complexes of ~250 kDa and 1 MDa in human fibroblast cell lines. We previously reported that mutations in MARS2 (methionyl-tRNA synthetase 2) result in decreased mitochondrial translation in ARSAL subjects (SPAX3 OMIM ID: 611390). We show here that complexes containing MARS2 do not co-sediment with mitochondrial ribosomes, and that MARS2 mutations result in an altered association of MARS2 with the mitochondrial ARSs complexes. This study suggests that like some of the cytoplasmic ARSs, mitochondrial ARSs occur in high-molecular-weight complexes, and that these associations might be important for the regulation of mitochondrial translation.

Autosomal recessive inheritance, severe to profound sensorineural hearing loss and partial agenesis of the corpus callosum are hallmarks of the clinically well-established Chudley-McCullough syndrome (CMS). Although not always reported in the literature, frontal polymicrogyria and gray matter heterotopia are uniformly present, while cerebellar dysplasia, ventriculomegaly and arachnoid cysts are nearly invariant. Despite these striking brain malformations, individuals with CMS do not in general present with significant neurodevelopmental abnormalities, except for hearing loss. Using a combined homozygosity mapping and whole exome sequencing approach in affected individuals from eight families (including the first-reported individuals), we identified four molecular variations (two single base deletions, a nonsense mutation and a canonical splice site mutation) in the G protein signaling modulator 2 gene, *GPSM2*, that underlie CMS. Mutations in *GPSM2* have been previously identified in people with profound, congenital, non-syndromic hearing loss. Subsequent brain imaging of these individuals revealed frontal polymicrogyria, abnormal corpus callosum and gray matter heterotopia, consistent with a CMS diagnosis; however, no ventriculomegaly was observed. The gene product, GPSM2, is required for orienting the mitotic spindle during cell division in multiple tissues, suggesting that the sensorineural hearing loss and characteristic brain malformations of CMS are due to defects in asymmetric cell divisions during development. Ongoing work includes *GPSM2* sequencing and detailed characterization of the neuroimaging findings in additional patients with CMS, as well as protein quantification and localization in patient fibroblasts.

Thrombospondin genes are required for development of normal cochlear function and maintenance. *M. Mustapha, D. Mendus, V. Sundaresan.* Otolaryngology-HNS, Stanford, Stanford, CA.

Recent studies reveal important roles for cell-adhesion molecules such as thrombospondins (TSPs) in promoting synapse formation during brain development and in repairing synaptic connection after stroke. For our efforts to identify genes involved in cochlear synapse formation and functional maturation, we hypothesize that cell adhesion proteins that are also upregulated during cochlear synaptogenesis and/or adulthood are important for these processes. In this study, we examine whether TSPs are involved in synapse formation and maintenance in the cochlea using recombinant mouse models of these genes. Our preliminary data using microarray and qPCR analysis on TSP genes 1–4 from whole cochlea revealed significant increase in TSP2–4 expression during a critical window of postnatal cochlear development with TSP1 expression picking up later in adulthood. Our auditory brain stem response (ABR) test on TSP1 and TSP2 mutants reveal elevated threshold in TSP2 mutants but not in TSP1 mutants at an early age. These data suggest a role for TSP2 in synapse functional maturation that is important for the onset of hearing. However, one-year old TSP1 mutant mice show an increase in ABR threshold at higher frequencies and decreased amplitude of response compared to wild type controls, suggesting a role for TSP1 in synapse maintenance. Our physiology data is in agreement with the roles predicated for these genes based on our expression studies. Counting of afferent and efferent synapse numbers in TSP2 and TSP1/2 mutants versus wild type mice does not show significant differences between these groups. Our next step would be to examine whether the synapses in the TSP mutant mice are functional using electrophysiology. To test the role for these genes in the recovery of the cochlea from noise injury, we exposed TSP2 and TSP1/2 mutant mice to a noise insult and measured ABR threshold after a recovery period. Data from these experiments showed that these mice were unable to recover from the noise injury compared to wild type controls indicating a deficit in repair mechanisms in these mice. Our results, taken together, indicate that TSPs 1 and 2 are both involved in different aspects of cochlear functional maturation, repair and maintenance and these genes are now candidates for screening in human patients with congenital and age-related hearing impairment.

2774T

Lack of the VPS35 Asp620Asn mutation in southern Italian patients with familial Parkinson's disease. *G. Annesi[1], M. Gagliardi[1, 2], P. Tarantino[1], F. Cavalcanti[1], T. Mirante[1], M. Caracciolo[1], A. Bagalà[1], A. Gambardella[1], A. Quattrone[3].* 1) Inst of Neurological Sciences, National Research Council, Mangone, CS, Italy; 2) University Magna Graecia,(CZ), Italy; 3) Institute of Neurology, University Magna Graecia, Catanzaro, Italy Neuroimaging Research Unit, Institute of Neurological Sciences, National Research Council, Germaneto (CZ).

Parkinson's disease (PD) is a common neurodegenerative disorder, affecting 2% of those over the age of 75 years. Although generally considered a sporadic disease, Mendelians forms of the disease are described (SNCA and LRRK2 for causing autosomal dominant PD and 3 genes causing autosomal recessive, juvenile PINK1, Parkin, DJ1). Recently using an exome sequencing based approach, 2 indipendent groups have identified a missense mutation in vacuolar protein sorting 35 homolog (VPS35 c.1858G>A; p.Asp620Asn) as the probable cause of late onset PD in a number of kindreds. To estimate the frequency of the Asp620Asn mutation in VPS35 in familial PD, we screened for this variant in a southern Italy PD cohort. Our population included 114 patients with familial PD, having at least 1 relative among their first degree, second degree, in third degree family members with a formal diagnosis of PD (major PD genes had been analyzed and positive cases (9 LRRK2) were not excluded. Genomic DNA was extracted from peripheral blood by standard method. The genotype was determined by genomic DNA amplification of a 229 bps fragment and sequencing was done on an ABI PRISM 3130 XL-AVANT Genetic Analyzer. This variant was not detected in any of the 150 analyzed familial PD cases, thus indicating that this mutation is rare among familial PD cases in the southern Italy. It would seem reasonable to conclude, therefore, that the recently published VPS35 mutation, is not a common cause of familial PD, in our population.

Avogadro University and Maggiore della Carita` Hospital, Novara, Italy.

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease mainly involving cortical and spinal motor neurons. Recently, molecular studies identified different mutations in ubiquilin-2 (UBQLN2) gene as causative of a familial form of X-linked ALS, 90% penetrant in females. Aim of our study was to analyze the UBQLN2 gene in a large cohort of familial and sporadic ALS patients, with or without frontotemporal dementia (FTD), and in patients with FTD only. We analyzed the UBQLN2 gene in 819 sporadic ALS cases (SALS), 226 familial ALS cases (FALS), 53 ALS-FTD patients, and 63 patients with a clinical record of FTD. Molecular analysis of the entire coding sequence was carried out in all FALS and ALS-FTD patients, while SALS and FTD patients were analyzed specifically for the genomic region coding for the PXX repeat tract. Healthy controls were 845 anonymous blood donors and were screened for the PXX repeat region only. We found five different variants in the UBQLN2 gene in five unrelated ALS patients. Three of them, including two novel ones, involved a proline residue in the PXX repeat region, and were found in three FALS cases. The other two were novel variants, identified in one FALS and one SALS patient. None of these variants were present in controls, while one control carried a new heterozygous variant. Our data support the role of UBQLN2 gene in the pathogenesis of FALS, being conversely a rare genetic cause in SALS even when complicated by FTD.

2776W

Genetics of Primary Microcephaly in Indian families. *A. Kumar[1], V. Bhat[1], G. Mohan[1], S.C. Girimaji[2].* 1) Molecular Reproduction, Development & Genetics, Indian Institute of Science, Bangalore, Karnataka, India; 2) Department of Child and Adolescent Psychiatry, National Institute of Mental Health and Neuro Sciences, Bangalore, Karnataka, India.

The development of the human brain, specially the cerebral cortex, is an intricate and complex process that involves generation of neuronal progenitors in periventricular zones, neuronal cell proliferation through symmetric and asymmetric cell divisions, and finally the migration of post-mitotic neurons to their final destinations. An understanding of the molecular mechanisms that guide these intricate and complex processes is facilitated by discovery of genes for Mendelian forms of cortical (brain) malformations, such as primary microcephaly (MCPH), which is characterized by a smaller than normal brain and mental retardation. Occasionally, MCPH patients also have other brain abnormalities such as pachygyria, polymicrogyria, simplified gyral pattern etc. We have been working on the genetics of MCPH for some time, which led to the discovery of a novel seventh gene for MCPH, STIL, in 2009. The other six MCPH genes are MCPH1, WDR62, CDK5RAP2, CEP152, ASPM and CENPJ. In May 2012, the eighth gene, CEP135, has been identified. We have continued to ascertain MCPH families and collected so far a total of 56 families. Interestingly, Sanger sequencing has shown mutations only in WDR62, ASPM and STIL genes in our families. The ASPM gene is found to be the most commonly mutated gene followed by STIL in Indian population. There are still many families in our dataset which do not harbor mutations in any of the eight known genes, suggesting the discovery of additional novel genes in future. We are currently using homozygosity mapping and whole-exome sequencing to identify the novel gene(s). A comprehensive analysis of our genetic analysis of Indian MCPH families will be presented and discussed.

2777T

ZIC1 AND ZIC4 DELETION AT 3q24 IS NOT CONSTANTLY ASSOCIATED TO DANDY-WALKER MALFORMATION (DWM). *S. Loddo[1], V. Parisi[1], L. Bernardini[1], A. Ferraris[1], A. Capalbo[1], L. Travaglini[2], G. Zanni[2], M.L. Di Sabato[3], S. Tumini[4], A. Novelli[1], V. Sabolic[5], E. Bertini[2], B. Dallapiccola[2], E.M. Valente[1].* 1) Cytogenetics Lab, CSS-Mendel Inst, Rome, Italy; 2) Bambino Gesù Children Hospital Rome-Italy; 3) Sapienza University of Rome Department of Child Neurology and Psychiatry Rome-Italy; 4) University of Chieti Department of Pediatrics Chieti-Italy; 5) St. Cyril and Methodius University Skopje-Macedonia.

The Dandy-Walker malformation (DWM) is one of the most frequent form of congenital cerebellar hypoplasia and is characterized by upward rotation of the cerebellar vermis and cystic dilatation of the fourth ventricle. It 's a heterogeneous condition, which may be associated with different cytogenetic abnormalities and malformation syndromes. The first genes implicated in its pathogenesis, ZIC1 and ZIC4, are to date deleted in a limited number of patients. We have recently identified by SNP-array 3 new cases of interstitial deletion 3q. Two patients, recruited within the project focused on birth defects of the cerebellum and brainstem (CBCD Project) with a diagnosis of classical DWM, show, respectively, the del3q23q26.1 and the del3q22.3q25.32 (~ 20Mb). In contrast, in the third patient a del3q23q24 (about 4.9 Mb) was detected, but MRI ruled out with certainty the DWM. The minimal deleted region shared by the three patients included the genes ZIC1 and ZIC4, while the two patients with DWM shared two additional regions: one proximal (0.5MB) and one distal (10 Mb) to candidate genes. The clinical phenotype of the patients was variable, with psychomotor retardation, facial dysmorphism and anomalies of extremities. This study confirms the usefulness of the search for chromosomal microrearrangements, especially in cases of syndromic DWM. The absence of cerebellar defects in the third patient suggests that hemizygosity of genes ZIC1 and ZIC4 is not sufficient for the onset of DWM and that there are other factors that may modulate phenotypic expression.

2778F

A frameshift mutation in the gene encoding folliculin-interacting protein 2 (FNIP2) associated with hypomyelination and tremors in the Weimaraner. *P. Patel[1], T. Pemberton[2], S. Choi[1], J. Mayer[3], F-Y. Li[1], N. Safra[4], D. Bannasch[4], K. Sullivan[5], B. Breuhaus[6], I. Duncan[3].* 1) Inst Gen Med, Univ Southern California, Los Angeles, CA; 2) Department of Biology, Stanford University, Stanford, CA 94305; 3) Department of Medical Sciences, School of Veterinary Medicine, University of Wisconsin - Madison, Madison, WI 53711; 4) Department of Population Health and Reproduction, School of Veterinary Medicine, University of California Davis, Davis, CA 95616; 5) Department of Medicine, University of Washington, Seattle, WA 981956; 6) College of Veterinary Science, North Carolina State University, Raleigh, NC 27606.

Proper myelination requires intricate interactions between glial cells and neurons. An important approach to unraveling the factors involved in these interactions and their respective roles in the process is the study of naturally occurring mutants in whom the process has gone awry. An autosomal recessive disorder characterized by hypomyelination and tremors was first described in 1987 in the Weimaraner breed. It is a widespread disorder with affected animals reported from throughout the US and also from Europe. At 10–12 days of age, a tremor involving the trunk and all four limbs is noted that worsens on ambulation. The degree of tremor may vary between siblings in a single litter; likewise the recovery is seen more quickly in less affected dogs, usually by 3–4 months while some severely affected dogs may retain a mild tremor for life. On necropsy, a unique zone of non- or hypomyelination is seen around the periphery of the spinal cord, especially of the ventral and lateral columns. In the brain, there is a more subtle but generalized decrease in myelin compared to controls. The cause of this myelin defect was heretofore unknown but it had been speculated to involve the early differentiation of oligodendrocytes, their migration throughout developing white matter or their early death. Towards positional cloning of the genetic defect leading to this disorder, we genotyped 48 animals : 35 from 3 unrelated pedigrees - 9 affected animals, 18 known carriers, and 8 phenotypically normal ("unaffected") animals who may or may not be carriers - and 13 unrelated animals ("singletons") - five affected animals, one known carrier, and seven phenotypically normal animals. Genome-wide association mapping localized the gene to a 5 Mb interval on chromosome 15. Homozygosity mapping further narrowed the interval to a 3.57 Mb region. Seventeen genes were examined for mutations and a deletion of a single A residue was identified in the gene encoding folliculin-interacting protein 2 (FNIP2). All 14 affected dogs were homozygous for the mutation, 8 obligate and 15 predicted carriers were heterozygous for the mutation, and 4 unaffected animals from the two pedigrees as well as 7/8 unrelated "control" dogs did not bear the mutation. One unrelated "control" dog was found to be heterozygous for the mutation. Further work is underway to determine the expression pattern of the gene and it relationship to the disease phenotype.

Familial cortical myoclonus with a mutation in NOL3. *J. F. Russell[1], J. L. Steckley[2], G. Coppola[3], A. F. G. Hahn[2], M. A. Howard[1], Z. Kornberg[1], A. Huang[3], S. M. Mirsattari[2], B. Merriman[3], E. Klein[3], M. Choi[4], H.-Y. Lee[1], A. Kirk[5], C. Nelson-Williams[4], G. Gibson[6], S. C. Baraban[1], R. P. Lifton[4], D. H. Geschwind[3], Y.-H. Fu[1], L. J. Ptacek[1].* 1) UCSF, San Francisco, CA; 2) London Health Sciences Center and University of Western Ontario, London, Ontario, Canada; 3) UCLA, Los Angeles, CA; 4) Yale, New Haven, CT; 5) Royal University Hospital, Saskatoon, SK, Canada; 6) University of British Columbia, Vancouver, BC, Canada.

Objective: Myoclonus is characterized by sudden, brief involuntary movements and its presence is debilitating. We identified a family suffering from adult-onset, cortical myoclonus without associated seizures. We performed clinical, electrophysiological, and genetic studies to define this phenotype. **Methods**: A large, four-generation family with history of myoclonus underwent careful questioning, examination, and electrophysiological testing. Thirty-five family members donated blood samples for genetic analysis, which included SNP mapping, microsatellite linkage, targeted massively parallel sequencing, and Sanger sequencing. In silico and in vitro experiments were performed to investigate functional significance of the mutation. **Results**: We identified 11 members of a Canadian Mennonite family suffering from adult-onset, slowly progressive, disabling, multifocal myoclonus. Somatosensory evoked potentials indicated a cortical origin of the myoclonus. There were no associated seizures. Some severely affected individuals developed signs of progressive cerebellar ataxia of variable severity late in the course of their illness. The phenotype was inherited in an autosomal dominant fashion. We demonstrated linkage to chromosome 16q21-22.1. We then sequenced all coding sequence in the critical region, identifying only a single co-segregating, novel, nonsynonymous mutation, which resides in the gene *NOL3*. Furthermore, this mutation was found to alter post-translational modification of NOL3 protein in vitro. **Interpretation**: We propose that Familial Cortical Myoclonus (FCM) is a novel movement disorder caused by mutation in *NOL3*. Further investigation of the role of *NOL3* in neuronal physiology may shed light on neuronal membrane hyperexcitability and pathophysiology of myoclonus and related disorders.

Mutations in PRRT2 result in familial infantile convulsions with marked variability in clinical expression and SUDEP. *P. Tarantino[1], G. Palamara[2], A. Labate[2,3], M. Gagliardi[1], L. Mumoli[2], E. Ferlazzo[2], F. Cavalcanti[1], U. Aguglia[2], G. Incorpora[4], A. Gambardella[1,2], G. Annesi[1].* 1) Institute of Neurological Sciences, National Research Council, Mangone, cosenza, Italy; 2) Institute of Neurology University Magna Græcia, Catanzaro, Italy; 3) Neuroimaging Research Unit, National Research Council, Germaneto, Catanzaro, Italy; 4) Unit of Paediatrics, University Hospital "Arezzo-Trifiletti", Ragusa, Italy.

Benign familial infantile seizures (BFIS) is an autosomal dominant disorder characterized by afebrile seizures that begin at age 3–12 months with a favorable outcome. A recent discovery has identified heterozygous mutations in PRRT2 on chromosome 16p, which encodes proline-rich transmembrane protein 2, in most families affected by BFIS. PRRT2 is also the major causative gene for familial paroxysmal kinesigenic dystonia (PKD), a rare disorder characterized by episodic attacks of choreoathetosis or dystonia. These results have corroborated the existence of familial infantile convulsions with paroxysmal choreoathetosis (ICCA, OMIM 602066) that shares overlapping clinical features with BFIS and PKD. In this study, we performed mutation screening of PRRT2 in our collected families with BFIS, ICCA or PKD phenotypes.The whole genomic region of PRRT2 was sequenced in seven Italian families, of which six with BFIS or ICCA phenotype, and one family with PKD phenotype. The previously reported mutation, c.649dupC (p.R217Pfs*7), was found in two families with BFIS phenotype, and in one family with ICCA. In an additional BFIS family, a missense mutation, c.718C/T (R240X), was identified. All these mutations co-segregated with the disease in these families and were not observed in 300 control subjects of matched ancestry. In the ICCA family, two affected members displayed a more complex phenotype with episodic ataxia, mental retardation and migraine attacks. In one family that also carried the c.649dupC mutation, one affected member died at age of 13 years of SUDEP. This study confirms the major role of PPRT2 mutations in families with BFIS phenotypes. Our findings also enlarge the clinical spectrum related to PRRT2 mutations and underscore the complexity of the phenotypic consequences of mutations in this gene.

2781F

Molecular analysis of *NIPA1* gene mutations in patients with spastic paraplegia. *F. Taroni[1], S. Caldarazzo[1], E. Sarto[1], M. Plumari[1], V. Martinelli[2], D. Pareyson[3], S. Baratta[1], D. Di Bella[1].* 1) Unit of Genetics of Neurodegenerative and Metabolic Diseases, Fondazione IRCCS Istituto Neurologico Carlo Besta, Milan, Italy; 2) Institute of Experimental Neurology, Fondazione Centro San Raffaele del Monte Tabor, Milan, Italy; 3) Unit of Neurology 8, Fondazione IRCCS Istituto Neurologico Carlo Besta, Milan, Italy.

Hereditary spastic paraplegias (HSP) are a clinically and genetically heterogeneous group of neurodegenerative disorders. Pure and complicated forms of the disease have been described. About half of HSP cases result from autosomal dominant mutations in *spastin* (SPG4), *atlastin-1* (SPG3A), or *REEP1* (SPG31) genes. Mutations in the *NIPA1* gene have been reported to be a rare cause of autosomal dominant (AD) pure (10 families) or complicated (2 families) HSP phenotypes (SPG6). Recent data indicate that the HSP-associated proteins NIPA1 and atlastin-1 are members of a common biochemical pathway that supports axonal maintenance. In 9 of the 12 SPG6 families reported to date, two recurrent mutations at a mutational hot-spot in exon 3 have been reported (c.316G>A or c.316G>C), both resulting in the same amino acid change (p.G106R). We screened a large cohort of Italian patients with spastic paraplegia for *NIPA1*mutations. *NIPA1* was analysed by high-resolution melting analysis (HRM) and/or direct sequencing in 240 unrelated HSP index cases, including 140 AD and 100 sporadic cases, negative for SPG4 mutations. The previously reported missense mutation c.316G>A/p.G106R was detected in a 2-generation family affected with a pure form of AD-HSP. Notably, the mutation was also found in 1 out of 100 sporadic patients. In both cases, the disease is characerised by adult-onset pure spastic paraplegia. In conclusion, in our population of patients with HSP, we detected*NIPA1* mutations in only 2 patients, both found to carry one of the two recurrent mutations in exon 3. Our data strongly support the hypothesis that *NIPA1* nucleotide c.316G is a hot-spot for recurrent mutations in SPG6. Furthermore, they indicate that *NIPA1* mutations are a rare cause of HSP, with a frequency <1%. As in the majority of SPG6 families reported to date, the clinical phenotype is characterised by pure slowly-progressive spastic paraplegia with adult onset.

2782W

Incomplete nonsense-mediated decay facilitates detection of a multi-exonic deletion mutation in SCGE. *J. Xiao, K. Marshall, M. LeDoux.* Department of Neurology, University of Tennessee Health Science Center, Memphis, Tennessee, 38163, USA.

Mutations in the maternally imprinted gene encoding ε-sarcoglycan (SGCE) represent the major cause of the myoclonus-dystonia syndrome (DYT11), an autosomal dominant disorder of reduced penetrance. Virtually all affected individuals have myoclonus, which is concentrated in the upper extremities, neck and trunk with infrequent involvement of the legs. Over half of patients have dystonia, usually affecting the neck or arms. Disease onset is usually in childhood or early adolescence but may appear in adults. Many affected individuals reported a dramatic reduction in myoclonus after consumption of alcohol. Psychiatric disorders including depression and anxiety can be prominent co-morbidities. Given that SGCE is maternally imprinted, penetrance is significantly higher when the mutant allele is inherited from the father. DYT11 may be caused by a variety of mutations in SGCE (nonsense, missense, insertions and deletions). Of the more than 70 SGCE mutations reported in the literature, 18 were large deletions disrupting at least one exon. Therefore, testing for exonic deletions should be considered in individuals with a classic phenotype in whom Sanger sequencing is unrevealing. However, standard methodologies for detection of exonic deletion mutations are expensive, labor intensive and can be produce false negatives. Herein, we report the use of cDNA derived from leukocyte RNA to identify a deletion mutation (Exons 4 and 5) of SGCE in a family with DYT11. Residual RNA from incomplete nonsense-mediated decay permitted reverse transcription to cDNA. Breakpoints of the 8,939 bp heterozygous deletion were then defined with long-range PCR and Sanger sequencing. Use of cDNA generated by reverse transcription of leukocyte RNA can reduce the costs associated with diagnostic genetic testing and can facilitate detection of deletion mutations.

2783T

Isoform-selective MeCP2-e1 deficient mice recapitulate the neurologic defecits of Rett syndrome. *D.H. Yasui[1], K.W. Dunaway[1,2], M.S. Golub[3], N.C. Schanen[4], J.M. LaSalle[5].* 1) Med Microbiology & Immunology, Univ California Davis, Med Sch, Davis, CA; 2) Genome Center, UC Davis, Davis, CA 95616; 3) Department of Environmental Toxicology, UC Davis, Davis, CA; 4) Nemours Biomedical Research Institute, Al Du Pont Hospital, Wilmington, DE; 5) UC Davis, MIND Institute, Sacramento, CA 95817.

Rett syndrome (RTT) is an X-linked dominant neurodevelopmental disorder characterized by the decline of language, social and motor skills between 6–18 months of age caused by mutations in MECP2 encoding methyl CpG binding protein 2 (MeCP2). Two protein isoforms, MeCP2-e1 and MeCP2-e2 are produced by alternative translation start sites encoded in alternatively spliced exon 1 and exon 2, respectively. As MECP2 mutations in RTT were primarily found in exons 3 and 4, previous mouse models of Rett syndrome focused on deletion of exons 3 and/or 4 that recapitulated some neurologic phenotypes of RTT including decreased survival. In contrast, Mecp2 exon 2 knockout mice exhibited normal neurologic function. Recent screening of RTT patients have revealed mutations in exon 1 but not exon 2, suggesting that MeCP2-e1 may be the critical RTT deficient isoform. To determine the clinical relevance of the less well characterized MeCP2-e1, we generated mice with isoform-selective ablation of MeCP2-e1 production through a single point mutation in the exon 1 translational start site. Western blotting and immuno-fluorescent (IF) analyses confirm the absence of MeCP2-e1 and reveal elevated levels of MeCP2-e2 despite an overall 50% reduction in total MeCP2 in Mecp2-e1 mutant brain. Mecp2-e1 mutant mice were born healthy and at the expected frequency suggesting that MeCP2-e1 is not essential for embryonic development. However, adult Mecp2-e1 mutant mice exhibited RTT like features including altered anxiety in the elevated plus maze, reduced sociability in the three chamber paradigm and gait abnormalities in tread-scan analysis in addition to reduced lifespan. Distinct sub-nuclear distribution of MeCP2-e1 versus MeCP2-e2 was observed by IF in brain, as MeCP2-e1 primarily localized to the nucleoplasm while MeCP2-e2 localized to heterochromatin domains in neurons. Consistent with immuno-localization studies, mass spectroscopic analysis of factors co-purifying with MeCP2-e1 revealed association with SFPQ splicing and Matrin3 nuclear matrix proteins in neuronal cells. These associations were confirmed by subsequent reciprocal co-immunoprecipitation and Western blot analysis along with MeCP2-e1 co-localization with SFPQ and Matrin3 in brain by IF. Collectively, these studies suggest unique biologic functions for Mecp2-e1 and MeCP2-e2 and demonstrate the relevance of MeCP-e1 to the RTT phenotype.

2784F

ARHGEF26/SGEF controls arteriosclerosis, retinal fovea, immunity and neurodevelopment. *P. Bitoun[1], E. Pipiras[2,3], B. Benzacken[2,3], A. Delahaye[2,3].* 1) Gen Med, CHU Paris-Nord, Hopital Jean Verdier, BONDY, France; 2) Histo-Embryo-Cytogenetics, CHU Paris-Nord,Hopital Jean Verdier, BONDY, France; 3) Inserm U676, Hopital Robert Debre, Paris.

Purpose: To identify the cause of a novel congenital syndrome with macular dystrophy, absence of fovea identified in a consanguineous family 6 yo girl with congenital nystagmus and low vision after informed consent. Methods: The family had complete ophthalmologic, neurologic examination, ERG, VEP, OCT, angiograms, brain MRI, genetic tests, array CGH and lipid profiles. Parents had vascular Doppler US. Antibody In situ hybridisation was performed in fetal Mouse eye and human fetal brain. Results: Proband had congenital nystagmus and prenatal corpus callosum agenesis. Vision was 20/200,no photophobia, night blindness or dyschromatopsia. Fundus showed macular atrophy with normal vessels w/o pigmentary deposits and small optic papilla. Angiography confirmed symetric macular atrophy with normal auto-fluorescence. Flash ERG, OP and dark adaptation were normal, absent pattern VEP response confirmed macular bundle defect. OCT showed macular atrophy with absent foveal pit, thin retina(102 µm OD and 92 OS) and interrupted photoreceptor layer. MRI also showed hippocampi hypoplasia. ABCA4 mutation testing was negative as well as screening of 18 known ARRP genes. Parents have normal visual acuity, ERG, VEP and OCT and retinal angiographs and brain MRI. Array CGH showed a 114kb homozygous 3q23 deletion upstream of 6th intron of the SGEF gene in proband and 2 sibs. Her sister was found to have a similar absence of foveal development on OCT as well as low vision and macular dystrophy, her brother had bilateral subclinical decreased foveal function on multifocal ERG with normal vision. Both girls have repeated infections: EBV hepatitis,dental abcesses... Asymptomatic parents harbor the same heterozygous deletion.SGEF antibody in situ hybridisation localised to E13.5 fetal mouse retina and hybridised to cortical region in 13.5WG human fetal brain. SGEF controls leucocyte trans-endothelial migration,1st phase of atherosclerosis. Mother with hypercholesterolemia of 212mg/dl and hyper-triglyceridemia had normal cervical arteries doppler ultrasound imaging without any sign of atherosclerosis at age 42 years. Conclusions: Present data suggests ARHGEF26/SGEF gene controls arteriosclerosis, macular cone development, immune function and axon midline crossing with apparently recessive inheritance. This deletion possibly has a protective effect against the development of arteriosclerosis blocking the 1st phase of atherosclerotic plaque formation.

Homozygosity mapping and exome sequencing in a Saudi-Arabian family with unspecified juvenile neurodegeneration. *E. Frackelton[1], P.M.A. Sleiman[1,2,3], L. Tien[1], S. Panossian[1], K. Xu[1], B. Tweddale[1], N. Abdel-Magid[1], C. Kim[1], Y. Housawi[4], H. Hakonarson[1,2,3].* 1) Ctr Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA; 2) Division of Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA; 3) Dept Pediatrics, Perelman School of Medicine, Univ of Pennsylvania, Philadelphia PA; 4) King Fahad Specialist Hospital-Dammam, Saudi Arabia.

A Saudi Arabian family of two healthy parents and three children all of whom were affected with an unspecified neurodegenerative condition was referred to us for sequencing after screening negative for a panel of potential candidate genes. All five family members were initially genotyped on a high density array (Illumina HH610) and homozygosity mapping carried out in plink. The three affected children shared 7 regions of homozygosity on chromosomes 1, 5, 6, 7, 11, 14 and 22. Two of the three affected sibs also had their exomes sequenced on an Illumina HiSeq 2000 to an mean depth of ~ 100x after exome capture and enrichment with the Agilent SureSlect 50Mb kit. Variants annotation and filtering was performed in ANNOVAR. The filtration gates included retaining variants that mapped to the regions of homozygosity, those that were shared between the affected sibs and were homozygous, and excluding variants that were represented in the publically available datasets. We identified a homozygous stop gain mutation Y790X in exon 17 of the PLA2G6 gene which was subsequently confirmed by sanger sequencing and shown to segregate with the phenotype in the family. PLA2G6 is a member of the phospholipase A2 (PLA2s) family which catalyze the hydrolysis of the sn-2 acyl-ester bonds in phospholipids, leading to the release of arachidonic acid and other fatty acids. Mutations of the PLA2G6 gene have previously been associated with Infantile Neuroaxonal dystrophy, Karak syndrome, Neurodegeneration with brain iron accumulation 2B, and with adult onset Parkinsonism (PD14). The Y790X mutation has been reported in classic infantile neuroaxonal dystrophy (INAD) Morgan et al. (2006). INAD is a rare, rapidly progressing disorder that usually begins between ages six months and three years with developmental regression, hypotonia, progressive psychomotor delay, and progressive spastic tetraparesis. Diagnosis of INAD is based on the identification of dystrophic axons on electron microscopic examination of nerve ultrastructure in a tissue biopsy. As axonal spheroids accumulate with age and may not be evident in all tissues, individuals with INAD may require multiple biopsies over time before axonal spheroids are identified. This study demonstrated the utility of exome sequencing in rapidly identifying the cause of conditions that can be difficult to classify clinically and thus sequence the appropriate candidate genes.

Neuropathology in POL-III related disorders: Myelin loss in 4H syndrome. *A. Vanderver[1], J. Schmidt[1], G. Carosso[1], D. Tonduti[2], G. Bernard[3], J. Lai[4], C. Rossi[5], M. Quezado[4], K. Wong[6], R. Schiffman[7].* 1) Center for Genetic Medicine, Children's National Medical Center, Washington DC; 2) Mondino National Institute of Neurology Foundation, University of Pavia, Pavia, Italy; 3) Montreal Children's Hospital, Montreal, Canada; 4) Department of Pathology, National Institutes of Health, Bethesda, MD; 5) Department of Pathology, Children's National Medical Center, Washington DC; 6) Department of Pathology, USAF, San Antonio, TX; 7) Institute of Metabolic Disease, Baylor Research Institute, Dallas, TX.

INTRODUCTION: Mutations in POLR3A and POLR3B, encoding the largest (catalytic core) subunits of human RNA Polymerase III (Pol III), were identified as causative of 4H Syndrome (hypomyelination with hypogonadotropic hypogonadism and hypodontia) and related hypomyelinating phenotypes, now referred to as Pol III related leukodystrophy. While mechanisms of pathogenesis remain to be elucidated, here we provide a first neuropathological description of brain tissue. METHODS: Brain tissue from a POLIII mutation-proven patient and age-matched controls were obtained according to an IRB approved protocol. Paraffin-embedded tissue was examined using standard immunohistochemistry approaches. Neuroimaging and clinical history on the 4H patient was obtained from the Myelin Disorders Bioregistry Project. RESULTS: Cerebral MRI findings show diffuse white matter signal abnormality consistent with a diagnosis of hypomyelination. Histologic analysis reveals variable myelin rarefaction and loss, reduction in axons, and reduction of oligodendroglia underlying most gyri, although myelin and oligodendroglia are better preserved surrounding small blood vessels. Astrogliosis is seen mostly in perivascular white matter, and rare CD68+ macrophages are seen juxtaposed to oligodendroglia. CONCLUSIONS: The present 4H patient's brain pathology reveals marked loss of oligodendroglia with severe loss of myelin. Astrogliosis, microgliosis, and macrophagic phagocytosis are mild compared to that found in other myelin compromising disorders. The observed CD68+ macrophagic reaction involving viable oligodendrocytes, as well as the observed reduction in IFN- β, are suggestive of an immunologic process. This affirms a primary myelin disorder in Pol III related leukodystrophy.

2787F

Identification of Homozygous WFS1 Mutations (p.Asp211Asn, p.Gln486*) Causing Severe Wolfram Syndrome and First Report of Male Fertility. *A. Haghighi[1], A. Haghighi[2], A. Setoodeh[3], N. Saleh-Gohari[4], D. Astuti[5], T.G. Barrett[5].* 1) The Hospital for Sick Children, University of Toronto, Toronto, Canada; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 3) Growth & Development Research Centre, University of Tehran/ Medical Sciences, Tehran, Iran; 4) Genetic Department, Kerman University of Medical Sciences, Kerman, Iran; 5) Diabetes Department, Institute of Child Health, Diabetes Department, University of Birmingham, Birmingham, UK.

Wolfram syndrome (WS) is a neurodegenerative genetic condition characterized by childhood-onset diabetes mellitus and optic atrophy. Other features of this syndrome include diabetes insipidus, sensorineural hearing loss, cerebellar ataxia, psychiatric illness, neuropathic bladder and hypergonadotrophic hypogonadism. There is no treatment available for WS. The mortality is high and only about 40% of patients survive beyond the age of 35 years. WFS1 is the main gene identified as the cause of Wolfram syndrome and encodes Wolframin, a transmembrane protein that is involved in the regulation the unfolded protein response. There is as yet no clear genotype-phenotype correlation in WS. We undertook a clinical and molecular study of severe WS in two consanguineous families from Iran. The clinical features of these two families were compared with each other and with the previously published cases of WS in order to correlate genotypes with phenotypic features. Direct sequencing of all the exons and intron-exon boundaries of WFS1 was undertaken in the index cases on an ABI 3730 DNA sequencer. We screened for mutations in first degree relatives of both families. The clinical diagnosis of Wolfram syndrome was confirmed by the presence of diabetes mellitus and optic atrophy in the index cases, who in addition had severe neurodegenerative complications. Despite the neurodegenerative complications, two affected males in the first family had fathered unaffected children. We identified two homozygous mutations: family 1: c.631G>A (p.Asp211Asn) in exon 5, and family 2: c.1456C>T (p.Gln486*) in exon 8. Heterozygous carriers were unaffected. Genotpying of a panel of markers in both father/child pairs confirmed a high probablility of paternity. This is the first report of male Wolfram patients who have successfully fathered children. Surprisingly, our patients also had, almost all the complications associated with Wolfram syndrome. Male hypogonadism has been a well reported feature of Wolfram syndrome, in contrast to affected females, for whom there are several reports of successful pregnancies. Data from mouse knockout models show reduced spermatogenesis and reduced fertility in males compared with females. Our findings have implications for genetic counselling for future families affected by these mutations, and raise the hope that some affected males may be able to father children.

Whole Exome Sequencing in Children with Unclassified, Sporadic, Early-Onset Epileptic Encephalopathies. *K.R. Veeramah[1], L. Johnstone[1], D. Wolf[1], R. Sprissler[1], T.M. Karafet[1], D. Talwar[2,3,4], R.P. Erickson[2,5], M.F. Hammer[1].* 1) Arizona Research Laboratories, University of Arizona, Tucson, AZ; 2) Department of Pediatrics, Arizona Health Science Center, Tucson, AZ; 3) Department of Neurology, Arizona Health Science Center, Tucson, AZ; 4) Center for Neurosciences, Tucson, AZ; 5) Department of Molecular and Cellular Biology, University of Arizona, Tucson, AZ.

Early-onset Epileptic Encephalopathies (EEEs) are brain disorders characterized by seizures that usually begin within the first year of life, followed by severe cognitive and behavioral impairment and deterioration. Many children are refractory to treatment and early death is not unusual. Some children with EEEs are classified within particular syndromes described by the International League Against Epilepsy (ILAE) with an emphasis on clinical utility, but because EEEs are highly phenotypically heterogeneous, many children remain unclassified. While a handful of genes such as *SCN1A* and *ARX* have been associated with EEEs, the underlying genetic etiologies in most children are unknown—a result that makes sense given the large number of genes that potentially could disrupt brain development. In fact, the large `genic target' has been presented as an evolutionary explanation for the relatively high incidence of severe neurological disorders in the general population. Thus, it is reasonable to hypothesize that many sporadic cases of EEE result from a spontaneous new (*de novo*) mutation in a diverse set of genes. Therefore whole genome and exome approaches are promising avenues for identifying pathogenic EEE mutations and associated genes. We recently identified a causal mutation in a young girl with EEE in a gene not previously associated with any seizure disorder, *SCN8A*, using a whole genome sequencing family approach. Building on this work we perform high-coverage (50–80X) whole exome sequencing in 15 children with undiagnosed sporadic EEEs as well as their unaffected parents. We then identify potentially pathogenic *de novo* (as well as recessive) mutations using our custom bioinformatics pipeline. In addition, we develop a systematic classification system that attempts to capitalize on detailed clinical and laboratory parameters scored in patients with EEEs over their lifespan. This system is based on various clustering, machine learning, and data-dimensionality-reducing methods that can quantify the phenotypic similarities and differences among EEE cases. Application of this classification system enables us to quantify the amount of phenotypic variation and subclass structure among our cohort. We then quantitatively explore the hypothesis that children with more similar phenotypic characteristics share causal EEE genes that are found in more similar developmental or metabolic pathways.

Determining the genetic architecture of Joubert syndrome. *D. O'Day[1,3], B.J. O'Roak[2], I.G. Phelps[1,3], J.C. Dempsey[1,3], I. Glass[1,3], H.C. Mefford[1,3], J. Shendure[2], D. Doherty[1,3].* 1) Department of Pediatrics, University of Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Seattle Children's Hospital, Seattle, WA.

Joubert Syndrome (JS) is a recessive ciliopathy characterized by cognitive impairment, hypotonia, abnormal respiratory pattern, abnormal eye movements and a distinctive hindbrain malformation, “the molar tooth sign.” Subsets of patients also develop retinal dystrophy, cystic kidney disease and liver fibrosis. JS is genetically heterogeneous, with causal mutations identified in 18 genes; however, no cohort of patients has been comprehensively sequenced. To determine the prevalence of each genetic cause, we used an efficient and inexpensive molecular inversion probe capture technique and next generation sequencing to sequence 16 of the known JS genes in 308 subjects representing 258 families. For captured basepairs, the sensitivity and positive predictive value were 99% and 98% respectively, compared to previously generated bidirectional Sanger sequencing data. Using the same data, we were also able to identify the common deletion of *NPHP1* as well as other small copy number variants. We identified causal mutations in 55% of the families, with 5 genes (*CC2D2A*, *TMEM67*, *CEP290*, *AHI1*and *TMEM216*) accounting for 35% of patients. The majority of mutations in *CEP290* were truncating, while other genes harbored mainly missense mutations, potentially indicating that each gene requires a different severity of loss of function to generate the JS phenotype. Missense mutations highlight domains of the proteins important for function. Previous genotype-phenotype correlations were borne out in the more comprehensive data; mutations in *CEP290* and *AHI1* were associated with retinal disease, while mutations in *TMEM67* were associated with liver fibrosis. Families in which the known genetic causes have been excluded provide a resource for identifying the remaining undiscovered causes of JS.

Genetics of Joubert Syndrome in the French Candian population. *M. Srour[1], J. Schwartzentruber[2], F.F. Hamdan[1], L.H. Ospina[3], L. Patry[1], D. Labuda[4], C. Massicotte[4], S. Dobrzeniecka[1], J.M. Capo-Chichi[1], S. Papillon-Cavanagh[4], M.E. Samuels[4], K.M. Boycott[5], M.I. Shevell[6], R. Laframboise[7], V. Désilets[4], D. Amron[1], E. Andermann[8], G. Sebire[9], B. Maranda[10], G.A. Rouleau[11], J. Majewski[8], J.L. Michaud[1] FORGE Canada Consortium.* 1) Centre of Excellence in Neurosciences of Université de Montréal and Sainte-Justine Hospital Research Center, Montréal, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montréal, Canada; 3) Department of Ophthalmology, Sainte-Justine Hospital Research Center, Montréal, Canada; 4) Sainte-Justine Hospital Research Center, Montréal, Canada; 5) Children's Hospital of Eastern Ontario Research Institute, Ottawa, Canada; 6) Division of Pediatric Neurology, Montreal Children's Hospital-McGill University Health Center, Montreal, Canada; 7) Department of Medical Genetics, Centre Hospitalier Universitaire Laval, Québec, Canada; 8) Department of Human Genetics, McGill University, Montréal, Canada; 9) Division of Neurology, Centre Hospitalier Universitaire de Sherbrooke, Sherbrooke, Canada; 10) Division of genetics, Centre Hospitalier Universitaire de Sherbrooke, Sherbrooke, Canada; 11) Centre of Excellence in Neurosciences of Université de Montréal, CHUM Research Center and Department of Medicine.

Joubert syndrome (JBTS) is an autosomal recessive disorder characterized by a mid-hindbrain malformation, developmental delay, ocular-motor apraxia and breathing abnormalities. To date, causal mutations have been identified in at least 16 genes, all of which are involved in non-motile cilia function. Though JBTS was first described in French Canadian (FC) siblings over 40 years ago, the causal gene has not yet been identified in this family, nor in most FC cases. This study aims to study the genetic basis of JBTS in the FC population. We have ascertained 28 FC individuals with JBTS from 22 families. We noted a regional clustering of 16 cases in the Lower St-Lawrence region, suggesting the possibility of a regional founder effect. SNP genotyping excluded the presence of a common homozygous mutation. We performed exome sequencing in 15 subjects. 9 individuals from 7 families (including the original JBTS family) carried rare compound heterozygous mutations in *C5ORF42*. Two missense variants (p.R1336W, p.A1564T) and a splicing mutation (c.7400+1G>A) were found in multiple subjects, whereas three other mutations, all truncating (p.P2136fs, p.R1602X, p.R2493X), were identified in single individuals. Genotyping 477 FC controls did not identify any of the 6 mutations. Exome sequencing also identified compound heterozygous mutations (p.D1556V, p.E1126K) in *CC2D2A*, a gene already known to be responsible for JBTS in 2 unrelated individuals. We performed whole-exome sequencing in 10 other FC individuals with JBTS from our cohort originating from other regions of Quebec. We identified 1 individual with mutations in *C5ORF42* (c.7400+1G>A and p.K2753fs), and 5 other individuals with mutations in *CC2D2A* (p.D1556V, p.E1126K, p.Y1568H, p.N1520S, p.1150_1151del). Screening for the recurrent p.D1556V and p.E1126K mutations in the remainder of the cohort identified 2 additional individuals with mutations in *CC2D2A*. Mutations in *C5ORF42* and CC2D2A are responsible for a large fraction of JBTS cases in the FC population, and there is presence of a complex founder effect. In the as yet unexplained individuals with JBTS, exome sequencing identified interesting variants in several candidate genes which we are in the process of validating.

2791W

Mechanisms underlying non-recurrent microdeletions causing neurofibromatosis type-1 (NF1). *J. Vogt[1], K. Bengesser[1], K. Claes[2], K. Wimmer[3], L. Messiaen[4], L. Kluwe[5], V.-F. Mautner[5], H. Kehrer-Sawatzki[1].* 1) Institute of Human Genetics, University of Ulm, Ulm, Germany; 2) Center for Medical Genetics, Gent University Hospital, 9000 Gent, Belgium; 3) Division of Human Genetics, Medical University Innsbruck, Innsbruck, Austria; 4) Medical Genomics Laboratory, Department of Genetics, University of Alabama at Birmingham, Birmingham, USA; 5) Department of Neurology, University Hospital Hamburg Eppendorf, Hamburg, Germany.

NF1 microdeletions encompassing the *NF1* gene region at 17q11.2 are present in 5–10% of patients with NF1. Whereas the mechanisms underlying recurrent *NF1* microdeletions have been investigated in greater detail, those underlying non-recurrent (atypical) *NF1* microdeletions are not well delineated. *NF1* microdeletions with non-recurrent breakpoints are heterogeneous in terms of their size, breakpoint position and number of deleted genes. Furthermore, extended sequence homology is not observed in the respective breakpoint regions. In this study, we investigated 12 atypical *NF1* deletions using high resolution custom made array CGH. We could assign the breakpoints to regions of 1.2–6 kb. In seven of these 12 atypical *NF1* deletions, we identified the breakpoints at the level of a few basepairs. Five of these seven deletions were mediated by non-homologous end joining (NHEJ) as concluded by the absence of or only minor (1–2bp) homology at the breakpoints. Two of these seven *NF1* deletions exhibited microhomologies of 24 and 33 bp at the breakpoint sites indicative of microhomology-mediated end joining (MMEJ) as underlying mechanism. We conclude that NHEJ or MMEJ are the prevailing mechanisms underlying non-recurrent *NF1* deletions that lack any complexity at the deletion breakpoint sites. However, four of the 12 *NF1* deletions investigated by us seem to represent complex rearrangements most likely caused by replication associated erroneous template switches. For one of these complex rearrangements we already have a breakpoint-spanning PCR fragment, which harbours multiple breakpoints, indicative of several rearrangements at the boundaries of the*NF1* microdeletion. This is most likely the result of replication-based errors. In order to characterize the complex rearrangements at the breakpoint sites of all four complex atypical *NF1*microdeletions, we want to perform a targeted capture and next generation sequencing (TCNGS) approach. Chimeric sequence reads will indicate breakpoint-spanning sequences and thus reveal the structure and orientation of sequences at the breakpoints. In summary, our study indicates for the first time, that also non-recurrent *NF1* microdeletions are mediated by a variety of mutagenic processes including mechanisms of double strand repair such as NHEJ and replication based mechanisms such as Fork stalling and template switches (FoSTeS).

The DYRK1A gene is a rare cause of Angelman-like syndrome with severe microcephaly and epilepsy. *JB. Courcet[1], E. Lopez[1], J. Thevenon[1,2], N. Gigot[1,2,3], L. Jego[1], C. Ragon[1,4], A. Masurel-Paulet[2], P. Callier[1,4], N. Marle[1,4], AL. Mosca-Boidron[1,4], F. Huet[1,2], C. Philippe[5], L. Lambert[6], P. Malzac[7], L. Faivre[1,2], A. Moncla[8], C. Thauvin-Robinet[1,2].* 1) Equipe émergente GAD (Génétique des Anomalies du développement), IFR Santé STIC, Université de Bourgogne, Dijon, France; 2) Centre de Génétique et Centre de Référence Anomalies de Développement et Syndromes Malformatifs de l'interrégion Grand-Est, Hôpital d'Enfants, CHU, Dijon, France; 3) Laboratoire de Génétique Moléculaire, Plateau Technique de Biologie, CHU Dijon, France; 4) Laboratoire de Cytogénétique, Plateau Technique de Biologie, CHU de Dijon, Dijon, France; 5) Laboratoire de Génétique et EA 4368, CHU de Nancy, Nancy, France; 6) Service de médecine infantile III et de génétique clinique, Laboratoire de génétique, Unité de génétique du service néonatale, Maternité régionale de Nancy, Nancy, France; 7) Département de Génétique Médicale, Laboratoire de génétique moléculaire, CHU de Marseille, Hôpital de la Timone, Marseille, France; 8) Département de Génétique Médicale, Unité de Génétique Clinique, CHU de Marseille, Hôpital de la Timone, Marseille, France.

Angelman syndrome (AS) belongs to the group of syndromic mental retardation (MR). Methylation anomalies at the SNRPN locus and UBE3A mutations are found in 85% of cases. Patients presenting with features compatible with AS (severe MR, microcephaly, epilepsy, absent speech and ataxia) but no AS genetic causes define the group of « Angelman-like » syndrome (AS-like). Recently, we identified a 69 kb deletion in 21q22 including the 5' part of the DYRK1A gene in a 3 year-old girl, presenting with intra uterine growth retardation (IUGR), facial dysmorphism, congenital microcephaly, seizures, ataxic gait, absent speech, and developmental delay. Four patients with intragenic DYRK1A rearrangements or overlapping 21q22 microdeletions including only DYRK1A have previously been reported with a similar phenotype. Thus, we hypothesized that DYRK1A mutations could be responsible for AS-like. The DYRK1A gene was studied in a cohort of 105 patients previously screened by methylation analysis on SNRPN locus +/− UBE3A sequencing and the following criteria: MR and at least two symptoms from AS spectrum (microcephaly < -2.5 SD, ataxic gait, seizures and/or speech delay). We identified a de novo frameshift DYRK1A mutation (c.290_291delCT; p.Ser97Valfs*) leading to DYRK1A haploinsufficiency in a 14 year-old patient with IUGR, persistent growth retardation, feeding difficulties during childhood, delayed language, MR, primary and secondary severe microcephaly (OFC= -6 SD) and epileptic seizures. Therefore, we aimed to delineate from this study and previously reported patients the criteria for sequencing the DYRK1A gene. When microcephaly, epilepsy and language delay/absent speech are considered as mandatory features, a DYRK1A mutation is found in 1/43 patients (2.3%). DYRK1A is believed to have an important role in controlling brain growth through neuronal proliferation and neurogenesis has been shown to be affected in MR disorders with primary microcephaly. DYRK1A protein is expressed in a gene dosage dependent manner so that, DYRK1A haploinsufficiency induce a reduced brain size in animal models. Numerous evidences support also the hypothesis that DYRK1A is implicated in neurodevelopmental alterations underlying the cognitive deficits of Down syndrome. Altogether, we show that DYRK1A is a rare cause of AS-like and the DYRK1A analysis could be discussed when patients present with MR, severe microcephaly, epilepsy and language delay/absent speech.

Exome Sequencing Reveals Cause of Hypomyelinating Leukodystrophy. *D.L. Dinwiddie[1], N.A. Miller[1], C.J. Saunders[1], S.E. Soden[1], G.M. Hobson[2], S.F. Kingsmore[1].* 1) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, MO; 2) Alfred I. duPont Hospital for Children, Nemours Biomedical Research, Wilmington, DE.

Here we present a case in which exome sequencing rapidly produced a molecular diagnosis for a patient with hypomyelinating leukodystrophy for whom years of costly conventional testing had not identified a molecular diagnosis. The patient had severe developmental delay, ataxia, nystagmus, external opthalmoplegia, hypometric saccades, and high myopia. Magnetic resonance imaging of the brain demonstrated severe failure of myelination of the corona radiate and centrum semi ovale. Through exome sequencing, two novel heterozygous missense variants were identified in the POLR3A gene (c.1160C>G; p.Ala387Gly and c.3781G>A; p.Glu1261Lys). We propose the use of exome sequencing for the diagnosis of genetically heterogeneous conditions such as hypomyelinating leukodystrophy as a cost-effective primary diagnostic tool.

2794W

Intractable epilepsy and tau protein pathology in a child with a defect in the synaptic vesicle recycling pathway. *D.A. Dyment[1], A. Smith[2], P. Humphreys[3], J. Woulfe[4], The. Forge Canada Consortium[5], D.E. Bulman[2], J. Schwartzentruber[6], J. Majewski[6], J. Michaud[7], K.M. Boycott[1].* 1) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, Canada; 2) Ottawa Hospital Research Institute; 3) Division of Neurology, Children's Hospital of Eastern Ontario, Ottawa, Canada; 4) Department of Pathology and Laboratory Medicine, The Ottawa General Hospital, Ottawa, Canada; 5) Forge Steering Committee is listed in Acknowledgements; 6) McGill University and Genome Quebec Innovation Centre; 7) Department of Pathology and Laboratory Medicine, Childrens Hospital of Eastern Ontario.

Individuals with Alzheimer disease have a well-recognized increased incidence of epilepsy though the exact mechanism is unclear. Here, we present a 6-year-old child of a consanguineous marriage with an intractable seizure disorder. The child's severe seizure disorder began at 9 days of life and was often continuous and refractory to treatment. An exhaustive neurological, metabolic and genetic workup was negative. At the time of his passing, he required G-tube feeding, he was cortically blind, had little motor skills and had never developed the ability to communicate verbally. Pathology of his brain showed generalized atrophy and severe loss of white matter, with moderate loss of neurons in the substantia nigra and tau protein positive neurofibrillary degeneration in most of the remaining neurons. Exome sequencing identified nine novel variants, seven of which were within regions of homozygosity as defined by a SNP microarray. Only one of these variants was a truncating mutation and expressed in the central nervous system. The gene identified was Synaptojanin1 and the observed C>T transition changes a p.R97X. A western blot of brain tissue of the patient showed no detectable synaptojanin protein present. Mouse knock-out models of synaptojanin1 from the literature result in mice that are ataxic, have convulsions and eventually die early in life. The gene product functions at the axon terminal to uncoat clathrin from the recycled synaptic vesicle. The child's homozygous defect at synaptojanin1 is likely responsible for his refractory seizure disorder; moreover, the homozygous mutation suggests that the unusual pathological finding of tau bodies and neurofibrillary tangles in a pediatric patient are related to an inherent defect at the synapse.

2795T

Novel *CDKL5* splicing variant in a boy with early-onset seizures. *R. Polli[1], G. Ho[2], E. Leonardi[1], E. Bettella[1], E. Fontana[3], B. Dalla Bernardina[3], J. Christodoulou[2], A. Murgia[1].* 1) Deptartment of Pediatrics, University of Padua, Padua, Italy; 2) NSW Centre for Rett Syndrome Research, The Children's Hospital at Westmead, Sydney, Australia; 3) Child Neuropsychiatry, University Hospital of Verona, Verona, Italy.

Genetic variants of the X-linked cyclin-dependent kinase-like 5 gene (*CDKL5*; OMIM 300203) cause a condition characterized by severe developmental delay, with a seizure onset in most before the age of three months. The CDKL5 disorder, previously considered a Rett syndrome variant, is now believed to be an independent clinical entity associated with early-onset epileptic encephalopathy. Mutations of the *CDKL5* gene have been mainly reported in females, while a few male subjects have been described with concomitant chromosomal alterations or carrying missense variants. In this study we report the case of a 2 year old boy with a very severe developmental disorder with early-onset drug-resistant seizures, hypotonia, and microcephaly. Folowing a metabolic work-up which showed no abnormalities, high resolution karyotype, and *MECP2* and *CDKL5* genetic testing was performed by dHPLC analysis and direct sequencing, followed by quantitative real-time PCR. A pathogenic mutation was found in the donor splice site of *CDKL5* intron 10, c.825+1G>T (NM_003159.2). The variant, not present in Rett syndrome specific databases, and not previously reported in literature, was found to be de novo. To establish the effect on splicing and to try and define the pathogenic relevance of this alteration, a study was conducted using a minigene system with a modified pBudCE 4.1 vector (Life Technologies, Carlsbad, CA) and transfection in COS-7 cells. The minigene experiments revealed that the mutation only partially affects the splicing of exon 10, allowing a proportion of the wild type transcript to be synthesized. This “leaky” mutation explains how an otherwise potentially severe pathogenic *CDKL5* mutation can be compatible with survival in a chromosomally normal male subject beyond the age of one year.

2796F

The molecular role of GTF2IRD1, a protein implicated in the neurodevelopmental features of Williams-Beuren syndrome. *P. Carmona-Mora[1], J. Widagdo[1], K.M. Taylor[1], R. Tsz-Wai Pang[1], P.W. Gunning[2], E.C. Hardeman[1], S.J. Palmer[1].* 1) School of Medical Sciences, Neuromuscular and Regenerative Medicine Unit, University of New South Wales, Sydney, Australia; 2) School of Medical Sciences, Oncology Research Unit, University of New South Wales, Sydney, Australia.

Williams-Beuren syndrome (WBS) is an autosomal dominant disorder caused by a hemizygous microdeletion within chromosome 7q11.23. Many of the physical abnormalities can be attributed to haploinsufficiency of elastin but the remaining unattributed features include a characteristic set of craniofacial abnormalities and a very distinctive neurocognitive profile involving visuospatial problems, reduced social anxiety and high incidence of psychopathologies including ADHD and phobias. Analysis of patients with atypical deletion breakpoints have shown that two related genes, *GTF2I* and *GTF2IRD1* encoding transcriptional regulator proteins, are responsible for the craniofacial and neurological defects but the molecular and cellular mechanism underpinning their role in the disease remains unclear. Mice with targeted null mutations of *Gtf2ird1* recapitulate some of the defects of WBS including a facial soft tissue abnormality and behavioural defects. We aim to reveal the normal function of the GTF2IRD1 protein using these mice as a model system, in combination with biochemical analyses to study molecular interactions. We have used a yeast two-hybrid screening system as an unbiased way to identify the protein binding partners of GTF2IRD1 and the pathways it integrates with. Secondly, we have conducted microarray studies using corpus striatum tissue from *Gtf2ird1* knockout mice in order to identify the transcriptional changes arising in this part of the brain, which shows high-level *Gtf2ird1* expression and is relevant to the potential cause of ADHD. Our yeast two-hybrid work has identified a panel of novel interacting partners including DNA binding proteins, chromatin modifying enzymes and proteins involved in post-translational modifications such as SUMO ligases and ubiquitination components. Our analysis of transcript profile in the striatum of knockout mice has revealed significant changes in genes involved in neuronal development and a cluster of immediate-early response genes that are known to correlate with heightened levels of motor activity. Together, these data suggest GTF2IRD1 acts as a nuclear adaptor protein that bridges connections between specific transcription factors and components of the chromatin modification machinery in order to regulate gene expression. Secondly, GTF2IRD1 levels and activity appear to be tightly controlled by post-translational mechanisms, which may be a characteristic feature of dosage sensitive genes causative of WBS.

2797W

Contribution of *POLR3A* and *POLR3B* recessive mutations to hypomyelinating leucodystrophy. *H. Daoud[1], M. Tétreault[2], K. Choquet[2], W. Gibson[3], M. Synofzik[4], B. Brais[2], A. Vanderver[5], G. Bernard[6].* 1) Centre of Excellence in Neuroscience of Université de Montréal, CHUM Research Center and the Department of Medicine, Montreal, H2L 2W5, Quebec, Canada; 2) Neurogenetics of Motion Laboratory, Montreal Neurological Institute, McGill University, Montreal, Quebec H3A 2B4, Canada; 3) Child and Family Research Institute, Department of Medical Genetics, University of British Columbia, Canada; 4) Centre for Neurology and Hertie-Institute for Clinical Brain Research, University of Tübingen, Tübingen, Germany; 5) Department of Neurology, Children's National Medical Center, Washington D.C., 20010, USA; 6) Departments of pediatrics, Neurology and Neurosurgery, Division of Pediatric Neurology, Montreal Children's Hospital, McGill University Heath Center, Montreal, Quebec, H3H 1P3, Canada.

Aims and Background: Leukodystrophies are a heterogeneous group of inherited neurodegenerative disorders characterized by abnormal central nervous system white matter. We recently showed that mutations in *POLR3A* and *POLR3B* genes, encoding the two largest subunits of RNA polymerase III (Pol III), are a major cause of three clinically overlapping hypomyelinating leukodystrophy phenotypes. Our aim was to investigate the presence and frequency of *POLR3A* and *POLR3B* mutations in patients with genetically unexplained hypomyelinating leukodystrophies. **Methods:** The entire coding region and the flanking exon/intron boundaries of *POLR3A* and *POLR3B* genes were amplified and sequenced in 12 patients with hypomyelinating leucodystrophies. **Results:** We identified six patients with recessive mutations in *POLR3A* and *POLR3B* genes. Three patients carry five novel mutations in *POLR3A*, among who two were compound heterozygotes and one homozygote. The other three patients have compound heterozygous mutations in *POLR3B*, including a common missense shared by these three patients and two novel mutations. **Conclusions:** To date, our group has described 27 mutations in *POLR3A* and *POLR3B*. Altogether, our results further support that *POLR3A*and *POLR3B* mutations are a major cause of hypomyelinating leukodystrophy and suggest that *POLR3A* mutations are more frequent.

2798T

Identification of disease causing mutations in the serine/threonine kinase VRK1 gene in two siblings with primary microcephaly, neuropathy and spinal muscular atrophy. *C. Gonzaga-Jauregui[1], W. Wiszniewski[1], J. Reid[2], D. Muzny[2], R.A. Gibbs[1,2], J.R. Lupski[1,3,4], Baylor-Hopkins Center for Mendelian Genomics.* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 4) Texas Children's Hospital, Houston, TX.

Targeted genomic capture and next-generation sequencing technologies have enabled the high-throughput sequencing of exomes to discover pathogenic variants in patients with rare or uncharacterized genetic diseases and the identification of new genes involved in disease. We have identified through genomic next-generation sequencing the genetic cause of the disease in two affected sisters that present with primary microcephaly, motor delay and infantile polyneuropathy for which the molecular diagnosis was not known and extensive clinical testing had been performed previously without concluding a specific etiologic diagnosis. We used targeted exome sequencing at 139 average depth of coverage in the youngest proband combined with whole genome sequencing using massively parallel sequencing by oligo ligation/detection technology, SOLiD, at ~30x average depth of coverage for the older sister in order to identify the most probable disease causing variants in these affected sisters. We identified more than 20,000 coding variants in each of the affecteds, with half of them being potential deleterious nonsynonymous or frameshifting variants; 3,000 of these were shared between both probands. Given the recurrent phenotype in this family, we hypothesized a recessive mode of inheritance and therefore examined the variant calls in this family for homozygous or compound heterozygous alleles amongst the affected sisters. We identified novel compound heterozygous missense deleterious mutations in the vaccine related kinase 1 gene, VRK1. VRK1 is a serine/threonine protein kinase involved in cell cycle progression and cell division; it has been observed to directly interact and phosphorylate p53, ATF2 and c-Jun, among other transcription factors important for cell proliferation. Mutations in VRK1 were recently reported to be responsible for Pontocerebellar hypoplasia type 1 (PCH1) in one consanguinous family. PCH1 is characterized by progressive microcephaly with central and peripheral nervous system involvement and motor dysfunction that resembles spinal muscular atrophy type 1, which can be misdiagnosed as axonal neuropathy. We demonstrate the utility of next-generation genomic sequencing approaches to answer a 10 year quest for an answer in a family with an undiagnosed rare phenotype and for which the findings can have tremendous clinical impact for the family including the enabling of prenatal diagnosis.

2799F

Molecular screening of patients with CMT2 disease. *G. Bergamin[1], C. Briani[2], E. Pegoraro[2], A. Martinuzzi[3], E. Battiston[1], F. Boaretto[1], M.L. Mostacciuolo[1].* 1) Departement of Biology, University of Padava, Padova, Padova, Italy; 2) Departement of Neurosciences, University of Padova; 3) E. Medea Scientific Institute, Conegliano Research Centre, Conegliano, Italy.

Charcot-Marie-Tooth disease type 2 (CMT2) comprises a group of clinically heterogeneous inherited axonal neuropathies. CMT2 is also genetically heterogeneous, but among the 13 genes associated to this phenotype, only 3 are found more frequently mutated in patients: MFN2, NEFL, and MPZ. In addition, mutations in CX32 can be found in CMT2 patients, especially in females with intermediate CMT phenotype. The aim of this study was to investigate the mutational spectrum of CMT2 disease in a cohort of 44 Italian patients, both familiar (23 cases) and isolated (21 cases). Direct sequencing was performed to detect mutations in the coding and splicing site-flanking regions of the MFN2, NEFL, MPZ and CX32 genes on genomic DNA from 44 unrelated CMT2 patients. In addition, rearrangements in PMP22 gene, that represent the most frequent cause of CMT1, were evaluated. In 14 of 44 index cases (about 32% of the cohort) we identified 15 mutations including 12 MFN2 (27,2%), 2 MPZ (4.5%) mutations and 1 PMP22 duplication (2,3%). In the MFN2 gene we found 9 missense (2 never reported before), 2 novel single amino acid deletions and 1 splice-site mutation. It is noteworthy that 1 patient affected by a severe axonal CMT resulted a compound heterozygote for 2 MFN2 mutations. The percentage of MFN2 mutations in CMT2 patients we found is in agreement with previous reports (16–33%), thus confirming that mutations in this gene are the primary cause of autosomal dominant CMT2. However we found that severe CMT2 phenotypes can be associated to recessive MFN2 mutations. The number of families with homozygous or compound heterozygous mutations in MFN2 described is increasing, so it is possible that recessive MFN2 mutations could be more frequent than expected. For this reason we propose that sequencing of MFN2 should be considered in the presence of severe CMT2 phenotype and also in the case of recessively inherited CMT2 disease. Interestingly we identified also a duplication in the PMP22 gene, thus suggesting that this gene, which is responsible for the majority of demyelinating CMT cases, can also cause axonal disease. For this reason we suggest to consider the analysis of PMP22 duplication in CMT2 patients, especially when the analysis of the other frequently-mutated genes is negative. In conclusion our data expanded the knowledge about the mutation frequencies of CMT2 associated genes and could contribute to the development of a diagnostic flow chart for CMT2 diseases.

2800W

Novel autosomal recessive syndrome characterized by manganese deficiency, cerebellar atrophy, skeletal dysplasia, and cognitive impairment caused by mutation in *SLC39A8*. *CL. Beaulieu[1], M. Galvez-Peralta[2], D. Redl[3], L. Huang[1], EG. Puffenberger[4], SC. Hampson[1], AE. Chudley[5], JN. Scott[6], RA. Hegele[7], DR. McLeod[3], AE. MacKenzie[1], DE. Bulman[1], JS. Parboosingh[3], DW. Nebert[2], AM. Innes[3], KM. Boycott[1] FORGE Canada Consortium.* 1) Children's Hospital of Eastern Ontario Research Institute, University of Ottawa, Ottawa, ON, Canada; 2) Department of Environmental Health and the Center for Environmental Genetics, University of Cincinnati Medical Center, Cincinnati, OH, USA; 3) Department of Medical Genetics and Alberta Children's Hospital Research Institute for Child and Maternal Health, University of Calgary, Calgary, AB, Canada; 4) Clinic for Special Children, Stratsburg, and Franklin and Marshall College, Lancaster, PA, USA; 5) Section of Genetics and Metabolism, Children's Hospital and the Department of Pediatrics and Child Health, University of Manitoba, Winnipeg, MB, Canada; 6) Department of Radiology, Foothills Hospital, Calgary, AB, Canada; 7) Robarts Research Institute and University of Western Ontario, London, ON, Canada.

Manganese (Mn) is an essential trace element acting as a cofactor for enzymes including mitochondrial superoxide dismutase. Mn deficiency in animal models is known to cause impaired growth, skeletal abnormalities, and ataxia. Recently, mutations in *SLC30A10* have been found to cause hypermanganesemia resulting in dystonia, parkinsonism, polycythemia, and liver disease. We have identified a homozygous mutation in *SLC39A8* (*ZIP8*) associated with manganese deficiency and cerebellar atrophy, hypotonia, strabismus, developmental delay, short stature, mild skeletal dysplasia, and connective tissue abnormalities. This novel autosomal recessive disorder was identified in three patients from three Hutterite families. An identity-by-descent mapping approach identified an associated 11.7 Mb region on chromosome 4q22-25 and a mutation, p.Gly38Arg, was identified in a conserved residue of *SLC39A8*. As a member of the solute carrier gene (SLC) superfamily, SLC39A8 transports Mn, Zn, and Cd across the plasma membrane with very high-affinity binding constants. Evaluation of trace element levels in affected patients revealed a severe biochemical defect with very low blood Mn levels (20 nM, compared to normal range of 273–278 nM) and high Mn levels excreted in the urine; the Zn deficiency was milder, likely due to redundancy (presence of other Zn transporters). To our knowledge, this is the first gene associated with a human Mn deficiency syndrome and provides insight into the role of Mn homeostasis in development and health.

GNAL is a new causative gene for Primary Dystonia. *T. Fuchs[1], R. Saunders-Pullman[2,3], I. Masuho[4], M. San Luciano[5], D. Raymond[2], S. White[1], E. Ainehsazan[1], N. Sharma[6], M.E. Ehrlich[7,8], K. Martemyanov[4], S.B. Bressman[2,3], L.J. Ozelius[1,8].* 1) Gen & Genomic Sci, Mount Sinai Sch Med, New York, NY; 2) Department of Neurology, Beth Israel Medical Center, New York, NY; 3) Department of Neurology, Albert Einstein College of Medicine, Bronx, NY; 4) Department of Neuroscience, The Scripps Research Institute, Jupiter, FL; 5) Department of Neurology, University of California, San Francisco, CA; 6) Department of Neurology, Massachusetts General Hospital, Boston, MA; 7) Department of Pediatrics, Mount Sinai School of Medicine, New York, NY; 8) Department of Neurology, Mount Sinai School of Medicine, New York, NY.

Dystonia is a movement disorder characterized by involuntary movements and abnormal postures. Primary torsion dystonia (PTD), defined clinically by the absence of neurological signs other than dystonia (or tremor) represents a complex, clinically heterogeneous group of movement disorders. Loci for 9 forms of PTD (DYT1, 2, 4, 6, 7, 13, 17, 21, and CIZ1) have been identified, most of which are inherited in an autosomal dominant (AD) manner with reduced penetrance. Using exome sequencing in two PTD families we identified a novel causative gene, GNAL, with a nonsense mutation resulting in premature stop codon in one family and a missense mutation in the other. To confirm GNAL as a dystonia causative gene and to assess the phenotypic spectrum associated with GNAL mutations, we performed Sanger sequencing of the entire coding region in more than 250 PTD subjects of mainly European origin with various PTD phenotypes. This screening revealed seven additional novel mutations in this gene. The phenotype associated with these mutations was predominated by cervical dystonia, with spread to cranial muscles in about half. Age-onset was between 10–54 years with a mainly segemental distribution. GNAL encodes the stimulatory alpha subunit, Gαolf, which links G-protein coupled receptors to downstream effector molecules and function as heterotrimers composed of alpha, beta and gamma subunits. It is expressed in the brain, with prominent enrichment in the striatum where it presumably couples both the dopamine type 1 receptors (D1R) and adenosine A2A receptors (A2AR) to the activation of adenylyl cyclase type 5 (AC5). Abundant evidence supports dysfunction of the basal ganglia and dopamine signaling in dystonia. In order to obtain mechanistic insight into the potential impact of missense mutations we studied their effect on D1R mediated Gαolf activation using bioluminescence resonance energy transfer (BRET)-based reporter system where Gαolf function could be assessed by its ability to influence the interaction between Gβγ subunits during receptor initiated cycle of nucleotide binding and hydrolysis. Several of the mutations tested in the assay reveal deficiencies in the efficiency of heterotrimer formation or coupling to D1R suggesting loss of function in the D1R-Gαolf signaling pathway is likely causative for PTD. GNAL mutations directly point to the dopamine signal transduction system as one of the origins of dystonia pathophysiology.

Analysis of Aicardi syndrome genome using array CGH and EXOME sequencing. *W. Liu[1], M. Bainbridge[2], A. Balasa[3], X. Wang[1], D. Murdock[2], R. Gibbs[2], I. Van den Veyver[1,4,5].* 1) Dept OB/GYN, Baylor Col Med, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030, USA; 3) USDA/ARS Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030, USA; 4) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA; 5) The Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, Houston, TX 77030, USA.

Background: Aicardi syndrome is a severe sporadic neurodevelopmental disorder that mostly affects females. It is thought to be caused by heterozygous defects in an essential X-linked gene, but a defect in an autosomal gene with sex-limited expression cannot be excluded. Despite multiple efforts, the cause of Aicardi remains unknown. To date, functional candidate-gene sequencing or genome-wide array genomic hybridization (aGH) on 244K arrays by us on 38 patients, as well as similar studies by others, have not revealed a causative copy-number variant (CNV) or candidate gene. Methods: Additional screening for CNVs in DNA from 5 Aicardi patients using a higher resolution 1M array and screening for coding-gene variants in 14 Aicardi families using whole-exome sequencing (WES) using two different capture designs was performed. Results: (1) CNV analysis: We found 182 CNVs (109 losses and 66 gains) of which 7 were loss or gain in different patients. Nine of the 66 gains were not previously reported. Only one of these contained a known gene, NXRN1, but could not be validated with quantitative PCR. No new CNVs were detected on the X chromosome. (2) WES: The first “trio” analysis on 3 Aicardi families using one capture design yielded 5 to 6 de novo sequence variants in each trio. The second WES experiment on 12 trios (1 of which was also included in the first 3) identified 5 SNPs on X chromosome, one of which in IL1RAPL1 was validated to be de novo. There were no other changes in IL1RAPL1, and the same SNP was not found in 10 other Aicardi families and 4 controls. Neither WES experiment yielded de novo variants in genes shared by all trios. Conclusion: this data, combined with those of published results, suggests that it is unlikely that Aicardi syndrome is caused by constitutional CNVs detectable on high-resolution arrays, or caused by constitutional point mutations in protein-coding genes detectable by WES.

2803W

Molecular analysis for Gaucher, Tay-Sach's and Sandhoff disease in Indian patients. *J. J. Sheth[1], M. A. Mistri[1], C. M. Ankleshwaria[1], P. Tamhankar[2], A. Bavdekar[3], CA. Datar[4], M. University, Baroda, India.

Mutations leading to Gaucher (GD), Tay-Sachs (TSD) and Sandhoff (SD) disease in India are yet unknown. Hence, we aimed to determine mutations spectrum for these disorders in Indian patients. In the present study, twenty-six, eighteen and six unrelated individuals who were clinically and biochemically confirmed to have GD, TSD and SD respectively were included. All subjects referred from various regions of India were investigated for mutation identification by ARMS, RFLP and DNA sequencing method. Out of 26 subjects with GD, L444P mutation was found in eleven (42.30%) patients, L444P/Rec NciI in three (11.53%), Rec NciI in three (11.53%) followed by R463C and R398Q in one each (7.69%) patient respectively and one patient was heterozygous for R463C, three were heterozygous for Rec NciI. Novel mutation I466S / Rec Nci I was observed in one case (3.84%), while remaining patients study is under process. In 15 of 18 subjects with TSD, six novel missense mutations were detected. The most common novel mutation c.1385A>T (p.E462V) was found in six (40%) unrelated families from Gujarat. In five (33.33%) patients novel mutations viz. c.340G>A (p.E114K), c.964G>A (p.D322N), c.964G>T (p.D322Y), c.1178C>G (p.R393P) c.1432 G>A (p.G478R) were found respectively and in one (6.66%) Iraqi patient previously reported mutation c.508C>T (p.R170W) was observed. Another known mutation in Ashkenazi Jewish, c.1274_1277 (p.Tyr427IlefsX5) was observed in homozygous and heterozygous status in one each (13.32%). In remaining three patients mutation is not found and study is under process. Of 6 subjects with SD, four novel mutations C.534_541delAGTTTATC (p.V179RfsX10), c.1563_1573delTATGGATGACG (p.M522LfsX2), c.1591_1592insC (p.R531KfsX22) and c.1417+1 G>A in one each (66.66%) respectively, one patient(16.66%) was heterozygous for c.850 C>T (p.R248X) nonsense mutation and one(16.66%) was heterozygous for c.1597C>T (p.R533C) missense mutation. These both mutations are known mutations reported in Italian and Iranian respectively. This study clearly demonstrates that L444P is the most common mutation in Indian GD patients while TSD and SD patients are more likely to have novel mutations. Nonetheless p.E462V mutation in HEXA gene seems to be more common in TSD patients from Gujarat.

Progress and challenges in elucidating the molecular genetic basis of cluster headache. *L. Southgate[1], S. Scollen[2], W. He[3], A. Moss[4], M.A. Simpson[1], B. Zhang[3], L. Xi[3], T. Schlitt[1], M. Weale[1], C.L. Hyde[3], J.C. Stephens[3], C. Sjöstrand[5], M.B. Russell[6], M. Leone[7], S.L. John[3], R.C. Trembath[1,8].* 1) Medical and Molecular Genetics, King's College London, London, United Kingdom; 2) Pfizer, Neusentis, PTx Precision Medicine, Granta Park, Cambridge, United Kingdom; 3) Pfizer, PTx Precision Medicine, Eastern Point Road, Groton, CT; 4) Pain & Sensory Disorders, Pfizer, Neusentis, Granta Park, Cambridge, United Kingdom; 5) Department of Neurology, Karolinska University Hospital Huddinge, Karolinska Institute, Stockholm, Sweden; 6) Department of Neurology, Research Centre, Akershus University Hospital, Oslo, Norway; 7) Carlo Besta National Neurological Institute, Milan, Italy; 8) Barts and The London School of Medicine & Dentistry, Queen Mary, University of London, London, United Kingdom.

Cluster headache (CH) is a trigeminal autonomic cephalalgia characterised by recurrent, relatively short-lived attacks of excruciating pain, often with regular periodicity. A genetic predisposition to CH has long been debated. Numerous epidemiological studies have reported an increased risk in relatives of CH sufferers and familial clustering supports a model of autosomal dominant inheritance with reduced penetrance. Although a few candidate gene studies have been performed, detecting moderate associations with the *HCRTR2* and *ADH4*genes, these have been limited by small sample size. We have established a large cohort of CH families, in which we have previously reported a genome-wide linkage scan. These data isolated a number of putative linkage loci; however, a single causative gene is yet to be identified, largely due to substantial genetic heterogeneity. To further delineate the genetic architecture underlying this condition, we have used an exome sequencing strategy in a subset of Northern European families. Exome capture was performed for ten probands using the Agilent SureSelect Target Enrichment System and paired-end sequence reads were generated on an Illumina Genome Analyzer IIx. After filtering of annotated variants to exclude synonymous polymorphisms and known or common variation, a total of 1711 novel heterozygous variants were detected. Exome data from related affected subjects were examined to limit the analysis to variants segregating with the CH phenotype. These variants were subsequently Sanger sequenced in all family members and those which did not segregate with affected subjects were excluded. Following segregation analysis, we have reduced our candidate list to a total of 45 genes with novel variants (range: 1–13 genes per pedigree). These genes are now being screened in our extended CH cohort to identify additional variants, providing further insight into the role of each gene in CH pathogenesis. Whilst the power of exome sequencing in rare Mendelian disease gene identification is now well-established, approaches to identify pathogenic variation with complexities such as locus heterogeneity and incomplete penetrance remain challenging. We have used a combination of exome and Sanger sequencing to detect novel coding variation segregating across CH families. The significance of such variants in CH pathogenesis remains to be elucidated; however these results now point to a potential genetic predisposition to this debilitating disorder.

2805F

Japanese Chin dogs with GM2 gangliosidosis are homozygous for a HEXA missense mutation and are a potential large animal model for Tay-Sachs disease. *D. Gilliam[1], A.C. Freeman[2], D.N. Sanders[3,6], R. Zeng[1], D.A. Wenger[4], G.S. Johnson[1], M.L. Katz[3], M. Vandenberg[2], S. Holmes[2], M. Kent[2], R. Rech[2], E. Howerth[2], S.R. Platt[2], D.P. O'Brien[5].* 1) Department of Veterinary Pathobiology, University of Missouri College of Veterinary Medicine, Columbia, MO; 2) College of Veterinary Medicine, University of Georgia, Athens, GA; 3) Mason Eye Institute, University of Missouri School of Medicine, Columbia, MO; 4) Department of Neurology, Thomas Jefferson University Jefferson Medical College, Philadelphia, PA; 5) Department of Veterinary Medicine and Surgery, University of Missouri College of Veterinary Medicine, Columbia, MO; 6) Plymouth State University, Plymouth, NH.

We evaluated two half-sibling Japanese Chin dogs which appeared to have the same GM2 gangliosidosis described in Japanese Chins over 25 years ago by Cummings et al. (Acta Neuropathol, 1985;67:247) and Ishikawa et al. (J Neurochem, 1987;48:860). Similar to the earlier disease descriptions, the neurodegeneration in the current dogs became apparent when the dogs were 11 and 16 months old and progressed rapidly over a period of 5 to 7 months until the dogs were euthanized because they showed cerebellar ataxia, blindness, severe tremors, mental dullness and disorientation. Also, consistent with the earlier reports, tissues from the affected half siblings had markedly increased concentrations of GM2 ganglioside and normal or increased β-hexosaminidase activities when measured with fluorogenic substrates, either 4-methylumbelliferyl-β-N-acetylglucosamine (MUG) or 4-methylumbelliferyl-β-N-acetylglucosamine-6-sulfate (MUGS). These biochemical findings resemble those from human patients with the AB variant of GM2-gangliosidosis, caused by mutations in GM2A. Surprisingly, the coding regions and intron-exon junctions from all four GM2A exons from the affected dogs harbored only common polymorphisms. GM2-gangliosidosis can also be caused by mutations in HEXA and HEXB, the genes that encode the respective α and β subunits of hexosaminidase A. No sequence variants were found in HEXB from the affected dogs; however, both dogs were homozygous for a HEXA:c967G>A missense mutation that predicts a p.E323K amino acid substitution. This mutation is the likely cause of the GM2-gangliosidosis in the Japanese Chins because the glutamyl moiety at codon 323 serves as the general acid/base in the catalytic site in the α subunit of hexosaminidase A. In further support of our contention that the HEXA:c967G>A missense mutation is causal, none of the 128 healthy Japanese Chins with DNA in our collection were HEXA:c967A homozygotes; instead, 123 were HEXA:c967G homozygotes and 5 were A/G heterozygotes. We believe that the β-hexosaminidase activity detected with MUGS in the affected dog tissues, but not present in tissues from comparable human patients, resulted from species-specific differences in the substrate specificity of the active site on the β subunit in hexosaminidases A and B. In conclusion, we have identified a HEXA:c967G>A missense mutation as the likely cause of the GM2 gangliosidosis in Japanese Chins, making these dogs a potential large animal model for Tay-Sachs disease.

Identification of Novel X-linked Intellectual Disability Genes by Human X Chromosome Exome Sequencing. *T. Wang[1,2], T. Niranjan[1,3], C. Skinner[4], M. May[4], L. Holloway[4], C. Schwartz[4].* 1) McKusick-Nathans Institute of Genetic Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Pediatrics, The Johns Hopkins University School of Medicine, Baltimore, MD; 3) Predoctoral Training Program in Human Genetics, The Johns Hopkins University School of Medicine, Baltimore, MD; 4) Greenwood Genetic Center, Greenwood, SC.

X-linked Intellectual Disability (XLID) is a group of genetically heterogeneous disorders caused by mutations in genes on the X-chromosome. More than 90 XLID genes have been identified, which account for ~2/3 of known XLID disorders. To systematically identify genes responsible for the remaining XLID disorders, we performed next-generation sequencing of the human X-exome in 56 affected males from 41 XLID families including two affected males in 15 families. Illumina sequencing libraries were generated from genomic DNA, enriched for the human X-exome using the Agilent SureSelect system, and sequenced using a HiSeq2000. This study achieved a mean coverage of 76-fold for the X-exome and 82.1% of the baits showed sufficient coverage for all samples. Approximately 1,500 variants were identified in each X-exome, 18% of which were mapped to coding regions. To enrich candidate disease-causing mutations, we first eliminated variants that were present in dbSNP and the “1000 Genomes” database. These filters effectively reduced the number of variants for validation. However, we noted that a small number of deleterious mutations in known XLID genes exist in dbSNP. We hypothesize that this is likely the result of inaccurate sample phenotyping, limited variant validation, and inclusion of sequence data from female carriers of XLID. To overcome these problems, we sequenced two affected males in some proband families to identify shared variants and eliminate variants that were present in a cohort of unrelated, affected males (n=48). This strategy achieved a significant reduction of variants for validation and successfully identified potential deleterious mutations in known XLID genes including ATRX, PLP1, OPHN1, MECP2, and MED12, as well as in novel candidate genes. We conclude that next-generation sequencing is a powerful tool for systematic characterization of known and novel disease-causing mutations in heterogeneous disorders such as intellectual disability. Current human reference databases, including dbSNP and the “1000 Genomes”, should be used with caution as automatic filters to remove non-disease-causing variants during data analysis.

2807T

Genetic studies to gain insight into the function of the MeCP2 domains in vivo. *L. Heckman[1,2], H. Zoghbi[1,2,3].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Jan and Dan Duncan Neurological Research Institute at Texas Children's Hospital, Houston, TX; 3) Howard Hughes Medical Institute.

Rett syndrome (RTT) is a debilitating neuropsychiatric disorder caused by mutations in the X-linked methyl-CpG binding protein 2 (*MECP2*) gene, which encodes for a protein with the same name (MeCP2). Many of the RTT-causing mutations create a truncating null allele, suggesting that RTT is due to a loss of MeCP2 function. Interestingly, overexpression of MeCP2 due to a duplication spanning *MECP2* also causes a progressive neurological syndrome that shares many features with RTT. Studies in mice that either lack (RTT model) or express 2X MeCP2 (duplication model) reveal that the loss and gain of MeCP2 has opposing effects on excitatory synapses and gene expression, suggesting that the duplication causes the disorder by a “hyperfunction” mechanism. However, the challenge has been to understand exactly what function of MeCP2 is being exaggerated when it is overexpressed. Traditionally, MeCP2 was believed to be a transcriptional respressor, yet gene expression data from animal models does not support this model. Newer hypotheses proposed that MeCP2 dampens transcriptional noise, such that in its absence, increased basal transcription leads to decreased expression of neuronal genes. This model, however, does not quite explain why doubling the protein will enhance expression of activity dependent neuronal genes. Another hypothesis proposes that overexpression of MeCP2 might titrate co-repressors, thus resulting in an increase of gene expression. To determine if DNA binding by the methyl-CpG-binding domain (MBD) is necessary for the neuronal dysfunction resulting from MeCP2 overexpression, I have generated mice that overexpress *MECP2* alleles with two different RTT-causing mutations: T158M, which reduces methyl-CpG binding and R111G, which abolishes methyl-CpG binding without affecting the structure of the MBD. Transgenic mouse lines that express each allele at levels similar to endogenous levels have been generated thus allowing me to study if doubling MeCP2 levels with an allele that compromises DNA binding activity is consequential. Behavioral, physiological and molecular studies of these alleles are ongoing both in the context of overexpression and in a MeCP2 null background. These models promise to provide new insight into the mechanism by which MeCP2 overexpression leads to neurological dysfunction.

2808F

Combination of linkage analysis and exome sequencing identifies a novel form of autosomal recessive syndromic intellectual deficiency linked to DNA damage response defect. *M. Langouet[1], A. Saadi[2], C. Bole-Feysot[3], P. Nitschke[4], A. Munnich[1], M. Chaouch[2], L. Colleaux[1].* 1) INSERM U781, Fondation IMAGINE, Université Paris Descartes, Hôpital Necker-Enfants Malades, Paris, France; 2) Département de Neurologie, Etablissement hospitalier spécialisé de Benaknoun, Alger, Algérie; 3) Plateforme de Génomique de la Fondation Imagine Paris, France; 4) Plateforme de Bioinformatique de l'Université Paris Descartes, Paris, France.

We ascertained a large Algerian consanguineous multiplex family in which three affected sibs presented with severe psychomotor delay, microcephaly, behavioral disorders, skeletal anomalies, and facial dysmorphism. Linkage analysis combined to exome sequencing allowed us to identify a previously unreported homozygous variation (c.1307T>A, p.I436N) in the *TTI2/C8orf41* gene. This mutation co-segregated with the disease, was not detected in 510 control chromosomes, nor was it present in an internal exome dataset of 125 individuals or among the 5,379 exomes available from the NHLBI Exome Sequencing Project. Moreover, this variant was predicted to be damaging by various in silico tools. *TTI2* encodes a 508 amino acid protein that has been recently characterized through its interactions with the TTI1 and TEL2 proteins as part of the Triple T complex. This complex plays a key role in the folding/maturation of PIKK (phosphatidylinositol 3-kinase-related kinases) proteins and is required for DNA damage signaling and ATM and ATR stability. TTI2, as TTI1 and TEL2, is essential to the stability and the function of the TTT complex and to cell survival in response to DNA damage.Western blots showed reduced amount of TEL2, TTI1 and TTI2 proteins in patient fibroblasts as compared to controls, suggesting that the p.I436N mutation results in destabilization of the whole TTT complex. Moreover, preliminary data suggest impaired ATM and ATR stability in these cells.

ID, microcephaly, developmental delay, facial dysmorphy and skeletal abnormalities are also observed in other DNA repair disorders. In addition, another missense mutation of this gene (p.P367L) has been recently identified in a second ARID family (Najmabadi et al, Nature 2011). Altogether, these data support the hypothesis that TTI2 is the disease causing gene.

Our findings further demonstrate the efficiency of high resolution sequencing strategies to unravel the molecular bases of ID syndromes. More importantly, they provide the first example of a human disorder related to a defect in TTT complex. Further experiments are now underway to evaluate DNA damage repair efficiency in patient cells and characterize in more details the effect of this TTI2 mutation on ATM/ATR signaling.

2809W

Neuronal cells generated through differentiation of stem cells isolated from patient's skin recapitulate the main features of Niemann Pick C disease. *A. Dardis[1], N. Bergamin[2], D. Cesselli[2], S. Zampieri[1], B. Bembi[1], A. Beltrami[2], CA. Beltrami[2].* 1) Regional Coordinator Center for Rare Diseases, University Hospital Santa Maria della Misericordia, Udine, Italy; 2) Department of Medical and Biological Sciences, University of Udine, Italy.

Niemann Pick C (NPC) disease is a neurovisceral lysosomal storage disorder due to mutation in NPC1 or NPC2 genes, characterized by the accumulation of endocytosed unesterified cholesterol, gangliosides and other lipids within the lysosomes/late endosomes. The analysis of the molecular pathways linking the lipid accumulation and cellular damage in the brain has been challenging due to the limited availability of human neuronal models. The aim of this study was to develop a human neuronal model of NPC disease by inducing neuronal differentiation of stem cells isolated from skin biopsies or fibroblasts in culture of NPC patients. Primitive cells from 3 NPC patients and 3 normal controls were isolated from skin biopsies and previously established skin fibroblast cultures adapting methods previously described [Beltrami et al, 2007]. After 3 passages in selective medium, cells obtained from both sources (hSKIN-MASC) displayed an antigenic pattern, determined by FACs analysis, characteristic of mesenchymal stem cells and expressed the stem cell markers Oct-4, Nanog, Sox-2 and nestin (analyzed by immmunofluorescence). hSKIN-MASC obtained from NPC patients showed a massive lysosomal accumulation of unesterified cholesterol when analyzed by filipin staining. After the induction of neural differentiation using methods previously described [Beltrami et al, 2007], remarkable morphologic changes were observed and cells became positive to markers of the neuronal linage NeuN and MAP2. Filipin staining and immunofluorescence analysis of GM2 ganglioside showed a clear lysosomal accumulation of cholesterol and GM2 only in cells from NPC patients. Differentiated NPC cells presented a morphology that was clearly different from normal cells and that closely resemble the morphology of cortical neurons of NPC patients. A quantitative analysis using the Neurite outgrowth image program, showed that differentiated cells from NPC patients presented longer neurites and a greater number of neurite extremities, segments, roots and node points, than differentiated cells from normal donors. In conclusion, we generated a human neuronal model of NPC disease by inducing neuronal differentiation of stem cells obtained from easily accessible sources, such as patient's cultured fibroblasts, without the need to express transgenes in target cells, avoiding confounding results due to the reprogramming process. The model described here recapitulates the main features of NPC disease.

Franco[1,10].* 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Institut für Humangenetik, Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany; 3) Unit of Molecular Neurogenetics, The Foundation “Carlo Besta” Institute of Neurology, Milan, Italy; 4) Departments of Genetics, Biology of Microorganisms, Anthropology and Evolution, University of Parma, Italy; 5) Integrated Microscopy Facility, Institute of Genetics and Biophysics “Adriano Buzzati Traverso”, CNR, Naples, Italy; 6) Centre de Genetique Humaine, Institut de Pathologie et de Genetique, Gosselies (Charleroi), Belgium; 7) Gemeinschaftspraxis für Humangenetik, Erfurt, Germany; 8) Schneider Children's Medical Center of Israel, Faculty of Health Sciences, Medical School for International Health, Ben-Gurion University of the Negev, Beer-Sheva, Israel; 9) Centro de Biología Molecular “Severo Ochoa”, CSIC-UAM and CIBER de Enfermedades Raras (CIBERER), Madrid, Spain; 10) Medical Genetics Services, Department of Pediatrics, Federico II University, Naples, Italy.

Intrinsic (mitochondrial) programmed cell death (PCD), plays an essential homoeostatic role, by selecting bioenergetically proficient cells suitable for normal tissue and organ development. In spite of intensive investigation on cellular and animal models, the impact of this crucial execution pathway in human disease remains mechanistically undefined. In particular, the link between apoptosis and mitochondrial disorders, i.e. primary defects of oxidative phosphorylation (OXPHOS), has not been persuasively demonstrated. On the other hand, a clearly developmental phenotype, Microphthalmia with Linear Skin lesions syndrome (MLS, OMIM 309801), is associated with mutations in *HCCS*, the X-linked gene encoding Holo-Cytochrome c-type synthase, which incorporates catalytically active heme-c moieties in the mitochondrial respiratory chain (MRC). Notably, *HCCS* mutations are present in a subset of MLS patients, the remaining ones being still undefined at the molecular level. To gain mechanistic insight on the molecular pathogenesis of the developmental defect in MLS, we first showed that, similar to MLS patients, *hccs*knockdown results in eye and brain abnormalities in medaka fish (*Oryzias latipes*). Next, we demonstrated that these defects are caused by increased PCD via apoptosome-independent caspase-9 activation, triggered by MRC impairment and overproduction of reactive oxygen species (ROS). Based on these results, we then screened MRC-related genes in *HCCS*-negative MLS patients, and found deleterious mutations in a poorly characterized structural subunit of cytochrome c oxidase (COX). These data indicate an essential role for the mitochondrial respiratory chain in organogenesis and define a new group of mitochondrial diseases hallmarked by apoptosis-driven abnormal development.

2811F

Whole Exome Sequencing Reveals Novel and Known Genes Mutations in a Cohort of Centronuclear Myopathy Patients. *P. Agrawal, O. Ceyhan, K. Schmitz, E. Dechene, M. Viola, K. Markianos, A. Beggs.* Medicine, Children's Hospital Boston, Boston, MA.

Centronuclear myopathies (CNM) are a group of rare heterogeneous congenital myopathies characterized by muscle weakness and low tone of varying onset, often needing respiratory, feeding and/or ambulatory assistance and characterized by presence of increased central nuclei on muscle biopsy. CNM is caused by mutations in the *MTM1*, *DNM2*, *RYR1* and *BIN1*. *MTM1*mutations cause a form of CNM known as X-linked myotubular myopathy (XLMTM) in about 50% of CNM cases, while *DNM2* and *RYR1* account for 15% each, and *BIN1* for <5%, leaving about 20% without a known gene. We performed whole exome sequencing (WES) in 28 CNM patients to identify known and novel gene mutations responsible for the disease. These were mostly small families with a single member diagnosed with CNM and no linkage data. *MTM1* and *DNM2* mutations were ruled out in majority of these patients, while *RYR1* and *BIN1* were not sequenced because of the large size (*RYR1*) and rarity (<5%) of the mutations (*BIN1*). WES was performed by Axeq technologies using Illumina platform and 10X coverage of the target regions was in 84–88% range for these samples. One of these 28 patients was identified to have *MTM1* duplication on clinical testing. Of the remaining 27, 2 had *DNM2* and 9 had *RYR1*mutations. Interestingly, there were 4 cases with *TTN* mutations. In summary, exome sequencing has identified molecular basis for 60% of patients with CNM. Work is underway to identify novel genes in the remaining 40% exomes.

2812W

Mutations in the human isoprenoid synthase domain containing gene are a common cause of congenital and limb girdle muscular dystrophies. *S. Cirak[1], AR. Foley[2], R. Herrmann[3], T. Willer[4], M. The secondary dystroglycanopathies are a recessively inherited diverse group of muscular dystrophies ranging in severity from congenital onset with severe cobblestone lissencephaly (Walker-Warburg Syndrome) to milder forms of limb girdle muscular dystrophy (LGMD). Their hallmark is the reduction of α-dystroglycan (ADG) glycosylation and an important part of this glycosylation is a unique O-mannosylation which regulates the interaction between ADG and extracellular matrix proteins including laminin alpha 2, perlecan and agrin. The genetic aetiologies of approximately 50% of the dystroglycanopathies have been attributed to nine genes that are involved in ADG glycosylation. Despite collaborative efforts of several international groups using traditional positional cloning, the causative genes for the unsolved dystroglycanopathy cases had escaped discovery. Recently biallelic loss of function mutations in the *isoprenoid synthase domain containing* (*ISPD*) have been described in Walker-Warburg syndrome. In a collaborative study with the UK10K Rare Disease Project from the Sanger Institute, using whole exome sequencing techniques, we have now discovered that mutations in *ISPD* are found in a significant proportion of ADG patients. The mutations identified are milder mutations, and the phenotype of affected patients ranges from muscle-eye-brain like disorders, to congenital muscular dystrophy without brain involvement and to limb girdle muscular dystrophy with or without evidence of brain involvement. While in eubacteria and in choloroblasts of higher plants ISPD orthologues are involved in the synthesis of isoprenoid precursors, this pathway is absent in eukaryotes and vertebrates and; therefore, the function of ISPD remains unknown. The mechanism of *ISPD* mutations leading to reduction of α-dystroglycan glycosylation needs to be uncovered; however, our ongoing screening shows that ISPD mutations are a common cause of dystroglycanopathies.

Prevalence of MECP2 mutations among girls presenting significant clinical overlap between Rett and Angelman syndromes. *T. M. R. de Assis[1], G. A. Molfetta[1,2], C. A. Ferreira[1], C. H. P. Grangeiro[3], W. A. Silva, Jr.[1,2].* 1) National Institute of Science and Technology in Stem Cell and Cell Therapy, Regional Blood Center of Ribeirão Preto; 2) Departament of Genetics, Medical School of Ribeirão Preto, University of São Paulo; 3) Medical Genetics Unit, Hospital of the Medical School of Ribeirao Preto, University of Sao Paulo.

Rett Syndrome (RS) is a developmental disorder caused by mutations in the MECP2 gene located on X chromosome, which affects females with an incidence of 1:10.000-1:15.000 newborns. Patients can present loss of spoken language, motor dysfunction, most notably hands-wash movements and gait disturbance, scoliosis, microcephaly, seizures, cardiac abnormalities, breathing disorder and mental retardation. These symptoms arise in 6 to 18 months old girls, after an apparently normal development. Angelman syndrome (AS) is a neurobehavioral disorder with an incidence of 1:10.000 newborns caused by defects of the UBE3A gene in chromosome 15q11–13. The syndrome is clinically characterized by central congenital hypotonia, delayed neuropsychomotor development, severe mental retardation, total lack of speech, excessive laughter, hyperactivity and dysmorphic features such as micro-brachycephaly, macrostomia, widely-spaced teeth, lingual protrusion, mandibular prognathism, strabismus and seizures. Both conditions can be difficult to diagnose in girls early in their development and the distinction from each other can be challenging due to both disorders being characterized by severe mental disability, microcephaly, speech disturbance, movement disorders with gait and/or truncal ataxia, and occasionally a similar facial appearance. This work focus on identifying and characterizing mutations along the coding region of the MECP2 gene in patients clinically diagnosed as RS or AS (biparental methylation pattern and no mutations in the UBE3A gene). DNA was extracted from blood samples after parents signing the informed consent form, and High Resolution Melting(HRM) technique and DNA sequencing were employed to screen for mutations. While searching for mutations in MECP2 exons, we have found a missense mutation (T158M) (GenBank X99686) in a patient previously diagnosed as RS and no alterations whatsoever in the group of patients clinically diagnosed as AS. The methodology is robust and efficient for detecting mutations in the MECP2 gene,confirming the diagnosis of patients suspected as RS, a subdiagnosed pathology due to its complex clinical suspicion. Furthermore, we postulate that the clinical diagnosis should be rigorously conducted in order to correctly screen patients to the appropriate laboratorial molecular approach. Genetic counseling was offered to the families carrying mutations. Financial Support: FAPESP (2011/11450-1), CTC, INCTC.

Identification of six novel *NF1* mutations in neurofibromatosis type 1 patients from the Azorean island of São Miguel (Portugal). *L. Mota-Vieira[1,2], B. Campos[3], R. Cabral[1,2], A.L. Rodrigues[4], A. Raposo[4], A. Carvalho[4].* 1) Mol Genetics & Pathol Unit, Hosp Divino Espirito Santo PD, Ponta Delgada, Azores Islands, Portugal; 2) Azores Genetics Research Group, Instituto Gulbenkian de Ciência, Lisbon, Portugal; 3) Molecular Genetic Diagnosis Centre, Bellvitge Biomedical Research Institute, Barcelona, Spain; 4) Pediatric Department, Hosp Divino Espirito Santo PD, Ponta Delgada, Azores Islands, Portugal.

Neurofibromatosis type 1 (NF1, OMIM 162200) is a common autosomal dominant complex disorder, affecting about 1 out of 3000 live births, regardless of family history, race, gender, or ethnic background. To date, 1163 different *NF1* mutations have been identified (HGMD accessed: May 31, 2012); most of them are unique to a particular family. In the present study, we describe the germline *NF1* mutation spectrum identified in a cohort of 13 patients, 11 unrelated and 2 first cousins, from the Azorean Island of São Miguel (137,830 inhabitants), located on the North Atlantic Ocean. All patients present the clinical features of neurofibromatosis type 1: café-au-lait spots (13, 100%), axillary and/or inguinal freckling (12, 92.3%), neurofibromas (6, 46.2%), optic glioma (2, 15.4 %) and/or Lisch nodules (2, 15.4 %). *NF1* mutation screening was performed using a cDNA-direct sequencing approach complemented with multiplex ligation-dependent probe amplification (MLPA) analysis for the detection of single and multiexon deletions or duplications. Until now, we identified the causative mutations in 10 patients: six are novel, and four are recurrent mutations. The novel mutations fall in the coding region (NM_000267.3): five are frameshift mutations (c.301delA in exon 4a, p.Thr101GlnfsX2; c.1498_1500delATTinsC in exon 10b, p.Ile500ProfsX10; c.2033dupC in exon 13, p.Ile679AspfsX21; c.2739dupA in exon 16, p.Arg914ThrfsX5; and c.5450_5451delGT in exon 29, p.Ser1817TyrfsX23), and one is a missense mutation (c.880A>G in exon 6, p.Met294Val that is predicted to affect neurofibromin function). The recurrent mutations reported so far consist of a complete deletion of the NF1 gene (Kayes LM et al., 1994), found in two patients, the nonsense mutation c.3721C>T in exon 22 (p.Arg1241X; Fahsold R et al., 2000) and the missense mutation c.1658A>C in exon 11 (p.His553Pro; Griffiths S et al., 2007). We are now finishing the analysis of the three other patients. If no pathogenic mutation is identified we will perform *SPRED1* mutation screening, since loss-of-function mutations in this gene cause a neurofibromatosis 1-like phenotype (Brems H et al., 2007). Finally, the epidemiological analysis revealed São Miguel Island (Azores, Portugal) has one of the highest incidence of neurofibromatosis type 1 in the world, approximately 1:2000 live births (lmotavieira@hdes.pt; Funding by the Government of the Azores).

2815W

A Pan-European study of the pathological C9orf72 hexanucleotide (G4C2) expansion associated with frontotemporal lobar degeneration and amyotrophic lateral sclerosis. *J. van der Zee[1,2], I. Gijselinck[1,2], L. Dillen[1,2], T. Van Langenhove[1,2], M. Cruts[1,2], C. Van Broeckhoven[1,2], the Belgian Neurology consortium and the European Early-Onset Dementia consortium.* 1) Neurodegenerative Brain Diseases Group, VIB Department of Molecular Genetics, Antwerp, Belgium; 2) Institute Born-Bunge, University of Antwerp, Antwerp, Belgium.

Three studies independently identified C9orf72 on chromosome 9p21 as the causal gene associated with frontotemporal lobar degeneration (FTLD) and amyotrophic lateral sclerosis (ALS). The primary gene defect is an outsized, pathological expansion of a hexanucleotide repeat sequence, G4C2, located in the C9orf72 promotor region. We developed an alternative repeat-based PCR assay on the sense strand that eliminates interference of a low complexity sequence located adjacent to the G4C2 repeat. This reverse repeat-based PCR assay combined with a bridging STR fragment length assay allowed reliable identification of carriers of a pathological G4C2 expansion as well as sizing of the normal repeat alleles. Subsequently, we determined the geographical prevalence of the C9orf72 expansion in a sizable pan-European cohort of FTLD and ALS patients, ascertained within a Belgian Neurology consortium and in a newly founded European consortium created to study early-onset dementia, the European EOD consortium. DNA and clinical information of a total of 1489 patients was collected, consisting of 1081 FTLD, 83 FTLD-ALS and 325 ALS patients. This allowed robust estimations of the prevalence and geographical distribution of the C9orf72 expansion in Europe. We calculated overall frequencies of 6% in FTLD, 33% in FTLD-ALS, and 10% in ALS. The frequencies increased in familial patients to 10% in FTLD, 57% in FTLD-ALS, and 38% in ALS. The C9orf72 expansion showed an age-dependent penetrance reaching 90% by the age of 70 years. In conclusion, the high frequency of the pathological C9orf72 expansion in FTLD and ALS patients makes it a primary mutation for clinical genetic testing. Hereto, the combined reverse repeat-based PCR and STR fragment length assays offer a reliable screening method with high analytical and clinical validity.

Identification of novel ALS genes using linkage analysis and next-gen sequencing. *K.L. Williams[1,2], J.A. Solski[1], J.C. Durnall[1], A.D. Thoeng[1,3], S. Warraich[1,2], G. Rouleau[4], G.A. Nicholson[1,2,5], I.P. Blair[1,2].* 1) Northcott Neuroscience, ANZAC Research Institute, Concord, NSW, Australia; 2) Sydney Medical School, University of Sydney, NSW, Australia; 3) Department of Physiology, University of Sydney, NSW, Australia; 4) Ste-Justine Hospital Research Centre, Montreal, Canada; 5) Molecular Medicine Laboratory, Concord Hospital, NSW, Australia.

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disorder that causes the progressive degeneration of motor neurons. Familial ALS accounts for approximately 10% of ALS cases with the remainder being sporadic. ALS is genetically heterogeneous. To date, known genes account for ~55% of familial cases. We aim to investigate known ALS genes and identify new ALS genes in a large cohort of Australian ALS families (n=187) using a combination of sequencing, traditional genetic linkage approaches and next-generation sequencing strategies. We also aim to implement a user-friendly pipeline for analysis of exome sequencing data. We analysed 187 ALS families for mutations in known ALS genes and determined that they account for 57.2% of Australian ALS families, and comprise SOD1 (13.9%), FUS (2.7%), TARDBP(2.1%), UBQLN2 (1.1%) and C9ORF72 (38.0%) mutations. To identify new loci for familial ALS, an 8cM genome-wide microsatellite linkage scan was performed on 51 individuals (affected, unaffected and obligate carriers) from two large informative families negative for all known ALS genes. Previous linkage analysis was performed on one of these families using a 10K Affymetrix SNP chip. Subsequent analyses have yielded suggestive linkage to several chromosomal regions. To reduce sequencing burden when new ALS genes are identified, a proband from each of our remaining 79 families was subjected to exome capture and sequencing (Agilent capture-SOLiD4 sequencing or Illumina TruSeq capture-HighSeq2000 sequencing). Bioinformatic analysis has required the development of a user-friendly pipeline. The genetic defects are yet to be identified among 42.2% of ALS families (79/187 families) within our cohort. The chromosomal regions implicated from our genome-wide linkage scans do not overlap previously identified loci, implicating substantial genetic heterogeneity. Linkage analysis in combination with exome capture and sequencing has allowed us a greater opportunity to identify novel ALS genes. Two candidate genes are currently being validated in extended patient and control cohorts, patient tissues and functional studies. The identification of these novel ALS genes will give insights into the biological basis of both familial and sporadic motor neuron degeneration, allow development of new disease models and provide new targets for therapeutic development.

The distributions of two SOD1 missense mutations in the pet dog population and their association with canine degenerative myelopathy, a model for amyotrophic lateral sclerosis. *R. Zeng[1], J. R. Coates[2], L. Hansen[1], G. C. Johnson[1], F. A. Wininger[2], M. L. Katz[3], G. S. Johnson[1].* 1) Department of Veterinary Pathobiology, University of Missouri College of Veterinary Medicine, Columbia, MO, USA; 2) 2Department of Veterinary Medicine and Surgery, University of Missouri College of Veterinary Medicine, Columbia, MO, USA; 3) Mason Eye Institute, University of Missouri School of Medicine, Columbia, MO, USA.

Canine Degenerative Myelopathy (DM) is a naturally occurring, progressive, adult-onset neurodegenerative disease and a potential large animal model for amyotrophic lateral sclerosis. The initial signs of DM include asymmetric general proprioceptive ataxia and spastic paresis in the pelvic limbs. Over a period of 9 to 12 months, affected dogs become nonambulatory paraplegic with proprioceptive deficits followed by lower motor neuron signs. Owners usually elect euthanasia at this stage. If euthanasia is delayed, clinical signs progress to flaccid tetraplegia and widespread muscle atrophy and may involve the brain stem with signs of dysphagia. Previously, we reported an association between DM and homozygosity for a c.118G>A missense mutation in the canine ortholog of SOD1 in five dog breeds. In addition, we have reported a case of DM in a single Bernese Mountain Dog that was homozygous for a SOD1:c.52G>T missense mutation. For the current report we used TaqMan allelic discrimination assays to estimate the breed-specific distributions of the SOD1:c.118A and SOD1:c.52T alleles in the canine pet populations. So far we have genotyped 26,898 dogs at SOD1:c.118G>A and 1,577 dogs at SOD1:c.52A>T. Representatives from 217 different dog breeds were genotyped at SOD1:c.118G>A and 115 of them were found to segregate the SOD1:c.118A allele. The Wire Fox Terrier breed had the highest SOD1:c.118A allele frequency: 0.94. Of the 60 breeds examined at SOD1:c.52A>T, the SOD1:c.52T allele was only found in members of the Bernese Mountain Dog breed, in which the allele frequency among the 884 genotyped breed members genotyped by us was 0.032. Only 2 Bernese Mountain Dogs were homozygous for the SOD1:c.52T allele: one has been euthanized because of DM, the other one is currently too young to develop signs. We also identified 24 Bernese Mountain Dogs that were SOD1:c.52A,c.118A/c.52T,c.118G compound heterozygotes. Pertinent clinical information was available for 6 of the 9 compound heterozygotes over 8 years of age. Four of the compound heterozygous Bernese Mountain Dog have developed clinical signs suggestive of DM; the other two died from unrelated diseases before their tenth birthday. In addition, we have examined 6 dogs from four different breeds that had histopathologically confirmed DM and were A/G heterozygotes at SOD1:c.118, but had no other SOD1 sequence variants. Finally, one German Shepherd Dog without any SOD1 sequence variants had histopathologically confirmed DM.

Explore the impact of parkin mutations in ER-associated protein degradation: cellular models for juvenile PD. *M. Alves-Ferreira[1], S. Morais[1], J. Sequeiros[1,2], I. Alonso[1,2].* 1) UnIGENe, IBMC, Porto, Portugal; 2) ICBAS, University of Porto, Portugal.

Parkinson disease (PD) is the second most common neurodegenerative disorder and is mainly characterized by motor dysfunction, as the result of selective loss of dopaminergic neurons. Although the aetiology and pathogenesis in PD are still poorly understood, central players causing rare genetic forms of PD should prove useful to understand idiopathic PD. Among these is an Autosomal Recessive-Juvenile Parkinson's disease (AR-JP) form, showing symptoms resembling idiopathic PD, although being characterized by a young age-at-onset (usually under 40). This disorder is caused by mutations in the PARK2 gene which encodes parkin, an E3-ubiquitin ligase that specifically recognizes its substrate protein, promoting its ubiquitination and subsequent degradation by the proteasome. Parkin misfolding seems to be the major mechanism for parkin inactivation. Recent observations support the existence of escorting machinery, which connects the ubiquitylated substrates at the ER-membrane with the 26S proteasome, in a process known as ER-associated degradation (ERAD). Also, it has been shown that misfolded proteins and aggregates, even when involving cytosolic proteins, are able to induce ER stress, probably by suppressing proteasome function, an essential component of the ERAD machinery. Our aim is to explore the role of ERAD in mutant parkin degradation by increasing ERAD capacity. To accomplish this SH-SY5Y cell lines transiently transfected with wild-type and mutant parkin as well as with or without VCP/p97, a key component of the ERAD machinery. We have selected 9 different mutations located in the different parkin domains that were introduced in a GFP-fused parkin construct. The basic characterization through florescence microscopy shows that two mutants (N52MfsX29 located in the ubiquitin-like domain and R275W located in the RING1 domain) are highly prone to aggregation. We are now exploring the impact VCP/p97 overexpression in aggregate formation/degradation. With this study we hope to provide further clues about the role of the ER in parkin-associated PD and in particular on the impact of the different mutations in the ERAD.

2819T

A nonsense mutation in DHTKD1 causes Charcot-Marie-Tooth disease type 2 in a large Chinese pedigree. *M. Gu[1], W. Xu[1], L. Sun[1], W. Guo[1], J. Ma[2], S. Chen[2], W. Huang[3], Z. Wang[1,4].* 1) Department of Medical Genetics, Shanghai Jiao Tong University School of Medicine (SJTUSM), Shanghai, China; 2) Department of Neurology and Institute of Neurology, Rui-Jin Hospital Affiliated to SJTUSM, Shanghai, China; 3) Chinese National Human Genome Centre at Shanghai, Shanghai, China; 4) Shanghai Research Centre for Model Organisms, Shanghai, China.

Charcot-Marie-Tooth (CMT) disease represents a clinically and genetically heterogeneous group of inherited neuropathies caused by molecular defects in more than 40 different genes. Based on clinical manifestation and electrophysiological properties, CMT can be classified into autosomal-dominant demyelinating (CMT1) and axonal (CMT2), X-linked (CMT1X), and autosomal-recessive neuropathies. Here, we report a five-generation family of 8 affected individuals with CMT2. Genome-wide linkage analysis showed no linkage to any known loci for CMT2. However, the disease phenotype was found to be closely linked to chromosome 10p13–14, the region spanning 5.41 Mb between D10S585 and D10S1477. DNA sequencing of mutations in 20 candidate genes in this region revealed a nonsense mutation c.1455T>G (p.Tyr485X) in exon 8 of dehydrogenase E1 and transketolase domain containing 1 (DHTKD1) in all 8 patients, but not in other unaffected individuals in this family and 250 unrelated normal persons. DHTKD1 mRNA level in peripheral blood of patients was found to be reduced to half of that in unaffecteds. In vitro studies showed that DHTKD1Tyr485X mRNA and truncated protein significantly decreased with rapid mRNA decay in transfected cells when compared to wild-type DHTKD1. Inhibition of nonsense-mediated mRNA decay (NMD) by UPF1 silencing was found to effectively rescue the decreased levels of mutant mRNA and protein. More importantly, both DHTKD1 silencing and overexpression of DHTKD1Tyr485X led to impaired energy production evidenced by decreased ATP, total NAD+ and NADH, and NADH levels. Thus, we identified a previously uncharacterized mutation in DHTKD1 as one of the causes of CMT2, implicating an important role of DHTKD1 in mitochondrial dynamics and neurological development.

Identification of the SPG46 gene by next generation sequencing in four families with autosomal recessive complicated spastic paraplegia. *G. Stevanin[1,2,3], R. Schule[4], K. Smets[5], E. Martin[1,3], S. Zuchner[6], L.J. Loureiro[7], A. Boukhris[8], A. Rastetter[1,3], T. de Coninck[5], M. Gonzalez[6], E. Mundwiller[1], F. Lamari[9], G. Gyapay[10], P. Coutinho[7], C. Mhiri[8], P. de Jongue[5], E. Kabashi[1], A. Brice[1,2].* 1) INSERM / UPMC UMR_S975 - NEB, Paris, France; 2) AP-HP, Groupe Hospitalier Pitié-Salpêtrière, Département de Génétique et Cytogénétique, Paris, France; 3) Ecole Pratique des Hautes Etudes, Paris, France; 4) University of Tuebingen, Germany; 5) University of Antwerp, Antwerpen, Belgium; 6) University of Miami, USA; 7) UnIGENe and Centro de Genética Preditiva e Preventiva, Institute for Molecular and Cellular Biology, Porto, Portugal; 8) Service de Neurologie, Hôpital Universitaire Habib Bourguiba Sfax, Tunisia; 9) APHP, Groupe Hospitalier Pitié-Salpêtrière, Service de Biochimie, Paris, France; 10) Genoscope, Evry, France.

Hereditary spastic paraplegias (HSP) are genetically and phenotypically heterogeneous disorders with various clinical profiles and modes of transmissions. The SPG46 locus was first reported to account for a rare form of complicated autosomal recessive spastic paraplegia mapped to chromosome 9. Using the next generation sequencing, we identified four different mutations in GBA2, including three truncating and one missense variants, that were found to segregate with the disease in four families. The overall phenotype was a complex HSP with mental impairment, cataracts and hypogonadism in males associated with thinning of the corpus callosum at brain MRI. Antisense morpholino oligonucleotides targeting the zebrafish GBA2 orthologous gene led to abnormal morphology and motor behaviour that were rescued by using the human wild type mRNA but not with the same mRNA carrying the missense change identified in two families. GBA2 encodes a microsomal non-lysosomal glucosylceramidase, an enzyme that catalyzes the conversion of glucosylceramide to free glucose and ceramid and the hydrolysis of bile acid 3-O-glucosides. The identification of the SPG46 gene is the starting point for the elucidation of the mechanisms underlying axonal degeneration in this complicated form of HSP and highlights lipid metabolism in these diseases.

2821W

A balanced (1q32;14q31) translocation associated with epilepsy, learning disability and leukaemia has breakpoints in developmental genes as detected by whole-genome sequencing. *M.I. Rees[1], S. Ali[1], R.H. Thomas[1], J.G. Mullins[1], M. Kerr[2], S.K. Chung[1].* 1) Neurology Research & Molecular Neuroscience, College of Medicine, Swansea, United Kingdom; 2) Centre for Learning Disability, Cardiff University, Cardiff, United Kingdom.

Next generation sequencing (NGS) technologies are rapidly evolving human genomic research and in the continual hunt for disease-causing genes. In a proof-of-principle experiment, whole-genome sequencing was used to identify the physical breakpoints in a constitutional translocation involving chromosomes 1q32 and 14q31 in an index-case with epilepsy, learning disabilities (LD) and a familial history of aggressive, treatment-resistant acute myeloid leukaemia (AML). Whole-genome sequencing revealed the exact translocation breakpoint confirming a gene-fusion between coding regions on chromosome 1 and chromosome 14 and was validated by Sanger sequencing. The gene on chromosome 1 has an unknown function and is poorly documented in the literature, whilst the gene on chromosome 14 is a neurodevelopmental regulator of the cell cycle and belongs to the FOX gene family. There is potential for the disrupted genes to have synergistic multi-system consequences and the coding regions of both genes have been used to mutation-screen panels of idiopathic epilepsy, learning disabilities, and cytogenetic-negative AML cases. We will present the exact nature of the gene fusion and the outcomes of the mutational scanning in the core phenotype presentations and the preliminary molecular characteristics of any fusion protein possibilities. These findings have predictive value for the at-risk members of the family and presented 2 new genes that may have impact in neurodevelopmental disorders and AML predisposition.

2822T

A *DYNC1H1* mutation causes a quadriceps-dominant neurogenic muscular atrophy. *S. Saitoh[1], Y. Tsurusaki[2], K. Tomizawa[3], A. Sudo[4], N. Asahina[5], H. Shiraishi[5], J. Ito[6], H. Tanaka[7], H. Doi[2], H. Saitsu[2], N. Miyake[2], N. Matsumoto[2].* 1) Dept Pediatrics, Nagoya City Univ, Nagoya, Japan; 2) Dept Human Genetics, Yokohama City Univ, Yokohama, Japan; 3) Dept Pediatrics, Nakashibetsu Town Hosp, Nakashibetsu, Japan; 4) Dept Pediatrics, Sapporo City General Hosp, Sapporo, Japan; 5) Dept Pediatrics, Hokkaido Univ, Sapporo, Japan; 6) Dept Pediatrics, Taiyo no sono, Date, Japan; 7) Dept Pediatrics, Asahikawa Habilitation Center, Asahikawa, Japan.

Exome sequencing unexpectedly identified a *DYNC1H1* mutation (c.917A>G; p.H306R) in a family presenting with a unique quadriceps-dominant form of neurogenic muscle atrophy. Two half sibs showed motor developmental delay and non-progressive muscle weakness and wasting predominantly in their quadriceps femoris muscle with different severity. Their mother was most mildly affected and only showed difficulty in squatting. Distal lower limbs were relatively preserved and upper limbs were not affected. Sensory involvement was indistinct. Muscle CT revealed muscle atrophy predominantly in quadriceps femoris muscle. Nerve conductive study revealed normal results in two sibs, while electromyography showed neurogenic change. Muscle biopsy from quadriceps femoris muscle of the elder sib showed grouping atrophy, presence of enlarged muscle fibers and fiber type grouping consistent with neurogenic etiology. The same mutation in *DYNC1H1* was recently reported in a pedigree with the axonal form of Charcot-Marie-Tooth disease, while three missense mutations (p.I584L, p.K671E, p.Y970C) were identified in familial patients with dominant spinal muscular atrophy with lower extremity predominance (SMA-LED). Our patients showed consistent clinical features with SMA-LED. Two de novo missense mutations (p.E1518K, p.H3822P) have also been identified in patients with severe intellectual disability and variable neuronal migration defects. Our study has confirmed that the same *DYNC1H1* mutation found in distal neuropathy also causes predominant motor neuron involvement, and suggests broad phenotypic effects of *DYNC1H1* mutations.

Late-onset Charcot-Marie-Tooth disease 4F caused by periaxin gene mutation. *S. Tokunaga[1], A. Hashiguchi[1], A. Yoshimura[1], K. Maeda[2], T. Suzuki[3], H. Haruki[4], T. Nakamura[1], H. Takashima[1].* 1) Dept Neurol Genetics, Kagosima university, Japanese Society of Neurology, Kagoshima, Japan; 2) Dept Neurol, National Hospital Organization Shiga hospital, Japanese Society of Neurology, Shiga, Japan; 3) Dept Neurol, joetsu General Hospital, Japanese Society of Neurology, Niigata, Japan; 4) Dept Neurol, Yamaguchi University Gtaduate School, Japanese Society of Neurology, Yamaguchi, Japan.

We identified the main features of Charcot-Marie-Tooth (CMT) disease, type 4F, caused by a periaxin gene (PRX) mutation in Japanese patients. Periaxin is known as one of the key myelination molecules, forming tight junction between myelin loop and axon. We collected 427 DNA samples from individuals with CMT or CMT-related neuropathy, negative for PMP22 duplication. We investigated PRX mutations using a purpose-built resequencing array screen during the period 2006–2012. We detected two types of PRX mutations in three patients; one patient showed a novel homozygous p.D651N mutation and the other two showed homozygous p.R1070X mutation. All PRX mutations reported so far have been of nonsense or frameshift type. In this study, we found homozygous missense mutation p.D651N. Aspartate 651 is located in a repeat domain; its position might indicate an important function. PRX mutations usually lead to early-onset, autosomal-recessive demyelinating Charcot-Marie-Tooth neuropathy 4F (CMT4F) or Dejerine-Sottas disease; their clinical phenotypes are severe. In our three patients, the onset of the disease was at the age of 27 years or later, and their clinical phenotypes were milder compared with those reported in previous studies. We showed a variation of clinical phenotypes for CMT4F caused by a novel, nonsense PRX mutation. .

Detection of slipped-DNAs at the trinucleotide repeats of the myotonic dystrophy type I disease locus in patient tissues. *M.M. Axford[1,2], Y-H. Wang[3], M. Nakamori[4], M. Zannis-Hadjopoulos[5], C. Thornton[4], C.E. Pearson[1,2].* 1) Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto,Toronto, Ontario, Canada; 3) Department of Biochemistry, Wake Forest University School of Medicine, Winston-Salem, NC, USA; 4) Department of Neurology, University of Rochester School of Medicine and Dentistry, Rochester, New York, USA; 5) Goodman Cancer Research Centre and Department of Biochemistry, McGill University, Montreal, QC, Canada.

Slipped-strand DNAs, formed by out-of-register mispairing of repeat units on complementary strands, were proposed over 50 years ago as transient intermediates in repeat length mutations, hypothesized to cause at least 30 neurodegenerative diseases. While slipped-DNAs have been characterized in vitro, evidence of slipped-DNAs at an endogenous locus in biologically relevant tissues, where instability varies widely, is lacking. The largest expansions typically arise in non-mitotic tissues such as cortex and heart. Here, using an anti-DNA junction antibody and immunoprecipitation, we identify slipped-DNAs at the unstable trinucleotide repeats (CTG)n•(CAG)n of the myotonic dystrophy disease locus in patient brain, heart, muscle and other tissues. Slipped-DNAs were present in chromatinized DNA. We characterized slipped-DNAs as clusters of slip-outs along a DNA, with each slip-out having 1–100 extrahelical repeats, where their levels correlate with the degree of repeat instability between tissues. Surprisingly, this supports the formation of slipped-DNAs as persistent products of repeat instability, and not merely as transient intermediates. These findings further our understanding of genetic variation and have prognostic implications.

2825T

A lyonization study in heterozygous females for X-linked Adrenoleukodystrophy. *F.S. Pereira[1], C. Habekost[2,3], U. Matte[1,3], L.B. Jardim[2,3,4,5].* 1) Gene Therapy Center, Experimental Research Center, Hospital de Clínicas de Porto Alegre, Rio Grande do Sul, Brazil; 2) Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Brazil; Post-Graduation Program in Genetics and Molecular Biology, Universidade Federal do Rio Grande do Sul, Brazil; 3) Post-Graduation Programs in Genetics and Molecular Biology, Universidade Federal do Rio Grande do Sul, Brazil; 4) Post-Graduation Programs in Medical Sciences, Universidade Federal do Rio Grande do Sul, Brazil; 5) Department of Internal Medicine, Hospital de Clínicas de Porto Alegre, Brazil.

The X-linked Adrenoleukodystrophy (X-ALD - OMIM 300100) is a genetic disorder of metabolism of peroxisomes, where the degradation of very long saturated fatty acids (VLCFA) is prevented or very limited. X-ALD is caused by a defect in the gene for the adenosine triphosphate (ATP)-binding cassette protein, subfamily D, member 1 (*ABCD1*) located on Xq28. X-ALD affects mainly the adrenal cortex, the myelin of the central nervous system and the central and peripheral axons of affected males. For unclear reasons, many heterozygous women develop a neurological condition in adulthood. The main hypothesis relates this to chromosome X lyonization. Aim: to assess the pattern of chromosome X inactivation in heterozygous women for X-ALD thereby identifying the predominantly expressed allele in women carriers. Methods: We selected heterozygous women belonging to families X-ALD accompanied in Medical Genetics Service from Hospital de Clínicas de Porto Alegre. Initially the *HUMARA* locus was amplified by PCR for identification of informative women (*HUMARA* carriers of alleles with different sizes). The informative samples were digested with *HpaII* enzyme and the chromosome X inactivation (CXI) skewness was calculated. We used a ratio of the area of the smaller peak (digested allele) to the sum of the areas of the smaller and larger peak (non digested allele). Results: Fifty-four women were included from 28 X-ALD families with at least one heterozygous woman molecularly identified. Among them, 90.7% (49/54) were informative for the *HUMARA* locus. Of the 17 women studied to date, 47% (8/17) showed a extremely skewed pattern of CXI (<0.1). Discussion: These data seem to indicate that most women heterozygous for X-ALD show a skewed pattern of lyonization. If this pattern will be related to phenotypic variability, remains to be studied.

Mutations in CUL4B, a member of the Cullin-RING ubiquitin ligase complex, cause syndromic X-linked intellectual disability associated with short stature. *A.K. Srivastava[1,3], M. Cook[1], K. Corrier[2], L. Lee[2], S.S. Cathey[1], F. Bartel[1], K.R. Holden[1], C. Skinner[1], A.D. Chaubey[1], B.R. DuPont[1], N. VerBerkmoes[2], R.J. Schroer[1].* 1) J. C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 2) Chemical Science Division, Oak Ridge National Laboratory, Oak Ridge, TN; 3) Department of Genetics & Biochemistry, Clemson University, Clemson, SC.

The ubiquitin-proteasome protein degradation pathway plays a major role in regulating expression levels of specific proteins in cells, and aberrations in this pathway have been implicated in the pathogenesis of several neurodevelopmental disorders, including intellectual disability (ID). Recently, we and others have identified mutations in CUL4B, a member of the Cullin-RING ubiquitin ligase complex, in patients with X-linked intellectual disability (XLID) syndrome. Here we report a novel CUL4B nonsense mutation (p.L163X) in two affected brothers with ID, grand mal seizures, relative macrocephaly, and short stature. In addition, we identified a novel copy number gain of approximately 2 kb involving the genomic region within the CUL4B gene in a male patient with severe cognitive impairment, short stature, behavioral issues and distinct facial features. Both alterations were inherited from phenotypically normal mothers who had highly skewed X-inactivation and expressed only the wild type CUL4B allele. The male patient with the duplication involving the CUL4B gene showed significantly reduced quantity of CUL4B transcript but no detectable wild type CUL4B protein. The CUL4B mutant allele in one of the affected male with the nonsense mutation was not completely degraded by the nonsense-mediated decay mechanism and produced a truncated CUL4B protein retaining the predicted nuclear localization signal but lacking the C-terminal cullin domain. In cultured neuronal cells, the truncated CUL4B protein was primarily localized to the nucleus and affected neurite outgrowth. Quantitative proteome analysis of lymphoblastoid cells (LCLs) from the patient with the p.L163X mutation and a normal control revealed several up-regulated proteins in the patient's LCLs that appear to be clinically relevant targets of CUL4B-mediated protein ubiquitination and degradation. Altogether, our study underlines the importance of the ubiquitin-proteasome protein degradation pathway in the pathogenesis of ID and provides insight into the underlying molecular and cellular mechanisms by which CUL4B impacts ID.

2827W

IDENTIFICATION OF NOVEL EXON SPLICE ENHANCERS (ESEs) IN THE GROWTH HORMONE GENE (*GH1*) MUTATED IN ISOLATED GH DEFICIENCY (IGHD). *D. Babu, I. Fusco, S. Mellone, M. Godi, A. Petri, F. Prodam, S. Bellone, P. Momigliano-Richiardi, G. Bona, M. Giordano.* Department of Health Sciences, University of Eastern Piedmont, Novara, Italy.

IGHD type II is may be caused by alteration of an ESE located at the first 7bp of exon 3 (ESE1), resulting in an increased level of the exon 3-skipped mRNA, normally present at low doses (about 5% relative to the wild-type mRNA). An increased level of this isoform, encoding a 17.5 kDa protein was demonstrated to exert a dominant negative effect on the secretion of the 22-kDa isoform, independently from the level of the wild-type. Another ESE (ESE2) was detected by *in vitro* mutagenesis from E3+19 to E3+32. We identified 3 IGHD patients out of 157 carrying variations in the *GH1* exon 3. Patient #1carried an already reported non-synonymous mutation E3+75G>C (Glu82Asp), patient #2 carried the two variations E3+90 C>T (Pro87Pro) and E3+101 A>T (Glu91Val) and patient #3 carried E3+90 C>T (Pro87Pro) and E3+84 G>A(Pro85Pro). These variants were absent in a panel of 400 normal chromosomes and were all originated by gene conversion events from one of the *GH1* cluster homologous genes. None of them was included in the already identified ESEs. However the *in silico* analysis suggested the presence of two other ESEs at nt E3+83-89 (ESE3:CGACACC) and E3+98-104 (ESE4:GGGAGGA). The mutations at positions E3+84 and E3+101 were predicted to completely abolish ESE3 and ESE4, respectively. We thus performed *in vitro* splicing analysis with constructs bearing the wild type *GH1*, and the *GH1* gene carrying the different mutations identified in the patients. The mRNAs from transfected GH4C1 rat pituitary cells showed the same level of the 22 kDa isoform in all the constructs. The GH-E3+75G>C mRNA splicing pattern was similar to that of the wild-type with the 17.5 kDa about 2–5% relative to the wild-type. Conversely, the GH-E3+84G>A and GH-E3+101A>T exhibited a significantly higher level of the 17.5 kDa band (about 30–35% with respect to the wild-type). Interestingly the 17.5 kDa isoform was completely absent in the GH-E3+90C>T mRNA. In conclusion we identified two novel ESEs in the *GH1* exon3 through the detection of mutations in IGHD patients. Two of these mutations E3+84 G>A and E3+101 A>T, cause an increased level of the dominant negative 17.5 kDa isoform. The analysis of the parents of the patients will reveal whether the mutations were inherited from the same parent or one from each parent or if they are *de novo* mutations.

2828T

Functional analysis of R75Q dominant mutation and in cis recessive mutation V37I of GJB2 gene causing hearing loss in a Korean Family. *J. Kim[1], J. Jung[2], Y. Kim[3], J. Choi[2], K. Lee[3].* 1) Lab Med, Yonsei University Wonju College of Medicine, Wonju, South Korea; 2) Otorhinolaryngology, Yonsei University College of Medicine, Seoul, South Korea; 3) Lab Med, Yonsei University College of Medicine, Seoul, South Korea.

Among different genes responsible for hereditary hearing loss, mutations in GJB2 gene, which encodes the gap junction protein connexin 26, are the most common cause of non-syndromic hereditary hearing loss. Interestingly, the phenotypic variation has been observed in different types of mutations. Here, we report a Korean family harboring two mutations R75Q which was reported as a dominant mutation and V37I reported as a recessive mutation in cis. Previously, R75Q has been reported in a family with hearing loss which was rescued by another recessive mutation c.35delG, which was located upstream of R75Q in cis, and the cause of the hearing loss in that family could not be identified. In our study, the propositus reported a bilateral sensorineural form of hearing loss with onset at 4 years and similar form of hearing loss was present in her father. Her grandparents and 7 siblings of her father were not affected. The sequencing analysis of GJB2 gene revealed R75Q and V37I mutations in affected individuals. The grandfather of the propositus had only heterozygote V37I and grandmother and siblings of the propositus' father revealed no mutation in GJB2 gene. Single strand DNA sequencing confirmed that R75Q and V37I resided on the same allele. Thus, R75Q arose de novo in propositus' father and transmitted to his daughter. In the biochemical permeability assay for different genotypes, we examined the cell-to-cell transfer of the impermeant dye Lucifer Yellow. Both the R75Q alone, and R75Q with V37I variant displayed highly defective intercellular dye transfer while V37I revealed a moderate deficit in GJ mediated biochemical coupling. For hemichannel functional study, the entry of PI dye through hemichannels was evaluated. As a result, cells transfected with R75Q and R75Q+V37I displayed significantly lower PI loading, indicating greatly reduced hemichannel activity. The PI loading efficiency was not significant between R75Q and R75Q+V37I. The V37I transfected cells demonstrated hemichannel activity reduced to less than 50% of the wild type. In contrast to other family harboring R75Q and c.35delG in cis, when a dominant mutation is in cis with a recessive mutation that does not cause premature protein truncation is not effected by the recessive mutation. Interpretation of mutations in GJB2 gene should be carefully reviewed and more in depth functional study is needed to help genetic counseling in families with hereditary hearing loss to avoid misguidance.

2829F

Progressive hearing impairment with homozygous deletion in GJB2 gene (Connexin-26) und normal newborn hearing screening. *N. Lublinghoff[1], E. Löhle[2], R. Birkenhäger[1].*1) University Medical Center Freiburg, Department of Otorhinolaryngology Killianstr. 5, D-79106 Freiburg, Germany (Head of Department: R. Laszig, PhD); 2) Department for Phoniatrics and Paedaudiology of the Department of Otorhinolaryngology of the University Medical Center Freiburg, Lehener Str. 88, D-79106 Freiburg, Germany (Head of Department: E. Löhle, PhD).

Hearing impairment is the most common sensorineural disease in humans. About one per 500 to 1000 neonates suffers at birth or in the first years from high-grade to severe hearing impairment. In 50% genetic alterations are the cause of prelingual hearing impairment. Another 50% of prelingual non-syndromic hearing impairment can be attributed to mutations in the GJB2 gene. The most widespread genetic change is the deletion mutation c.35delG, this means a total loss of function. In the studied patient population we have 133 patients with a homozygous deletion mutation in GJB2 gene (c.35delG) and 27 patients who are heterozygous for this mutation on one allele and heterozygous for another loss-of- function mutation in GJB2 gene. We found a normal newborn hearing screening (oto-acoustic emissions, OAE) in 8,6% and a progressive hearing impairment in 20,6%. Analysis of the literature revealed that various teams have similarly concluded that some of the patients with the homozygous gene defect c.del35G have unremarkable findings in neonate hearing screening. Cryns et al. showed in about 11% of the cases they examined that a mild to moderate hearing impairment was initially observed in patients with the homozygous gene defect c.del35G. Snoeckx et al. reported even higher results in an international multicenter study, in which about 28% of 889 patients who carried the above homozygous gene defect presented initially with mild to moderate hearing impairment. This group found similar results in other homozygous function-loss mutations. Pargarkar et al., Norris et al. and Putcha et al. also demonstrated this in a smaller percentage of their patients. Orzan et al. showed that in just over 50% of 79 children who later presented with severe hearing impairment had normal findings in the first 3–6 months of life in the neonate hearing screening. This fact suggest that homozygous deletion mutation in GJB2 gene (c.35delG) does not always contribute to an congenital hearing impairment, but to a progressive hearing loss that might develop over the first month and years of life. The molecular background is not fully understood. Possibly so called modifier genes attribute to different phenotypic characteristic in identical genotypes. Additionally, we have to reevaluate the value of OAE for newborn hearing screening, keeping in mind that one positive result is no warranty for a normal development of hearing function, but a result that should be checked in the course.

2830W

Bestrophin mutation within Ca^{2+} binding domain alters Cl^- conductance. *S. Brar[1], B. Pattnaik[1,2,3], P. Halbach[1], S. Tokarz[1], D. Pillers[1,3].* 1) Pediatrics, University of Wisconsin, Madison, WI; 2) Opthalmology, University of Wisconsin, Madison, WI; 3) Eye Research Institute, University of Wisconsin, Madison, WI.

Best Vitelliform Macular Dystrophy (Best's disease or BVMD) is an autosomal dominant juvenile-onset macular degeneration associated with more than 100 mutations in the 585 amino acid protein, bestrophin. Clinical and histological features of BVMD include vitelliform lesions in the macula. A distinct genotype-phenotype correlation based on these mutations has yet to be delineated, and may be due in part to the impact on the three dimensional structure and function of the protein in the context of the mutation. Bestrophin is a Cl- ion-channel present in the retinal pigment epithelium (RPE), and is activated by intracellular Ca2+. The RPE is a monolayer of post-mitotic cells located between the neural retina and the choroidal vasculature. Ion channels in the RPE support many functions by controlling the ion and nutrient environment of the photoreceptors, and by forming the blood-retinal barrier. We hypothesized that mutations that affect Cl- conductance are a basis for some of the retinal phenotypes associated with BVMD. We sought to physiologic phenotype disease associated mutation, Asn296His, located within the hotspot Ca2+-binding domain. Using site-directed mutagenesis, we introduced the Asn296His within human bestrophin protein (hBest1). The physiology of the wildtype and mutant protein was tested by transiently expression in Chinese Hamster Ovary (CHO) cells. Whole cell current was measured after inducing intracellular Ca2+ changes by activation of G-protein Coupled Receptor. We found that bestrophin functions as a Ca2+ activated Cl- channel. The Asn296His mutation generates a non- functional channel which does not respond to physiologic changes in intracellular Ca2+ in CHO cells. Permeability of the mutant channel to other anions is also altered. The mutation Asn296His is situated within the intracellular loop of bestrophin, which is comprised of a cluster of amino acid residues lining the Ca2+ binding pocket. We found that this mutation alters Ca2+ sensitivity of the channel which confirmed that Ca2+ binding gates this channel open. The results established a direct relationship between the Ca2+ binding site mutation and altered Cl- conductance in support of the hypothesis that hBest1 is a Ca2+-activated Cl- channel. By altering the physiological ionic homeostasis across the RPE, the photoreceptor outersegment is not metabolized resulting in the accumulation of debris between RPE and retina and thus the characteristic clinical phenotype.

Functional characterization of *SLC2A9* allelic variants in Czech population. *B. Stiburkova[1], O. Hurba[1], V. Krylov[1,2], A. Mencikova[2].* 1) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Czech Republic; 2) Department of Cell Biology, Faculty of Science, Charles University in Prague, Czech Republic.

Urate (uric acid) is the major end product of purine degradation in humans and higher primates. Serum urate concentration is determined by the balance between production and elimination. Correlation between increased serum uric acid level (hyperuricemia) and hypertension, cardiovascular disease, insuline resistance, metabolic syndrome and renal disorders has been described. Transport mechanisms for urate are localized in renal proximal tubule, where urate is secreted and extensively reabsorbed. The most causative gene influencing the level of serum uric acid is *SLC2A9* gene (transporter GLUT9). The aim of the project is to clarify frequency, role and the effect of allelic variants of urate transporter *SLC2A9* to the serum level of uric acid in statistically significant cohort of Czech population. Methods used: retrospective cohort of 869 subjects, which were already biochemically and clinically characterized; selection of 150 subjects with normouricemia and 59 subjects with pathological levels of serum uric acid. After identification of allelic variants (PCR amplification and sequencing analysis) further detailed studies using expression system of *Xenopus laevis* oocytes were performed. Analysis of *SLC2A9* revealed 14 sequence variations in the intronic regions. 12 allelic variants were found in exonic regions: six substitutions (p.S41S, p.L108L, p.T125T, p.G136G, p.I168I, p.L189L) and six transitions (p.G25R, p.T275M, p.D281H, p.V282I, p.R294H, p.P350L). cDNA mutant variants were prepared from both isoforms of wild type GLUT9 using mutagenesis kit. In vitro transcribed cRNAs were then microinjected into growing *Xenopus laevis* oocytes. The function analysis for *SLC2A9* including subcellular localization, colocalization and processing dynamics and transport of proteins are in process. Results from the study could contribute to the elucidation of genetic basis of serum uric acid concentration; clarify the interference among major urate transporter, hyperuricemia and gout. This study was supported by grant IGA MZ NT/11322-4/2010 from the Ministry of Health of the Czech Republic.

2832F

Identification of a missense mutation outside the forkhead domain of FOXL2 causing a severe form of BPES type II. *H. Haghighi-Kakhki[1], A. Haghighi[2], H. Verdin[3], N. Piri[4], N. Saleh-Gohari[5], E. De Baere[3].* 1) Faculty of Medicine, Mashhad Azad University, Mashhad, Iran; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 3) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 4) Department of Ophthalmology, Alavi Eye Hospital, Ardebil University of Medical Sciences, Ardebil, Iran; 5) Department of Genetics, Kerman University of Medical Sciences, Kerman, Iran.

Blepharophimosis-ptosis-epicanthus inversus syndrome (BPES) is a developmental disease characterized by a complex eyelid malformation associated or not with premature ovarian failure (POF). BPES is essentially an autosomal dominant disease, due to mutations in the forkhead box L2 (FOXL2) gene, encoding a forkhead transcription factor. More than one hundred unique FOXL2 mutations have been described in BPES in different populations, many of which are missense mutations in the forkhead domain. Here, we report on a very severe form of BPES resulting from a missense mutation outside the forkhead domain. A clinical and molecular genetic investigation was performed in affected and unaffected members of an Iranian family with BPES. The FOXL2 coding region was sequenced in an index case. Targeted mutation testing was performed in 8 family members. We have identified a heterozygous FOXL2 missense mutation c.650C>G (p.Ser217Cys) co-segregating with disease in members of a three-generation family with BPES type II. Only few missense mutations have been reported outside the forkhead domain so far. They were all found in mild BPES, in line with in vitro studies demonstrating mostly normal localization and normal or increased transactivation properties of the mutant proteins. Unlike previous studies reporting missense mutations outside the forkhead domain, affected members of the family studied here showed a severe BPES phenotype, with bilateral amblyopia due to uncorrected ptosis. As this was observed in all affected individuals of different generations, this might be attributed for instance to a cis-effect of regulatory variants within or outside the transcription unit modulating the expression of mutant FOXL2. This hypothesis was tested by sequencing of the UTRs and by copy number screening of the upstream regulatory domain of FOXL2, covering previously described regulatory deletions, but no variations were found. Several alternative possibilities, such as subtle sequence changes in regulatory elements, or promoter variations cannot be ruled out however. In conclusion, this is the first study demonstrating a severe BPES phenotype resulting from a FOXL2 missense mutation outside the forkhead domain, expanding our knowledge about the phenotypic consequences of missense mutations outside the forkhead domain in BPES. The phenotypic effect of the identified mutation seems to be tissue-specific, as no ovarian involvement was observed in any of the affected females here.

2833W

The UBIAD1 prenyltransferase links menaquione-4 synthesis to cholesterol metabolic enzymes. *M. Nickerson[1], A. Bosley[2], J. Weiss[3], B. Kostiha[1], W. Brandt[4], T. Andresson[2], T. Okano[5], M. Dean[1].* 1) Cancer & Inflammation Program, National Cancer Institute, Frederick, MD; 2) Laboratory of Proteomics and Analytical Technologies, SAIC-Frederick, National Cancer Institute, Frederick, MD; 3) Department of Ophthalmology, Louisiana State University, New Orleans, LA; 4) Department of Bioorganic Chemistry, Leibniz Institute of Plant Biochemistry, Halle (Saale), Germany; 5) Department of Hygienic Sciences, Kobe Pharmaceutical University, Higashinada-ku, Kobe, Japan.

Schnyder corneal dystrophy (SCD) is an autosomal dominant disease characterized by missense alterations of UBIAD1 and deposition of cholesterol in the cornea leading to progressive opacification and loss of visual acuity. UBIAD1 was recently shown to synthesize menaquinone-4 (MK-4), a form of vitamin K, but causal mechanisms of disease are unknown. Here we report novel genetic and biochemical data that clarifies the role of UBIAD1 in SCD. We report a novel G>A mutation altering UBIAD1 glycine 177 to glutamic acid (p.G177E) in six SCD families, including four families from Finland who share a likely founder mutation. We observed significantly reduced MK-4 synthesis by p.G177-mutant UBIAD1 due to disruption of transmembrane helices and active site residues. We show UBIAD1 binds to and co-localizes with HMGCR and SOAT1, enzymes catalyzing cholesterol synthesis and storage, respectively. Docking simulations indicated cholesterol bound to UBIAD1 in the substrate binding cleft and overlapped with GGPP binding, a MK-4 substrate, suggesting competition between metabolites. Impaired MK-4 synthesis is a first biochemical defect identified in SCD and suggests that topical administration of MK-4 should be investigated as a treatment for SCD patient corneas. Our data identifies a role for endogenous MK-4 in maintaining cornea health and visual acuity. These results are discussed in light of recent data showing vitamin k is an electron carrier in mitochondria able to reverse symptoms of Parkinson's disease.

2834T

Intergenic or 5'UTR deletion of Transcription factor 4 (TCF4) gene in Pitt-Hopkins syndrome. *J. Lee[1,3], S-U. Moon[1], E. Shin[2], S. Hassed[3], J. Chanloner[3], X. Wang[3], S. Li[3].* 1) Pathology, Korea University, Seoul, South Korea; 2) Genome Research Center, Neodin Medical Institute 2-3, Seoul, 133–847 Korea; 3) Department of Pediatrics, OUHSC, OK, 73014, USA.

Haploinsufficiency of transcription factor 4 (TCF4) gene, encoding a basic helix-loop-helix (bHLH) transcription factor, has been identified as the molecular mechanism underlying Pitt-Hopkins syndrome (PHS), which is characterized by mental retardation, distinctive facial features including a wide mouth, and intermittent hyperventilation followed by apnea. Recent analysis of 112 individuals with PHS delineated the TCF mutational spectrum, with 40% point mutations, 30% small deletions/insertions, and 30% microdeletions. Most of these were private mutations and generated premature stop codons. Here, we present two cases with intergenic deletion and one case with 5' UTR deletion of TCF4 gene in patients with PHS phenotypes. Reduced level of RNA expression of TCF gene was confirmed by subsequent real time quantitative PCR. In conclusion, haploinsufficiency of TCF gene due to the intergenic or 5' UTR deletions may not be rare and high density array CGH will facilitate the diagnosis of PHS.

2835F

No evidence of genetic difference for clinical severity between monozygotic twins with Rett syndrome. *T. Kubota[1], K. Miyake[1], T. Hirasawa[1], Y. Minakuchi[2], A. Toyoada[2].* 1) Department of Epigenetic Medicine, Interdisciplinary Graduate School of Medicine and Engineering, University of Yamanashi, Chuo, Yamanashi, Japan; 2) Comparative Genomic Laboratory, Center for Genetic Resource Information, National Institute of Genetics, Research Organization of Information and Systems, Mishima, Shizuoka, Japan.

Thanks to the advancement of sequencing technology, mutations have been identified in neuronal molecules as causes of neurodevelopmental disease such as autism. In order to identify a new related gene, we performed re-sequencing in discordant monozygotic twins with Rett syndrome. In this twins, twin 1 exhibited severe neurological features starting from infancy, whereas twin 2 showed no symptom until 3 years of age, although they share the same frame-shift mutation in MECP2 gene and have similar X-chromosome inactivation patterns in lymphocytes. We initially identified 28 twin 1-specific SNPs (130 billion bp, read coverage 43.3x) and 16 twin 1-specific SNPs (116 billion bp, read coverage 38.5x) by next-generation sequencing (Hiseq 2000, Solexa) in lymphocytes and differential 19 SNPs between the twins by array-based method (SNP/CNV BeadChip) in fibroblasts, but nor were any reproducible differences. Therefore, we did not find evidence of DNA-nucleotide differences that explained clinical severity. We are now currently investigating genetic differences in copy number variations and epigenetic differences in DNA methylation.

2836W

Two-nucleotide deletion of the ATP7A gene, leading not to premature termination, but to translation reinitiation, produces mild phenotype in a male Menkes disease patient. *T. Wada[1], T. Murakami[1], H. Shimbo[1], H. Osaka[1], H. Kodama[2].* 1) Pediatric Neurology, Kanagawa Children's Med Center, Yokohama, Kanagawa, Japan; 2) Dept Health Dietetics, Teikyo Heisei Univ, Tokyo, Japan.

It is important to determine the relationship between the clinical phenotype and genotype of genetic diseases in clinical practice. In general, frameshift mutations that is, any downstream change that adds or removes a non-integral number of codons, or a number of nucleotides that is not a multiple of three would be expected to produce a premature termination codon, or abnormal splicing. Nonsense-mediated decay works for these mutations, detecting mRNAs containing premature termination codons and degrading them, resulting in no expression of the mutated gene. So, in X-linked diseases, male patients with frameshift mutations are expected to have a severe or leven phenotype. Here, we report a case of an 11-month-old male patient with Menkes disease, an X-linked recessive copper metabolism disorder, caused by mutations in ATP7A (NIM300011). His genomic DNA shows two-nucleotide deletion at exon 4 out of 23 exons (c.1137_1138delTG) of the ATP7A gene, but his clinical phenotype involves unexpectedly mild symptoms. Characterization of his ATP7A mRNA shows no abnormal splicing. Analysis of ATP7A protein in cell lysate obtained from his cultured fibroblast shows a smaller form in size. Our findings suggest that translation reinitiation takes place at downstream internal codons, leading to the synthesis of N-terminally-truncated and partially functional Menkes proteins, which are probably missing of some copper-binding domains. Our results suggest that an apparent frameshift mutation cannot always lead to the production of a premature termination codon, and these patients can exhibit unexpectedly mild phenotypes.

Smith Magenis Syndrome (SMS) is a complex disorder associated with del17p11.2. SMS clinical presentation includes behavioral, sleep, skeletal, and neurological abnormalities among others. Most SMS features are caused by haploinsufficiency of the RAI gene, whose function remains poorly understood. With the goal of determining the underlying mechanisms linking RAI1 mutations with neurobehavioral phenotypes present in SMS we compared the phenotype of Rai1+/− mice (“Rai1 specific” model of SMS) with Df(11)17/+ mice (model of SMS with deletion of 17p11.2 syntenic region). Three main phenotypic domains were tested: social interactions, communication, and repetitive behaviors. We found that Rai1+/− mice showed a similar decrease in dominant behavior and increase in preference for social novelty as the Df(11)17/+ mice, confirming Rai1 main role in social behaviors. Given this link between Rai1 haploinsufficiency and impairment in social outcomes, we focused the analysis of RAI1 mutations found in SMS patients on transcriptional regulation of its endogenous target BDNF, a mediator of neural plasticity linked to social exposure. We defined two groups of mutations: 1) early truncating mutations and 2) missense mutations mapping to the C-terminal region. The first group exhibited exclusive cytoplasmic localization (in contrast to the nuclear localization of full length RAI1) and inability to activate transcription through the BDNF enhancer. We analyzed lymphoblastoid cells from a SMS patient carrying RAI1 c.3103insC, belonging to this first group, by cell fractionation and western blot. We found a protein of the size of truncated Rai1 in the cytoplasm fraction and another of full length size in the nucleus, confirming the in vitro data of abnormal localization of early truncation mutants of Rai1. The second group did not activate BDNF enhancer mediated transcription despite having a correct nuclear localization. In summary, our data further implicate Rai1 as a main player in the neuro-behavior aspects of SMS in mice. In addition, our in vitro results indicate that the different groups of mutations have different molecular outcomes. However; a common theme appears to be a reduction of total RAI1 transcription factor activity. This may explain the phenotypic similarity between SMS patients (and mouse models) harboring big deletions vs RAI1 mutations, and certainly gives a clue to explore therapeutic interventions.

2838F

RAB11FIP1 interacts with the BLOC-1 complex to retrieve melanogenic proteins from the recycling pathway and a dominant negative mutation in *RAB11FIP1* causes Hermanksy-Pudlak Syndrome Type 10 (HPS-10). *A.R. Cullinane[1], J. Pan[1], M.A. Merideth[1], J.A. Curry[1], J.G. White[2], M. Huizing[1], W.A. Gahl[1].* 1) Medical Genetics Branch, NHGRI (NIH), Bethesda, MD; 2) Department of Laboratory Medicine, University of Minnesota, Minneapolis, MN.

Hermansky-Pudlak Syndrome (HPS) is a genetically heterogeneous disorder of lysosome-related organelle (LRO) biogenesis and is characterized by oculocutaneous albinism and a bleeding diathesis. There are currently 9 known genes that cause HPS, all of whose protein products function in the biogenesis of LROs. The Biogenesis of Lysosome related Organelle Complex 1 (BLOC-1) contains 8 subunits but relatively little is known about the intracellular function of the complex, although a role in endosomal protein sorting has been suggested. Using his-tagged BLOC-1 subunits expressed in HEK293 cells and mass spectroscopy, we discovered that RAB11FIP1 is a novel interacting protein of the BLOC-1 complex. *RAB11FIP1* encodes a RAB11A interacting protein that homo-dimerizes to interact with RAB11A. A yeast-2-hybrid assay showed that the Dysbindin subunit of BLOC-1 directly interacts with RAB11FIP1; this was confirmed by co-immunoprecipitation and confocal immunofluorescence microscopy in melanocytes. Here we report a girl who had previously been screened for mutations in HPS-1 through HPS-6 and all the genes encoding the BLOC-1 complex. No mutations were found, although the patient had typical signs and symptoms of HPS and a cellular phenotype mimicking that of BLOC-1, i.e., increased plasma membrane cycling and endosomal accumulation of a melanogenic protein, TYRP1. Whole exome sequencing revealed a de novo heterozygous frameshift mutation in *RAB11FIP1*. The short protein fragment from this allele was expressed and interacted with the full-length protein, resulting in a dominant negative effect. Known cargos of the BLOC-1 complex in melanocytes are TYRP1 and ATP7A. How these cargos traffic to LROs was unknown, but we discovered that GFP-TYRP1 traffics to the plasma membrane, is endocytosed and only then directed to LROs. We demonstrated that TYRP1 interacts with the AP-1, AP-2 and AP-3 complexes, allowing this trafficking to occur. ATP7A, however, appears to traffic directly to endocytic vesicles, where RAB11FIP1 and the BLOC-1 complex are required for retrieval to LROs. Taken together, these data suggest a function of the BLOC-1 complex in retarding protein recycling by forming a physical brake between early endosomes (through the BLOC-1 interactor, Syntaxin-13) and recycling endosomes (through the BLOC-1 interactor, RAB11FIP1). This would allow more time for proteins to be retrieved from the endosomal compartment (by the AP-3 complex) and directed to LROs.

Two novel RRM2B gene mutations in a patient with autosomal recessive progressive external ophthalmoplegia, encephalopathy and cytochrome c oxidase deficiency.N. *S. Hauser[1], R. Bai[2].* 1) Medical Genetics, Childrens Hospital Central California, Madera, CA; 2) GeneDx Inc, Gaithersburg, MD 20877.

Abstract: We describe a male child born to healthy parents at 32 weeks gestation. Baby was 5lbs 9oz. He remained in the NICU for several weeks. He had difficulty with GERD in the first months of life, but no other medical problems. The patient was the third child in a sibship of 3, the 2 siblings were healthy. Mother described him as a placid baby, never demanding, with myopathic facial features. Parents described him as “weaker” as compared to his other siblings. At 7 mos of age he was still working on head control, and had not yet achieved the ability to sit up. Five days prior to admission at 7.5mos of age, he lost head control and the ability to eat. Parents brought him to the local ER, where he was admitted. During his admission, he became progressively weaker. He eventually required a tracheostomy and g-tube. Currently, he has minimal spontaneous movement, ophthalmoplegia, ptosis and seizures. The diagnosis of cytochrome C oxidase deficiency was made from muscle biopsy. The muscle biopsy showed abnormal mitochondria with structural abnormalities, reduced cytochrome C oxidase by enzyme histochemistry and increased neutral lipid. Mitochondrial respiratory chain testing showed a reproducible deficiency in cytochrome C oxidase activity to 13% of the normal reference mean. Complexes II-III were also reduced at 16% of the normal mean. Citrate synthase activity was elevated at 234% of control, a marker for mitochondrial content. Molecular Genetic Testing: Sequencing results of the following individual genes-SCO1, SCO2, SURF1, COX10, COX15, COX6B1, and FASTKD2 were normal. Sequence analysis of a panel of 24 nuclear genes (BCS1L, COQ2, COX10, COX15, COX6B1, DGUOK, DLD, MPV17, OPA1, PDHA1, PEO1, POLG, POLG2, RRM2B, SCO1, SCO2, SLC25A4, SUCLA2, SUCLG1, SURF1, TACO1, TIMM8A, TK2, and TYMP) identified two heterozygous novel missense mutations in the RRM2B gene- G200E (c.599 G>A, GGA>GAA) and E105K (c.313 G>A, GAA>AAA), both are non-conservative amino acid changes, at highly conserved positions, not seen in the general population or any available online mutation/variant database, and are predicted to be disease-causing. No multiple mtDNA deletions were detected in the patient's muscle specimen by long range PCR. The mtDNA content of the patient's muscle biopsy was approximately 2% of age matched controls. Conclusion: We conclude the cytochrome C oxidase deficiency noted on this patients muscle biopsy is caused by these two novel mutations in the RRM2B gene.

Isogenic D4Z4 contracted and non-contracted immortal muscle cell clones as a model for FSHD. *S. van der Maarel[1], Y. Krom[1], J. Dumonceaux[2], K. Mamchoui[2], B. den Hamer[1], V. Mariot[2], E. Negroni[2], L. Geng[3], R. Tawil[4], S. Tapscott[3,5], B. van Engelen[6], V. Mouly[2], G. Butler-Browne[2].* 1) Human Genetics; S4-P, Leiden University Medical Center, Leiden, Netherlands; 2) Thérapie des maladies du muscle strié, Institut de Myologie, UM76, UPMC Université Paris 6, Paris, France; 3) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, Washington, United States of America; 4) Department of Neurology, University of Rochester, Rochester, New York, United States of America; 5) Department of Neurology, University of Washington, Seattle, Washington, United States of America; 6) Radboud University Nijmegen Medical Centre, Department of Neurology, Nijmegen, the Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is associated with a contraction of the D4Z4 repeat on chromosome 4. Contracted repeats show a reduction in heterochromatic markers and derepression of the DUX4 retrogene. The complex (epi)genetic etiology of FSHD and the high clinical variability complicates investigations on the pathogenic mechanism underlying FSHD. Taking advantage of the high prevalence of somatic D4Z4 repeat array contractions in FSHD we generated a clonal myogenic cell model from a mosaic patient where each clone is genetically identical except for the D4Z4 repeat array size, being either non-contracted or contracted. D4Z4 contracted and non-contracted clones retain their myogenic properties but D4Z4 contracted clones differ from non-contracted clones by a variegated pattern of DUX4 expression in sporadic nuclei. Consistently, the consequences of DUX4 expression can only be observed in D4Z4 contracted clones, including the differential expression of previously described DUX4 targets. In immunodeficient mice, D4Z4 contracted and non-contracted clones participate equally in in vivo muscle regeneration, further expanding the potential of these clones. These cell lines can be used for pair wise comparisons to identify FSHD-specific differences and are expected to become valuable tools for for high throughput drug screens.

MEFV Second Exon Variation Analysis in Familial Mediterranean Fever. *A.K. Kirectepe[1], G. Celikyapi Erdem[1], O. Kasapcopur[2], E. Tahir Turanli[1,3].* 1) Dr. Orhan Öcalgiray Molecular Biology-Biotechnology and Genetics Research Center, Istanbul Technical University, Istanbul, Turkey; 2) Department of Pediatric Rheumatology, Cerrahpasa School of Medicine, Istanbul University, Istanbul, Turkey; 3) Molecular Biology and Genetics Department, Science and Letter Faculty, Istanbul Technical University, Istanbul, Turkey.

Objective: Familial Mediterranean Fever is an autoinflammatory disorder, which is related with MEFV gen mutations and defects of expression regulation. Previous studies showed that there are different alternatively spliced forms of MEFV gene. Our group previously showed that second exon deleted MEFV transcript (MEFV-d2) is increased in FMF patients compared to healthy controls (p= 0.026). In this study, we aimed to analyze whether the transcript difference is related to second exon variations. Methods: DNA was isolated from venous blood of FMF patients and healthy controls, which are in attack-free period (N=50). Second exon of MEFV was sequenced. Analysis of the sequence results was performed by Genious 4.8.5 and was compared to MEFV variations from literature and infevers database. Results: D102D (FMF patients=44%, healthy controls=51%), G138G (FMF patients= 66%, healthy controls=71%), A165A (FMF patients=72%, healthy controls= 71%), and R202Q (FMF patients=61%, healthy controls=50%), which are located on second exon of MEFV, are the most commonly observed variations in FMF patients and healthy controls. Student T test analysis on FMF patients with healthy controls found no significant difference in MEFV-d2 mRNA levels between samples with or without variations. Conclusion: MEFV-d2 transcription difference was not related to MEFV second exon variations in our study sample. We aim to increase the sample size to assess the significance of our results.

Role of NLRP7 in Recurrent Hydatidiform Moles and Reproductive Wastage. *R. Slim[1], C. Messaed[1], E. Akoury[1], W. Chebaro[1], W. Buckett[1], J. Arseneau[1], P. Sauthier[2].* 1) McGill University, Montreal, Canada; 2) Hôpital Notre-Dame, Gynécologie oncologique.

Hydatidiform mole is an aberrant human pregnancy with no embryo that has puzzled scientists in all civilizations. To date, two genes, NLRP7 and C6orf221, with causal roles in this condition have been identified. NLRP7 is a major gene for this condition and is mutated in 50%–80% of analyzed patients with recurrent moles, depending on family history and ethnicity. C6orf221 is a recently identified gene and available data indicate that C6orf221 plays a minor role in the causality of recurrent moles because only 5% to 15% of analyzed patients with recurrent moles, who are negative for NLRP7 mutations, have mutations in C6orf221. NLRP7 is a member of the nucleotide oligomerization domain like-receptor protein with roles in inflammation and apoptosis. We showed that cells from patients with NLRP7 mutations have normal intracellular pro-ILB synthesis and processing but defective mature IL1B secretion. Within the cells, NLRP7 localizes to the Golgi, microtubule organizing center, and associates with microtubules. The association of NLRP7 with microtubules is in line with the postzygotic cleavage abnormalities leading to complex mosaicism and aneuploidies observed in some patients with NLRP7 mutations. We believe that the defective IL1B secretion of cells from patients with NLRP7 mutations make the patient more tolerant to the growth of aberrant molar conceptions and the retention of these conceptions to later gestational stages contribute to the molar phenotype. Our data implicate NLRP7 in several forms of reproductive wastage, unravel new mechanisms for reproductive wastage, and open new avenues of research to better understand gestational choriocarcinomas, which may develop after any type of pregnancy, but most commonly after hydatidiform moles.

A novel *GUCY2D* mutation, V933A, causes central areolar choroidal dystrophy. *A.E. Hughes[1], W. Meng[1], A.J. Lotery[2], D.T. Bradley[1].* 1) Centre for Public Health, Queen's Univ Belfast, Belfast, United Kingdom; 2) Clinical Neurosciences Research Group, University of Southampton, UK.

The purpose of our study was to identify the genetic cause of central areolar choroidal dystrophy (CACD) in a large Northern Irish family. We previously reported linkage of the locus for CACD in this family to an interval of approximately 5 cM on chromosome 17p13 flanked by polymorphic markers D17S1810 and CHLC GATA7B03. We undertook sequence capture, massively-parallel sequencing and computational alignment, base-calling and annotation to identify a causative mutation. Conventional sequencing was used to confirm the results. Deep sequencing identified a single-base substitution in guanylate cyclase 2D, membrane (retina-specific) (*GUCY2D*). The novel mutation segregated with the disease phenotype and resulted in substitution of valine by alanine at position 933, within the catalytic domain of the protein. It altered a motif that is strongly conserved in a large number of distantly related proteins across several species, and was predicted to have a damaging effect on protein activity. Mutations in *GUCY2D* have previously been associated with dominant cone rod dystrophies (CORD6) and recessive forms of Leber's congenital amaurosis (LCA). This is the first report of *GUCY2D* mutation causing CACD and adds to our understanding of genotype-phenotype correlation in this heterogeneous group of choroidoretinal dystrophies.

Novel splice site mutations in NPHS1 gene in Indian congenital nephrotic syndrome patients. *S. sharma, A. Bagga, M. Kabra.* All India Institute of Medical Sciences, New Delhi, India.

Congenital nephrotic syndrome (CNS) is defined as nephrotic syndrome that manifests within the first 3 months of life. Mutations in the NPHS1 gene encoding Nephrin, are a major cause for CNS. It is found at a relatively high frequency in Finns. Following approval by the Institute Ethics Committee and parental consent, we investigated the prevalence of disease-causing mutations in NPHS1 gene in 10 Indian patients with CNS. Mutation analysis was done for all the exons and exon/intron boundaries of NPHS1 gene using PCR and direct sequencing. Two novel homozygous splice site mutations were found in 2 different patients and were absent in 25 ethnically matched controls. The first mutation (c.712+2T>G) was present at donor splice site and the second mutation (c.713-2A>G) was present at acceptor splice site. The evaluation of splice sites and potential splice sites was performed using the Genie program http://www.fruitfly.org/seq_tools/splice.html) human splicing finder (http://www.umd.be/HSF/. Both the mutations were predicted to disrupt normal splicing and insertion of intronic sequence in mRNA. Our findings indicate that, even though CNS is not very common in India, it is important to include it as a possibility in genetic counselling.

Genetic Basis of Prune Belly Syndrome: Screening the Candidate Genes. *L. Baker, S. Harrison, C. Granberg, C. Villanueva.* Pediatric Urology, Univ Texas Southwestern, Dallas, TX.

Prune-belly syndrome (PBS) is a multi-system congenital anomaly complex of unknown cause. The male predominance of PBS and families with multiple individuals affected by PBS suggest a genetic basis. Recently, two genes, hepatocyte nuclear factor-1-beta (HNF1B) and muscarinic acetylcholine receptor M3 (CHRM3), have been found to cause PBS-like syndromes that included clinical features atypical for PBS. A PBS-like disorder was reported in 2 patients with large chromosomal deletions involving HNF1B, a transcription factor important in embryonic mesodermal and endodermal development. The CHRM3 gene was implicated after one inbred kindred with 6 affected brothers were found to carry a deleterious CHRM3 homozygous mutation. Previously, we found no significant point mutations in HNF1B in 32 PBS patients. Our objective was to test the role of these genes in PBS by screening for sequence mutations in CHRM3 and for copy-number variations (CNVs) in HNF1B. With IRB approval, PBS patients have been prospectively enrolled since 2001 in our Pediatric Genitourinary DNA Repository. DNA was extracted from blood lymphocytes for genetic testing. To assess for CHRM3 mutations, the 1773bp single coding exon of CHRM3 was PCR amplified and sequenced. A multiplex ligation-dependent probe amplification (MLPA) P241-B1 MODY kit (MRC Holland) was used to screen for CNVs in HNF1B and data analysis was performed with GeneMarker (Softgenetics) while a DNA sample with a known HNF1B microdeletion served as a control. DNA samples from 42 probands (40M:2F) with typical features of PBS were tested. Sequencing of the CHRM3 gene revealed no novel non-synonymous mutations in this cohort. MLPA testing for intragenic CNV in HNF1B in this PBS cohort revealed no microdeletions or microduplications. Although HNF1B and CHRM3 are candidate PBS genes, no genetic alterations in these genes were found in our large series of patients with typical PBS features, suggesting that mutations in CHRM3 and HNF1B are not common causes of typical PBS. Thus, the search for the genetic basis of PBS continues.

2846T

DNA Copy-Number Variations in Persistent Cloaca Patients. *S. Harrison, L. Baker.* Urology, Univ Texas Southwestern, Dallas, TX.

Persistent cloaca is a severe human malformation affecting females in which the urinary, genital, and lower intestinal tracts terminally converge to share a single common outlet channel, called a cloaca. Persistent cloaca occurs in 1:50,000 live births and requires multiple corrective surgeries. Cloaca is a devastating anomaly as upper renal tract malformations are commonly associated and as many as 50% of cloaca patients develop renal failure requiring dialysis or transplantation. Currently, only a few genes have been suggested to cause persistent cloaca, however mutations in the genes have only been found in isolated cases or in patients in which the cloaca phenotype is part of a multisystem syndrome. Genomic copy-number variations (CNV) have been shown to account for previously unexplained genetic diseases by identifying candidate genes or regions involved in various disorders. The purpose of this study was to analyze the role of CNVs in persistent cloaca patients. Blood samples from 14 cases of persistent cloaca were prospectively tested by whole genome comparative genomic hybridization (CGH) using the array version current (V8.1 or V8.3) at the time of ascertainment (Baylor Medical Genetics Laboratory, Houston TX). CNV screening by CGH identified 5 patients with abnormal results (~36%). Three cases had 0.240–1.113Mb duplications on 3p26.3, 16p11.206, and 21q22.3, all of which are likely benign. More importantly, two patients had possible cloaca-causing CNVs. The first case carries a 0.517Mb duplication on 16p13.2 encompassing a single gene. This CNV is paternally inherited, suggesting a possible cause of persistent cloaca as this phenotype only affects females. The second case of significance carries a de novo 7.341Mb deletion on 1q32.1q32.3 encompassing 47 genes. The fact that these CNVs are either paternally inherited or de novo suggests both regions are candidate regions for cloaca. Further investigations within these CNVs may lead to identification of causal genes for human persistent cloaca.

Whole genome sequencing reveals a deletion of the last exon of *FAN1* in Basenji dogs with adult-onset Fanconi syndrome. *G. S. Johnson[1], F. H. Farias[1], T. Mhlanga-Mutangadura[1], J. F. Taylor[2], D. P. O'Brien[3], R. D. Schnabel[2].* 1) Department of Veterinary Pathobiology, University of Missouri, Columbia, MO; 2) Division of Animal Sciences, University of Missouri, Columbia, MO; 3) Department of Veterinary Medicine and Surgery, University of Missouri, Columbia, MO.

Fanconi Syndrome (FS) is a generalized proximal tubule reabsorption deficiency, characterized by metabolic acidosis, amino aciduria, glucosuria, and phosphaturia. An autosomal recessive, adult-onset FS occurs in Basenji dogs. Linkage analysis and homozygosity mapping restricted the FS locus to 2.7 Mb of CFA3 containing 16 genes. We used NextGen sequencing technology (Illumina GAIIx and Hi-Seq 2000) to generate a 12.4-fold coverage whole genome sequence of a Basenji affected with FS. The reads were aligned to the canine genome reference sequence (build 2.1) with NextGENe software (SoftGenetics). None of the 244 annotated exons within the targeted region contained credible causal sequence variants; however, 16 exons fell partially or completely within gaps in the aligned basenji sequence, mostly associated with high G-C content. We therefore compared the depth-of-coverage profiles for the affected basenji sequence to profiles from similarly generated whole-genome sequences from 3 other dogs with different heritable diseases. A unique 334 bp gap was detected in the Basenji sequence. Sanger sequencing across the gap revealed a 321 bp deletion which included the last exon of *FAN1*. Homozygosity for the deletion allele was strongly associated with FS in a cohort of basenjis. The *FAN1* gene symbol stands for Fanconi-anemia Associated Nuclease 1, so named because its encoded protein, FAN1, interacts with components of the Fanconi anemia (FA) pathway for DNA-crosslink repair. FA and FS are two seemingly distinct diseases referred to with eponyms honoring Swiss pediatrician Guido Fanconi. The last exon of *FAN1*encodes part of a VRR-NUC nuclease domain, believed to be of functional importance. We here report that canine FAN1 deficiency causes FS, not FA as predicted by others based on previous cell culture experiments. If FAN1 deficiency is found to cause FS in additional species, the name of the gene can be changed to Fanconi-syndrome Associated Nuclease 1 without a gene symbol change.

Formation of a novel N-glycosylation motif in integrin α3 due to a rare *ITGA3* gene polymorphism causes congenital nephrotic syndrome and interstitial lung disease. *K.Y. Renkema[1], N. Nicolaou[1], C. Margadant[2], S.H. Kevelam[1], M.R. Lilien[3], M.J.S. Oosterveld[3], M. Kreft[2], A.M. van Eerde[1], R. Pfundt[4], P.A. Terhal[1], B. van der Zwaag[1], N. Sachs[2], R. Goldschmeding[5], N.V.A.M. Knoers[1], A. Sonnenberg[2].* 1) Medical Genetics, University Medical Center Utrecht, Utrecht, Netherlands; 2) Cell Biology, Netherlands Cancer Institute, Amsterdam, Netherlands; 3) Pediatric Nephrology, Wilhelmina Pediatric Hospital, University Medical Center Utrecht, Netherlands; 4) Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 5) Pathology, University Medical Center Utrecht, Netherlands.

Congenital nephrotic syndrome and interstitial lung disease is a rare multiorgan disorder, characterized by disrupted basement membrane structures. Causal *ITGA3* gene mutations were recently identified, but the underlying disease mechanism remained poorly understood. We describe a patient who presented with glomerulosclerosis, proteinuria, and neonatal respiratory distress, who died 7 months after birth due to respiratory insufficiency. A genome-wide screening for structural variations revealed a homozygous region of 19.2 Mb on chromosome 17 that included *ITGA3*. Sanger sequencing of the *ITGA3* gene that encodes integrin α3, revealed a homozygous missense mutation c.1045G>T; p.A349S, which was functionally characterized. Immunostaining in a transfected cell model showed appropriate cell surface localization for the wild-type but no surface localization for the mutant integrin α3. This was consistent with the lack of integrin α3 protein expression in the kidneys of our patient. Moreover, the mutation resulted in a *de novo* formation of an N-glycosylation motif, causing hyperglycosylation of integrinα3. Normally, integrin α3 forms heterodimers with integrin β1, though conformation of the mutant form was disrupted, preventing it from associating with β1 integrin. Increased ubiquitination supports that the mutant integrin α3 gets targeted for degradation before exiting the endoplasmatic reticulum. Our findings underscore the role of integrin α3β1 as the main regulator of basement membrane integrity in kidney tissue. We suggest that hyperglycosylation of integrin α3 finally resulting in complete lack of α3β1 expression on the basement membrane, is a new pathogenic mechanism causal for nephrotic syndrome and interstitial lung disease. Importantly, *ITGA3* gene screening was implemented in DNA diagnostics at our institute, having important consequences for genetic counseling of patients and their relatives.

2849T

Defining the phenotypic specificity of Schimke immuno-osseous dysplasia. *M. Morimoto, C. Myung, K. Beirnes, D. Leung, H.K. Fam, K. Choi, Y. Huang, C.F. Boerkoel.* Department of Medical Genetics, Child and Family Research Institute, University of British Columbia, Vancouver, BC, Canada.

Background: Schimke immuno-osseous dysplasia (SIOD), a rare autosomal recessive multisystem disorder, is caused by mutations in the *SMARCAL1* gene. The SMARCAL1 enzyme diffusely binds open chromatin and globally affects transcription. We hypothesize therefore that SMARCAL1 gives rise to the pathognomonic features of skeletal dysplasia, renal failure, immunodeficiency and vascular disease by pathologically altering the expression of specific genes in the affected tissues.

Methods: We assessed the genetic interactions of *SMARCAL1* with the Notch, Epidermal Growth Factor, Wingless, Decapentaplegic and Hedgehog developmental pathways through an F_1 genetic screen in *Drosophila melanogaster* to measure the suppression or enhancement of ectopic wing veins induced by the overexpression of SMARCAL1. We also assessed the expression of key developmental pathways in SIOD autopsy tissue through gene expression arrays, quantitative reverse transcriptase PCR and immunofluorescence.

Results: Mutations of the Notch pathway strongly enhanced, mutations of the Wingless and Epidermal Growth Factor pathways strongly suppressed, and mutations of the Decapentaplegic and Hedgehog pathways had no effect or weakly suppressed the ectopic wing vein phenotype of SMARCAL1 overexpression. Consistent with these observations, SMARCAL1-deficient patient kidney showed increased expression of several Notch signaling pathway members and targets.

Conclusion: We conclude that SMARCAL1 deficiency preferentially alters expression of specific genes in different tissues and thereby causes the pathognomonic features of SIOD. Specifically, we postulate that SMARCAL1 deficiency increases Notch signaling in the kidney to induce the focal segmental glomerulosclerosis of SIOD.

High-throughput mutation analysis in patients with a nephronophthisis-associated ciliopathy applying multiplexed barcoded array-based PCR amplification and next-generation sequencing. *E.A. Otto[1], J. Halbritter[1], K. Diaz[1], B. Tarrier[2], M. Chaki[1], C. Fu[1], J.L. Innis[1], S.J. Allen[1], R.H. Lyons[2], C.J. Stefanidis[3], H. Omran[4], N.A. Soliman[5,6].* 1) Dept Ped, Univ Michigan, Ann Arbor, MI; 2) DNA Sequencing Core, Univ Michigan, Ann Arbor, Michigan; 3) Pediatric Nephrology, "A. and P. Kyriakou" Children's Hospital, Athens, Greece; 4) Dept Ped and Adolescent Medicine, Univ Hospital Münster, Münster, Germany; 5) Center of Pediatric Nephrology & Transplantation, Cairo Univ, Cairo, Egypt; 6) Egyptian Group for Orphan Renal Diseases (EGORD), Cairo, Egypt.

Objective: To identify disease causing mutations within coding regions of 11 known NPHP genes (*NPHP1-NPHP11*) in a cohort of 192 patients diagnosed with a nephronophthisis-associated ciliopathy, at low cost. **Methods:** Mutation analysis was carried out using PCR-based 48.48 Access Array microfluidic technology (Fluidigm) with consecutive next generation sequencing. We applied a 10 fold primer multiplexing approach allowing PCR-based amplification of 480 amplicons (251 exons) for 48 DNA samples simultaneously. After 4 rounds of amplification followed by indexing all 192 patient-derived products with different barcodes in a subsequent PCR, 2×100 paired end sequencing was performed on one lane of a HiSeq2000 instrument (Illumina). Bioinformatics analysis was performed using "CLC Genomics Workbench" software. Potential mutations were confirmed by Sanger sequencing, shown to segregate with the affected status, and were absent from 96 control individuals. **Results:** NGS sequencing and bioinformatics analysis resulted in 62.1 million mapped reads with a median exon coverage depth of 449× per patient. Furthermore, 168/192 DNA samples (87.5%) and 134/251 exons (93.2%) consistently showed sufficient coverage depth above 30×, required for reliable heterozygous mutation calls. We identified pathogenic mutations in 35/192 patients (18%) and discovered 23 novel mutations in the genes *NPHP3* (7), *NPHP4* (3), *IQCB1* (4), *CEP290* (5),*RPGRIP1L* (1), *SDCCAG8* (2) and *TMEM67* (1). Additionally, we found 40 different single heterozygous missense variants of unknown significance. **Conclusions:** We conclude that the combined approach of array-based multiplexed PCR-amplification on a Fluidigm Access Array platform followed by NGS is highly cost-efficient and strongly facilitates diagnostic mutation analysis in broadly heterogeneous Mendelian disorders.

Founder mutation in *RPSPH4A* identified in patients of Hispanic descent with Primary Ciliary Dyskinesia. *M.A. Zariwala[1], M.W. Leigh[2], S.D. Davis[2], M.C. Armstrong[3], M.L. Daniels[3], J.L. Carson[3], M. Hazucha[3], S.S. Dell[4], M.R. Knowles[3], Genetic Disorders of Mucociliary Clearance Consortium.* 1) Department of Pathology & Laboratory Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 2) Department of Pediatrics, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 3) UNC School of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 4) The Hospital for Sick Children, Toronto, Ontario, Canada.

Primary ciliary dyskinesia (PCD) is an autosomal recessive, genetically heterogeneous disorder manifested by neonatal respiratory distress, otitis media, sinusitis, situs abnormalities (in ~50% term Kartagener syndrome), bronchiectasis, and male infertility. The diagnosis of PCD has traditionally been based on defining ciliary ultrastructural defects. Establishing a diagnosis is challenging as at least one-third of PCD patients are now recognized to have normal ciliary ultrastructure and/or questionable central apparatus (CA) defects (apparent in only a small portion of cilia). In PCD, nasal nitric oxide (nNO) levels are low (<100nl/min versus ~300nl/min for controls). Genetic testing is emerging as a diagnostic tool, and currently 14 genes are known to harbor mutations that account for two-thirds of PCD cases. Many of these genes have not been adequately tested in the large cohort of patients. *RSPH4A* encodes radial spoke head protein 4A, and mutations are reported in few PCD patients with CA defects. We performed mutation profiling in 32 unrelated patients who had a clinical phenotype of PCD (including situs abnormalities in 7 patients) and low nNO levels (<100 nl/min). Ciliary ultrastructure was variable in the 32 patients; 17 normal, 5 with CA defects and 10 with questionable CA defects. Sequencing of all 6 exons and splice-sites identified novel biallelic mutations in 4 patients of Hispanic descent of which 3 were homozygous for c.921-3_6delAAGT mutation and one was compound heterozygous for c.921-3_6delAAGT and c.1732_1733delG mutations. All of these patients had questionable CA defect. One patient of Caucasian descent was heterozygous for novel p.S39X mutation. None of the patients harboring mutations had situs abnormalities. Interestingly, 7 of the 9 mutant alleles were identical and present in patients of Hispanic descent, suggesting this may be a founder mutation. Reverse transcriptase PCR analysis on total RNA from lymphoblastoid cell lines from a patient harboring homozygous c.921-3_6delAAGT mutation revealed out-of-frame deletion of exon 2 (r.687_921del) leading to premature translation termination signal. In conclusion, IVS2-3_6delAAGT splice-site mutation in *RSPH4A* is a common cause of PCD in patients of Hispanic descent with questionable ciliary ultrastructure, and genetic testing for this mutation can ascertain PCD. This abstract was funded by MO1RR00046, UL 1 RR025747, R01HL071798, U54 HL096458-06, R01HL094976-02 and 5UC2HL102923-02.

Leri's pleonosteosis results from defective SMAD signaling. *S. Banka[1], S. Cain[2], J. Urquhart[1], S. Carim[1], S. Daly[1], G. Erdem[1], M. Bottomley[1], D. Donnai[1], B. Kerr[1], H. Kingston[1], C. Kielty[2], W.G. Newman[1].* 1) Department of Genetic Medicine, University of Manchester, Manchester, United Kingdom; 2) Faculty of Life Sciences, Wellcome Trust Centre for Cell-Matrix Research, Manchester, United Kingdom.

We report the novel molecular and phenotypic characterization of Leri's Pleonosteosis [MIM 151200]. This rare autosomal dominant condition is characterized by flexion contractures of the interphalangeal joints, limited motion of multiple joints, chronic joint pains, facial dysmorphism, bony overgrowths, short broad metacarpals, metatarsals and phalanges, short stature and scleroderma-like thickening of skin. We genotyped the two most distantly related individuals in a multigenerational family with Leri's pleonosteosis by Affymetrix SNP6.0 array. Copy number analysis revealed a shared, approximately, 1Mb duplication of chromosome 8q22.1. The tandem duplication segregated with the phenotype within the family, as confirmed by QPCR and FISH. This duplication was not present in copy number polymorphism databases or in over 500 controls. We identified an overlapping 8q22.1 duplication in an unrelated patient with Leri's pleonosteosis to confirm the causal relationship. The minimum critical region consists of six genes, including GDF6 (growth/differentiation factor 6) and SDC2 (syndecan-2). GDF6 belongs to a subgroup of BMP signaling molecules that include GDF5 and 7, which are important for joint formation during embryonic development. Syndecan-2 is a transmembrane heparan sulfate proteoglycan with a known role in linking cellular interactions with extra-cellular matrix. We show that the causal duplication in Leri's pleonosteosis results in dysregulated SMAD signaling in dermal fibroblasts. The phenotypic descriptions of Leri's pleonosteosis have been inconsistent and our findings demonstrate, for the first time, a single underlying molecular basis for the phenotypic spectrum due to dysregulated SMAD/TGF-β signaling. Previously, loss of function mutations of GDF6 were described in Klippel-Feil syndrome. Our results demonstrate the importance of the balance between BMP signaling during joint development and role of syndecan-2 in this pathway. Leri's pleonosteosis can now be added to a growing list of disorders, including stiff skin syndrome, Myhre syndrome, acromicric dysplasia and geleophysic dysplasia, with overlapping phenotypes and dysregulated SMAD/TGF-β signalling pathways. These findings provide an opportunity to trial TGF-β inhibitors and provide further insight into the role of TGF-β in connective tissue ageing and in arthritis and scleroderma.

Abnormal Type I Collagen Folding and Matrix Deposition in a Cyclophilin B KO Mouse Model of Recessive Osteogenesis Imperfecta. *W.A. Cabral[1], E. Makareeva[2], M. Weis[3], S. Leikin[2], D.R. Eyre[3], J.C. Marini[1].* 1) Bone & Extracellular Matrix Branch, NICHD, NIH, Bethesda, MD; 2) Section on Physical Biochemistry, NICHD, NIH, Bethesda, MD; 3) Orthopaedic Research Laboratories, University of Washington, Seattle, WA.

Osteogenesis Imperfecta (OI) is a heritable disorder characterized by bone fragility and growth deficiency. Recessive OI is due to mutations in genes encoding proteins involved in collagen post-translational interactions. The most frequent cases (Types VII-IX OI) involve the components of the collagen prolyl 3-hydroxylation complex, CRTAP, prolyl 3-hydroxylase 1 (*LEPRE1*) and cyclophilin B (CYPB; *PPIB*). The function of α1(I) Pro986 3-hydroxylation is unknown, but a role in alignment and cross-linking of fibrils in matrix is speculated. PPIB, a prolyl cis-trans isomerase, is thought to be the major PPIase responsible for the rate-limiting step in collagen helix formation. To further characterize the role of 3-hydroxylation complex components in collagen folding, *Ppib*-null mice were generated using a gene-trap ES cell clone with a β-geo reporter construct inserted in the first intron of *Ppib*. The heterozygous clone was shown by real-time RT-PCR to have half-normal *Ppib* expression. Homozygous *Ppib* knockout mice were verified by RT-PCR to have complete absence of *Ppib* transcripts in skin, fibroblasts, femurs and calvarial osteoblasts. In growth curves from 2 wks-6 mos of age, *Ppib*-/- mice weigh 33% less than WT and Het littermates. Ppib protein was absent and P3h1 reduced 50% reduction on western blots of -/- cultured fibroblast and osteoblast lysates, with half-normal amounts of Ppib in +/− cells. As expected, α1(I) P986 3-hydroxylation of fibroblast and osteoblast collagen was severely reduced (11 and 5% of WT, respectively). In agreement with previously described patients with decreased P986 3-hydroxylation, collagen from *Ppib*-/- cells had delayed helix formation in direct intracellular folding assays with the expected retarded electrophoretic mobility on SDS-Urea PAGE. However, both thermal stability and 5-lysyl and 4-prolyl hydroxylation of α1(I) chains were normal, suggesting collagen post-translational glycosylation might be altered. In *Ppib*-/- fibroblast and osteoblast cultures, acid-labile and pepsin-soluble collagen deposition was decreased to 20–30% of WT cultures and cannot be attributed to reduced secretion, which was only moderately delayed on pulse-chase analyses of secretion kinetics. These data suggest unique roles for Ppib in collagen post-translational processing, trafficking and extracellular matrix incorporation in addition to a role as a folding chaperone.

Differential contributions of P3H1 to collagen processing in the pathogenesis of Osteogenesis Imperfecta. *EP. Homan[1], C. Lietman[1], I. Grafe[1], J. Lennington[1], R. Morello[2], WR. Hogue[2], D. Napierala[3], MM. Jiang[1,4], B. Dawson[1,4], TK. Bertin[1], Y. Chen[1], R. Lua[1], O. Lichtarge[1], J. Hicks[5], MA. Weis[6], DR. Eyre[6], B. Lee[1,4].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR; 3) Oral and Maxillofacial Surgery, School of Dentistry, University of Alabama at Birmingham, Birmingham, AL; 4) Howard Hughes Medical Institute, Baylor Collage of Medicine, One Baylor Plaza, Houston, TX; 5) Pathology, Texas Children's Hospital, Baylor College of Medicine, Houston, TX; 6) Orthopædics and Sports Medicine, University of Washington, Seattle, WA.

Mutations in Cartilage Associated Protein (CRTAP), prolyl 3-hydroxylase 1 (P3H1), and Cyclophilin B (CypB) have been identified as causative of Osteogenesis Imperfecta (OI). These proteins form a complex that functions to 3-hydroxylate a single proline residue on the alpha 1 chain of type I collagen and acts as a cis/trans isomerase (PPIase) activity, a function essential for proper collagen folding. This 3-prolyl hydroxylation may not be integral to the structural integrity of collagen; however, its absence may disrupt protein-protein interactions integral for proper collagen folding. P3H1 and CRTAP stabilize each other and when one is absent, the other is degraded. Mutations in this complex result in hypomorphic or loss of function (LOF) alleles. It is unclear what roles the 3-hydroxylation and/or the PPIase play in the pathogenesis of OI. This project studies the contribution of P3H1 hydroxylation and how it pertains to the pathogenesis of OI by inactivating the hydroxylase domain while maintaining the protein and complex structure. We identified a residue that is considered critical for the hydroxylase function and generated a mutant P3H1 cDNA construct containing an alanine substitution at this residue. We demonstrated by immunofluorescence and Western blot that we rescued the stability of CRTAP in the LOF cells transduced with WT or mutant P3H1 cDNA. Analysis of prolyl 3-hydroxylation by collagen mass spectrometry indicates that the enzymatic activity of P3H1 is abolished. These data suggest that the mutant can maintain the stability of the P3H1 complex, thus maintaining the PPIase function, while abolishing enzymatic activity. To understand how absent 3-hydroxylation pertains to the pathogenesis of OI, recombineering was utilized to introduce the same alanine substitution into the P3H1 locus. In our knock in (KI) mice, we observed normal modification, which is in contrast to the P3H1 KO mice. Compared to control mice and in contrast to P3H1 null mice, the KI mice are normal in appearance and growth. However, analysis of the trabecular bone shows reduced BMD with decreased Tb Th, increased Tb Sp, and decreased BV/TV, whereas cortical bone parameters are normal. We have established a novel mouse model that recapitulates the bone phenotype but not the cartilage, growth, and connective tissue phenotype of recessive OI. These observations support differential tissue contributions of P3H1 hydoxylation to collagen processing in the pathogenesis of OI.

Characterization of transient receptor potential vanilloid channel 4 (TRPV4) in metatropic dysplasia primary cell lines. *L.M. Hurd[1, 2], S.M. Kirwin[1], K.M. Vinette[1], M.B. Bober[3], W.G. Mackenzie[4], R.L. Duncan[2], V.L. Funanage[1].* 1) Molecular Diagnostics Laboratory, Nemours/Alfred I. duPont Hospital for Children, Wilmington, DE; 2) Biological Sciences, University of Delaware, Newark, DE; 3) Division of Genetics, Department of Pediatrics, Nemours/Alfred I. duPont Hospital for Children, Wilmington, DE; 4) Department of Orthopedics, Nemours/Alfred I. duPont Hospital for Children, Wilmington DE.

Transient receptor potential vanilloid 4 (TRPV4) is a non selective calcium permeable ion channel that is an important mediator of both chemical and physical stimuli. Autosomal dominant mutations in TRPV4 have been shown to cause a spectrum of skeletal dysplasias that includes brachyolmia, spondylometaphyseal dysplasia, Kozlowski type (SMDK) and metatropic dysplasia. Metatropic dysplasia is one of the more severe TRPV4 dysplasias and is characterized by short stature, metaphyseal widening, marked platyspondyly, and progressive kyphoscoliosis. Electrophysiologic studies have shown the channel to be constitutively active, resulting in increased baseline calcium in cells transfected with TRPV4 mutations. However, to date there have not been any published results on the activity of the channel in primary cell lines from patients with metatropic dysplasia. We have a cohort of patients diagnosed with metatropic dysplasia who carry TRPV4 mutations, and have isolated cells from skin, bone and cartilage tissues of these patients. Using conventional PCR genetic sequencing analysis, we have identified a novel mutation, a G800D mutation in exon 15, codon 800 (G>A) resulting in a non-synonymous change from glycine to aspartic acid. Using quantitative multiplex fluorescent PCR, we have also identified a novel duplication of TRPV4 in which the duplication encompasses the entire gene. Protein and mRNA isolated from biopsies has confirmed TRPV4 is expressed in cells derived from skin, bone and cartilage using western blot and rt-PCR analysis. Intracellular calcium imaging with fura-2 showed that TRPV4 mutant cells have increased baseline calcium concentrations when compared to controls. Furthermore, TRPV4 mutant cells exhibit a decreased response to the TRPV4 agonist 4 alpha-phorbol 12, 13-didecanoate (4αPDD) when compared to control cells ($p<0.01$). Additionally, we would like to further characterize channel activity with patch clamping studies. Characterizing channel activity in primary cells from patients with metatropic dysplasia provides insight into the cellular mechanisms associated with this pathology. Once endogenous channel activity is defined, the mechanism by which aberrant channel activity contributes to metatropic dysplasia can be further elucidated and provide potential therapeutic targets.

Exome sequencing identifies a *de novo* missense mutation in *TGF-β1* in a sporadic patient with craniotubular bone dysplasia. *D. Li[1,8], A. Haghighi[2,8], F. Salehzade[3], L. Tian[1], H. Haghighi-Kakhki[4], C. Kim[1], E. Frackelton[1], F. Otieno[1], H.-D. Nah[5,6,9], H. Hakonarson[1,7,9].* 1) The Center for Applied Genomics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, USA; 2) The Wellcome Trust Center for Human Genetics, University of Oxford, Oxford, UK; 3) Department of Pediatrics, Ardabil University of Medical Sciences, Ardebil, Iran; 4) Faculty of Medicine, Mashhad Azad University, Mashhad, Iran; 5) Division of Plastic and Reconstructive Surgery, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, USA; 6) Division of Plastic Surgery, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA; 7) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA; 8) These authors contributed equally and considered joint first authors; 9) Equal contribution.

Autosomal dominant craniometaphyseal dysplasia (CMD, [OMIM 123000]) is a rare genetic disorder characterized by early progressive hyperostosis and sclerosis of cranial bones associated with abnormal modeling of the metaphyses. Generally radiographic examination in patients with CMD manifests diffuse hyperostosis of the cranial base, cranial vault, facial bones, and mandible and osseous obliteration of paransal sinuses and mastoid air cells. Additionally, patients may have other features, including facial paralysis and blindness resulting from cranial nerve compression, and hearing loss. Several mutations in *ANKH*, which is the only gene known to be associated with CMD so far, were found in the patients that have an affected parent. However, it's likely that the simplex cases have de novo mutations in *ANKH* and other genes. We captured exomes of a patient with the initial diagnosis of CMD based on typical metaphyseal widening feature and skull bone sclerosis, on which mutation analysis in *ANKH* was negative, together with the unaffected parents and brother, and subsequently performed sequencing analysis by Hiseq2000 with an effective mean coverage of 65 folds. The variants being studied were filtered against the 1000 Genomes Project, 5400 exomes from NHLBI GO Exome Sequencing Project and Complete Genomics 69 whole genome panel. We obtained 12 *de novo* variants in the proband, who doesn't have a family history of the disease. Of those variants, the only fitting disease-causing candidate for this case is Transforming Growth Factor-β1 (*TGF-β1*), which is a multi-functional protein acting on cell growth, differentiation, and morphogenesis of many different cell types. The novel mutation in *TGF-β1* affected a highly conserved residue of predicted damaging as determined by various algorithms, including both SIFT and Polyphen. Follow-up Sanger sequencing confirmed the heterozygous state of the mutation only in proband. Interestingly, different mutations in *TGF-β1* are known to cause the Camurati-Engelmann disease (CED), progressive diaphyseal dysplasia diagnosed by hyperostosis and sclerosis of the diaphyses of long bones. As the CED progresses, the metaphses may be also affected. A closer scrutiny of the phenotype of this proband is under way as a potential form of atypical presentation of CED. We are currently conducting follow-up functional studies to elucidate the disease causing mechanisms that will be presented together with detailed phenotypic characterization.

An Intracellular Role for FGFR2 in Bent Bone Dysplasia Syndrome. *C.L. Neben[1,2], B. Idoni[1,2], A. Sarukhanov[3], D. Krakow[3,4], A.E. Merrill[1,2].* 1) CCMB, Ostrow School of Dentistry, USC, Los Angeles, CA; 2) Department of Biochemistry, Keck School of Medicine, USC, Los Angeles, CA; 3) Department of Orthopaedic Surgery, David Geffen School of Medicine, UCLA, Los Angeles, CA; 4) Department of Human Genetics, David Geffen School of Medicine, UCLA, Los Angeles, CA.

Fibroblast Growth Factor Receptor 2 (FGFR2) is a crucial regulator of bone formation during development. While it is known that FGFR2 coordinates osteoprogenitor cell proliferation and differentiation, it remains unclear how the receptor couples these distinct cellular processes. Most FGF ligands mediate their biological effects extracellularly by activating membrane bound FGFRs. Upon activation, FGFRs autophosphorylate intracellular tyrosine residues and recruit adapter proteins juxtamembrane to launch ERK1,2, PLCγ, and PI3K/AKT cascades that subsequently regulate cell growth and differentiation. Some FGFs, such as FGF2, lack a signal sequence and can reside within the cell to regulate proliferation through nuclear routes presumed to be FGFR independent. Through an analysis of the pathophysiology of the recently described lethal skeletal disorder Bent Bone Dysplasia-*FGFR2* type (BBD), we have identified a new activity of FGFR2: our data suggests that the receptor acts within the nucleus to regulate bone formation. We previously showed that the dominant *FGFR2* mutations in BBD reduce receptor levels at the plasma membrane and markedly diminish responsiveness to extracellular FGF2. In this study we find that the mutations concomitantly enhance receptor localization to the nucleus and alter responsiveness to intracellular FGF2. We define how dual activities of FGFR2 at the plasma membrane and in the nucleus regulate bone formation by employing the mutant receptor in both an *in vitro* and *in vivo* approach. Using an osteoblast culture assay, we determine how FGFR2 activation of the ERK1,2, PLCγ, and PI3K/AKT cascades are differentially regulated by the mutant receptor. Utilizing the chick embryonic system, we uncover the influence of the mutant FGFR2 on skeletal development by driving targeted overexpression in the osteoprogenitor cells through *in ovo* electroporation. Together our findings support a distinct role for nuclear FGFR2 during the proliferation and differentiation of osteoprogenitor cells during bone formation.

ZDHHC13 is a Key Regulator in Postnatal Epiphyseal Development. *I.W. Song[1,2,3], W.R. Li[1,2], J.Y. Wu[1,2], M.T. Lee[1,2], Y.T. Chen[1,2].* 1) Institute of Biomedical Sciences, Academia Sinica,Taipei, Taiwan; 2) National Center for Genome Medicine, Academia Sinica,Taipei, Taiwan; 3) Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan.

Palmitoylation is a reversible post-translational 16-carbon fatty acid modification of the protein and is involved in a variety of physiological processes. It is mediated by DHHC-containing palmitoyl acyl-transferases (PATs) family of enzymes. We have previously shown that Zdhhc13 is a PAT and mice carry recessive Zdhhc13 mutation results in alopecia, amyloidosis and osteoporosis. Here we investigated the pathogenic mechanism of the severe osteoporosis and growth retardation in these mice. Histology of Zdhhc13 mutant mice at 2 weeks of age displayed disorganization in growth plate structure caused by narrowed hypertrophic zone and reduced proliferating chondrocyte and defective ecdochondral ossification and significant delay in the development of secondary ossification center (SOC). In addition, we demonstrated that Zdhhc13 expressed in and regulated the differentiation and function of osteoclasts, osteoblasts and chondrocytes. This regulation was most evidently at 2 weeks of age. In summary, we demonstrated that Zdhhc13 is a novel regulator in postnatal skeletal development. Moreover, we provided the first in vivo and in vitro evidences that palmitoylation acts as a key temporal regulator in skeletal development. This finding also reveals a new aspect in osteoporosis pathogenesis.

Identification of novel genes downstream of FGFR2 contributing to coronal suture synostosis in a murine model for Crouzon syndrome. *S. Kumar, E. Peskett, J.A. Britto, E. Pauws.* Neural Development Unit, Institute of Child Health, London, London, United Kingdom.

The C342Y mutation in the 3rd Ig-like domain of FGFR2 is the most frequent genetic cause of Crouzon syndrome(CS). Patients present with a combination of coronal suture synostosis and midfacial hypoplasia that frequently requires complex craniofacial surgery. Although much is known about FGF signalling in developing cranial sutures and the biochemical effect of FGFR2 mutations causing CS, little is known about genes or complex pathways occuring downstream of aberrant FGFR2 signalling directly responsible for the process of synostosis. By studying the phenotypic serial progression from E16.5 till P21 in a CS mouse model carrying the orthologous C342Y mutation, we found a divergence in phenotype between wild-type (WT) and $Fgfr2^{C342Y/+}$ (Mut) calvaria after E17.5. We hypothesized that Mut E17.5 coronal sutures would be enriched for genes playing a role in the pathogenesis of coronal suture synostosis.Bilateral micro-dissection of WT and Mut mouse calvaria isolated the dorso-medial aspect of the coronal suture with some flanking frontal and parietal bone. RNA was extracted and analysed using an Affymetrix microarray. Initial expression data analysis identified 51 candidate genes that were regulated by at least 1.5-fold ($p<0.05$). We further shortlisted five novel candidate targets (Dpt, Osr1, Nov, Dlk1 and Kera) which were downregulated up to 3.5-fold in mutant coronal sutures. Knowledge of these genes being previously reported as regulatory factors during osteoblast and chondrocyte differentiation made us suspect them to be putative downstream effectors following constitutive activation of the FGFR2 signalling pathway and play a role in the development and maturation of the coronal suture. These findings were independently validated using Taqman qPCR assays. In-situ hybridizations for Dpt and Osr1 were then performed in sagittal sections of E17.5 WT and mutant heads. Osr1 was found in both fronto-parietal osteogenic fronts outlining frontal and parietal bones, periosteum and skin. Dpt expression was also found in both dermis and outline of periosteum in the WT frontal bone additionally being within the substance of periosteum overlying frontal bone. Further spatio-temporal expression analysis will confirm the precise role these genes may play during the ontogeny of sutural mesenchyme. Our preliminary findings set the stage for directed investigation and analysis of putative effectors downstream to FGFR2 responsible for craniosynostosis in CS.

Identification of copy number variants in 413 isolated talipes equinovarus patients: role of transcriptional regulators of limb development. *D.M. Alvarado[1], J.G. Buchan[4], S.L. Frick[6], J.E. Herzenberg[7], M.B. Dobbs[1,5], C.A. Gurnett[1,2,3].* 1) Departments of Orthopaedic Surgery; 2) Pediatrics; 3) Neurology; 4) Division of Biology and Biomedical Sciences, Washington University, St. Louis, MO; 5) St. Louis Shriners Hospital for Children St. Louis, MO; 6) Levine Children's Hospital, Charlotte, NC; 7) Sinai Hospital, Baltimore, MD.

Clubfoot is one of the most common congenital musculoskeletal anomalies and has a worldwide incidence of 1 in 1000 births. A genetic predisposition to clubfoot is evidenced by the high concordance rate in twin studies and the increased risk to first-degree relatives. Despite the frequency of isolated clubfoot and the strong evidence of a genetic basis for the disorder, few causative genes have been identified. In this study, we hypothesize that rare and/or recurrent copy number variants are associated with isolated clubfoot and that these copy number variants are likely to contain genes that are important for limb development. We performed a genome-wide screen for rare deletions and duplications in 413 isolated clubfoot patients using the Affymetrix 6.0 array. Segregation analysis and gene expression in mouse E12.5 limb buds were used to determine the significance of copy number variants. We identified 74 rare, gene-containing copy number variants that were present in clubfoot probands and not present in 759 controls or in the Database of Genomic Variants. The overall frequency of copy number variants was similar between clubfoot patients compared to controls. Twelve rare copy number variants segregate with clubfoot in multiplex pedigrees, and contain the developmentally expressed transcription factors and transcriptional regulators *PITX1, TBX4, HOXC13, UTX, CHD1,* and *RIPPLY2*. Our results suggest an important role for genes involved in early embryonic patterning in clubfoot etiology that can now be tested with large scale sequencing methods.

Mutation of *B3GAT3* causes skeletal dysplasia in a consanguineous clan from Nias. *B.S. Budde[1], S. Mizumoto[2], R. Kogawa[2], C. Becker[1], J. Altmüller[1], H. Thiele[1], P. Frommolt[1,3], M.R. Toliat[1], J.M. Hämmerle[4], W. Höhne[5], K. Sugahar[2], P. Nürnberg[1,3], I. Kennerknecht[6].* 1) Cologne Center for Genomics, Universität zu Köln, Cologne, Germany; 2) Laboratory of Proteoglycan Signaling and Therapeutics, Faculty of Advanced Life Science, Graduate School of Life Science, Hokkaido University, Sapporo, Japan; 3) Cologne Cluster of Excellence on Cellular Stress Responses in Aging-Associated Diseases (CECAD), Universität zu Köln, Cologne, Germany; 4) Yayasan Pusaka Nias, Gunung Sitoli, Nias, Sumatra Utara, Indonesia; 5) Institute for Biochemistry, Charité University Hospital, Berlin, Germany; 6) Institute of Human Genetics, Westfälische Wilhelms Universität, Münster, Germany.

Nias is a unique island belonging to Indonesia. The people of Nias are still organized into patrilineal descent groups or clans. In contrast to other Southeast Asia island populations, studies on genetic diversity in Nias revealed severe bottleneck or founder events in its history giving rise to a high incidence of endemic syndromes. We describe one family with disproportionate short stature and bone dysplasia in two branches. Interestingly, the affected individuals of one of the two branches displayed a milder phenotype than the other. We conducted a genome-wide linkage scan in the branch with the more severe phenotype and determined a candidate region of 10.2 cM on chromosome 11. Sequencing of individual candidate genes did not reveal the disease-causing variant. We then performed whole-exome sequencing in one affected child. By scrutinizing variants in the linkage interval on chromosome 11 we noticed a possibly damaging homozygous missense variant in the gene *B3GAT3*. All affected individuals of the Nias clan are homozygous for the variation that could not be detected in 350 chromosomes of ethnically matched controls. Recently, Baasanjav et al. published their results on a family characterized by joint dislocations and heart defects caused by a different mutation of the same gene, c.830G>A (p.Arg277Gln). Here we describe a second mutation of *B3GAT3* associated with skeletal dysplasia, c.419C>T (p.Pro140Leu). No heart involvement was known but examination of one affected individual is scheduled to figure out if a heart phenotype is present in our family as well. *B3GAT3* encodes β-1,3-glucuronyltransferase (GlcAT-I). GlcAT-I catalyzes an initial step of proteoglucan synthesis by transferring glucuronic acid onto the trisaccharide-protein linkage structure of proteoglycans. The mutation p.Pro140Leu lies within the donor substrate binding subdomain of the catalytic domain of GlcAT-I. A proline-to-leucine exchange could influence the correct folding of the protein since the affected proline residue seems to be located on the surface according to crystallographic data. A multiple alignment shows that p.Pro140 is highly conserved among mammals, amphibians and insects. Functional studies are in progress in order to analyze the degree of damage caused by the mutation at the cellular level. Preliminary results show that the recombinant GlcAT-I (p.Pro140Leu) exhibited a significant reduction in the enzymatic activity compared to the wild-type enzyme.

Mutation analysis of the *BIN1* gene performed to evaluate the cause of centronuclear myopathy in two fetuses of consanguineous parents from Sudan. *N. Dohrn[1], A. Petersen[2], P. Skovbo[3], I.S. Pedersen[4], A. Ernst[4], H. Krarup[4], M.B. Petersen[1].* 1) Department of Clinical Genetics, Aalborg Hospital, Aalborg, Denmark; 2) Institute of Pathology, Aalborg Hospital, Aalborg, Denmark; 3) Department of Obstetrics and Gynecology, Aalborg Hospital, Aalborg, Denmark; 4) Section of Molecular Diagnostics, Aalborg Hospital, Aalborg, Denmark.

Arthrogryposis multiplexa congenita (AMC) is a rare congenital disorder characterized by multiple joint contractures. The condition can be caused by both genetic and environmental factors. Genetic causes include single gene defects (AD, AR and X-linked), chromosomal disorders and mitochondrial defects. The underlying condition can be a neuropathic abnormality, muscle abnormality, connective tissue abnormality, dermal abnormality, space limitations in uterus, maternal disease or impaired vascularity. The common pathway is the lack of fetal joint movement. Most commonly abortion is performed before exact clinical diagnosis can be made and the etiology is often only detected at autopsy. We present a consanguineous Nubian couple from Wadi Halfa, Sudan. The woman's great grandfather was the grandfather of the husband. The woman was 24 years old at the first pregnancy where ultrasound (US) was used in the 13thgestational week to diagnose AMC, leading to a termination of the pregnancy in week 14+2. Array-CGH was made on the aborted tissue and showed a normal result. In the second pregnancy increased nuchal translucency and AMC were observed during an US scan in the 13th gestational week and pregnancy was terminated in week 13+5. Karyotype was normal 46,XX. A full autopsy including CNS together with muscle histopathological examination of the two foetuses revealed identical malformations including a greater variation in muscle fibre diameter and more centrally located myocyte nuclei than expected for the gestational age, and a diagnosis of centronuclear myopathy, CNM, was proposed. Due to the observation of identical affection of two female foetuses of consanguineous healthy parents, we hypothesize that we are dealing with a case of AR CNM due to a mutation in the *BIN1* gene. Around five previous cases with a histologically and molecular proven diagnosis of CNM with *BIN1* mutation have been reported. None of the reported cases were diagnosed in pregnancy indicating a more severe phenotype in our family and perhaps due to a novel *BIN1* mutation. The *BIN1* gene consists of 20 exons and some of which are alternatively spliced. Currently 14 different transcripts are listed in the ENSEMBL database. We are in the process of carrying out bidirectional sequencing of all 20 exons and exon/intron boundaries. DNA extracted from peripheral blood samples and cell cultures are available from parents and aborted foetuses, respectively.

Novel ROR2 mutations in patients with autosomal recessive Robinow syndrome. *J. Mazzeu[1, 2], H. Kayserilli[3], C.A. Kim[4], D. Brunoni[5], P.C. Pieri[4], A. Richieri-Costa[6], H. van-Bokhoven[7], H.G Brunner[7], A.M. Vianna-Morgante[2].* 1) Programa de Pós graduação em Ciências Genômicas e Biotecnologia, Universidade Católica de Brasilia, Brasilia, Brazil; 2) Departamento de Genética e Biologia Evolutiva, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brazil; 3) Medical Genetics Department, Istanbul Medical Faculty, Istanbul University, 34093, I{{av}}stanbul, Turkey; 4) Departamento de Genetica, Instituto da Criança, Universidade de São Paulo, São Paulo, Brazil; 5) Departamento de Genética Médica, Universidade Federal de São Paulo, São Paulo, Brazil; 6) Departamento de Genética, Hospital de Reabilitação de Anomalias Crânio-faciais, Universidade de São Paulo, Bauru, Brazil; 7) Radboud University Nijmegen Medical Center Department of Human Genetics 855, Nijmegen, The Netherlands.

Robinow syndrome (RS) is a genetically heterogeneous condition characterized by mesomelic limb shortening associated with distinct facial features and genital anomalies that can be inherited as autosomal dominant or autosomal recessive. The clinical picture in recessive RS is more severe, with more marked limb shortening and costovertebral segmentation defects with rib fusion. Recessive RS is caused by mutations in the *ROR2* gene, mapped to 9q22, which encodes an orphan receptor with tyrosine-kinase activity. We screened exons 1–9 of the *ROR2*gene by Sanger sequencing in five unrelated probands. Three probands had affected sibs. Three novel mutations have been identified: c.323G>A (p.R108Q) in exon 3, which changes an amino acid at the Ig-like domain (two families); c.675delG (p.E293fs*444) in exon 6 and c.2074C>A (p.P692T) in exon 9, both affecting the tyrosine-kinase domain. The two families with the same mutation in exon 3 are allegedly unrelated and a common ancestor could not be identified based on the family history, but a founder effect cannot be excluded since they come from the same region. In the fifth patient we did not identify any mutations by sequencing but we failed to amplify exons 4 and 5. We then performed MLPA for *ROR2* (P179 - MRC Holland) that confirmed homozygosity for a deletion including both exons. This study contributes to the characterization of novel *ROR2* mutations causing recessive RS, and describes for the second time a multiple exon deletion suggesting that MLPA should be included as a screening method for confirmation of a clinical diagnosis of RRS. Financial support: FAPESP (CEPID 98/14254-2), CNPq.

Whole Exome Sequencing Identifies Mutations in the Nucleoside Transporter Gene *SLC29A3* in Dysosteosclerosis, a Form of Osteopetrosis. *P. Campeau[1], J.T. Lu[2,3], G. Sule[1], M.-M. Jiang[1], Y. Bae[1], S. Madan[1], W. Högler[4], N.J. Shaw[4], S. Mumm[5,6], R.A. Gibbs[1,2], M.P. Whyte[5,6], B.H. Lee[1,7].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 3) Department of Structural and Computational Biology & Molecular Biophysics, Baylor College of Medicine, Houston, TX, USA; 4) Department of Endocrinology, Birmingham Children's Hospital, Birmingham, UK; 5) Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, St-Louis, MO, USA; 6) Division of Bone and Mineral Diseases, Washington University School of Medicine at Barnes-Jewish Hospital, St Louis, MO, USA; 7) Howard Hughes Medical Institute, Houston, TX, USA.

Dysosteosclerosis (DSS) is a form of osteopetrosis which distinguishes itself from other forms by the presence of skin findings, platyspondyly, and metaphyseal osteosclerosis with relative lucency of widened submetaphyseal portions of long bones. In two patients with DSS, we identified homozygous or compound heterozygous missense mutations in SLC29A3 by whole exome sequencing. This gene encodes a nucleoside transporter implicated notably in pigmented hypertrichosis with insulin-dependent diabetes (PHID) and H syndrome, conditions with little or no skeletal involvement. This transporter is essential for lysosomal function in mice. We demonstrate the expression of *SLC29A3* in osteoclasts in vivo, and reduced osteoclast differentiation and function in patients with DSS. The marked pleomorphic nature of this nucleoside transport defect suggests a new mechanism for the control of osteoclast differentiation and function.

Polymorphisms in osteoporosis and their associations with bone metabolism. *R. Richterová[1], P. Cibulková[1], A. Bóday[1], D. Stejskal[1], P. Novosad[2], P. Fojtík[3], P. Hrdý[2].* 1) P&R LAB a.s., Laboratory of molecular biology, Nový Jic{{ak}}ín, Czech Republic; 2) Mediekos Labor s.r.o. Osteological centre Zlín; 3) Centre of Gastrointestinal Care, Vítkovická nemocnice a.s., Ostrava - Vítkovice.

Background: Osteoporosis is a disease of bones that leads to an increased risk of fracture, the bone mineral density (BMD) is reduced, bone microarchitecture deteriorates, and the amount and variety of proteins in bone is altered. Osteoporosis in the Czech Republic is affected approximately 500 000 women and 200 000 men. It is a polygenic disease and subtle genetic polymorphisms might have biological effects in its pathogenesis. Epidemiological studies have shown that the variance in BMD is geneticaly determined. Vitamin D receptor (VDR) BsmI polymorphism, estrogen receptor alpha (ESR1) polymorphism PvuII and LDL receptor-related protein 5 (LRP5) polymorphisms Val667Met and Ala1330Val genes are the most frequently analyzed osteoporosis. From anamnestic indicators a frequency of bone fractures and smoking were followed. Materials and Methods: Patients with osteoporosis was screened for 4 SNPs in 3 genes mentioned above. DNA was isolated from whole blood, and amplified real time PCR using hydrolysation and FRET probes. Osteological parameters were then compared with genotype. Results: A group of 1051 patients from Central Moravia region was analysed. We followed a frequency of polymorphisms occurrence and its relation to individual parameters of bone phenotype, bone mineral density in femoral neck and lumbar spine area, markers of bone remodelation (osteocalcin; C-terminal peptide collagen I, beta crosslaps in patients sera) and risk of fractures were analysed. Demographic characteristics of individual genotype were with no significant difference. The acquired results show significantly lower BMD in homozygotes BB in Femoral Neck and Lumbar Spine area and a significantly lower occurrence of fractures in patients of genotype bb. Relation among polymorphism BsmI and bone turnover markers were not proved. In observed groups we analyzed phenotypes selected bones and discovered statistical significant difference between tested polymorphism. Conclusion: Our findings have proven a similar association among genotype BB of gene polymorphism BsmI for VDR and selected bone phenotypes. In particular, we managed to prove a statistically significant correlation with BMD in Femoral Neck area and Lumbar Spine area. Further on, we have proven a connection with a higher frequency of fractures with this genotype in a population of patients with postmenopausal osteoporosis.

2866W

Combination of Whole-Genone cytogenetics array, High-throughput SNP genotyping, homozygosity mapping and Sanger sequencing identify FXN gene expansion leading to Axonal peripheral neuropathy and ataxia phenotype in two consanguineous families from North West Africa. *H. Azzedine[1], B. Hubert[2], W. Amer[3], F. Ferrat[3], M. Chaouch[3], F. Lagace[4, 5], R. Fetni[4, 5], C. Paisan-Ruiz[6].* 1) Medical genetics, DGM Faculty of Biology and Medicine, CHUV-Unil Lausanne, Switzerland; 2) Department of Neurology, Mount Sinai School of Medicine; 3) service de neurologie, Hopital de Ben Aknoun, Alger, Algeria; 4) PROCREA Cliniques, Montréal, (QC) Canada; 5) CHU saint Justin research center, Montréal, (QC) Canada; 6) Departments of Neurology, Psychiatry, Genetics and Genomic Sciences, Friedman Brain Institute, Mount Sinai School of Medicine.

Friedreich Ataxia (FRDA) is severe autosomal recessive neurodegenerative disorder due to the abnormal expansion of GAA repeats in the FXN gene, leading to heterochromatin gene silencing. The consequence of this mechanism is the very low level of FXN mRNA. In normal conditions, FXN gene product is a small protein (frataxin) with a large specter tissue expression. It's involved in mitochondrial iron metabolism via the biosynthesis of iron-sulfur clusters (ISCs). Iron is necessary for energy production, DNA and neurotransmitters synthesis, phospholipid metabolism and myelination. Loss of myelinated axons in peripheral neurons, the degeneration of posterior columns of the spinal cord and the loss of peripheral sensory fibers constitute some major pathological development of FRDA. Other cardiac, skeletal and sensory abnormalities are also observed. In this study we present 2 consanguineous North African families with a combined phenotype of axonal neuropathy and ataxia as an autosomal recessive trait. We performed both Affymetrix Cytogenetics Whole-Genome 2.7M Array and High-throughput SNP genotyping. The later was carried out using HumanOmniExpress beadchips, containing 733,202 genome-wide tag SNPs, and the HiScanSQ system (Illumina). All genotyping quality assessments were undertaken according to the appropriate options within the Genome studio program (GS; Illumina). Data analysis revealed four regions of homozygosity were identified in each family. However, only one region, in chromosome 9, was shared by both. This region encompasses the FXN gene. By sequencing of all the FXN exons, no mutation was found in any patient. Sequencing of the first intron of the gene revealed an abnormal homozygous expansion of 500 GAA repeats in the 2 affected individuals of the first family. Interestingly, in the second family, one patient had 800 repeats in one chromosome and only 100 in the other, while he is homozygous for the SNP haplotype in the region of interest. His affected sibling is homozygous for a 500 triplet repeats. The parents of each family and their healthy children were in the normal allele expansion range ($8 \leq GAA \leq 20$). We did not investigate the FRDA locus as a primary genetic testing intention because the clinical data did not well overlap with the phenotype of Friedreich Ataxia. More clinical investigations are ongoing to reevaluate the scale of the disease in all the patients, especially this one with “heterozygous” expansion.

Exome sequencing in small families segregating autosomal dominant non-syndromic hearing loss. *H. Azaiez[1,2], E. Shearer[1], K. Booth[1], M. Hildebrand[3], N. Meyer[1], RJH. Smith[1].*1) Department of Otolaryngology, University of Iowa, Iowa City, IA, USA; 2) Institut Pasteur de Tunis, Tunis, Tunisia; 3) Austin Health, Department of Medicine, University of Melbourne.

In small families segregating autosomal dominant non-syndromic hearing loss (ADNSHL), the OtoSCOPE platform, which includes all genes known to be implicated in ADNSHL, can be used to identify possible deafness-causing mutations. The `solve' rate for these families with OtoSCOPE is 52%, reflecting the fact that deafness is extremely heterogeneous and that there are many mapped loci for which causal genes remain unknown. Here we show that in OtoSCOPE-negative families with insufficient meioses for classical linkage analysis, a combination of segregation analysis-exome sequencing approach can reduce the number of variants of unknown significance (VUSs) to an actionable number. In the family described here, DNA samples were available for six informative meioses making this family too small for classical linkage analysis. After excluding variants in known ADNSHL genes using OtoSCOPE, whole exome sequencing was completed on three patients. The unfiltered analysis of the whole exome data using our Galaxy bioinformatics platform identified 822 non-synonymous, splice site or coding indel variants that were on the `short' list of VUSs for further study, a number too large to consider. However filtering by regions-of-interest based on segregation analysis reduced the possible ADNSHL-causing variants to only five. Sanger sequencing of these five variants identified p.R185P in Homer2 as the only variant that segregated with hearing loss phenotype. The p.R185P variant is located in exon 6, with R185 being highly conserved in vertebrates. Polyphen2 predicts this change to be probably damaging with a score of 0.996, and Mutation Taster predicts the change to be disease causing with a score of 0.999. This case study shows the power of combining a platform like OtoSCOPE to rule out known-genes followed by novel gene discovery coupling segregation analysis with exome sequencing.

Application of Massive Parallel Sequencing for Mutation Discovery and Genetic Diagnosis of Hereditary Hearing Loss in Chinese DFNA families. *H. Yuan[1], J. Cheng[1], Y. Lu[1], X. Zhou[2], X. Zhang[2], R. Choy[3].* 1) Inst of Otolaryngology, Chinese PLA General Hospital, Beijing, China; 2) Bioinformatics Division, Tsinghua National Laboratory of Information Science and Technology, and Department of Automation, Tsinghua University, China; 3) Department of Obstetrics and Gynaecology, Chinese University of HongKong, HongKong.

Hearing loss is the most common birth defect and sensorineural hearing loss (SNHL) results from malfunction of inner ear. Because of the hereditary features of SNHL, genetic diagnosis has exceptionally high value in the medical practice for detecting hereditary hearing loss. Giving that there are more than 200 known genes associated with SNHL, a method with high throughput diagnostic capability but greatly reduced cost such as massively parallel sequencing (MPS) may replace Sanger sequencing and array in clinical application to identify the genetic cause of SNHL. In this study, we developed a target enrichment method that enables the capture of known regions of the human genome (252 genes) associated with SNHL on a single reaction for high throughput mutation identification by MPS platform. We designed target intervals with Agilent SureSelect platform and ran 12 samples with the MPS kit to find their unknown mutations. We use an in-house built computation pipeline based on GATK to align reads to the human reference genome and call variants from the alignments. For confirming the QC filter, all candidate causal variants were closer examined with IGV software and tested by Sanger sequencing. Although barcode pooling often generates unequal amount of total sequences, we observed per-target read-depths were highly correlated between pooled pairs in the same dilution unit. We observed that mitochondrial DNA which designed as a single target turned out to be over 100 fold deeper than non-MT targets. For majority of our samples, about 40%~50% of the total bases map to MT. For the six DFNA families (2 samples in each family), mutations in TECTA, COCH and MYO6 are shared in 3 families, respectively. Linkage and Sanger sequencing data supported co-segregation of these mutations with the phenotypes in these DFNA families. Three DFNA families did not find the causal mutations by this MPS approach. Four possibilities might be account for the failure of mutation identification in these DFNA families: (1) causal variants on known genes were missed due to incomplete coverage; (2) hearing loss within the same family may be caused by more than one causal variants of known genes; (3) patients with phenocopy denied the real positive variants; (4) novel DFNA genes underlying the hearing loss in these families.

Autosomal recessive congenital ichthyosis (ARCI) is a severe genodermatosis characterized by extensive scaling of the entire skin, variable erythema, and often a collodion encasement at birth. ARCI has been suggested as a disorder characterized by disturbance of the cornified lipid envelope of terminally differentiated keratinocytes. Using a combined strategy of linkage analysis in an extended pedigree of German descent with multiple consanguinity and whole-exome sequencing of samples from two patients, we identified one single homozygous mutation in the candidate region with a >100-fold coverage. It is a missense mutation in *CERS3*, the gene for ceramide synthase 3, which completely co-segregated in the pedigree. Ceramide synthases are a family of tissue and acyl chain length-specific N-acyl transferases. *CERS3* is mainly expressed in skin and testis and synthesizes ceramides of C24 and longer acyl chains. In order to analyse the importance of long chain ceramides for epidermal barrier function, we have modelled the disease in vitro using 3D full-skin equivalents with either patient keratinocytes or keratinocytes with siRNA-mediated knockdown of *CERS3*. Disease models demonstrated only slightly reduced epidermal barrier function compared to wild-type models using Lucifer Yellow penetration assays. This finding is in line with the patient phenotype characterized by generalized superficial, whitish scaling and without any atopic manifestations. Morphological analysis of skin biopsy specimens showed mild acanthosis and orthohyperkeratosis with a moderate thickening of the stratum corneum as well as cleft-like inclusions, partly containing melanosomal remnants, in horny lamellae and irregular vesicular structures in the granular layer. The ceramide profile of patient keratinocytes showed a specific loss of C26 NS and ND ceramides and an increase in C16 ceramides. We have found loss of C26 ceramide synthesis in cells overexpressing mutant *CERS3*, compared to cells transfected with wild-type *CERS3*, which demonstrates that loss of CerS3 activity is the underlying cause for these changes. Taken together, we have identified *CERS3* as a new gene for ARCI. Our findings point out that synthesis of long acyl chain ceramides through CerS3 is a crucial first step for formation of the cornified lipid envelope, which then involves other enzymes mutated in forms of ARCI such as 12R-lipoxygenase, epidermal lipoxygenase-3, and transglutaminase-1.

The NIH Undiagnosed Diseases Program: Defining Pathogenicity for Personalized Medicine. *C.F. Boerkoel III, M.C. Malicdan, D. Adams, C. Toro, C. Tifft, W.A. Gahl, T. Markello.*NIH Undiagnosed Diseases Program, NIH/NHGRI, Bethesda, MD.

Human disease arises by maladaptation of humans to their ecological niche. Rare diseases, which affect ~8% of the population, frequently arise from strong genetic and epigenetic mutations causing maladaptation within a stable ecological niche. Within this context, a precise diagnosis is the first step to understanding illness and defining appropriate therapies. The NIH Undiagnosed Diseases Program uses genomics to approach diagnoses for ill individuals whose diseases have otherwise eluded identification. Even extending the genomic analysis to the community of the family, we confront the difficulty of defining what sequence variants are responsible for disease. In the absence of an epidemiological association, we consider four levels of evidence for pathogenicity: 1) statistical likelihood that the variant will occur in healthy individuals; 2) empiric evidence for pathological consequences of the variant on protein function; 3) associative evidence from systems biology considerations; and 4) recapitulation of disease in a model organism. Based on a study of a rare distal myopathy identified in a single family, we conclude that, in some instances, a systems biology approach garners sufficient evidence to prove disease causation and thereby abrogates the need for epidemiological association or attempt at full recapitulation of the disease in model organisms.

Efficient search for allelically heterogeneous disease genes in whole genome or exome datasets. *K. D'Aco, M.A. Aquino, N.M. Pearson.* Knome, Inc., Cambridge, MA.

Intro: Searches for disease genes often focus on single kindreds, which implicate one causal variant at a time; or large case/control cohorts. which are hard to gather for rare diseases, and may incur noise from heterogeneous and/or weakly penetrant etiology. Rare diseases that trace to diverse penetrant inherited or de novo variants in one or a few genes, however, can be powerfully studied in modest-sized samples of multiple unrelated probands, often with closely related controls. But without strong prior information (e.g., from linkage mapping), such studies require robust formal methods for ranking candidate genes with etiology too varied for single-kindred methods, and too penetrant to be efficiently discovered by conventional rare variant burden tests. Method: We developed a candidate gene search method that, unlike other rare variant search methods, leverages the fact that, in diseases tracing to rare penetrant variants in one or a few genes, no case is likely to carry more than one (if dominant/recessive) or two (if compound heterozygous) causal variants. We presume that, among a set of k probands, a causal gene harbors a set of j<=k (dominant/recessive) or j<=2k (compound heterozygous) functionally suspect variants, where each proband — but no control - carries a minimal set of one or two such variants at appropriate zygosity. We then search for genes that best fit those criteria among cases but not controls, scoring each gene by how closely it satisfies them, and by a permutation-based p-value to exclude genes that likewise satisfy random case/control distributions. Genes are then jointly ranked by these numbers to shortlist candidates for further investigation. Discussion: Using this method we successfully shortlisted the causal gene in published exome data from ten Kabuki syndrome patients. Our method readily incorporates variant weights and filters, sample kinship, and recessive/compound heterozygous searches. And it can take as input arbitrary groupings of variants, such as multi-gene sets or regulatory regions.

From large-scale clinical recruitment to identification of a novel mutation in ADAMTSL2 in a family with Ehler-Danlos Syndrome. *A.S. Desai[1], D. Hadley[1], L. Tian[1], C. Kim[1], E. Frankelton[1], R. Chiavacci[1], F.G. Otieno[1], F. Mentch[1], H. Hakonarson[1], K. Wang[2], S. Pannosian[1].* 1) The Center for applied Genomics, CHOP, Philadelphia, PA. 19104, USA; 2) University of Southern California, Los Angeles, CA, 90007, USA.

The Center for Applied Genomics at The Children's Hospital of Philadelphia conducts large-scale clinical recruitment of subjects for genomic analysis. Biological samples are drawn from children and clinical surveys and electronic medical records (EMRs) are linked to those collected samples. Clinical surveys and samples from parents and siblings are also collected when possible. For > 85% of subjects recruited consent to re-contact is given. Through systematic data mining of >80K EMRs from subjects, we identified samples for a family with Ehler-Danlos Syndrome (EDS) with permission to re-contact. EDS is a rare dominant connective tissue disorder that primarily affects skin, joints, muscle and blood vessels. To date, only nine mutations for EDS are known with limited available clinical molecular tests. Furthermore, EDS is known to be associated with osteogenesis imperfecta (OI). To identify the underlying genetics of EDS in the family we identified (negative for known mutations), the parents were re-contacted to verify the family's affected status. The family consisted of an affected male proband, with an affected father, unaffected mother, unaffected sister, and unaffected maternal half brother. We performed exome sequencing on all family members and used ANNOVAR to identify non-synonymous variants that fit a dominant inheritance pattern. We identified 50 of these variants absent from public databases, one of which was a novel missense mutation within the ADAMTS like 2 (ADAMTSL2) gene. Known mutations for the rare type 7C form of EDS includes ADAMTS2 which belongs to the same protein family as the defective ADAMTSL2 gene we found. Sanger sequencing of 9 other EDS samples in our biobank showed the novel heterozygous mutation was unique to the affected family. Our work is significant not only because it illuminates the pathophysiology of EDS for the affected family and the field at large, but also because it demonstrates the utility of unbiased large-scale recruitment and biobanking in understanding rare Mendelian diseases. Families with most other Mendelian disorders for which genetic variants have been found were biasedly recruited by clinical experts; but the majority of rare Mendelian diseases may go unsequenced under such a recruitment model. With unbiased large-scale clinical recruitment we strive to sequence as many rare Mendelian diseases as possible, and this work in EDS serves as a successful proof of concept to that effect.

Exome sequencing for the knowledge-driven and unbiased disease-mutation search of mitochondrial respiratory chain disorder. *M. Kohda[1], Y. Tokuzawa[2], Y. Moriyama[2], H. Kato[3], N. Uehara[2], Y. Nakachi[1], N. Matoba[1], S. Tamaru[4], Y. Kishita[2], T. Yamazaki[5], M. Mori[6], K. Murayama[7], Y. Mizuno[2], A. Ohtake[5], Y. Okazaki[1,2].* 1) Saitama Medical University, Hidaka, JapanDivision of Translational Research, Research Center for Genomic Medicine, Saitama Medical University, Hidaka, Saitama, Japan; 2) Division of Functional Genomics & Systems Medicine, Research Center for Genomic Medicine, Saitama Medical University, Hidaka, Saitama, Japan; 3) Division of Developmental Biology, Research Center for Genomic Medicine, Saitama Medical University, Hidaka, Saitama, Japan; 4) Department of Obstetrics and Gynecology, Saitama Medical University Hospital, Moroyama, Saitama, Japan; 5) Department of Pediatrics, Saitama Medical University, Moroyama, Saitama, Japan; 6) Department of Pediatrics, Jichi Medical University; 7) Department of Metabolism, Chiba Children's Hospital.

Mitochondria are small organelles and serve as the powerhouse of the living cells because they generate vital energy in their respiratory chain system consisting of protein complexes I to V. Mitochondrial respiratory chain disorder (MRCD) is an intractable disease that develops in childhood. It is a highly frequent inborn error of metabolism that occurs in one out of every 7,000 births. Prominent symptoms develop in such organs as the brain, heart, and muscles, where a great deal of energy is required. In most cases, effective treatment has not been established yet. It is known that various gene abnormalities cause defects of the protein complexes of the respiratory chain, which results in mitochondrial dysfunction. However, identification of the causative gene and the understanding of pathogenic mechanism of MRCD remain largely unsolved. We have started a project to reveal the pathological mechanism of MRCD at the neural cell level using samples obtained from patients with MRCD. In this study, various data and findings such as information obtained using high-throughput sequencers, knowledge of genome informatics and cell biology, and clinical observations will be utilized to understand why various symptoms develop in a tissue-specific manner in patients with MRCD, while mitochondria are ubiquitously existent in all cells. We report current progress and strategy of this project, which uses not only knowledge-driven approach but unbiased *ab initio* approach with high-throughput exome sequencing followed by experimental confirmation. Our study will illustrate how large-scale sequencing, coupled with functional prediction and experimental validation, can identify disease mutations in single patients.

2874F

Exome Sequencing for Disease Gene Discovery in Jeune's Asphyxiating Thoracic Dystrophy. *P. Taylor[1], S. Wu[2], SF. Nelson[1,3], DH. Cohn[1,2], D. Krakow[1,2].* 1) Department of Human Genetics, University of California, Los Angeles, California, USA; 2) Department of Orthopaedic Surgery, University of California Los Angeles, California, USA; 3) Department of Pathology and Laboratory Medicine, University of California, Los Angeles, California, USA.

Jeune's Asphyxiating Thoracic Dystrophy (JATD) is a clinically heterogeneous, autosomal recessive skeletal dysplasia characterized primarily by an abnormally narrow thorax with short ribs and short limbs. It has an estimated incidence of ~1 out of every 126,000 live births. Most patients die in early infancy and childhood from respiratory insufficiency due to a small thorax. To date, four genes and one additional locus have been found to cause JATD in an autosomal recessive fashion. All four known genes are essential for normal primary cilia function. We employed the use of exome sequencing of seven unrelated patients affected with JATD to identify candidate mutations responsible for or contributing to the disorder. To maximize the success of gene discovery, we used Agilent's SureSelect Exome Pull Down capturing 50 Mb of the protein-coding exome. Each sample library was sequenced using a single lane of Illumina HiSeq. We generated 252Gb of paired-end sequence data with a mean coverage of 115X per sample. The sequencing data was aligned using Novoalign and variants were called using the Genome Analysis Toolkit. Variants were filtered against dbSNP135, 69 complete Genomics samples, 95 NIEHS EGP exome samples, 5400 exomes from the NHLBI Exome Sequencing Project, and 40 in-house exome samples. Only mutations that were present in the above controls in the homozygous state were removed from the candidate list. After filtering, potential disease-causing mutations representing two known genes and four novel genes were found in all seven individuals. In particular, one individual had two novel, predicted-damaging mutations in the gene *TRAF3IP1* in the compound heterozygous state. *TRAF3IP1* is a known cilia gene that has been found to play an essential role in ciliogenesis and embryonic development (Berbari et al. 2011. Dev Biol 360:66–76). We are currently characterizing these mutations in *Trypanosoma brucei*.

2875W

Seeking causative genes for human congenital general anosmia in multiply-affected Israeli families. *A. Alkelai[1], T. Olender[1], D. Oz-Levi[1], I. Keydar[1], R. Milgrom[1], E. Feldmesser[1], E. Ben-Asher[1], E.K Ruzzo[2], D.B. Goldstein[2], E. Pras[3,4], D. Lancet[1].* 1) Dept. of Molecular Genetics, The Weizmann Institute of Science, Rehovot, Israel; 2) Center for Human Genome Variation, Duke University School of Medicine, Durham, North Carolina 27708, USA; 3) The Danek Gertner Institute of Human Genetics, Sheba Medical Center, Ramat Gan, Israel; 4) The Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel.

General anosmia (the inability to sense odors) has negative effects on life quality, including impaired food and beverage enjoyment, social interactions and avoidance of poison and fire. An estimated 2.5–5% of the general population suffers from acquired general anosmia or hyposmia. In contrast, congenital general anosmia (CGA) affects merely <0.1%, and appears in isolated or syndromic forms. In specific cases, family members of patients with syndromic anosmia (Kallmann syndrome) have been found to suffer from the isolated form of CGA. While for an appreciable number of syndromic CGA types a causative gene has been identified, none of the isolated CGA instances have been genetically deciphered. Most of the reported isolated CGA cases are sporadic, and family-based studies are relatively rare, primarily because samples are difficult to ascertain. In our previous report (Feldmesser et al, Chem Senses 32:21–30, 2007) we have recruited 66 families of Jewish origin and performed whole-genome linkage analysis for selected families with multiple affected individuals with suspected founder variation. This study did not reveal significant linkage, probably due to small family size. We now report whole-exome next-generation sequencing in 9 individuals from three of these families. Each family was separately analyzed under the appropriate mode of inheritance (dominant, recessive and dominant with partial penetrance). We focused on family-shared variants present at minor allele frequency <0.05 in the 1000 Genomes Project, in 5000 exomes of the NHLBI database and in our own 50 exomes of Jewish individuals. These variants involved functionally reasonable genes, including such appearing in our recently constructed database of CGA candidate genes. Among these was neuropilin 2 (*NRP2*), a modulator of semaphoring 3A (*SAMA3A*) reportedly deleted in a form of Kallmann's syndrome. All implicated variants are now being further validated, examined for co-segregation in additional family members, and screened for low frequency in ethnically matched healthy controls. The identification of specific pathogenic functional CGA variants will help elucidate the molecular basis of general olfactory sensitivity.

Studying a locus for bilateral congenital perisylvian polymicrogyria: Linkage analysis, Cytoscan HD Array and Target Enrichment/Sequencing approaches. *F.R. Torres[1], S.S. Tsuneda[1], E.H. Yamamoto[1], R. Secolin[1], M.G. Borges[1], W.T.S.T. Ide[1], C.S. Rocha[1], F.M. Artiguenave[1], F. Cendes[2], M. Guerreiro[2], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, UNICAMP, Campinas, SP, Brazil; 2) Department of Neurology, UNICAMP, Campinas, Brazil, SP, Brazil.

Bilateral congenital perisylvian polymicrogyria (BCPP) is the most common form of polymicrogyria. Familial recurrence was described for BCPP and different patterns of inheritance have been identified. Recently, chromosome Xq28 has been identified as a candidate locus for BCPP. This is a highly repetitive region, making it prone to non-homologous recombination events. We have identified a large family with an X-linked dominantly inherited BCPP. The aim of this study is to identify the deleterious event involved leading to BCPP in this family. To identify the candidate locus, linkage analysis was performed using 18 microsatellite DNA markers located in Xq27-q28 region. Subsequently, the candidate locus identified was captured with SureSelectXT technology (Agilent Technologies) and sequenced in a high-performance Hiseq Illumina sequencing machine (Illumina). In addition, in order to assess whether a submicroscopic structural rearrangement is involved in BCPP, three patients carrying the same haplotype were submitted to HD Cytoscan Array (Affymetrix). Linkage analysis identified a 13Mb candidate region on Xq27.2-q27.3. This locus is approximately 16Mb more centromeric than the first reported Xq28 locus. The Xq27.2-q27.3 region was captured and sequenced with 50x coverage. Approximately 3402 SNPs present in several genes were indentified. HD Cytoscan Array analysis did not reveal structural chromosome rearrangements in patients carrying the affected haplotype. We conclude that gross chromosomal abnormalities are not involved with BCCP etiology in this family, thus point mutations or small deletions are likely to be the event leading to this syndrome. Bioinformatics analysis of high performance sequencing data revealed two genes as potential candidates for BCPP etiology in the family studied. Putative roles related to development and/or cell division pathways make the two candidate genes identified relevant for BCPP.

Targeted Exome Sequencing for Molecular Diagnostics of Heterogeneous Genetic Disorders: Primary Ciliary Dyskinesia. *J.-L. Blouin[1,2], J. Bevillard[2], M. Guipponi[1,2], C. Gehrig[1], A. Vannier[2], F. Santoni[2], S.E. Antonarakis[1,2], F. Fellmann[3], S. Fokstuen[1], R. Lazor[4].* 1) Dept Genetic Medicine and Laboratory, Univ Hosps Geneva, Geneva, Switzerland; 2) Dept Genetic Medicine and Development, University of Geneva School of Medicine, Geneva, Switzerland; 3) Medical Genetics, CHUV, Lausanne, Switzerland; 4) Dept of Respiratory Medicine, CHUV, Lausanne, Switzerland.

Monogenic diseases with extensive genetic heterogeneity are laborious and expensive to molecularly diagnose by conventional sequencing or other indirect mutation screening due to the large number of genes. This had been partially overcome by microarray to either detect known mutations or resequencing a few genes. Today wide availability and decreasing cost of high throughput sequencing (HTS) as well as various DNA selection (DS) methods allow the analysis from dozens to thousands of genes even entire exome in a single experiment. Although this is now widely used in research, translating these techniques in molecular diagnostics is a challenge. We tested here a combination of targeted exome DS and HTS in patients with Primary Ciliary Dyskinesia (PCD) in order to develop a comprehensive molecular diagnostic method, and also a research tool to identify novel causative genes. PCD is a recessively inherited respiratory ciliopathy, caused sofar by 14 genes. Despite tremendous efforts in the past 15 years, genetic etiology remains unknown in more than 60% of cases. Liquid phase capturing was designed for all coding exons of known and candidate genes for PCD as well as other ciliopathies for a total of 164 genes including 3298 exons. Patient DNA libraries after DS are analyzed in a single lane (multiplexing indexed libraries) of a HT sequencer. Data were analyzed using a locally developed pipeline using BWA for alignment, SAMtools for variant calling, and ANNOVAR for annotation of all sequence changes, including functional prediction, allele frequency (dbSNP, 1000-genomes). We prioritized non-synonymous, frameshift, splicing, and indel variants according to novelty, quality score, and putative pathogenicity. We have provided sofar diagnostics in 2 of 5 patients showing compound heterozygous mutations, both in gene DNAH11, the most frequent and large PCD gene with 79 exons. Patient 1 had a nonsense (p.Arg3666*) and a frameshift mutation (p.Pro3606Hisfs*23), both confirmed by Sanger sequencing to be in trans. Patient 2 carried 2 deletions creating premature termination of the protein as p.[Arg761Serfs*10];[Val2957Trpfs*9]. Analysis of a number of additional patients is currently ongoing. Targeted exome sequencing of candidate genes presents advantage of lower analysis cost than entire exome and avoiding incidental findings. It holds considerable promises as next generation diagnostics of such highly heterogeneous monogenic disorders in clinical practice.

Mutations affecting components of the SWI/SNF complex cause Coffin-Siris syndrome. *N. Matsumoto, Y. Tsurusaki, N. Miyake.* Department of Human Genetics, Yokohama City Univ Grad Sch of Med, Yokohama, Japan.

Coffin-Siris syndrome (CSS; MIM 135900) is a rare congenital anomaly syndrome characterized by growth deficiency, intellectual disability, microcephaly, coarse facial features and hypoplastic nail of the fifth finger and/or toe. The majority of patients are sporadic, being compatible with autosomal dominant inheritance with unknown genetic cause(s). By exome sequencing, we found de novo SMARCB1 mutations in two of five typical patients with Coffin-Siris syndrome, a rare autosomal dominant anomaly syndrome. SMARCB1 is a subunit of switching defective/sucrose nonfermenting (SWI/SNF) complexes. The SWI/SNF complexes play important roles in lineage specification, maintenance of stem cell pluripotency and tumorigenesis, known as one of chromatin-remodelers regulating the accessibility to target genes and gene expression by dynamic alterations of the chromatin structure. Since SMARCB1 is a subunit of SWI/SNF complexes, we screened 15 other subunits of SWI/SNF complexes in 22 Coffin-Siris syndrome patients. Nineteen patients (87%) showed a germline mutation in one of five SWI/SNF subunits: SMARCB1, SMARCA4, SMARCE1, ARID1A or ARID1B. The various types of mutations in different SWI/SNF components resulted in similar CSS phenotypes. This suggests that these complexes coordinately regulate chromatin structure and gene expression. This is the first report of germline mutations in SWI/SNF complexes associated with a multiple congenital anomaly syndrome, highlighting novel biological aspects of SWI/SNF complexes in humans. Aknowledgments: Drs. Okamoto N, Ohashi H, Kosho T, Imai Y, Hibi-Ko Y, Kaname T, Naritomi K, Kawame H, Wakui K, Fukushima Y, Homma T, Kato M, Hiraki Y, Yamagata T, Yano S, Mizuno S, Sakazume S, Ishii T, Nagai T, Shiina M, Ogata K, Ohta T, Niikawa N, Miyatake S, Okada I, Mizuguchi T, Doi H, and Saitsu H are highly appreciated for contributing to this work.

Identifying Mutations Causing Atypical Progeria by Exome Sequencing and CNV Analysis. *K.M. McSweeney[1], L.B. Gordon[2,3,4], J. Xu[1], W. Ping[1], M.F. Arlt[1], J. Li[1], T. Glover[1].* 1) Dept. Human Genetics, University of Michigan, Ann Arbor, MI; 2) The Progeria Research Foundation, Boston, MA; 3) Dept. of Pediatrics, Brown University, Providence, RI; 4) Dept. of Anesthesia, Harvard Medical School, Boston, MA.

Progeria is a rare genetic disease characterized by a rapid aging phenotype. The classically defined form of progeria is Hutchinson-Gilford Progeria Syndrome (HGPS), an autosomal dominant form of progeria characterized by growth delay, alopecia, loss of subcutaneous fat, stiff joints, and vascular disease, but normal intelligence. HGPS is caused by a point mutation (c. 1824 C>T; G608G) that creates a cryptic splice site 150nt upstream of the 3' end of exon 11. This results in a 50 amino acid deletion, including an endoproteolytic cleavage site for the ZYMPSTE24 protease. The resulting disease-causing protein is an immature form of the lamin A protein called “progerin”. Progerin remains localized at the nuclear lamina resulting in nuclear blebbing and nuclear envelope instability, which is believed to be one cause of the premature aging phenotype. Other progeroid diseases are caused by mutations involving lamin A or its processing factors, or mutations in DNA damage response genes such as the WRN helicase. However, the genes responsible for many cases of progeroid diseases are unknown. We performed whole exon sequencing on nine patients with “atypical” progeria who show some phenotypes similar to classical HGPS but lack mutations in *LMNA* and *ZPMTSE24*. SNP array analysis for CNV and homozygosity detection was also performed on all nine patients and these data were considered together with the exome sequences. We obtained an average of 174 million sequencing reads and a range of 150- to 237-fold genome coverage for each patient sample. The data were analyzed and filtered using a number of state of the art algorithms and revealed 5–10 deleterious mutations in each patient in candidate genes. These genes were chosen for their involvement in nuclear membrane structure/function, DNA damage response, lipid metabolism, and other functions related to the progeria phenotype. Currently, parental DNA is being analyzed to determine the mode of inheritance of each mutation in each unrelated patient. Identification of causative genes will not only be of direct importance to affected patients and their families, but may have great impact on the understanding of the aging process and its associated disorders.

Diagnostic Sequencing Applications Using the Ion Torrent. *D. Muzny[1], X. Wang[1], C. Buhay[1], M. Wang[1], H. Dinh[1], J. Reid[1], D. Wheeler[1], L. Lotta[2], E. Boerwinkle[1,3], R. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) 2Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, Milan, Italy; 3) 3University of Texas Health Science Center at Houston, School of Public Health, Houston, TX 77030.

Since its introduction to the Human Genome Sequencing Center (HGSC) in January 2011, the Ion Torrent PGM platform has demonstrated a tremendous capacity growth, as well as great flexibility. The platform has been ideal for amplicon experiments, including AmpliSeq designs. These have been largely focused on validation of putative variants discovered on other platforms. The amplicon sequencing to characterize more than 5,000 variant sites from different cancer and genetic discovery projects has been straightforward and has only been limited by the capacity to produce the multiple PCR products. To extend the utility of the device we have now performed targeted gene panel capture sequencing on the PGM platform. This required modifications to the library construction process to improve complexity, incorporate multiplexing and allow for the use of sub-microgram DNA amounts in library and hybridization. Capture variant discovery has been demonstrated using a custom design (~1Mb), targeting exons from all 167 known retinal disease genes. The procedure was calibrated using a well characterized (hapmap) sample, yielding 99.59% (1181/1185) overall accuracy, with a total of just four erroneous SNP calls identified. PGM target sequencing was then applied to diagnosis of two retinitis pigmentosa (RP) patient families. Disease causing mutations in Ush2A have been identified and validated in both RP families representing the first reported human patient cases diagnosed on the PGM. In addition, eight regional capture designs as well as exome sequencing have now been evaluated using the PGM pipeline ranging in size from 0.1 to 43Mb in target regions. Thrombosis and X Chromosome capture designs as well as whole exome sequencing have resulted in the identification of putative and causative variants. These experiments have been supported by advances in a highly configurable variant caller specifically for Ion Torrent validation applications. The platform is now demonstrated to be suitable for a clinical setting where accuracy and rapid cycle time are essential.

Next Generation Sequencing Reveals an Allelic Variant of GLI2 in a Turkish Pedigree with a unique clinical phenotype. *D. Pehlivan[1], A. Yesilyurt[2], C.G. Gonzaga-Jauregui[1], E. Karaca[1], Y. Pehlivan[3], S. Guran[4], R.A. Gibbs[1,5], J.R. Lupski[1,6,7].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Medical Genetics, Dr. Zekai Tahir Burak Women Health Training and Research Hospital, Ankara, Turkey; 3) Department of Internal Medicine, University of Gaziantep, School of Medicine, Gaziantep, Turkey; 4) Department of Medical Genetics, Gulhane Military Medical Academy, Ankara, Turkey; 5) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 6) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 7) Texas Children's Hospital, Houston, TX, USA.

The GLI2 gene was discovered and so-named for its amplification in gliomas of the brain. Beside its overexpression in tumoral tissues, simple mutations (small deletions, missense mutations) in this gene were reported in association with holoprosencephaly sequence. GLI2 is one of three vertebrate transcription factors implicated as obligatory mediators of Sonic hedgehog (SHH) signal transduction. Diminished SHH signaling is associated with the most common forebrain defect in humans, holoprosencephaly, which includes cyclopia, a phenotype also seen in mice and other vertebrates with defective Shh signal transduction. We report a homozygous missense mutation in GLI2 in a consanguineous family with a unique phenotype. A 22 year-old male patient, born from first degree cousin marriage, was referred to medical genetics due to hypernasal speech. Physical examination revealed additional dysmorphic facial features including triangular and elongated face, frontal upsweep, narrow forehead, bitemporal narrowing, thick and medially-flared eyebrows, prominent tubular nose, prominent columella, thin upper lips, retromicrognathia, partial cutaneous syndactyly on both feet, and an inability to move the tongue. To the best of our knowledge, this phenotype is unique and there is no similar reported case in the published literature. Family history showed two additional affected sisters with similar findings and two healthy siblings. Homozygosity mapping and whole-exome sequencing of DNA from two affected individuals revealed the same candidate genes. Segregation analysis showed that only the GLI2 variant is segregating in the family. The mutation is confirmed with Sanger sequencing. This result indicates that exome sequencing can be important to elucidating the molecular etiology of extremely rare, novel clinical phenotypes and to explore allelic variants of known genes.

Rapid and efficient mutation detection in the hundreds of target genes by bench-top next generation sequencer with custom target capture method. *A. Shimizu[1], C. Torii[2], N. Suzuki[3], H. Mutai[3], J. Kudoh[4], R. Kosaki[5], T. Matsunaga[3], K. Kosaki[2].* 1) Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan; 2) Center for Medical Genetics, Keio University School of Medicine, Tokyo, Japan; 3) Laboratory of Auditory Disorders, National Institute of Sensory Organs, National Tokyo Medical Center, Tokyo, Japan; 4) Laboratory of Gene Medicine, Keio University School of Medicine, Tokyo, Japan; 5) Division of Medical Genetics, National Center for Child Health and Development, Tokyo, Japan.

In combination with massively parallel sequencing using next-generation sequencers and custom sequence capture methods for restricted target genomic regions is possible and accessible to identify the mutation from hundreds of known disease genes at a lower cost per sample. We focused on studies of patients with hearing loss and some other congenital disorders. Our regions of the interest genes spanning 860 kb and including 5,477 coding exons of 309 genes. With eArray, online custom design tool (Agilent Technologies, Inc.), we have designed and manufactured more than 29,000 capture probes that targeted the genomic region of interest. We failed to design probes for only 31 kb (3.6%) of target coding regions. The fragmented genomic DNA samples from patients and their family members were captured by our custom probes and sequenced using MiSeq sequencer (Illumina, Inc.) that generated 150 bp (six samples in one lane) paired-end reads. The sequencer generated more than 2 million reads with 600 Mb sequences per sample. These sequences were aligned to the human genome reference sequence using BWA (version 0.6.1). Over 99.7% of the targeted regions were sequenced, 75.6% of sequence reads were on the target region and the average depth of target coverage was x167, with 96% of bases covered by ≥10 reads. Genome analysis toolkit package was used to perform local realignment, map quality score recalibration and SNPs/indels calls for each individual. We removed potential PCR duplicates by using Picard. We identified and labeled the identified SNPs and indels within the targeted coding regions and that overlapped with known SNPs that were reported in the dbSNP version 135, the 1000 Genomes Project and our in-house Japanese SNPs dataset. We annotated the novel variants and known variants with clinical significance using snpEff, ANNOVAR and a custom analysis pipeline. We also used commercial available software packages Avadis NGS (Agilent Technologies, Inc.), CLC Genomics Workbench (CLC bio) and NextGENe (Next-Gen, Inc) for comparing to the detected mutations. We have identified the potentially deleterious mutations in half of the patients, and validation of the identified mutations is currently underway using Sanger sequencing. Our study indicated that the combination of bench-top type next-generation sequencer and target sequence capture methods provide cost effective, accurate and rapid diagnosis of congenital disorders.

2883F

Identification of candidate genes associated with autosomal dominant pulmonary fibrosis by whole-exome sequencing. *W. Wiszniewski[1], C.G. Gonzaga-Jauregui[1], T.J. Vece[2], D.M. Muzny[3], M.N. Bainbridge[3], J.G. Reid[3], R.A. Gibbs[3], J.R. Lupski[1], Baylor-Hopkins Center for Mendelian Genomics.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Familial pulmonary fibrosis (OMIM#178500) is a rare and progressive lung disease that presents initially with shortness of breath and later progresses to end stage lung disease. The histopathological analysis of lung tissue shows varying degrees of inflammatory and fibrotic changes. Most cases are sporadic, however it has been estimated that familial form is responsible for 0.5–2% of cases of idiopathic pulmonary fibrosis. Susceptibility to pulmonary fibrosis has been associated with sequence variants in 6 genes including TERC, TERT, SFTPA1, SFTPA2 and MUC5B. We have identified two large families with familial pulmonary fibrosis and autosomal dominant mode of inheritance. In the first family, the disease was diagnosed in 8 cases in 4 generations, in the second family in 5 cases in 2 generations. We have selected two affected individuals from each family for whole-exome sequencing studies. We have identified deleterious variants in candidate genes that are potentially associated with the observed phenotype.

Family matters: Exome sequencing can identify causal variants in isolated probands through family-based studies. *H. YU[1], C.R Coughlin[1], E.A. Geiger[1], M. Friederich[1], L. Medne[2], J.E. Ming[2], E.H. Zackai[2], J.L. Van Hove[1,3], X. Gai[4], G.H. Scharer[1,3], T.H. Shaikh[1,3].* 1) Section of Clinical Genetics and Metabolism, Department of Pediatrics, University of Colorado School of Medicine, Aurora, CO; 2) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Intellectual and Developmental Disabilities Research Center, University of Colorado School of Medicine, Aurora, CO; 4) Department of Molecular Pharmacology and Therapeutics and Center for Biomedical Informatics, Loyola University Chicago Stritch School of Medicine, Maywood, IL.

Exome sequencing has proven to be a powerful tool for gene discovery especially when applied to multiple related or unrelated individuals with a similar phenotype. This paradigm limits the application of exome sequencing, as the vast majority of individuals with multiple anomalies do not have a specific genetic diagnosis or present with phenotypes that are unique to the patient. Our work demonstrates successful strategies for novel gene discovery as well as establishment of causality in single probands with a variable spectrum of multiple congenital anomalies or inborn errors of energy metabolism. Exome sequencing was performed in six probands and their unaffected parents to obtain >50X average coverage per sample. Following standard bioinformatics for variant calling and annotation, candidate genes were highlighted using parental data and testing all possible modes of inheritance. This resulted in <5 candidate genes per proband, which were further examined in the context of the patient's phenotype. In Patient 1, who had blepharophimosis ptosis and epicanthus inversus syndrome (BPES) plus developmental delay, cryptorchidism and digital abnormalities, we identified a de novo mutation in *KAT6B*, a histone acetyltransferase gene. *KAT6B* has recently been implicated in related but phenotypically variable genetic disorders. In Patient 2, who had progressive neurodegeneration, intractable seizures, myoclonus, extrapyramidal movement and biochemical evidence for a mitochondrial disorder, we identified compound heterozygous, missense mutations in a very strong candidate gene. This candidate, a nuclear gene required in mitochondrial function, has not been previously associated with mitochondrial disease. Single, very strong candidate genes were identified in Patients 3–5. The candidate gene in Patient 3 may be a novel gene in the methylmalonic aciduria and homocystinuria pathway, as the patient had biochemical findings associated with Cobalamin C deficiency. In Patient 6 we had more than one candidate gene. For novel genes identified, proof of causality was pursued using animal models or transfection studies to show complementation. We demonstrate that causal gene mutations can be identified in a single proband with the use of appropriate family-based studies followed by confirmatory functional analyses to establish causality.

2885T

Whole Exomic Triangulation and Systems Biology Identify Novel Pathogenic Substrates for Autosomal Dominant Long QT Syndrome. *N.J. Boczek[1], DJ. Tester[2], JR. Giudicessi[1, 3], TJ. Kamp[4], MJ. Ackerman[2,5,6].* 1) Mayo Graduate School, Mayo Clinic, Rochester, MN; 2) Department Molecular Pharmacology and Experimental Therapeutics, Windland Smith Rice Sudden Death Genomics Laboratory, Mayo Clinic, Rochester, MN; 3) Mayo Medical School, Mayo Clinic, Rochester, MN; 4) Deparment of Medicine, Cardiovascular Section, and the Cellular and Molecular Arrhythmias Research Program and Inherited Arrhythmias Clinic, University of Wisconsin, Madison, WI; 5) Department of Medicine, Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 6) Department of Pediatrics, Division of Pediatric Cardiology, Mayo Clinic, Rochester, MN.

Long QT syndrome (LQTS) is the most common cardiac channelopathy with 13 elucidated LQTS-susceptibility genes. An estimated 20% of LQTS cases remain genetically elusive. We combined whole exome sequencing (WES), genomic triangulation, and bioinformatic/systems biology approaches to identify the pathogenic substrate responsible for non-syndromic, LQT1–13 genotype negative, autosomal dominant LQTS in a multigenerational pedigree and established the spectrum and prevalence of the elucidated gene among a large cohort of unrelated patients with genotype negative/phenotype positive LQTS. WES was completed on the symptomatic index case (QTc = 498ms), unaffected father (QTc = 383ms), and affected maternal aunt (QTc = 479ms). Genomic triangulation (removal of variants shared between the index case and unaffected father, and unshared variants between the index case and affected maternal aunt) in combination with bioinformatic tools including the published LQTS interactome and 3 disease network analysis gene prioritization ranking algorithms (ToppGene, Endeavor, and SUSPECTS), were used to identify potential disease-causing candidate variants. The index case's exome contained 46,307 variants. Of the 698 rare, nonsynonymous, single nucleotide variants and insertions/deletions, 65 variants remained after genomic triangulation. Only 6 of these variants resided within the published 1629 node LQTS interactome and P857R-CACNA1C was ranked number 1 by all 3 disease network algorithms. P857R-CACNA1C co-segregated with the disease in all affected individuals of the multigenerational pedigree making it the most probable pathogenic mutation. The *CACNA1C* encoded L-type calcium channel (Cav1.2) α-subunit missense mutation involves a highly conserved residue localizing to a critical PEST domain in the II-III linker. Subsequent mutational analysis identified 4 additional mutations within *CACNA1C* in ~4% of our larger LQTS genotype negative/phenotype positive cohort. Two of these mutations also involved highly conserved residues within Cav1.2's PEST domain. This study provides evidence that coupling WES and bioinformatic/systems biology is an effective strategy for the identification of potential disease causing mutations. The identification of a *CACNA1C* mutation co-segregating with disease in a single pedigree and multiple mutations residing in the PEST domain suggests that *CACNA1C* perturbations are *bona fide* pathogenic substrates for classical, autosomal dominant LQTS.

2886F

X-exome sequencing identifies the causal variant in a large pedigree with X-linked intellectual disability, truncal obesity, gynecomastia, hypogonadism and unusual face. *J.K.P. van Amstel[1], M. Harakalova[1], M.J. van den Boogaard[1], R.J. Sinke[2], S. van Lieshout[1], M. van Tuil[1], K. Duran[1], I. Renkens[1], P.A. Terhal[1], C.G.F. de Kovel[1], I.J. Nijman[1], M.M. van Haelst[1], N.V.A.M. Knoers[1], G. van Haaften[1], W.P. Kloosterman[1], R.C.M. Hennekam[3], E. Cuppen[1].* 1) Dept of Medical Genetics, Univ Medical Ctr (UMCU), Utrecht, The Netherlands; 2) Dept of Genetics, Univ Medical Ctr (UMCG), Groningen, The Netherlands; 3) Dept of Pediatrics, Acad Medical Ctr (AMC), Amsterdam, The Netherlands.

We characterized a large Dutch family with 7 males affected by a rare syndrome of X-linked intellectual disability (XLID), hypogonadism, gynaecomastia, truncal obesity, short stature, small head, short ears and recognizable craniofacial deformities. Eight females in this pedigree showed a much milder expression of the phenotype, comprising learning disorder and recognizable facial features. We performed X chromosome exome (X-exome) sequencing in five individuals from this family and identified a novel intronic variant in a histone deacetylation family member. The gene is located in the region for which linkage was established in this family with a maximum LOD-score of 4.93. The variant was shown to affect normal splicing, resulting in exon skipping and introduction of a premature stop. The mutation completely co-segregates with the phenotype in this family and is absent in Dutch controls or available exome databases. Interestingly, affected female carriers show a markedly skewed X-inactivation pattern in blood where all cells show the mutated chromosome X completely inactive. The mutated gene is important for epigenetic control of developmental processes and a knock-out model supports the facial phenotype present in our patients. In summary, we provide genetic evidence for the involvement of the histone deacetylation pathway in a syndromic form of XLID.

Completing the BBS jigsaw by exome sequencing and phenotype-genotype correlations: LZTFL1 a BBSome related gene associated with developmental features is BBS17. *H. Dollfus[1,4], F. Stutzmann[1], M. Gerard[2], A. Verloes[3], E. Schaefer[1,4], C. Stoetzel[1], V. Marion[1].* 1) Laboratoire de génétique médicale, AVENIR INSERM- Université de Strasbourg, Strasbourg, France; 2) CHU de Caen servicede génétique de Caen, France; 3) Unité de génétique clinique, Hôpital Robert Debré, Paris, France; 4) CARGO, Centre de référence génétqiue ophtalmologqiue, Hôpitaux Universitaires de Strasbourg, France.

Introduction: Bardet-Biedl syndrome is an emblematic recessive and genetically heterogeneous ciliopathy characterized by polydactyly, retinitis pigmentosa, obesity, cognitive impairment and kidney dysfunction. To date, 20% of the BBS patients have no mutation identified in the 16 known BBS genes. Exome sequencing has proven to be a valuable approach to identify new ciliopathy genes. Material and methods: Single nucleotide polymorphism analysis followed by exome sequencing was performed on a consanguineous family diagnosed with Bardet-Bield syndrome with additional unusual developmental features namely insertional polydactyly and situs inversus. Results: A homozygous 5-bp deletion was identified in LZTFL1 encoding a protein known to be related to the BBSome as an important regulator of BBSome ciliary trafficking and Shh signaling. No transcript was found in the fibroblast cells of one affected individual. Sonic Hedgehog (SHH) signalling cascade analysis on the patient's fibroblasts showed significant increase for Smo. Patched and Gli2 indicated substantial activation of Shh signalling. Conclusions: We show that mutation in LZTLF1 (or BBS17), leads to a BBS phenotype with an enhanced developmental phenotype with Shh signaling abnormalities.

Simultaneous identification of single nucleotide mutations and DNA copy number aberrations in neurodevelopmental disorders by exome sequencing. *AM. Sulonen[1, 2], H. Almusa[1], H. Edgren[1], P. Ellonen[1], L. Forsstrom[3], T. Linnankivi[4], S. Knuutila[3], J. Saarela[1].* 1) Institute for Molecular Medicine Finland, FIMM, 00290 Helsinki, Finland; 2) National Institute for Health and Welfare, 00290 Helsinki, Finland; 3) Department of Pathology, Haartman Institute and HUSLAB, University of Helsinki and Helsinki University Central Hospital, 00290 Helsinki, Finland; 4) Department of Child Neurology, Children's Hospital, University of Helsinki and Helsinki University Central Hospital, 00290 Helsinki, Finland.

Neurodevelopmental disorders include well known syndromes, but also a wide variety of yet uncharacterized syndrome-like phenotypes. If acquired etiology cannot be indicated, genetic causes are considered. However, genetic background is multiform; *de novo*-mutations and familial variants are typical, which makes genetic testing complicated with conventional, single mutation or gene targeted methods. We show here, how next-generation exome sequencing can be used to identify both single nucleotide variants (SNV) and copy number variations (CNV), thereby providing a comprehensive genetic profile of patients with neurodevelopmental disorders for the use of clinical diagnostics.

Three families with multiple affected children were selected for the study. Array comparative genomic hybridization (aCGH) was previously performed for the families: Family 1 shared a heterozygous deletion of *RTN4RL1* in the patients, which has not been previously associated with developmental disorders. Patients of family 2 had a heterozygous 5.3 Mb deletion in 9q22, which was also carried by their cognitively normal father. Family 3 had no anomalous findings in aCGH. Two patients from each family and two healthy individuals were captured with NimbleGen SeqCap v3.0 exome capture kit and sequenced on Illumina HiSeq2000. SNVs were called with an in-house built variant identification and annotation pipeline VCP. For CNV identification we developed a method, Exo-CNV, which is based on copy number ratios from test vs. reference samples, derived from RPKM-normalized exon coverages. Mean exon coverages of other than familial samples were used as reference.

We identified 67, 111 and no novel, non-synonymous SNVs and 48, 64 and 36 CNVs shared in the patients of families 1, 2 and 3, respectively. When SNPs seen in the 1000Genomes were also included, six non-synonymous shared variants were identified in the family 3. CNVs identified with aCGH were verified with Exo-CNV. Detailed analyses of the genes affected by identified mutations and CNVs, and genotyping of potential disease causing variants in all family members are ongoing.We developed a pipeline that efficiently and comprehensively identifies family specific mutations possibly underlying neurodevelopmental disorders. Combination of SNV and CNV identification further enlightens the complexity of familial disorders.

***USP9X* mutation in a child with developmental delay and multiple congenital anomalies.** *M.S. Brett[1], A.H.M. Lai[2], E.C.P Lim[1], J.R. McPherson[3], B.W.M Cham[2], Z.J. Zang[4], P. Tan[4], S. Rozen[3], E.C. Tan[1].* 1) KK Research Centre, KK Women's & Children's Hospital, Singapore; 2) Department of Pediatrics, KK Women's & Children's Hospital, Singapore; 3) Neuroscience and Behavioral Disorders, Duke-NUS Graduate Medical School, Singapore; 4) Cancer and Stem Cell Biology Program, Duke-NUS Graduate Medical School, Singapore.

We describe a patient with intellectual disability and developmental delay (ID/DD) and multiple congenital anomalies (MCA) including facial dysmorphisms, Dandy-Walker malformation, ventricular septal defect, anal stenosis and bilateral post-axial polydactyly. She is the first child of healthy, unrelated parents of Chinese ancestry with no significant family history. Her karyotype was normal and array CGH with an Agilent 400K array did not detect any clinically significant aberrations. Massively parallel sequencing with a selected panel of 355 genes that have been associated with ID/DD and MCA was carried out on the child. Targeted exon capture was performed using the Agilent SureSelect system and sequenced on an Illumina HiSeq. The mean sequencing depth was 798 and 85% of the targeted regions were covered >10X. After filtering out the variants present in dbSNP and the 1000 Genome project there were a total of 107 single nucleotide variants (SNVs) in the targeted genes. The SNVs were further filtered by severity of predicted effect, gene function, evolutionary conservation, presence in locus-specific mutation databases and correlation with patient phenotype. SNVs were selected for validation by Sanger sequencing followed by testing of parental DNA. Sequencing identified a heterozygous *de novo* canonical splice site mutation c.1986-1G>T in the *USP9X* (Ubiquitin specific peptidase 9, X-linked) gene at chrX: 41025124 (hg19) which is predicted to lead to the deletion of exon 15 in the RNA splicing process. The gene codes for a deubiquitylating enzyme and has an important regulatory role at the level of protein turnover. It has been shown to be an essential component of the TGFβ/BMP signalling cascade and specifically deubiquinates SMAD4. A truncating mutation in *USP9X* has been identified in a family with XLMR but no other reports have associated *USP9X* mutations with ID/DD and MCA. In conclusion, targeted gene sequencing has identified a canonical splice site mutation in the *USP9X* gene that could be causative of some or all of the phenotypes in this patient. Identification of further patients with mutations in the *USP9X* gene will be needed to confirm the association with ID/DD and MCA.

2890W

Congenital cataracts, hypomyelination, progressive microcephaly, digital anomalies: a new recessive syndrome due to mutations in a nucleoporin gene? *E. Geraghty[1], G. Carvill[1], I. Glass[1,2], R. Kapur[3], D. Doherty[1,2], H. Mefford[1,2].* 1) Dept. of Pediatrics, Div. of Genetic Medicine, University of Washington, Seattle, WA; 2) Seattle Children's Hospital, Seattle, WA; 3) Dept. of Laboratories, Seattle Children's Hospital, Seattle, WA.

We report two affected siblings with congenital cataracts, congenital heart defects, prenatal onset ventriculomegaly, progressive microcephaly, severely delayed myelination, thin corpus callosum, hypotonia, and hand and foot dysmorphia. The first girl presented with hypotonia, congenital cataracts, unilateral preaxial polydactyly and gracile fingers. Echocardiogram showed bicuspid aortic valve. She developed central hypoventilation and died of respiratory failure at 5 months. She had extensive genetic testing with normal blood and skin karyotype, Affymetrix 6.0 SNP array, plasma amino acids, urine organic acids, acylcarnitine profile, very long chain fatty acids, 7-dehydroxycholesterol, *BCOR* sequencing, chromosome breakage studies, transferrin isoelectric focusing and TORCH titers. Her sister was identically affected except that she had partial anomalous pulmonary venous return (PAPVR) and a normal aortic valve and did not have polydactyly. She died at five weeks of age. Autopsy in the second sibling revealed gliosis of cerebrum, cerebellum, brainstem and spinal cord, as well as streak ovaries and polysplenia. Given the similar findings in both girls, we suspected a new autosomal recessive (AR) syndrome. We performed exome sequencing in the first sibling and filtered the data to identify nonsynonymous variants present in <1% of 1537 subjects from the Exome Sequencing Project (ESP; http://snp.gs.washington.edu/EVS/). Filtering for genes with rare homozygous or compound heterozygous variants identified 19 candidate genes. We excluded 17 candidates because variants were not confirmed by Sanger sequencing or segregation was not consistent with AR disease. *CCDC99*has a homozygous missense change in both girls that is heterozygous in 0.5–1% of controls. *NUP188* harbors a 4-bp deletion causing a frameshift and premature stop on the maternal allele and a nonsense mutation on the paternal allele. Neither is seen in controls, and no truncating or splice site variants in *NUP188* are present in 5400 ESP exomes. NUP188 is a component of the highly conserved Nup93 nucleoporin subcomplex and may help restrict the passage of transmembrane proteins into the inner nuclear envelope. Left-right patterning defects caused by*NUP188* knockdown in *X. tropicalis* are intriguing, since one sibling had PAPVR and polysplenia. Future work will focus on identifying additional patients and evaluating patient fibroblasts for defects in *NUP188* expression, localization and function.

Trio-exome sequencing identifies mutations of the gene encoding the histone acetyltransferase KAT6B/MYST4 in individuals with the Young-Simpson syndrome. *K. Kurosawa[1], K. Enomoto[1], T. Kondoh[2], S. Mizuno[3], M. Adachi[4], K. Muroya[4], Y. Yamanouchi[6], T. Nishikawa[1], N. Furuya[1], M. Tominaga[1], T. Naruto[1], K. Ida[1], Y. Kuroda[1], T. Sengstag[5], R. Manabe[5], M. Masuno[6].* 1) Division of Medical Genetics, Kanagawa Children's Med Ctr, Yokohama, Japan; 2) Division of Developmental Disabilities, The Misakae-nosono Mutsumi Developmental, Medical and Welfare Center, Isahaya, Japan; 3) Department of Pediatrics, Central Hospital, Aichi Human Service Center, Kasugai, Aichi, Japan; 4) Division of Endocrinology and Metabolism, Kanagawa Children's Med Ctr, Yokohama, Japan; 5) Omics Science Center, RIKEN Yokohama Institute, Yokohama, Japan; 6) Genetic Counseling Program, Graduate School of Health and Welfare, Kawasaki University of Medical Welfare, Kurashiki, Japan.

Young-Simpson syndrome (YSS), also known as Say-Barber-Biesecker variant of Ohdo syndrome or Say-Barber-Biesecker-Young-Simpson syndrome (SBBYSS), is a pleiotropic disorder characterized by skeletal, endocrine, and neurological abnormalities. To identify the molecular basis of YSS, we performed whole-exome sequencing of one proband-parent trio and one independent case. Two different protein-truncating mutations in the highly conserved histone acetyltransferase gene KAT6B/MYST4 were found to be heterozygous in the cases, respectively. The mutations were confirmed by Sanger sequencing. Sequencing of the KAT6B/MYST4 in 4 additional affected individuals identified disease-causing mutations in all probands, including two recurrent de novo alterations. 5 out of the 6 individuals had the protein-truncating mutations, but one patient, who represented mild phenotype, had a mutation of three-bases deletion resulting in a truncated product for only one amino acid residue in the glutamic acid-rich region. Our results confirmed that trio-based exome sequencing is a powerful approach to discover genes causing sporadic developmental disorders. These findings indicated that histone acetylation has a crucial role in early human development.

2892F

Exome sequencing identifies a missense mutation of ANKRD26 in autosomal dominant Thrombocytopenia. *C. Kim[1], P.M.A. Sleiman[1,2,3], L. Tien[1], S. Panossian[1], K. Xu[1], B. Tweddale[1], N. Abdel-Magid[1], E. Frackelton[1], Y. Housawi[4], H. Hakonarson[1,2,3].* 1) Ctr Applied Genomics, CHOP, Philadelphia, PA; 2) Dept Pediatrics, Perelman School of Medicine, Univ of Pennsylvania, Philadelphia PA; 3) Division of Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA; 4) King Fahad Specialist Hospital-Dammam, Saudi Arabia.

Thrombocytopenia-2 is an autosomal dominant nonsyndromic disorder characterized by decreased numbers of normal platelets, resulting in a mild bleeding tendency. Laboratory studies show no defects in platelet function or morphology, and bone marrow examination shows normal numbers of megakaryocytes and normal maturation stages, suggesting defective platelet production or release. Recently, Pippucci et al. (2011) identified 6 different heterozygous mutations in the 5-prime promoter region of the ANKRD26 gene in 9 of 20 unrelated families with THC2 subsequently expanding that to 21 families (Noris et al, 2011). All of the mutations occurred in a highly conserved 19-nucleotide stretch. In vitro functional expression assays in Dami human megakaryoblastic cells indicated that the mutations resulted in increased expression, particularly when the cells were stimulated toward maturation. The findings suggested a gain-of-function effect. We carried out exome sequencing in two affected members, one affected parent and an affected child, of a family with presumed dominant thrombocytopenia that had screened negative for all known genetic mutations. Coding sequences were enriched using the Agilent SureSelect 50Mb kit and the resultant libraries sequenced on an Illumina HiSeq 2000 to a mean depth of ~100X. Following variant annotation and filtration with ANNOVAR, 42 heterozygous variants that were shared between the two affected individuals and not present in a large number of control chromosomes remained. The 42 variants included a D158G missense mutation in the ANKRD26 gene. The mutation was confirmed by sanger sequencing and shown to segregate with the phenotype in the family. Gain of function mutations in the 5'-UTR of ANKRD26 have recently been reported to be causal of THC2, however, no missense mutations have yet been reported in this gene. Functional characterization of the D158G missense mutation is ongoing to determine if it confers a gain of function effect on the ANKRD26 protein. In combination with the 5' UTR mutations described by Pippucci et al. (2011) and Noris et al (2011) our finding that missense mutations within the open reading frame of ANKRD26 can result in thrombocytopenia could place ANKRD26 as a significant cause of thrombocytopenia.

2893W

Holoprosencephaly (HPE) : Identification of new candidate genes by high throughput sequencing of family trios. *V. David[1,2], C. Dubourg[1,2], M. De Tayrac[1], V. Dupé[1], M. Aubry[5], L. Ratié[1], S. Mercier[1,3], J. Mosser[1,4], S. Odent[1,3].* 1) Faculté de Médecine, UMR 6290 CNRS/IGDR,Université Rennes1, Rennes, France; 2) Génétique Moléculaire, CHU Pontchaillou, Rennes, France; 3) Génétique Clinique, Hopital sud, Rennes, France; 4) Génomique médicale, CHU Pontchaillou, Rennes, France; 5) Plateforme Biogenouest, Université Rennes1, Rennes, France.

Holoprosencephaly (HPE), the most common developmental defect (1/250 conceptuses, 1/10000 newborns), is caused by a failure to form the midline of the forebrain and midface. The etiology of HPE has pointed to a strong genetic component complicated by locus heterogeneity. Genetic anomalies in the four main genes (SHH, ZIC2, SIX3, TGIF) were identified in only 30% in the largest European series of 645 HPE probands. Clinical feature is extremely variable and many mutation carriers are unaffected. Except for ZIC2 mutations, genetic anomalies are inherited in 70% of the cases from one of the parents,. These latter are asymptomatic or carrying a microform of HPE, suggesting the implication of a second anomaly arising de novo or inherited. Our objective is thus to identify new genes involved in HPE. Recent findings and literature reports showed that exome sequencing of family trios could lead to the identification of new mutations in Mendelian diseases We thus have selected 10 well characterized family trios where one of the parents (asymptomatic or with a microform) was carrying a heterozygous mutation in one of the major HPE genes SHH, SIX3 or TGIF, transmitted to the offspring with a very severe HPE form (alobar or semilobar HPE). We postulated that this phenotype was due to a second de novo or inherited event. Each member of the family trios has been studied for the four main HPE genes and for copy number variations by CGH array analysis (Agilent, 180K) and only one of the parents carried a mutation in SHH, SIX3 or TGIF. Exome sequencing of these trios are pending and the results will be presented. They should seek a second mutation in new genes in these severe HPE cases. This will lead to a better knowledge of the physiopathology and improve genetic counseling of the disease.

2894T

Exome sequencing reveals a novel de novo GNAS gene mutation in a boy with usual presentation of pseudohypoparathroidism. *M. J. Dasouki[1], S. E. Soden[2,3,5], E. G. Farrow[2,3,4,5], C. J. Saunders[2,3,4,5], D. L. Dinwiddie[2,3,4,5], N. A. Miller[2,3,5], S. F. Kingsmore[2,3,4,5].* 1) Departments of Pedaitrics & Internal Medicine, University of kansas Medical Center, Kansas City, KS, 66160, USA; 2) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, Missouri 64108, USA; 3) Department of Pathology, Children's Mercy Hospital, Kansas City, Missouri 64108, USA; 4) Department of Pediatrics, Center for Pediatric Genomic Medicine, and Department of Pathology, Children's Mercy Hospital, Kansas City, Missouri 64108, USA; 5) School of Medicine, University of Missouri-Kansas City, Kansas City, Missouri 64108, USA.

The bi-parentally imprinted GNAS complex locus (GNAS) is known to be associated with multiple endocrine, skeletal and neurologic abnormalities including pseudohypoparathyroidism (OMIM#103580, #603233, #612462), progressive osseous heteroplasia (OMIM#166350) and Albright Hereditary Osteodystrophy (OMIM#174800). In a 26 month old Caucasian boy with congenital hypothyroidism, growth hormone deficiency, vascular & hyperostotic skull, metopic craniosynostosis, and developmental delay, serum PTH & FGF23 levels where elevated. Blood chromosomes and oligonucleotide Chromosomal Microarray Analysis were normal. Exome sequence analysis revealed a novel de novo, inactivating GNAS p.Leu164Pro (c.491T>C) variant that was predicted to be damaging, and was heterozygous in the affected child and absent in both parents. The unusual clinical presentation in this child coupled with the overlapping phenotype reported by Graul-Neumann et al (AJMG, 2009) expand the clinical spectrum in individuals with mutations in GNAS. Exome sequencing with CLIA-compliant confirmation enables diagnosis of inherited diseases that feature clinical or genetic heterogeneity that obfuscates clinical diagnosis by expert physicians or conventional, targeted testing.

Clinical Diagnostic Exome identifies novel mutations in the *C20orf7* gene, a mitochondrial complex I assembly factor, in a Taiwanese infant with Leigh's disease. *J.J. Wei[1], K.D. Gonzalez[1], X. Li[1], H.M. Lu[1], H. Lu[1], R. Chang[2], R. Wang[2], J. Abdenur[2], W. Zeng[1].* 1) Ambry Genetics, Aliso Viejo, CA; 2) Division of Metabolic Disorders, Children's Hospital of Orange County, Orange, CA.

We report a 14 month-old Taiwanese girl of non-consanguineous union with failure to thrive, gross motor delay, nystagmus, and dysphagia. Laboratory findings are significant for lactic acidosis, ketosis, and abnormal levels of urine organic acids; brain magnetic resonance imaging (MRI) studies demonstrate partial agenesis of the corpus callosum, as well as progressive T2 weighted hyper-intensities in the brain stem, thalamus, and frontal lobes. The family history was negative for similar phenotypes. Additional molecular testing of the mitochondrial genome,*SURF1*, and *POLG* did not reveal any pathogenic mutations. Due to the heterogeneous nature of this patient's symptoms, clinical diagnostic exome sequencing was performed and revealed that the proband has compound heterozygosity for two novel missense mutations: c.155A>C (p.K52T) in exon 1 and c.836T>G (p.M279R) in exon 9 of the *C20orf7* gene (also known as*NDUFAF5*). Co-segregation analysis using Sanger sequencing confirmed that the mother and father each carried one mutation. These two amino acids are completely conserved throughout vertebrates. Furthermore, both alterations are predicted to be possibly damaging and deleterious by Polyphen and SIFT in silico analyses, respectively. *C20orf7* encodes a complex I assembly factor with a predicted N-terminal mitochondrial leader sequence and is imported into the mitochondria; C20ORF7 dysfunction is consistent with the patient's clinical diagnosis of Leigh's disease. Mutations in *C20orf7* have been associated with mitochondrial complex I deficiency, but they have been previously reported in two Ashkenazi Jewish families, as well as consanguineous Moroccan and Egyptian families, with symptoms ranging from neonatal-onset, fatal Leigh's disease to a childhood-onset syndrome of progressive spasticity and choreoathetosis. The proband shares the findings of nystagmus, dysphagia, hypotonia, and MRI T2-hyperintense brain lesions with the previously reported patients. In addition, this report demonstrates that *C20orf7*-related Leigh's disease is a pan-ethnic disease not limited to individuals of North African or Ashkenazi Jewish descent.

De Novo Mutations in MLL Cause Wiedemann-Steiner Syndrome. *W.D. Jones[1,2,3*], D. Dafou[4], M. McEntagart[1], W.J. Woollard[4], F.V. Elmslie[1], M. Holder-Espinasse[5,6], M. Irving[6], M. Lees[2], A.K. Saggar[1], S. Smithson[7], R.C. Trembath[8], C. Deshpande[6], M.A. Simpson[4].* 1) SW Thames Regional Genetics Service, St George's, University of London, London, SW17 0RE, United Kingdom; 2) NE Thames Regional Genetics Service, Great Ormond Street Hospital for Children, Great Ormond Street, London, WC1N 3JH, United Kingdom; 3) University of Cambridge, Cambridge, United Kingdom, *from 1st August 2012; 4) Division of Genetics and Molecular Medicine, King's College London School of Medicine, Guy's Hospital, London, SE1 9RT, United Kingdom; 5) Service de Génétique Clinique, Hôpital Jeanne de Flandre, Lille, 59037, France; 6) Clinical Genetics, Guy's and St Thomas' NHS Foundation Trust, Guy's Hospital, London, SE1 9RT, United Kingdom; 7) Department of Clinical Genetics, St Michael's Hospital, Bristol, BS2 8EG, United Kingdom; 8) Queen Mary University of London, Bart's and The London School of Medicine and Dentistry, Charterhouse Square, London, EC1M 6QB, United Kingdom.

Excessive growth of terminal hair around the elbows (hypertrichosis cubiti) has been reported both in isolation and in association with a variable spectrum of associated phenotypic features. Hypertrichosis cubiti is present in some, but not all, individuals reported under the clinical classification of Wiedemann Steiner syndrome, a congenital multiple anomaly syndrome associated with short stature, a distinctive facial appearance, and intellectual disability. We identified six individuals with hypertrichosis cubiti associated with short stature, a distinctive facial appearance, and intellectual disability, consistent with a diagnosis of Wiedemann-Steiner syndrome. Utilising a whole exome sequencing approach, we identified de novo mutations in MLL in five of the six individuals. Each of the five mutations is predicted to result in premature termination of the protein product. Expression studies demonstrated that transcripts arising from the mutant alleles are subject to nonsense-mediated decay. MLL encodes a histone methyltransferase, which regulates chromatin-mediated transcription, through the catalysis of methylation of histone H3K4. Our findings define the genetic basis of Wiedemann-Steiner syndrome, provide further evidence for the role of haploinsufficency of histone modification enzymes in congenital multiple anomaly syndromes and further illustrate the importance of the regulation of histone modification in development.

2897T

Targeted resequencing of known and candidate epilepsy genes in 500 patients with epileptic encephalopathies. *G. Carvill[1], B.J. O'Roak[2], S.C. Yendle[3], J. Cook[1], N. Krumm[2], S.F. Berkovic[3], J. Shendure[2], I.E. Scheffer[3], H.C. Mefford[1].* 1) Department of Pediatrics, Division of Genetic Medicine, University of Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Epilepsy Research Center and Department of Medicine, University of Melbourne, Austin Health, Australia.

Epilepsy is one of the most common neurological disorders, with a lifetime incidence of 3%. The epileptic encephalopathies (EE) are the most severe of all the epilepsies. Patients typically present with refractory epilepsy with multiple seizure types, cognitive arrest or regression, and have a poor prognosis. Several EE genes and EE-associated CNVs have been described, but a systematic mutation screening approach across multiple EE has not been undertaken and most cases have an unknown etiology. Using molecular inversion probes for targeted capture followed by multiplexed next generation sequencing, we developed a protocol for high-throughput resequencing and copy number variant (CNV) detection of 32 known and 40 candidate genes in a cohort of 518 EE patients. To date, we have analyzed data from 365 individuals for 13 known and 19 candidate EE genes with 93% of targeted nucleotides sequenced at >25 fold coverage. At this coverage threshold we detected 100% of known single nucleotide variants from 20 individuals with variant calls from exome sequencing (n= 609), and 13 individuals with known disease-causing mutations. Additionally, using read depth data, normalization and a standard score analysis we were able to detect 86% of known CNVs from 15 individuals. Segregation analysis of rare, possibly damaging variants in known EE genes detected in 317 EE probands revealed pathogenic changes in *SCN1A*, *GABRG2*, *CDKL5*, *GRIN2A* and *PCDH19*in five families and possibly pathogenic inherited changes in an additional five families. The clinical manifestations of mutation carriers often differed from those previously described, broadening the clinical spectrum of phenotypes associated with known EE genes. We also observed intra-familial variability and incomplete penetrance. Rare variants within our candidate genes, comprising glutamate transporters, the NA+/K+ transporter ATPase-interacting proteins and synaptic vesicle exocytosis proteins is ongoing. Putative CNVs will be validated using a custom oligonucleotide array with high-density coverage of all target genes. In conclusion, we present a cost-effective, efficient method of screening multiple EE genes in large cohorts that will transform molecular testing in EE, enabling rapid early diagnosis, informing prognosis, treatment and genetic counseling.

Deciphering the genetic basis of progressive myoclonus epilepsies by exome sequencing. *M. Muona[1,2,3], S.F. Berkovic[4], L. Dibbens[5], K.L. Oliver[4], T. Joensuu[6,7,8], E. Hämäläinen[1,2], A. Palotie[1,2,9], A.-E. Lehesjoki[6,7,8].* 1) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton CB10 1SA, UK; 3) Public Health Genomics Unit, National Institute for Health and Welfare, Helsinki, Finland; 4) Epilepsy Research Center, Department of Medicine, University of Melbourne, Austin Health, West Heidelberg, Victoria 3081, Australia; 5) School of Pharmacy and Medical Sciences, University of South Australia, Adelaide, Australia; 6) Folkhälsan Institute of Genetics, University of Helsinki, Helsinki, Finland; 7) Haartman Institute, Department of Medical Genetics and Research Program's Unit, Molecular Medicine, University of Helsinki, Helsinki, Finland; 8) Neuroscience Center, University of Helsinki, Helsinki, Finland; 9) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA.

Progressive myoclonus epilepsies (PMEs) are a clinically and genetically heterogeneous group of rare, usually recessive, inherited disorders. In a subset of PMEs cognition is essentially preserved and the clinical features are confined predominantly to action myoclonus, tonic-clonic seizures, and ataxia. The paradigmatic form of this is Unverricht-Lundborg disease (ULD), which is caused by mutations in the *CSTB* gene. Other genes for ULD-like phenotypes include *GOSR2* and *SCARB2*. However, a significant number of PME patients do not have mutations in these genes. The identification and characterization of additional PME genes are prerequisites for improved diagnostics of the disease, which relies strongly on genetic testing of the patients. Moreover, it potentially helps to understand the underlying pathogenesis, which is currently largely unknown.

Here, we aimed to identify novel genes underlying patients with a ULD-like phenotype by exome sequencing. We studied 38 patients who have been collected worldwide and excluded for mutations in *CSTB*, *GOSR2*, and *SCARB2* by Sanger sequencing. Based on the clinical variation in the phenotypes we hypothesize that they represent more than one molecular entity. The cases are mostly singletons and a proportion is from consanguineous marriages. We carried out exome sequencing by Illumina Hi-Seq 2000 and selected potentially deleterious variants - either homozygous or compound heterozygous - of essential splice site, nonsense, frameshift, and nonsynonymous types. Additional filtering criteria were based on variant population frequencies, i.e., variants with a 1000 Genomes minor allele frequency of 1% or higher were excluded. Preliminary analysis of the sequencing data confirmed the absence of disease causing mutations in the three known genes for ULD-like phenotypes. Next, we analyzed genes previously linked to other PMEs or epilepsy. Results from this analysis suggest that a small subset of patients may carry causal variants in known epilepsy or PME genes (*EFHC1*, *CLN6*, *EPM2B*). This indicates the clinical diagnosis for these individuals might need re-evaluation or that one gene can contribute to more than one subtype of PME. Finally, we searched for novel PME genes by looking for predicted deleterious variants shared by multiple patients. Potential variants in genes without a previous connection to epilepsy have emerged. All the preliminary results require technical and functional validation.

2899W

Mutations in a Zinc Finger Protein cause a Novel Autosomal Recessive Mental Retardation Syndrome Identified Through Homozygosity Mapping & Whole Exome Sequencing of a Single Affected Individual. *M. Kambouris[1,2], T. BenOmran[3,4], Y. AlSarraj[1], R. Ali[3], M. Almureikhi[3], K. Erraffi[1], H. ElShanti[1,5].* 1) Molecular Genetics & DNA Diagnostics, Shafallah Medical Genetics Center, Doha, Qatar; 2) Yale University School of Medicine, Genetics, New Haven, CT, USA; 3) Clinical & Metabolic Genetics, Department of Pediatrics, Hamad Medical Corporation; 4) Weill Cornell Medical College, Doha, Qatar; 5) University of Iowa, Pediatrics, Iowa City, IA, USA.

A consanguineous Arab family affected by an autosomal recessive disorder characterized by severe mental retardation and failure to thrive, was studied by Illumina's 700K SNP genotyping, candidate gene mutation screening and whole exome sequencing for one affected member. Clinical findings include ptosis, bilateral epicanthic folds, striking midface hypoplasia, downturned mouth corners, thin upper vermillion, prominent ears, bilaterally short 4th metatarsal bone, bilateral 5th finger camptodactyly, mildly limited mobility in both knees and hypotonia. The gene was mapped by homozygosity mapping to 4 possible intervals, as the number of family members was insufficient for a significant LOD score. The positional candidate MAP2K1 was sequenced. No pathogenic mutations identified. Whole exome target enrichment sequencing was performed on ABI SOLiD4 and Illumina HiSeq platforms for a single-affected individual. Six non-synonymous variants were positioned within the homozygosity intervals. Two affected evolutionary highly conserved amino acids with damaging effects according to PolyPhen and SIFT protein-modeling software, were validated by Sanger sequencing and co-segregate with the disease phenotype. The variants were absent in 188 ethnically matched control chromosomes. One gene shows very limited expression in brain while the other, a Zinc Finger Protein, appears to be the disease causing mutation. Zinc Finger Proteins -a family of DNA & RNA binding proteins- are transcriptional regulators controlling developmental cascades of gene expression especially during fetal brain development. Mutations in Zink Finger domains interfere with normal brain development, are associated with non-syndromic X-linked mental retardation with impairments in adaptive behavior and manifest during the developmental period causing severe mental retardation. The c.C5054G [p.S1685W] mutation affects 2 of the 3 ZNF407 isoforms, is located in the last 1/3rd Zink finger domains and affects a serine residue in the alpha-helical part adjoining two zinc-finger domains probably eliminating the functionality of downstream domains and interfering with expression of various genes under ZNF407 control during fetal brain development. Homozygosity mapping and whole exome sequencing of a single affected individual was most effective, least labor demanding and most economical approach in identifying the mutation for this novel autosomal recessive Zinc Finger Protein mental retardation syndrome.

2900T

Exome sequencing of seven cases affected by a congenital muscular dystrophy with hyperlaxity (CMDH) belonging to five French-Canadian families. *M. Tetreault[1,2], G. D'Anjou[3], J. Mathieu[4], M. Vanasse[3], B. Brais[1].* 1) Neurogenetics of motion laboratory, Department of Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada; 2) Laboratoire de neurogénétique de la motricité, Centre d'Excellence en Neuromique de l'Université de Montréal, CRCHUM, Montréal, Québec, Canada; 3) Clinique des maladies neuromusculaires, Centre de réadaptation Marie-Enfant, Hôpital Sainte-Justine Hospital, Montréal, Québec, Canada; 4) Clinique des maladies neuromusculaires, Carrefour de Santé de Jonquière, Saguenay, Québec, Canada.

Over the past two decades, there have been major advances in defining the genetic bases of congenital muscular dystrophies (CMD). Genetic research has allowed the identification of more than 14 genes responsible for various forms of CMDs. Despite the great progress in this field, there are still a significant percentage of cases for which the mutated gene is unknown. This is particularly the case for milder forms. Novel genomic techniques like Next-Generation DNA Sequencing (NGS) open new avenues in the elucidation of genetic defects causing monogenic disorders such as CMD. We recruited a French Canadian (FC) cohort (27 cases, 24 families) from Southwestern Quebec affected by CMDH. Homozygosity mapping using SNPs genotyping (Illumina OmniExpress) on an informative consanguineous family have allowed us to identify six homozygous region shared by the two affected members. The two affected cases and the mother from the consanguineous family as well as five other affected individuals from three FC families were sent for exome sequencing at Perkin Elmer service lab. The Agilent SureSelect 50Mb kit was used for exons capture and the sequencing was performed on an Illumina HiSeq. A list of rare candidate variants shared by affected individuals that lie in the homozygote regions are being investigated as possibly causing this milder form of CMD. The uncovering of the genetic bases of muscular dystrophies serve as the essential original building blocks on which successful new therapeutic approaches can be designed.

Diagnosis of syndromic autism using a 62-gene next generation sequencing panel: experience from a clinical diagnostic laboratory. *J.R. Jones, M.J. Basehore, S. McGee, K.J. Champion, M.J. Friez.* Molecular Diagnostic Laboratory, Greenwood Genetic Center, Greenwood, SC.

Autism spectrum disorders (ASD) are complex neurobehavioral conditions that become evident in childhood and persist as lifelong disabilities. These common disorders affect as many as one in 88 children. Coexisting genetic disorders are found in a subgroup of patients with autism (estimated to be between 11 and 37 percent). Many of these genetic disorders have overlapping clinical features, and often numerous single gene sequencing tests are ordered before a pathogenic alteration is identified in a patient. Analyzing these genes one at a time by Sanger sequencing can be costly and time-consuming and may even lead to a delay in diagnosis. In an effort to provide comprehensive testing for this subgroup of patients with syndromic autism in a more rapid and cost-effective manner, the Molecular Diagnostic Laboratory of the Greenwood Genetic Center (GGC) collaborated with investigators from the Emory Genetics Laboratory and RainDance Technologies™ to design a Next Generation Sequencing (NGS) Panel for 62 genes associated with ASD (available commercially from RainDance Technologies™ as the ASDSeq™ Research Screening Panel). These genes were selected to represent the most common single gene etiologies associated with a syndrome that includes autism as a significant clinical feature. The panel was validated at GGC, and diagnostic testing became available in January of this year. Thus far, 66 samples have been submitted for clinical testing. We will discuss the results for these patients and summarize the coverage of this panel along with other run statistics. We have already identified several pathogenic mutations including a mosaic *MECP2* mutation that was previously missed by Sanger sequencing. Our initial findings indicate that this panel provides comprehensive testing for patients with syndromic autism and may also serve as a useful 2nd tier test for patients with features overlapping those of Rett and Angelman syndromes.

2902W

Empowering a clinical genetic setting through the introduction of whole exome sequencing in prenatal and postnatal investigations. *C. Pangalos[1,2], B. Hagnefelt[2], Z. Agioutantis[3], C. Konialis[2].* 1) Clinical Genetics, InterGenetics -Diagnostic Genetic Center, Athens, Greece; 2) Molecular Genetics, InterGenetics -Diagnostic Genetic Center, Athens, Greece; 3) Mineral Resources Engineering, Technical University of Crete, Hania, Greece.

Until now, the `classical' approach to the diagnosis of genetic disorders involves the targeted investigation of specific genes (1–5); however, in everyday clinical practice the geneticist is often confronted with diagnostic riddles, involving rare Mendelian disorders and complex traits, for which phenotype-driven, Sanger sequencing-based testing rarely yields meaningful results. In the last 10 months, we have applied WES in 12 complex clinical cases, involving: an 18yr old male exhibiting multiple renal abnormalities coupled to progressive visual impairment; 3 fetuses, following termination of pregnancy, with skeletal and genital anomalies; an adult with complex poly-neuropathy of unknown etiology; an adult with atypical polycystic kidney disease; an adult with progressive hearing loss; a newborn with possible Treacher-Collins syndrome; a young child with epileptic encephalopathy; a young child with possible Joubert syndrome; a female with degenerative kidney disease and an adult with possible Zellweger syndrome. Exome enrichment was performed using Agilent SureSelect Human All Exon V4 capture, followed by NGS on an Illumina GAIIx at >50x coverage. Sequence alignment and identification of variants was achieved utilizing NextGENe v2.1 sequence analysis software (SoftGenetics), while a custom pipeline (Exome data Management Application - EMA) was developed for variant filtering and mutation identification. In the first of the 2 completed cases to date, known or novel pathological heterozygous mutations were identified in each of 4 genes (NPHP4, RPGRIP1L, CC2D2A, AVIL), consistent with a diagnosis of multi-allelic cilliopathy with retinal degeneration. In the second case of a fetus with skeletal and genital anomalies, a novel pathological hemizygous mutation c.194A>G within the NSDHL gene on Xq28 was identified, and its presence was confirmed in the carrier mother. The presence of this novel mutation in the male fetus is most likely associated with malformation syndromes caused by dysfunction in cholesterol biosynthesis, in agreement with the clinical findings. As WES is proving to be an extremely powerful tool, it may appear as an attractive alternative to often cumbersome clinical evaluation of the patient. Our experience highlights the added value of this new technology when applied in an integrated clinical setting, proving in fact that detailed phenotypic information is a valuable resource for unraveling the genetic causes of complex phenotypes.

2903T

Use of whole exome sequencing to determine the genetic etiology of inherited congenital cataracts. *L.M. Reis[1], R.C. Tyler[1], E.V. Semina[1,2].* 1) Department of Pediatrics and Children's Research Institute, Medical College of Wisconsin, Milwaukee, WI; 2) Department of Cell Biology, Neurobiology and Anatomy, Medical College of Wisconsin, Milwaukee, WI.

Pediatric cataracts are observed in 1–15 per 10,000 births, with 10–25% of cases attributed to genetic causes. Genetic studies have identified mutations in over 34 genes associated with congenital/ juvenile forms of cataracts, but the exact frequencies of mutations in these genes are not known and many cases are still awaiting molecular diagnosis. We screened FOXE3 and PITX3 in 32 probands with congenital cataract and identified two mutations (one in each gene) in probands with cataract and microcornea. The remaining 30 probands were submitted for whole exome sequencing through Perkin Elmer with Geospiza analytical tools; independent gene sequencing was used to confirm identified variants and to screen genes with poor coverage through whole exome sequencing. Initial analysis of known cataract genes in the first 15 set of probands with autosomal dominant congenital cataracts is completed. Probable disease-causing mutations in known genes were identified in nine families including HSF4, CRYBB1, GJA8, BFSP2, CRYGC, CRYGS, CRYGD, and MIP. Ongoing analysis in the remaining 6 families will seek to identify disease-causing mutations in novel genes, utilizing affected and unaffected family members to confirm co-segregation with disease phenotype. Analysis of data from a second set of 15 probands with cataract is ongoing. These data confirm the genetic heterogeneity of congenital cataract, verify the efficacy of utilizing whole exome sequencing to screen a large number of known genes, and suggest that there are additional disease genes yet to be identified.

2904F

A next generation sequencing assay for the diagnosis of the Noonan spectrum of disorders. *A.B. Santani, T. Tischler, A. Sasson, J. Perin, M. Sarmady, E. Frackelton, B. Tweddale, N. Abdel-Magid, S. Panossian, P. Warren, H. Feret, M. Deardorff, A. Wilkens, M. Italia, B. Ruth, J. Miller, E. Zackai, D. Monos, E. Rappaport, H. Hakonarson, P. White, C. Stolle.*Children's Hospital of Philadelphia, 3615 Civic Center Blvd, Philadelphia, PA., USA.

The Noonan spectrum of disorders (NSD) includes Noonan, Costello, LEOPARD and Cardiofaciocutaneous syndromes. This is a clinically heterogeneous group of syndromes with overlapping phenotypic and genetic features. Mutations in multiple genes have been associated with this group of disorders. Testing for NSD using traditional gene sequencing technology can be costly and time consuming. Next generation sequencing (NGS) offers an alternative approach for simultaneous analysis of multiple genes at a reduced cost and improved turnaround time. We have developed and clinically validated a targeted resequencing approach to identify mutations in 11 genes (PTPN11, RAF1, SOS1, BRAF, HRAS, NRAS, KRAS, MEK1, MEK2, SHOC2, CBL) associated with NSD.Amplification of the coding exons and intron/exon boundaries was performed using microdroplet PCR, followed by SOLiD sequencing. After enrichment, up to 10 specimens were barcoded and then pooled for sequencing on a single lane of the SOLiD 5500xl. Sequence alignment, variant detection and annotation were performed using VARify, an in-house bioinformatics workflow. The average depth of coverage was greater than 2000 fold. Approximately 96% of bases had greater than 30X coverage. Amplicons with less than 30X coverage for any base were subjected to Sanger sequencing. On average, less than 5% of amplicons per sample required Sanger sequencing. The ability of this targeted NGS assay to detect mutations in patient samples was validated by resequencing of 25 blinded specimens of known genotypes, of which 6 were from patients with previously characterized disease causing mutations. Analytical performance of the assay was evaluated by comparing genotyping results (obtained by SNP array or Sanger sequencing) and mutation data to NGS results. A total of 168 variants, including 142 single base mutations and 26 indels (up to 6bp), were used for the comparison. All disease causing mutations were correctly identified in all positive control samples; no mutations scored as pathogenic were identified in any negative control samples (no false positives). SNP concordance was 100%. These results demonstrate that both the analytical sensitivity and analytical specificity of the assay is 100%. In summary, we have demonstrated that targeted NGS is a highly sensitive approach for detecting disease causing mutations in genes involved in the Noonan spectrum of disorders and should decrease the time from clinical evaluation to molecular diagnosis.

2905W

French Canadian Founder Mutation in the SBDS Gene causing Shwachman-Diamond Syndrome. *L. Steele[1,2], M. Eliou[1], J.M. Rommens[4], P.N. Ray[1,2], T.L. Stockley[1,3].* 1) Paediatric Lab Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Dept of Molecular Genetics; 3) Dept of Laboratory Medicine and Pathobiology; 4) Program in Genetics and Genome Biology, University of Toronto, Toronto, Ontario Canada.

Shwachman-Diamond syndrome (SDS) is an autosomal recessive disorder caused by mutations in the *SBDS* gene, and is characterized by exocrine pancreatic dysfunction, haematological and skeletal abnormalities. The *SBDS* gene (7q11) has an adjacent pseudogene, *SBDS-P* with 97% sequence identity, and the majority of *SBDS* mutations (>80%) arise from gene conversion between exon 2 of the *SBDS* gene and the *SBDS-P* pseudogene. The Molecular Genetics laboratory has offered clinical molecular diagnostic testing for *SBDS* mutations since 2004 (440 probands tested). Molecularly-confirmed SDS probands have either two recurrent mutations in *SBDS* exon 2 from gene conversion, or one recurrent exon 2 mutation and a rare, family-specific mutation in one of the other exons of the *SBDS* gene. Objective: During clinical testing, it was noted that 5 SDS probands had the same rare *SBDS* mutation in exon 1, c.120del, with the second mutation a known recurrent mutation in exon 2 (c.258+2T>C). Recurrent *SBDS* mutations have not been reported outside of exon 2. Further investigation indicated all 5 probands were of French Canadian background, suggestive of a founder mutation. The objective of this study was to determine if the c.120del *SBDS* mutation is a French Canadian SDS founder mutation, using the 5 identified probands and family members. Methods: Sequence analysis of *SBDS* exon 1–5 was performed in all probands, and siblings and parents were tested by targeted mutation analysis as available. Haplotype analysis using STR markers flanking the *SBDS* gene was performed on all samples, and family haplotypes constructed and compared. Results and Conclusions: STR analysis of markers flanking the *SBDS* gene was suggestive of a shared region in four of five families, extending from 3.9 Mb proximal to 0.8 Mb distal of the *SBDS* gene. One of five families had identical shared markers proximal of the gene, but with different markers 0.6 Mb distal of the gene. Overall, results are suggestive of the*SBDS* c.120del mutation being a shared founder in the French Canadian population. Based on our SDS cohort, of whom a total of 48 are of French Canadian background, the incidence of c.120del mutation in SDS probands is may be up to 1 in 20. Therefore, if a child is of French Canadian descent, has failure to thrive and cystic fibrosis testing is negative; a health care provider may want to think of SDS as the frequency of the c.120del mutation appears to be prevalent in this population.

2906T

Confirmation of Cause and Manner of Death Via a Comprehensive Cardiac Autopsy Including Whole Exome Next-Generation Sequencing. *D.J. Tester[1], JJ. Maleszewski[2], TM. Kruisselbrink[2], MJ. Ackerman[1,3,4].* 1) Department of Molecular Pharmacology & Experimental Therapeutics, Mayo Clinic, Rochester, MN; 2) Department of Lab Medicine and Pathology, Mayo Clinic, Rochester, MN; 3) Department of Internal Medicine/Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 4) Department of Pediatric and Adolescent Medicine/Division of Pediatric Cardiology, Mayo Clinic, Rochester, MN.

Annually, the sudden death of thousands of individuals under the age of 35 remains unexplained or poorly characterized despite a medico-legal investigation. Heritable cardiac channelopathies/cardiomyopathies like long QT syndrome (LQTS), catecholaminergic polymorphic ventricular tachycardia (CPVT), Brugada syndrome (BrS), hypertrophic cardiomyopathy (HCM), dilated cardiomyopathy (DCM), and arrythmogenic cardiomyopathy (ARVC) underlie a significant number of sudden unexplained deaths in the young (SUDY). Whole exome sequencing (WES)-based molecular autopsy may provide an efficient manner to identify genetic defects responsible for SUDY. In this pilot study, a WES molecular autopsy was performed on autopsy blood-derived genomic DNA from an otherwise healthy 16-year-old girl who was found dead in her bedroom. Post-mortem examination revealed a moderately enlarged heart with normal ventricular septum to free wall ratio. Histologically, myocyte disarray was noted in the anterolateral left ventricle. Following exome capture, the resulting DNA libraries were sequenced at 96% coverage with a read depth of 35x. Variants were called against the hg19 human reference and analyzed using the TREAT workflow. Following sequencing, gene-specific surveillance of all known LQTS, CPVT, BrS, HCM, DCM, and ARVC genes (68 total) was performed to identify putative disease causing mutation(s). The SUDY victim's exome contained 30,008 variants. Of these, 98 genetic variants were observed among the 68 channelopathy/cardiomyopathy associated genes surveyed. Twenty seven were non-synonymous variants. However, only 1 mutation (R249Q-MYH7) was absent in all publically available exome databases including the 1000 genome project, the NHBLI exome sequencing project, and the 12000 exome chip. Mutations in the MYH7-encoded myosin heavy chain beta (MHC-β) account for ~ 40% of HCM. Specifically, R249Q-MYH7 has been associated previously with familial HCM, sudden death, and impaired MHC-β actin-translocating and actin-activated ATPase activity. Pedigree expansion efforts are currently underway. This is the first report of a post-mortem whole exome sequencing-based cardiac molecular autopsy to confirm the underlying pathogenic substrate most likely responsible for the sudden unexpected death of an otherwise healthy adolescent. WES followed by gene specific surveillance may be a highly efficient and cost-effective approach as part of a comprehensive cardiac autopsy.

2907F

Diagnostic Exome Sequencing Uncovers Mendelian Inheritance in Neurological Disease. *E.C. Chao[1], X. Li[1], K. Gonzalez[1], A. Fatemi[2], J. Cohen[2], w. Zeng[1].* 1) Ambry Genetics, Aliso Viejo, CA; 2) Department of Neurogenetics, Kennedy Krieger Institute and Johns Hopkins School of Medicine, Baltimore, MD.

Whole exome sequencing for clinical diagnostics has been long anticipated, and was first launched by Ambry Genetics one year ago. Here, we describe the two successfulreports of exome sequencing for clinical diagnostic purposes. We sequenced protein-coding regions of the genome (exome) in two families with severe neurologic phenotypes. Both had evaded diagnosis through clinical evaluation and extensive testing over many years. In one family two brothers, with severe mental retardation, autistic features, and self injurious behaviors, were compound heterozygotes for two missense mutations in the *ELP2* gene, which was recently correlated with the phenotype of autosomal recessive intellectual disability (ARID). Each unaffected parent carries one of these mutations; two additional siblings tested by co-segregation analysis carry one and zero of the mutations. In a second case, an adolescent male with spastic diplegia and developmental delay had initially been characterized as suffering from perinatal hypoxic brain injury. Extensive biochemical and genetic testing remained inconclusive. A homozygous nonsense mutation identified in exon 33 of *ALS2*, along with his clinical history is highly consistent with a diagnosis of Infantile-Onset Ascending Hereditary Spastic Paralysis (IAHSP). These findings demonstrate the clinical utility of exome sequencing for diagnostic purposes and highlight initial successes for early adopters of this methodology.

Whole Exome Sequencing Identifies Potential Homozygous Mutations in a Family with Two Sisters With Brain Malformation. *E. KARACA[1], D. PEHLIVAN[1], C.G. GONZAGA-JAUREGUI[1], M. OZEN[2], A. YUKSEL[3], W. WISZNIEWSKI[1], A. STRAY-PEDERSEN[1], D. MUNZY[4], R.A. GIBBS[1,4], J.R. LUPSKI[1,5,6], Baylor-Hopkins Center for Mendelian Genetics.* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Department of Medical Genetics, Cerrahpasa School of Medicine, Istanbul, Turkey; 3) Department of Pediatrics, Bezmialem University, Istanbul, Turkey; 4) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 6) Texas Children's Hospital, Houston, TX, USA.

Disorders disrupting normal brain development represent clinically and genetically heterogeneous group which are caused by genomic alterations that involve many different genes. Although recent advances in genomic technologies have led to the discovery of many novel genes that are involved in brain development, many more are likely waiting to be brought to light. To this end, we performed exome sequencing in one family with two affected sisters, born from consanguineous marriage, both showing atrophy of the cerebral cortex, hypoplastic corpus callosum and brain stem, and also having treatment resistant epilepsy, microcephaly, severe growth and developmental delay without speech. Clinical features did not fit with any known syndrome. Exome sequencing revealed probable deleterious mutations in six candidate genes which have not been described before as mutated in brain malformation syndromes. Functional studies of these genes will be performed in order to elucidate their functional impact. Increasing use of exome sequencing approaches, along with other recent genomic technologies, will greatly help to identify causative genes not only in disorders of brain development, but also in other disorders showing Mendelian inheritance.

2909T

Recessive mutations in *MYL2* cause infantile fiber type disproportion and cardiomyopathy. *M. A. J. Weterman[1], P. B. Barth[2], K. Y. van Spaendonck-Zwarts[3], E. Aronica[4], B.-T. Poll-The[2], O. Brouwer[5], J. P. van Tintelen[6], Z. Qahar[1], E. J. Bradley[1], M. B. de Wissel[1], L. Salviati[7], C. Angelini[7,8], L. van den Heuvel[9], Y. E. M. Thomasse[10], A. P. Backx[11], G. Nuernberg[12,13], P. Nuernberg[12,13,14], F. Baas[1].* 1) Dept Genome Analysis/Neurogenetics, K2-213, AMC/UvA, Amsterdam, Netherlands; 2) Div. Pediatric Neurology, Emma Children's Hospital, AMC, Amsterdam, the Netherlands; 3) Dept. Clinical Genetics, AMC, Amsterdam, the Netherlands; 4) Dept. (Neuro)Pathology, AMC, Amsterdam, the Netherlands; 5) Dept. Pediatric Neurology, UMCG, Groningen, the Netherlands; 6) Dept. Genetics, University of Groningen, UMCG, Groningen, the Netherlands; 7) Dept. Pediatrics, University of Padua, Italy; 8) IRCCS S. Camillo, Venice, Italy; 9) Nijmegen Centre for Mitochondrial Disorders, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands; 10) Dept. of Pediatrics, Pediatric Intensive Care Unit, UMCG, Groningen, the Netherlands; 11) Div. Pediatric Cardiology, Emma Children's Hospital, AMC, Amsterdam, the Netherlands; 12) Cologne Center for Genomics, Cologne, Germany; 13) CMMC, University of Cologne, Cologne, Germany; 14) CECAD, University of Cologne, Cologne, Germany.

IFTDC, a severe disorder with features of fibre type disproportion, myofibrillar disorganization, infantile onset of cardioskeletal myopathy, and early death under 6 months of age was previously reported in three Dutch families. Multipoint parametric linkage analysis of six Dutch patients resulted in the identification of a homozygous region of 2.1 Mb on chromosome 12 that was shared between all Dutch patients with a LOD score of 10.82. Sequence capture and analysis of the entire linkage region identified a homozygous mutation in the last acceptor splice site of the *MYL2* gene as the underlying genetic cause thereby enabling genetic testing for this fatal disorder. *MYL2* encodes a regulatory light chain myosin (MLC-2V). The mutation results in use of a cryptic splice site upstream of the last exon causing a frameshift and replacement of the last 32 codons by 20 different ones. Whole exome sequence analysis of an Italian patient with similar clinical features showed compound heterozygosity for two other mutations affecting the same exon of *MYL2*. The three found mutations disrupt the C-terminal tails of the encoded proteins, affecting the second domain of the two EF-hands which are assumed to function as calcium sensors. Upon binding of calcium, they can undergo a conformational change critical for interactions with downstream targets. Immunohistochemical staining of muscle tissue of the Dutch patients shows a diffuse and mostly weak expression of the mutant protein without the clear fiber specificity seen in normal muscle tissue, while normal protein is absent. Heterozygous missense mutations in *MYL2* have been known to cause dominant hypertrophic cardiomyopathy, however, none of the parents showed signs of cardiomyopathy. In conclusion, the identification of mutations in the last exon of *MYL2* has revealed the cause of this disorder which is a novel autosomal recessive myosinopathy due to defects changing the C-terminal tail of the ventricular form of the myosin regulatory light chain.

2910F

Molecular diagnosis in Stargardts disease through a tiered sequencing approach. *J. Zaneveld[1], H. Wang[1], F. Wang[1], L. Mao[2], K. Zhang[2], Y. Duan[2], J. Zhu[2], J. Chiang[3], R. Chen[1].*1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Institute for Genomic Medicine, UCSD, San Diego, CA; 3) Casey Eye Institute, Oregon Health and Science University, Portland, OR.

Stargardts disease is a form of early onset macular degeneration known to be caused by mutations in ABCA4. In order to find disease causing alleles in patients lacking known Stargardts mutations, we have proceeded with a tiered sequencing approach. First, patient DNA from genes known to cause retinal disease were sequenced using capture sequencing technology. If we were unable to identify a strong candidate for the disease causing allele(s) within the capture region, we proceeded with whole exome sequencing and, when possible, linkage analysis. Using this approach, we have analyzed three large families affected with Stargardts disease, as well as 24 sporadic cases of the disease. Analysis is ongoing, but so far we have identified several novel disease causing allele candidates, as well as a candidate for a novel Stargardts disease causing gene. This research raises the strong possibility that there are novel Stargardts disease genes, and demonstrates the utility of capture sequencing in molecular diagnosis.

2911W

Identification of mutations in the prostaglandin transporter gene SLCO2A1 in Japanese patients with pachydermoperiostosis. *J. Kudoh[1], T. Sasaki[2,3], A. Shimizu[4], A. Shiohama[1], A. Pachydermoperiostosis (PDP), also known as primary hypertrophic osteoarthropathy, is a rare genetic disorder characterized by 3 major symptoms: pachydermia including cutis verticis gyrata (CVG), periostosis, and finger clubbing. In addition, several other symptoms, including sebaceous hyperplasia, hyperhidrosis, and arthropathy have also been reported. Recently, a homozygous mutation in the gene HPGD, which encodes 15-hydroxyprostaglandin dehydrogenase (15-PGDH), was found to be associated with PDP. We have also attempted to find HPGD mutations in Japanese PDP patients; however, no HPGD mutations have been identified so far, suggesting the existence of other causative gene(s) responsible for PDP in the Japanese population. We therefore aimed to identify a novel responsible gene for PDP using exome sequencing by next-generation DNA sequencer (NGS). Four PDP patients, including 2 patient-parent trios were enrolled in this study. Entire coding regions were captured using the SureSelect Human All Exon v4 (Agilent Technologies, Inc.) and sequenced with the Genome Analyzer IIx (Illumina, Inc.) to identify candidate mutations associated with PDP. The candidate mutations were subsequently sequenced using the Sanger method. To determine clinical characteristics, we analyzed histological samples, as well as serum and urinary prostaglandin E2 (PGE2) levels for each of the 4 PDP patients, and one additional patient with idiopathic CVG. From initial analyses of exome sequencing data we identified mutations in the solute carrier organic anion transporter family member 2A1 (SLCO2A1) gene, encoding prostaglandin transporter (PGT), in all of the three PDP patients examined. Follow-up Sanger sequencing identified 5 different SLCO2A1 mutations (c.940+1G>A, p.E427_P430del, p.G104Ter, p.T347I, p.Q556H) in 4 unrelated PDP patients. However, no significant mutation in the SLCO2A1 gene was identified in the sole patient with CVG. Among the 8 alleles of SLCO2A1 mutant genes identified in this study, 4 (50%) included the same splice-site mutation c.940+1G>A. Haplotype analysis indicated that the c.940+1G>A mutation is a founder mutation in the Japanese population. Although the SLCO2A1 gene is only the second gene discovered to be associated with PDP, it is likely to be a major cause of PDP in the Japanese population.

CIAS1 mutations associate with familial Mediterranean Fever in Turkish patients and a novel V734G mutation in MEFV. *E. Yosunkaya[1], N. Buyru[2].* 1) Dept. Medical Genetics, Istanbul Univ. Cerrahpasa Medical Sch., Istanbul, Turkey; 2) Dept. Medical Biology, Istanbul Univ. Cerrahpasa Medical Sch., Istanbul, Turkey.

Familial Mediterranean Fever (FMF), an autosomal recessive disease, affecting people originating from Mediterranean basin, is characterized by short lasting acute serositic attacks. The frequency and duration of attacks and accompanying clinical features not only vary among patients, but also between the attacks of a patient. It is suggested that the phenotype is affected by genotype, environmental factors, epigenetic mechanisms and other modifying genes. Symptoms mainly consisting of fever, abdominal and articular pain are due to inflammation cascade problems. It is understood that abnormal pyrin, resulting from MEFV gene mutations, would be inadequate to inhibit the effect of cryopyrin, so inflammation is triggered. In this study with 192 patients referred for MEFV mutation testing, we examined the genotype-phenotype correlations in FMF and investigated CIAS1 gene mutations, which are known to be responsible from cryopyrinopathies. The relationship between MEFV genotypes and the phenotypes with regard to the demographical, clinical and laboratory findings in patients showed statistically significant correlations in approximately 30 parameters. DNA sequencing of the 5' end of the 10th exon of the MEFV gene, which involves most FMF mutations was also performed. A novel V734G mutation was identified in an FMF patient. We detected V200M and L307P mutations in the CIAS1 gene in 6 people with various MEFV mutations. In conclusion, our data, which correlated nearly 30 phenotypic parameters with MEFV genotypes also revealed that V734G, a novel mutation in MEFV gene is responsible from FMF in a patient, and V200M and L307P mutations in CIAS1 gene might have modifying effects on the FMF phenotype.

2913F

Exome sequencing of a dog trio affected with a canine progressive retinal degeneration. *SJ. Ahonen[1,2,3], H. Lohi[1,2,3].* 1) Dept. of Veterinary Biosciences, University of Helsinki, Finland; 2) Dept. of Molecular Genetics, the Folkhälsan Institute of Genetics, Finland; 3) Dept. of Medical Genetics, Research Programs Unit, Molecular Medicine, University of Helsinki, Finland.

Retinitis pigmentosa (RP) is a group of inherited diseases in humans causing retinal degeneration and gradual decline of vision due to a loss of photoreceptor cells function. Primarily RPs are rod degenerations followed by loss of cone function. Many causing genes have been found in humans, but still there are RP patients with unknown genetic cause. Canine progressive retinal atrophy (PRA) is a reminiscent of human RP. PRAs are characterized as well by progressive loss of retinal photoreceptor cells, usually leading to complete loss of vision. Dogs have been successfully used as animal models for human RPs and several mutations have been found in both species. Continental Toy Spaniels include both Phaléne and Papillon breeds, which are separated only based on the posture of the ears. Genetically the breeds are the same and littermates are registered either as Phalénes or Papillons based on their ear positions. Continental Toy Spaniels are affected by a bilateral progressive retinal degeneration with similarities to progressive rod-cone degeneration caused by prcd-gene. We studied a trio of Phalénes with parents and a PRA affected dog to identify the potential coding PRA mutation using exome capture followed by Illumina sequencing. The affected dog was diagnosed with bilateral retinal degeneration at the age of 3 years. Both parents were examined healthy over the age of 6 years. Based on the pedigree analysis, PRA was assumed to be recessively inherited. Data analysis revealed over 150000 single nucleotide variants (SNV) and 36000 indels in each individual. About 26% of SNVs and 0.3 % of indels were known SNPs. Filtering with the assumption of the autosomal recessive mode and using seven other dogs from two other breeds as controls decreased the number of variants to 63 SNVs and 21 indels for validation study in a larger sample cohort. Candidate variants were prioritized according to the relevant function, retinal expression or possible association with retinal degeneration in other species. Ongoing validation is likely to identify a causative gene for PRA in the Continental Toy Spaniels and benefit human RP research as the causative gene can be tested in human RP patients.

Mutations in NESP4, a KASH domain protein linking the nucleus to the cytoskeleton, lead to hearing impairment in humans and mice. *K.B. Avraham[1], Z. Brownstein[1], H.F. Horn[2], D.R. Lenz[1], S. Shivatzki[1], A. Dror[1], K.J. Roux[3], S. Kozlov[4], B. Burke[2], C.L. Stewart[2].* 1) Department of Human Molecular Genetics and Biochemistry, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 2) Institute of Medical Biology, A*STAR, Singapore; 3) Sanford Research/USD Children's Health Research Center, Sioux Falls, SD, USA; 4) National Cancer Institute, Frederick, MD, USA.

Hereditary hearing loss in humans and mice is shown for the first time to be caused by mutations in Spectrin-repeat containing, nuclear envelope 4 protein (NESP4/SYNE4/C19orf46) that is essential for the maintenance of sensory outer hair cells. Two families of Jewish Israeli-Iraqi origin presented with autosomal recessive non-syndromic hearing loss, designated DFNB76. Linkage analysis and exome capture followed by paired-end massively parallel sequencing led to the detection of a 2 nucleotide deletion in the coding region of *NESP4*, with exon skipping leading to a predicted truncation. *Nesp4*$^{-/-}$ mice were found to have a similar pattern of hearing loss, as determined by auditory brainstem response (ABR). First identified in secretory epithelial cells, NESP4 is a KASH-domain protein that resides in the outer nuclear membrane (ONM) as part of the nuclear envelope-associated LINC (Linker of Nucleoskeleton and Cytoskeleton) complexes. These complexes consist of KASH domain proteins in the ONM and SUN domain proteins in the inner nuclear membrane (INM), which together link the nucleoplasm to the cytoskeleton. We found NESP4 to be expressed in the mouse cochlea, in the inner and outer hair cell ONM. Significantly, in the *Nesp4*$^{-/-}$ mice, outer hair cells are formed, but gradually to die as the cochlea matures, leading to progressive hearing loss that is complete by 2 months of age. *Sun1*-null mice exhibited similar cochlear abnormalities. Our findings mark NESP4 and SUN1 as essential proteins for cochlear outer hair cell viability and hearing, potentially due to their role in maintaining correct nuclear position in the outer hair cells of the sensory epithelia.

2915T

Genetic characterization of a large keratinization disorder cohort, utilizing whole exome sequencing to discover mutations in known and novel genes. *L.M. Boyden[1], C. Tian[2], C. Saraceni[2], E. Loring[1], L. Milstone[2], R.P. Lifton[1], H. Vernon[3], D. Zand[4], A.S. Paller[5], K.A. Choate[2].* 1) Department of Genetics, Yale University School of Medicine, New Haven, CT; 2) Department of Dermatology, Yale University School of Medicine, New Haven, CT; 3) Commonwealth Dermatology, Richmond, VA; 4) Children's National Medical Center, Washington, DC; 5) Department of Dermatology, Northwestern University Feinberg School of Medicine, Chicago, IL.

Disorders of keratinization (DOK) are severe skin diseases featuring generalized or local scaling with additional epidermal and systemic sequelae. There is substantial heterogeneity, with dominant, recessive, X-linked, and sporadic forms. Over 50 genes have been identified for DOK, yet mutations in these genes explain only a portion of observed phenotypes. Currently there is no systematic method facilitating both comprehensive identification of mutations in known genes and discovery of novel genes. We have recruited a cohort of 180 well-phenotyped DOK kindreds. We are employing a tiered strategy whereby cases are first screened for mutations in commonly causative genes, and then whole exome sequencing is used either to identify mutations in other known DOK genes or for novel gene discovery. To date, pre-screening for mutations in 8 genes has been performed in 147 kindreds, with mutations identified in 82. In cases of autosomal recessive congenital ichthyosis (ARCI), homo- or compound heterozygous mutations were seen in TGM1, ALOX12B, NIPAL4, CYP4F22, SPINK5, and ALOXE3. In cases of dominant epidermolytic hyperkeratosis (EHK) or ichthyosis with confetti (IWC), heterozygous mutations in KRT1 and KRT10 were observed. Whole exome sequencing of 45 remaining cases has revealed 18 with mutations in known genes. ARCI cases were found to have mutations in ABCA12, PNPLA1, ALOXE3, CYP4F22, and TGM1. Dominant disease included a palmoplantar keratoderma patient with a LOR mutation, and a patient diagnosed with EHK harboring a mutation in KRT2 (known to cause phenotypically similar ichthyosis bullosa of Siemens). Exome sequencing allowed discoveries that would have been overlooked by traditional approaches. In one example, a patient born of consanguineous union was found to be compound heterozygous for ABCA12 mutations, a genetic diagnosis that would have been missed by homozygosity mapping. In another, a patient with severe syndromic ichthyosis had been seen by at least 6 experts and presented at a national dermatology meeting, with no definitive diagnosis. Exome sequencing revealed a hemizygous mutation (R429H) in MBTPS2, an X-linked gene known to cause the typically milder ichthyosis syndromes IFAP and KFSD, but severe disease in the case of R429H. Discovery efforts within the remaining cohort are underway, including sequencing of parent-child trios to identify de novo mutations. Several genes are currently under investigation as potential novel causes of DOK.

X-linked Familial Focal Segmental Glomerulosclerosis with First-Degree Heart Block caused by a mutation in the NXF5 gene. *T. Esposito[1], R.A. Lea[2], B.H. Maher[2], D. Moses[2], H.C. Cox[2], S. Magliocca[1], V. D'Alessio[1], A. Angius[3], T. Titus[4], T. Kay[4], A. Parnham[4], F. Gianfrancesco[1], L.R. Griffiths[2].* 1) Inst Gen & Biophysics, Italian Natl Res Council, Naples, Naples, Italy; 2) Genomics Research Centre, Griffith Health Institute, Griffith University, Queensland, 4222, Australia; 3) Institute of Genetic and Biomedical Research, National Research Council of Italy, Cagliari, Italy; 4) Gold Hospital Gold Coast, Queensland, 4222, Australia.

Focal segmental glomerulosclerosis (FSGS) is a disease that attacks the kidney's filtering system (glomeruli), causing serious scarring. FSGS is a cause of nephrotic syndrome in children and adolescents and is an important cause of kidney failure in adults. There are currently several genes known to cause the hereditary forms of FSGS that have contributed to the understanding of disease pathology. We recruited a large, multigenerational Australian pedigree of 89 individuals in which FSGS co-segregates with first-degree heart block. Only males exhibit the full form of both disorders, which is suggestive of X-linked recessive inheritance. Of further interest is the occurrence of renal tumours in this family, which has added another element of complexity to understanding the genetic basis of the disease. This family appears to be unique. There have been no reports of any family co-inheriting these disorders, nor has there been a previous report of FSGS transmitted in an X-linked fashion. Through a combined approach of linkage and haplotype analysis, we found that the disease gene(s) reside in a 21.19 cM interval between the markers DXS8077 and DXS8064. We then used a whole exome sequencing approach to identify a mutated gene. Nuclear RNA Export Factor 5 (NXF5) is located in the linkage interval and segregated with the disease phenotype in the pedigree. Moreover, the R113W mutation, in NXF5 gene, was predicted to be deleterious by bioinformatics tools implying a causative role and was not found in a healthy population. The NXF5 gene belongs to the NXF gene family which, in humans, also includes the NXF1, NXF2 and NXF3 genes, all clustered on Xq22.1, except NXF1, which is located on chromosome 11. Evolutionary conservation analysis shows high similarity for these proteins. Interestingly, the arginine at position 113 is highly conserved in all genes of this family and all species. In eukaryotes, the nuclear export of mRNA is mediated by nuclear export factor 1 (NXF1) receptors. As demonstrated in mice, Nxf7 which is analogous to the human NXF5 gene, has cytoplasmic RNA transport factor properties. It has further been shown that Nxf7 interacts with cytoplasmic microtubules and actin filaments and is involved in cellular motility. Functional studies are now ongoing to determine the functional consequence of this novel mutation to development of FSGS and heart block phenotypes.

Mutations in *SLC52A2* impaire riboflavin transport and cause Brown-Vialetto-Van Laere syndrome. *T.B. Haack[1,2], C. Makowski[3], Y. Yao[4], E. Graf[1], M. Hempel[2], T. Wieland[2], U. Tauer[3], U. Athing[5], J.A. Mayr[6], P. Freisinger[7], H. Yoshimatsu[4], K. Inui[4,8], T.M. Strom[1,2], T. Meitinger[1,2], A. Yonezawa[4], H. Prokisch[1,2].* 1) Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg 85764, Germany; 2) Institute of Human Genetics, Technische Universität München, Munich 81675, Germany; 3) Department of Pediatrics, Technische Universität München, Munich 80804, Germany; 4) Department of Pharmacy, Kyoto University Hospital, Kyoto 606-8507, Japan; 5) Department of Clinical Chemistry, Städtisches Klinikum München, Munich 80804, Germany; 6) Department of Paediatrics, Paracelsus Medical University Salzburg, Salzburg 5020, Austria; 7) Department of Pediatrics, Klinikum Reutlingen, Reutlingen 72764, Germany; 8) Kyoto Pharmaceutical University, Yamashina-ku, Kyoto 607-8414, Japan.

Brown-Vialetto-Van Laere syndrome (BVVLS [MIM 211530]) is a rare neurological disorder presenting with infancy onset sensorineural deafness and ponto-bulbar palsy. Mutations in*SLC52A3* coding for riboflavin transporter 2 (hRFT2) have been recently identified as the molecular genetic correlate in a number of BVVLS individuals. Exome sequencing of a BVVLS individual lead to the identification of compound heterozygous mutations in *SLC52A2*, a new member of the riboflavin transporter family coding for riboflavin transporter 3 (hRFT3). Functional studies confirmed that the gene products of both mutant alleles have reduced riboflavin transport activities. While mutations in *SLC52A3* are associated with decreased plasma riboflavin levels, concordant with a role of *SLC52A3* in riboflavin uptake from food, the *SLC52A2*-mutant individual showed normal plasma riboflavin concentrations, a finding in line with a postulated function of *SLC52A2* in riboflavin uptake from blood into target cells. We initiated an oral high-dose riboflavin supplementation which lead to moderate clinical improvement. However, saturation of intestinal uptake capacity and high rates of renal excretion are likely to limit maximum riboflavin blood concentration. We therefore now started an intravenous riboflavin regimen. Evaluation of the clinical efficacy is ongoing.

2918T

Identification of a causative variant underlying nonsyndromic autosomal-dominant intellectual disability in an extended family. *N. Jinawath[1], B. Pupacdi[2], E. Wohler[3], V. Charoensawan[4], D. Wattanasirichaigoon[5].* 1) Research Center, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 2) Chulabhorn Research Institute, Bangkok, Thailand; 3) Kennedy Krieger Institute, Baltimore, MD, USA; 4) Department of Biochemistry, Faculty of Science, Mahidol University, Bangkok, Thailand; 5) Department of Pediatrics, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand.

Intellectual disability (ID) is a common neurodevelopmental disorder with global prevalence between 1 and 3%. Despite its high prevalence, little is known about the genetics of nonsyndromic intellectual disability (NSID). In this study, we set out to identify a causative variant in an extended Thai family with NSID. This family exhibits a four-generation pedigree with extensive history of NSID in every generation, including six affected males and two affected females. The proband is a 5-year-old female with moderate to severe intellectual disability and mildly dysmorphic facies. Her father has mild intellectual disability, and her mother and siblings are phenotypically normal. Karyotype, FISH for DiGeorge syndrome, subtelomeric FISH, and CGG expansion analysis of *FMR1* were all normal. We performed copy number variation (CNV) analysis using the Illumina HumanCytoSNP-12 Beadchip in five affected members of this family, including the proband, and identified no pathogenic or unknown significance CNVs. Assuming that the inheritance pattern is autosomal dominant, we analyzed allele sharing between the five affected individuals using SNPduo and narrowed down the genomic regions which share one allele (Identity by State (IBS) = 1) to 460 Mb. To identify causative variants, we performed whole genome sequencing (WGS) of the proband. We first focused our analysis on exonic regions, which included 16,426 single nucleotide variants (SNV) using ANNOVAR. After filtering out synonymous SNVs and those nonsynonymous SNVs that were in the dbSNP135 and 1000 Genomes databases, considered benign by SIFT and Polyphen, and outside of IBS1 shared regions, we were left with 32 genes with heterozygous missense SNVs. Among these candidates was *SPTAN1*, a gene on chromosome 9q34.11 that belongs to a family of widely-distributed filamentous cytoskeletal proteins known to cause intellectual disability. Dominant-negative mutations in this gene are the cause of early infantile epileptic encephalopathy-5. Additionally, we also identified two known autism and ID-related genes, *ABCA2* and *FASN*, in the 14 small deletion CNVs analyzed from WGS data that overlapped with shared IBS1 regions. The validation of these findings in other affected family members is underway. We propose that genome-wide genotyping analysis of multiple affected members in combination with whole genome sequencing of a proband may help simplify the identification process of causative variants in large family studies.

Targeted Exome Capture and Paired-End Massively Parallel Sequencing Reveals New Mutations for Human Hereditary Deafness in the Middle East. *M. Kanaan[1], Z. Brownstein[2], A. Abu Rayyan[1], D. Karfunkel[2], D. Dweik[1], Y. Bhonker[2], A. Yeheskel[3], L. Friedman[2], N. Kol[4], O. Yaron[4], V. Oron-Karni[4], M. Frydman[2,5], N. Shomron[4,6], K.B. Avraham[2,4].* 1) Department of Biological Sciences, Bethlehem University, Bethlehem, Palestinian Authority; 2) Department of Human Molecular Genetics and Biochemistry, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 3) Bioinformatics Unit, George S. Wise Faculty of Life Sciences, Tel Aviv University, Tel Aviv, Israel; 4) Genome High-Throughput Sequencing Laboratory, Tel Aviv University, Tel Aviv, Israel; 5) Danek Gartner Institute of Human Genetics, Sheba Medical Center, Tel Hashomer, Israel; 6) Department of Cell and Developmental Biology, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Identification of genes responsible for medically important traits is a major challenge in human genetics. While classic techniques such as linkage analysis and Sanger sequencing have led to the discovery of over 100 genes for hearing loss, many more genes remain to be discovered. This is particularly true of the Middle Eastern population, with a large number of different ethnic groups and high rates of consanguinity. Exome capture and massively parallel sequencing can be exploited to address this challenge for hereditary deafness, a highly genetically heterogeneous disease. A targeted capture pool was used for identifying mutations in all known human genes and human orthologs of mouse genes responsible for hearing loss. The Agilent SureSelect Target Enrichment system was used to capture the genomic regions harboring 284 genes including a total of 118 human protein-coding genes, three human microRNAs and the human orthologues of 163 genes associated with inner ear expression or deafness in the mouse. The final capture design targeting 4,475 exons from the 284 genes was 1.86 Mb. The multiplexed libraries representing 96 Palestinian Arab and Israeli Jewish patients (48 libraries per lane) were analyzed with paired-end sequencing at a read length of 2×101 bp, using the Illumina HiSeq 2000. The median base coverage was 113-641X, with minimal coverage of 84% at 10 reads per base and 73% at 30 reads. SNP, indel and CNV analyses were performed. Coordination with homozygosity mapping in consanguineous families optimized bioinformatics analysis. Novel mutations in previously known human deafness genes were discovered. Most compelling, a number of mutations were found in genes previously known only to be involved in mouse deafness. Protein structure predictions were made to provide insight into how the mutations lead to hearing loss. An increase in the number of known genes will have implications not only for the Middle East, but worldwide, as many mutations first found in this region have turned out to be present in other populations. This strategy allows for improved diagnostics, facilitating discovery of the causative mutation in an economically and temporally feasible manner, and establishing etiologically-based genetic counseling and hearing loss management. Further gene discovery will allow for a better understanding of the mechanisms of hearing loss, facilitating therapeutic development. Funded by the National Institutes of Health (NIDCD) R01DC011835.

Defective ion transport in sweat glands cause generalized isolated anhidrosis. *J. Klar[1], M. Sobol[1], K. Mäbert[1], M. Tariq[2], M. Rasool[2], M. Jameel[2], T. Naeem[2], N.A. Malik[2], A. Johansson[1], L. Feuk[1], S.M. Baig[2], N. Dahl[1].* 1) Department of Immunology, Genetics and Pathology and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 2) Human Molecular Genetics Laboratory, National Institute for Biotechnology and Genetic Engineering (NIBGE), Faisalabad, Pakistan.

Anhidrosis is defined as reduced or absent perspiration in response to an appropriate stimulus. Reports on congenital isolated generalized anhidrosis with morphologically normal sweat glands are extremely rare. We have identified a consanguineous Pakistani family comprising in total 13 individuals affected by generalized and isolated anhidrosis segregating as an autosomal recessive trait. Affected individuals show no other associated ectodermal abnormalities and they present with normal hair, teeth and skin. The patients suffer from heat intolerance and exposure to heat results in severe uncomfort with increased body temperature accompanied by a compensatory increase of heart rate. Starch-iodine test on skin surface of affected individuals excluded normal hydrolysis of starch supporting complete anhidrosis.

To identify the genetic basis for this inherited form of anhidrosis we performed autozygosity mapping using SNP array (Affymetrix 250k Nsp array). We identified a single homozygous region on chromosome 13 and subsequent fine mapping using microsatellite markers confirmed a shared homozygous region in all affected individuals. A custom array of the entire candidate region (NimbleGen Sequence Capture Microarrays, Roche) was used to enrich for DNA in one affected individual. High throughput sequencing (Illumina HiSeq) of enriched DNA identified a unique homozygous missense variant after filtering against common polymorphisms in available databases. The missense variant alters an evolutionary conserved codon and it segregates in a homozygous state with the disease in all affected family members. Software predictions indicate that the mutation has a severe functional impact on the protein which is involved in intercellular ion signaling. Histological analysis of paraffin sections from human skin using an antibody specific to the gene product confirms expression in eccrine sweat glands.

We present herein and to our knowledge, the first examples of a gene behind isolated anhidrosis. The findings emphasize the critical role of ion binding and transport in normal sweating.

2921T

Exome sequencing identifies a Novel Mutation in GJA1 as the Cause of Alopecia, Leukonychia, Skin Hyperkeratosis and Craniofacial Anomalies. *Z. Lin, H. Wang, J. Zhang, Q. Chen, M. Lee, X. Wang, R. Li, Y. Yang.* Dermatology, Peking University First Hospital, Beijing, Beijing, China.

Background Exome sequencing, the next-generation sequencing technology, is a powerful and cost-effective approach for dissecting the genetic basis of monogenic disorders, even clinically undiagnosed diseases. Objectives To identify the causative gene of a familial case presenting with alopecia, leukonychia, skin hyperkeratosis and craniofacial anomalies using exome sequencing. Methods Mutation analyses of KRT1, KRT10, GJB2 and GJB6 were performed in the proband. Exome sequencing was applied subsequently to identify the causative gene, followed by Sanger sequencing for verification and to rule out the possibility of single nucleotide polymorphism (SNP). Results No pathogenic mutations were detected in KRT1, KRT10, GJB2 or GJB6. Among the filtered variants obtained by exome sequencing, a missense mutation (p.Gly8Val) in GJA1 was noted and verified by Sanger sequencing. Cosegregation of the mutation with the phenotype in the family was confirmed and the possibility of SNP was excluded. Conclusions We identified a novel missense mutation in GJA1 underlying the phenotype of alopecia, leukonychia, skin hyperkeratosis and craniofacial anomalies in a familial case by exome sequencing.

Animal models are required to understand the molecular mechanisms of metabolic bone disorders in which imbalances of bone metabolism and mineralization lead to a variety of different phenotypes. Spontaneous mutations, targeted mutations and conventional knockout models are routinely used to study the molecular mechanism of a putative mutation. Random N-ethyl-N-nitrosourea (ENU) mutagenesis is a complementary approach to obtain mouse models for human diseases. Within a large-scale genome-wide Munich ENU Mutagenesis Project mutant mouse models for metabolic bone disease were identified using three blood plasma parameters (total alkaline phosphatase activity (ALP), total calcium (Ca), and inorganic phosphate (Pi) levels) which were commonly used as biochemical markers in patients with metabolic bone disease. All mutants were generated on a C3HeB/FeJ genetic background. The availability of massively parallel sequencing provides an opportunity to sequence mouse mutants with manageable costs at an appropriate time. Here, we describe two different sequencing strategies based on next generation sequencing technology, (1) chromosome sequencing, and (2) exome sequencing, to identify novel genes involved in phosphate homeostasis and bone metabolism. In two mutant mouse lines with high ALP activity (BAP004, BAP005), the disease causing mutations were identified by linkage analysis, chromosome sorting and whole chromosome sequencing (BAP004: Jak1 c.1933T>C, p.Ser645-Pro and BAP005: Asgr1 c.815A>G, p.Tyr272Cys). We performed exome sequencing using in-solution exome capture (Agilent) on HiSeq2000 instruments (Illumina) in 19 mutant mouse lines (3 recessive and 16 dominant lines) and one C3HeB/FeJ wt line as control. We identified between 3 and 42 SNVs (single nucleotide variants) in each mutant mouse line. Mapping data (chromosomal linkage) were available for 8 mouse lines. Each putative SNV was evaluated using segregation analysis of a cohort of mutant and control mice by capillary sequencing. To date, we identified one candidate gene within the 3 recessive mutant mouse lines. Within the 16 dominant mouse lines 7 candidate SNVs (4 novels and 3 common) were identified, 7 mouse lines are currently under investigation, and in 2 mouse lines no mutation has been identified yet. For the specific evaluation of the potential causative SNVs further studies as functional analysis or association to human diseases are necessary.

2923W

Exome sequencing identified a novel mutation in CACNA1S in a Japanese family with Malignant Hyperthermia. *N. Matoba[1], H. Iwasa[2], M. Kohda[1], Y. Yatsuka-Kanesaki[2], Y. Ichihara[3], H. Kikuchi[3], Y. Suzuki[4], S. Sugano[4], Y.K. Hayashi[5], I. Nishino[5], Y. Okazaki[1,2].* 1) Division of Translational Research, Research Center for Genomic Medicine, Saitama Medical University, Hidaka, Saitama, Japan; 2) Division of Functional Genomics & Systems Medicine, Research Center for Genomic Medicine, Saitama Medical University, Hidaka, Saitama, Japan; 3) Department of Anesthesiology, Saitama Medical University Hospital, Moroyama, Saitama, Japan; 4) Laboratory of Functional Genomics, Department of Medical Genome Sciences, Graduate School of Frontier Sciences, the University of Tokyo, Minato-ku, Tokyo, Japan; 5) Department of Neuromuscular Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry (NCNP), Kodaira, Tokyo, Japan.

Background Malignant Hyperthermia (MH) is a disorder of skeletal muscle triggered by some anesthetics and muscle relaxants. MH is frequently inherited in an autosomal dominant manner. To date, 6 genetic regions associated with MH have been reported, but only 2 genes have been identified, which are *RYR1* (encoding ryanodine receptor 1) and *CACNA1S*(encoding L-type Ca^{2+} channel subunit α). Approximately, 80% of patients with MH have mutated *RYR1*. As previously reported (Carlos, et al.,2006), we experienced a MH case without*RYR1* mutations by mutation screening of entire *RYR1* coding region.

Methods We performed whole-exome sequencing of 5 individuals of a Japanese family with MH using Hiseq2000(Illumina). Three of them were healthy and the rest were the carriers. (diagnosed by the rate of Ca^{2+} induced Ca^{2+} release from SR)

About 23,000 genetic variants in the exon/splicing sites were identified per individual. To reduce the numbers of variations and identify potentially pathogenic mutations, we used network analysis and expression analysis following a prioritization scheme like previously reported (Hoistchen et al., 2010).

Results Three carriers had 243 variants in common and those were not identified in healthy individuals. 158 candidate genetic variants remained after excluding the known variations (MAF>0.01 in dbSNP132). After comparison to the genes predicted by either network analysis or expression analysis, we identified p.I639V mutations in *CACNA1S*. The mutation was confirmed by Sanger sequencing of the DNA from the family including proband. The position of the mutation is likely on transmembrane (S6 of repeat II) according to Uniprot and the corresponding amino acid was highly conserved.

Conclusion We identified a novel heterozygous mutation in *CACNA1S* in the proband and two carriers that was unidentified in the healthy subjects in the family. Further work includes electrophysiological analysis for confirmation. Also, we are currently working on the exome sequencing analysis of additional families with MH.

Identification of a novel missense mutation in RAD51 in a large family with congenital mirror movements. *O.E. Onat[1], S. Gulsuner[1], R. Bilgen[2], G.M. Dal[1], K. Bilguvar[3], H. Boyaci[4,5], K. Doerschner[4,5], H. Uysal[2], M. Gunel[3], T. Ozcelik[1,6].* 1) Department of Molecular Biology and Genetics, Faculty of Science, Bilkent, Ankara 06800, Turkey; 2) Department of Neurology, Akdeniz University Hospital, Antalya 07058, Turkey; 3) Department of Neurosurgery, Department of Neurobiology and Department of Genetics, Center for Human Genetics and Genomics and Program on Neurogenetics, Yale University School of Medicine, New Haven, CT 06510, USA; 4) Department of Psychology, Faculty of Economics, Administrative and Social Sciences, Bilkent University, Ankara 06800, Turkey; 5) National Research Center for Magnetic Resonance, Bilkent University, Ankara 06800, Turkey; 6) Institute of Materials Science and Nanotechnology, Bilkent University, Ankara 06800, Turkey.

Congenital mirror movements (CMM) are a rare and heterogeneous group of disorders characterized by involuntary contralateral movements of mainly the upper extremities during intentional movements on the opposite side. Isolated cases are usually familial and suggest autosomal dominant inheritance with incomplete penetrance. In two chromosome 18 linked families, causative mutations were identified in DCC (Science 328:592, 2010; MRMV1; MIM:157600). Here, we describe a three-generation consanguineous Turkish family with six members affected by CMM. Linkage analysis with a dominant model and 90 percent penetrance parameters resulted in peaks on 15q13.3-q21.1, 15q26.2, and 19q12 with maximum multipoint LOD scores of 3.6, 2.6, and 2.6, respectively. However, a region of homozygosity segregating with the phenotype was not observed, and thus excluded the possibility of recessive inheritance of the disease allele in this consanguineous family. Whole-exome sequencing of an affected individual uncovered 7 coding, 33 intronic and 3 intergenic novel variants located within the three linkage intervals, which were filtered against the dbSNP132 dataset. Segregation analysis, population filtering using 1000 genomes and EVS data sets, and conservation considerations using prediction tools revealed a novel missense mutation (c.404C>T [p.T134N], RefSeq accession number NM_002875) in exon 5 of RAD51 (MIM:179617), consistent with the dominant inheritance of the disease allele in the family. The mutation resides in the highly conserved AAA (ATPases associated with diverse cellular activities) domain of the protein, and it was not observed in 436 chromosomes from healthy individuals coming from a geographical matched region. Recently, truncating mutations in RAD51 were identified in two families with CMM (Am J Hum Genet 90:301,2012; MRMV2; MIM:614508). Our findings support the totally unexpected role of RAD51 in neurodevelopment and further suggest that alterations of this gene may lead to neurological phenotypes.

Genitopatellar syndrome (GPS [MIM 606170]) is a rare disorder in which patellar aplasia or hypoplasia is associated with external genital and renal anomalies, congenital flexion deformities of the limbs, distinctive facial features, corpus callosum agenesis, and severe intellectual disability. To search for disease alleles in GPS we undertook whole exome sequencing of six unrelated affected individuals. All had characteristic clinical features of GPS. As sibling recurrence of GPS has previously been observed, we initially compared the six exome profiles under a model of a rare autosomal-recessive inheritance, but did not identify any gene harboring novel homozygous or compound heterozygous protein-altering variants in more than one individual. Subsequently, we interrogated these data under the assumption that each of the causative alleles is dominant and had arisen *de novo*; requiring at least one previously unobserved heterozygous nonsynonymous or splice-site substitution or a coding insertion or deletion in the same gene in all six individuals. This process did not reveal a single gene matching the criteria in all six individuals. However, evaluation of these data with a prior expectation of genetic heterogeneity highlighted *KAT6B* as the only candidate gene harboring previously unobserved heterozygous variants in five of the six individuals; a single nonsense variant (c.3877A>T p.Lys1293X) and three frameshift indels, including a 4 bp deletion observed in two unrelated affected individuals (c.3768_3771del p.Lys1258GlyfsX13, c.3680_3695del p.Asp1227GlufsX11, and c.3773dup p.Trp1259ValfsX12). All identified mutations are located within the terminal exon of the gene and are predicted to generate a truncated protein product lacking evolutionarily conserved domains. Using an RT-PCR approach we demonstrate that total abundance of *KAT6B* transcript in individuals with GPS is equivalent to wild-type controls and were able to detect a protein of the size of the predicted truncated KAT6B in primary skin fibroblasts from an affected subject. *KAT6B* encodes a member of the MYST family of histone acetyltranferases. We demonstrate a reduced level of both histone H3 and H4 acetylation in patient-derived cells suggesting that dysregulation of histone acetylation is a direct functional consequence of GPS alleles. These findings define the genetic basis of GPS and illustrate the critical and complex role of the regulation of histone acetylation during development.

We report a sibling pair with focal facial dermal dysplasia (FFDD) Type IV manifesting as lesions resembling aplasia cutis located in a preauricular distribution on both cheeks along the line of fusion of the maxillary and mandibular facial prominences. Both children had small, intraoral polyps on their buccal mucosa, a finding that has not previously been reported. Mutations in the*TWIST2* gene, causative for Setleis syndrome, were excluded in both offspring. We assumed autosomal recessive inheritance and used exome sequencing to identify novel sequence variants that were shared by both siblings. We found two mutations in *CYP26C1* - c.844_851dupCCATGCA, predicting p.Glu284fsX128, a tandem duplication of 7 basepairs that was inherited from the children's mother and c.1433G>A, predicting p.Arg478His, that was inherited from their father and that was predicted to be deleterious. Sequencing of additional type IV FFDD patients revealed that three previously reported individuals (Prescott et al., 2006) were homozygous for the same duplication as found in this family. The duplication was present in 1/250 (0.3%) Caucasian control chromosomes, 0/200 Hispanic control chromosomes and 1/236 (0.4%) chromosomes from individuals with eye or diaphragmatic birth defects. *Cyp26c1* is involved in retinoic acid (RA) degradation, together with *Cyp26a1* and *Cyp26b1*, and the gene is expressed in the first pharyngeal arch at the location of embryological fusion of the maxillary and mandibular processes. There is no known phenotype in animal models of loss of gene function on a wildtype background. The effects of disordered retinoid metabolism on skin development have previously been studied in *Cyp26b1* homozygous null mice, which have reduced thickness of the cornified layer of skin, reduced filaggrin and arrest of hair follicle growth at E17.5 and E18.5. Experiments using RA-soaked beads at specific developmental stages in embryonic chicken skin explant cultures also showed that the beads can create a radial zone of inhibition of skin appendage formation (Chuong et al., 1992), demonstrating that excess RA may induce skin defects. The low frequency of the duplication in control chromosomes poses the question as to whether variable in-utero exposure to retinoids can influence penetrance of the phenotype. We conclude that mutations in *CYP26C1* are associated with FFDD type IV in humans. Chuong et al. Development 1992;115:839; Prescott T et al. Eur J Med Genet 2006;49:135.

2927T

Identity-by-Descent Mapping Reveals a New Locus for Primary Congenital Glaucoma, GLC3E, on Chromosome 19p13.2. *H. Verdin[1], B.P. Leroy[1, 2], B. D'haene[1], F. Coppieters[1], S. Lefever[1], P.G. Kestelyn[2], E. De Baere[1].* 1) Center for Medical Genetics, Ghent University, Ghent, Belgium; 2) Department of Ophthalmology, Ghent University Hospital, Ghent, Belgium.

Primary congenital glaucoma (PCG) is caused by developmental anomalies of the trabecular meshwork and the anterior chamber angle, resulting in an increased ocular pressure (IOP) and optic nerve damage from birth or early infancy. The prevalence of PCG is estimated to be 1:10.000 in Western populations with higher prevalences in inbred populations. In general PCG displays an autosomal recessive inheritance and is genetically heterogeneous. To date, four PCG loci are known (GLC3A-D), in which two genes have been identified, *CYP1B1* and *LTBP2*. Here, we aimed to map the disease gene in a large, four-generation consanguineous family with PCG, originating from Jordan. Mutations in known PCG genes (*CYP1B1* and *LTBP2*) as well as anterior segment dysgenesis genes (*FOXC1* and *PITX2*) were excluded respectively. Identity-by-descent (IBD) mapping was performed in six affected members using genomewide SNP genotyping with 250K arrays (Affymetrix). Several gene prioritization tools were used to make a selection of candidate genes for Sanger sequencing. Two affected individuals underwent exome enrichment (TruSeq Exome Enrichment Kit, Illumina) and sequencing (2×100 cycles, HiSeq, Illumina). The CLC Genomics Workbench (CLC bio) was employed for read mapping and variant calling. The common IBD regions did not overlap with any known PCG loci. Filtering on both size of the region and number of consecutive homozygous SNPs revealed a new candidate region on 19p13.2, named GLC3E. This region measures 2.67 Mb and contains 93 genes. Using prioritization tools, *BEST2* was selected as the best candidate gene. Indeed, *Best2* is expressed in non-pigmented epithelial (NPE) cells of ciliary body, which is responsible for formation of aqueous humour. Also, *Best2*$^{-/-}$ mice have significantly lower IOP than wild type littermates. Sanger sequencing of the *BEST2* coding region in affected individuals revealed no mutations however. Exome sequencing was performed in two affected individuals. Data analysis is ongoing. We identified a potential new PCG locus, named GLC3E, confirming the genetic heterogeneity of PCG, and representing a unique opportunity to identify the third PCG gene.

2928F

Mutations in *HOXB1* cause autosomal recessive congenital facial palsy with sensorineural hearing loss and strabismus. *B.D. Webb[1], S. Shaaban[2, 3, 4], H. Gaspar[1, 5], L.F. Cunha[1], C.R. Schubert[3, 6], K. Hao[1], C.D. Robson[7], W. Chan[2, 8], C. Andrews[2, 3, 8], S. MacKinnon[9], D.T. Oystreck[10, 11], D.G. Hunter[9], A.J. Iacovelli[1], X. Ye[1], A. Camminady[5], E.C. Engle[2, 3, 8, 9], E.W. Jabs[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Department of Neurology, Children's Hospital Boston, Boston, MA; 3) Department of Neurology, Harvard Medical School, Boston, MA; 4) Department of Ophthalmology, Mansoura University, Daqahlia, Egypt; 5) Institute of Human Genetics, University Hospital Freiburg, Freiburg, Germany; 6) Department of Pediatrics, Harvard Medical School, Boston, MA; 7) Department of Radiology, Children's Hospital Boston, Boston, MA; 8) Howard Hughes Medical Institute, Chevy Chase, MD; 9) Department of Ophthalmology, Children's Hospital Boston, Boston, MA; 10) Department of Ophthalmology, College of Medicine, King Saud University, Riyadh, Saudi Arabia; 11) Division of Ophthalmology, University of Stellenbosch, Tygerberg, South Africa.

The HOX genes are a family of highly conserved, homeodomain-containing transcription factors which specify regional differences along the anterior-posterior axis during early development. In this study, we utilized whole exome sequencing to identify a causative gene mutation in *HOXB1* in a family with autosomal recessive congenital facial palsy with hearing loss and strabismus. 175 additional probands with similar clinical features were screened for mutations in *HOXB1* (102 with a diagnosis of Moebius syndrome) and a second family was identified with the same homozygous *HOXB1* c.619C>T mutation. The clinical features of these two families were examined and correlate extensively with the phenotype of the *Hoxb1*$^{-/-}$ knock-out mouse reported previously. This Arg207Cys HOXB1 missense variant identified results in a substitution at the highly conserved arginine 5 residue of the homeodomain, which when mutated in other proteins is known to cause human disease. Modeling of the mutant HOXB1/PBX1 complex shows reduction in affinity for DNA. Additionally, transfection experiments show differential activation of the mutant versus wild-type HOXB1 for its auto-regulatory element. Because both affected families were of conservative German American background, haplotype analysis was performed and both families shared a common haplotype, suggesting a founder mutation. Here is the first demonstration of human developmental disorders that can be classified as HOXB1opathies.

2929W

Genetic heterogeneity underlying female infertility and sensorineural hearing loss and identification of *LARS2* as a third gene for Perrault syndrome. *S.B. Pierce[1], T. Walsh[1], R. Michaelson-Cohen[2], R.E. Klevit[3], M.-C. King[1], K. Gersak[4], E. Levy-Lahad[2].* 1) Department of Medicine (Medical Genetics), University of Washington, Seattle, WA; 2) Medical Genetics Institute, Shaare Zedek Medical Center, Jerusalem, ISRAEL; 3) Department of Biochemistry, University of Washington, Seattle, WA; 4) Department of Obstetrics and Gynecology, University Medical Center, Ljubljana, SLOVENIA.

Perrault syndrome is a heterogeneous recessive disorder characterized by ovarian dysgenesis in females and sensorineural hearing loss in males and females, with additional neurological symptoms present in some cases. We previously identified mutations in two genes, *HARS2* and *HSD17B4*, as the cause of Perrault syndrome in two families, reflecting this genetic heterogeneity. *HARS2* encodes the mitochondrial histidyl-tRNA synthetase and thus is required for translation of proteins encoded by the mitochondrial genome. *HSD17B4* encodes a 17beta-hydroxysteroid dehydrogenase, which is a peroxisomal enzyme involved in fatty acid beta-oxidation and steroid metabolism. Through exome sequencing, we have now identified mutations in a third gene, *LARS2*, encoding the mitochondrial leucyl-tRNA synthetase, as the cause of Perrault syndrome in two other families. The proband of a consanguineous Palestinian family, and her two brothers with hearing loss, are all homozygous for the private variant *LARS2 c.1565C>A* (p.T522N). The proband of a non-consanguineous Slovenian family is compound heterozygous for private variants *LARS2 c.1076delT* and *LARS2 c.1886C>T* (p.T629M). LARS2 p.T522N affects a conserved residue adjacent to residues involved in leucyl-adenylate substrate binding, suggesting that this mutation may alter enzyme activity. *LARS2 c.1076delT* leads to a stop at codon 374 of the 903-amino acid protein. LARS2 p.T629M affects a residue in the leucyl-specific insertion domain, whose role in catalysis is poorly understood. We are evaluating the functional consequences of this mutation at the transcript and protein levels. A role for leucyl-tRNA synthetase in maintenance of fertility is supported by a previously identified mutation in the *Caenorhabditis elegans* homolog *lars-2*, which results in a loss of germ cell differentiation and sterility. The fact that *LARS2*, like *HARS2*, is involved in mitochondrial translation also supports a causal role for the *LARS2* mutations in Perrault syndrome. Other families with Perrault syndrome under study in our laboratory do not carry mutations in *HARS2*, *HSD17B4*, or *LARS2*. Causative mutations in still other genes will expand our understanding of the biology underlying Perrault syndrome.

2930T

Exome sequencing in apparently recessive and apparently X-linked HSP families identifies an ATL1 mutation hotspot which is associated with low penetrance dominant inheritance. *C. Beetz[1], R.E. Varga[1], H. Fadel[2], R. Schüle[3, 4], I. Valenzuela[5], F. Speziani[4], G. Rudenskaja[6], G. Nürnberg[7], H. Thiele[7], J. Altmüller[7], V. Alvarez[8], J. Gamez[9], P. Nürnberg[7], S. Zuchner[4].* 1) Institute of Clinical Chemistry, University Hospital Jena, Jena, Germany; 2) Department of Neurology, Al Kortobi Hospital, Tangier, Morocco; 3) Department of Neurodegenerative Disease, Hertie-Institute for Clinical Brain Research and Center for Neurology, Tübingen, Germany; 4) Hussman Institute for Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 5) Clinical Genetic Unit, Hospital Vall d'Hebrón, Barcelona, Spain; 6) Genetic Counselling Department, Medical Genetics Research Centre, Russian Academy of Medical Sciences, Moscow, Russia; 7) Cologne Centre for Genomics, University of Cologne, Cologne, Germany; 8) Laboratory of Molecular Genetics -Genetic Unit, Hospital Universitario Central de Asturias, Oviedo, Spain; 9) Department of Neurology, Hospital Universitari Vall d'Hebron, VHIR Universidad Autonoma de Barcelona, Barcelona, Spain.

The hereditary spastic paraplegias (HSPs) are a diverse group of movement disorders. They are classified according to age at onset (early vs. late), clinical presentation (pure vs. complex), and mode of inheritance, or according to the genetic defect. Despite >45 loci and >20 HSP genes identified, cumulative frequencies derived from studies targeting individual genetic forms seem to not even explain 80% of cases. This may partially be due to inappropriate patient selection for such gene-centred investigations. We performed exome sequencing in index cases from two large families in which several members each suffer from clinically pure, early onset forms of HSP. Consanguinity of the parents in family 1 and only males being affected in family 2 suggested autosomal recessive and X-linked inheritance, respectively. A homozygous variant in ATL1 (c.1244G>A, p.R415Q), i.e. a well-established gene for the autosomal dominant form SPG3A, was the only plausible variant in family 1. It was also homozygous in two other patients but, surprisingly, heterozygous in the fourth patient and in seven unaffected family members. In family 2, none of the variants found on the X-chromosome segregated. However, all patients carried one ATL1 c.1243C>T (p.R415W) allele and this variant was shared by at least five unaffected females and one unaffected male. Interestingly, p.R415W has been reported by one previous study where it was also associated with reduced penetrance. We subsequently identified one out of 87 apparently sporadic patients and two out of 23 dominant families to also harbour the p.R415W mutation. Direct or indirect evidence for non-manifesting carriers was again obtained. As geographic origin and haplotype analysis argued against a founder effect for p.R415W, we considered a mutation hotspot. Indeed, bisulfate sequencing revealed c.1243 and c.1244 to represent a completely methylated CpG dinucleotide, spontaneous deaminations of which would explain the above transition mutations. A substantial fraction of the patients diagnosed in the present study would not routinely have entered targeted ATL1 sequencing (apparently X-linked, apparently recessive, apparently sporadic). SPG3A due to alterations at the mutation hotspot we identified may therefore be a rather frequent but currently underestimated cause of HSP. Consequently, we suggest targeted screening for c.1243 and c.1244 alterations in all patients with pure and/or early onset HSP regardless of family history.

2931F

Autosomal Recessive Lethal Congenital Contractural Syndrome Type 4 (LCCS4) Caused by a Mutation in MYBPC1. *O.S. Birk[1,2], B. Markus[1], G. Narkis[1], R.Z. Birk[3], I. Cohen[1], D. Landau[2].* 1) Morris Kahn Center for Human Genetics, National Institute for Biotechnology in the Negev, Ben-Gurion University, Beer-Sheva, Israel; 2) Genetics Institute, Soroka Medical Center, Beer-Sheva, Israel; 3) Ariel University Center, Ariel, Israel.

Autosomal recessive lethal congenital contractural syndrome (LCCS) is a severe form of neuromuscular arthrogryposis. We previously showed that this phenotype is caused in two unrelated inbred Bedouin tribes by homozygous mutations in either ERBB3 or in PIP5K1C of the phophatidyl inositol pathway. However, the molecular basis of the same phenotype in other tribes remained elusive. Whole exome sequencing identified a novel LCCS founder mutation within a minimal shared homozygosity locus of ~1Mb in two affected individuals of different tribes: a homozygous premature stop producing mutation in MYBPC1, encoding myosin binding protein C, slow type. A dominant miss-sense mutation in MYBPC1 was previously shown to cause mild distal arthrogryposis. We now show that a recessive mutation abrogating all functional domains in the same gene leads to LCCS. This study highlights the power of whole exome sequencing in elucidating the molecular basis of phenotypes common to remotely related individuals in inbred communities.

2932W

Exome sequencing of a pedigree with Caudal Regression Syndrome (CRS). *G. CHENG[1], E.HM. WONG[2], PC. SHAM[2], S.S. CHERNY[2], S. MAAS[3], S.W. SCHERER[4], C.R. MARSHALL[4], S.L. PEREIRA[4], P.KH. TAM[1], M.M. GARCIA-BARCELÓ[1].* 1) Department of Surgery, Li Ka Shing Faculty of Medicine, University of Hong Kong, Hong Kong; 2) Department of Psychiatry, Li Ka Shing Faculty of Medicine, University of Hong Kong, Hong Kong; 3) Department of Pediatrics and Clinical Genetics, Academic Medical Center Amsterdam, Netherlands; 4) Department of Molecular and Medical Genetics, The Centre for Applied Genomics and Program in Genetics and Genomic Biology, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada.

Caudal Regression Syndrome (CRS) is a rare, congenital disorder characterized by varying degrees of agenesis of the caudal spine, and is usually associated with general anomalies of other systems. Although maternal diabetes is a well-known risk factor, the exact cause of CRS is still unknown. CRS mainly occurs sporadically, except for Currarino syndrome (CS) or CRS sub-phenotype IV, which follows an autosomal-dominant pattern of inheritance. We present a three generation Caucasian family of 11 individuals of whom 6 are affected with CRS subtype III or V based on the sacral/coccygeal agenesis pattern. A presacral mass was present in 5 of the 6 affected individuals. The medical history of family was re-assessed and the phenotype/individual ID was confirmed. G-banding karyotype of the affected members was normal. To identify the genetic defect underlying the disorder, DNA from the 11 family members were submitted to whole genome single nucleotide polymorphism genotyping (Omni2.5) and whole exome sequencing. Further, using 31,520 pruned tag SNPs, parametric linkage analysis using MERLIN revealed 4 linkage peaks with LOD score≈1.8 under the autosomal dominant inheritance model. The linkage peak regions lied in chr1, chr11 and chr12 and spanned 19.57Mb (ranges from 1.3Mb to 8.2 Mb; ≈ 33.18cM). Whole exome sequencing for the identification of causal variants was performed using Illumina HiSeq platform with TruSeq Exome enrichment kit, and SOLID5500 platform with Agilent SureSelect Exome enrichment kit. The sequencing data retrieved ≈65K recalibrated single nucleotide variants/insertions/deletions for each individual on average and the output showed a concordance rate of 96.2% with Omni2.5 (reads mapping by bwa/bfast+bwa/mrsFast; post-processing and variants calling by GATK pipeline/mpileup/Varscan/freebayes). Besides, we performed structural variants (SVs) calling from Omini2.5 density file using PennCNV, iPattern, QuantiSNP, or CNVPartition as well as from the exome sequencing data using BreakDancer-Max, VariationHunter, Pemer, SpitRead or ExomeDepth. Filtering for causal variants was performed according to 1) novel small variants within the linkage peak regions which were shared only by patients; 2) large structural variants (>0.1Mb, based on the tag SNP resolution for linkage analysis) each of which were examined for the inheritance pattern observed. Several plausible genes with functional mutations have been identified.

2933T

Loss of function mutations in OMIM genes reveal a burden of disease susceptibility in a consanguineous population. *K.A. Fakhro[1], J.L. Rodriguez-Flores[2], N.R. Hackett[2], J. Salit[2], J. Fuller[2], J.A. Malek[1], L. Chouchane[1], R. Badii[3], A. Al-Marri[3], J.G. Mezey[2,4], R.G. Crystal[2].* 1) Dept of Genetic Medicine, Weill Cornell Medical College, Doha, Qatar; 2) Dept of Genetic Medicine, Weill Cornell Medical College, New York, NY; 3) Hamad Medical Corporation, Doha, Qatar; 4) Dept of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

Exome sequencing was used to study genetic variation in the Qatari population. We sequenced 100 healthy Qataris (50X average depth, with >80% of sites at >10x depth) representing the 3 major Qatari genetic subpopulations. Reads were aligned to the GRCH37 human reference genome using BWA 0.59, variants were called using GATK 1.2 and annotated using SNPEFF 2.1. A total of 174×10^3 variants were identified with quality scores >50, of which 585 were predicted to cause loss of function (frameshift/stop-gain/splice) in 435 unique OMIM disease genes. Of these, 184 (35%) were high-quality, novel Qatari variants (absent from public databases) of which 115 were observed in 2 or more individuals, suggesting a population allele frequency ≥1%. In order to enhance specificity, we discarded all mutations that occur in highly repetitive regions and poly-N tracks or that occurred at a position that was within 2 bp of at least 1 common SNP or indel and any variants in alternatively spliced exons. After filtering, there were a total of 20 high-confidence loss of function mutations in 20 unique OMIM genes. Ten of these were single-base substitutions that led to stop-gains, 3 were single-base substitutions of a conserved splice-site residue within 2 bp of the intron/exon junction, 6 were insertions (1–2 bp), and 1 a deletion (1 bp). All exonic substitutions resulted in the introduction of stop-codons within the transcript in silico, with a median resultant truncated protein size of 48% of full-length (range 8–95%). None of these truncations occurred in an alternatively spliced exon, suggesting that the majority of these mutations could affect gene expression levels. Half of these mutations (n=10) truncated genes responsible for autosomal recessive severe childhood disease. For example, 22 individuals (AF 11%) had a single-base substitution resulting in a stop-gain in TBX15 (Cousin syndrome; truncated protein size: 66%) and 13 individuals had a 2-base insertion resulting in a downstream stop-codon in NPHP3 (nephronophthisis; truncated protein size 42%). Further, truncations in the thyroid receptor TSHR (hypothyroidism) and insulin receptor INSR (diabetes mellitus) were observed at frequencies of 11.5% and 2% respectively. Overall, the carrier frequency for these 20 mutations was rare-to-moderate (mean 4.9%, range 1–12%), which bears significant implications for a region of the world with a high rate of consanguinity.

2934F

Causal Gene Discovery in Mendelian Disorders Using Whole Exome Sequencing. *S. Jhangiani[1], M. Bainbridge[1], J. Lu[1], M. Wang[1], H. Dinh[1], Y. Han[1], J. Santibanez[1], M. Caramins[3], P. Campeau[2], B. Lee[2], J. Reid[1], J. Lupski[2], E. Boerwinkle[1], D. Muzny[1], R. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas; 3) South Eastern Sydney Area Health Service, Sydney, Australia.

Using next-generation sequencing technologies with predominantly whole exome applications, the Human Genome Sequencing Center has generated 14Tb of high quality data for greater than 1,500 exomes in efforts towards discovering causative alleles for Mendelian disorders. More than 100 studies, extending locally from the Texas Medical Center to worldwide collaborations, have ranged in disorders including neurological, skeletal, cardiac, tumor formation, immunological and other phenotypes. Our high-throughput multiplexed capture pipeline, producing 2K capture libraries per month, has enabled cost efficient and high quality data production. A new implementation to the pipeline enables automated annotated variant file generation using Atlas SNP 2 for SNP identification. The utility of whole exome sequencing and an automated pipeline has proven to be highly effective in associating genes with diseases. Exome sequencing can be used to elucidate specific pathways responsible for diseases. For three individuals with genitopatellar syndrome, a skeletal dysplasia expressing cerebral and genital anomalies, exomes were sequenced and showed *de novo* heterozygous truncating mutations in *KAT6B*. Mutations in this gene resulted in a loss of the highly conserved transcription activation domain affecting skeletogenesis. In a study of spinocerebellar ataxia two related individuals were sequenced using two orthogonal chemistries and shared a rare deleterious hemizygous mutation on *GJB1*. This gene has been identified in patients with CMT and Dejerine-Sottas syndrome. This work supports the use of using whole exome sequencing in the discovery of disease causing alleles.

Whole genome sequencing and copy number analysis of exome sequencing in two families with split-hand/split-foot malformation identifies chromosomal rearrangements affecting putative exonic enhancers. *H. Lango Allen[1], R. Caswell[1], P. Turnpenny[1,2], C. Turner[1,2], C. Wragg[3], W. Xie[1], M. Weedon[1], X. Xu[1], S. Ellard[1].* 1) Peninsula Medical School, University of Exeter, Exeter, UK; 2) Department of Clinical Genetics, Royal Devon and Exeter Hospital, Exeter, UK; 3) Regional Genetics Unit, Southmead Hospital, Westbury on Trym, Bristol, UK.

We report three individuals from two families with split-hand/split-foot malformation (SHFM) in whom next generation sequencing was performed to investigate the cause of their phenotype.

The first proband has a de novo balanced translocation t(2;7)(p25.1;q22) identified by karyotyping following a normal array CGH result. To characterise the breakpoints, we undertook paired-end whole genome sequencing on a single Illumina HiSeq2000 lane, and obtained mean coverage of 8x. This was sufficient to characterise the breakpoints: there were seven read pairs where one of the pairs mapped to chromosome 2 and the other to chromosome 7, and there were four reads partially mapping to both chromosomes, i.e. across the breakpoints. The exact breakpoints were confirmed by Sanger sequencing of a single PCR product. The chromosome 7 breakpoint is situated within the SHFM1 locus on chromosome 7q21.3 and results in the physical separation of the recently identified DYNC1I1 exonic enhancers (eExons) from their target genes, *DLX5* and *DLX6*, implicated as candidates for SHFM in mouse knockout models.

The mode of inheritance within the second family was thought to be X-linked recessive, and exome sequencing was performed to search for a mutation within the SHFM2 locus at Xq26 in the affected proband and his uncle. No coding mutation was found but copy number analysis of exome data identified a ~100kb deletion within the chromosome 7 SHFM1 locus. The *DLX5*and *DLX6* genes are disomic, but the deletion includes the putative *DYNC1I1* exon 15 and 17 enhancers.

Split hand foot malformation type 1 is an autosomal dominant trait with reduced penetrance and variable expression. We have narrowed the critical region from 0.9Mb to 0.1Mb and this deletion provides further evidence for a key role of DYNC1I1 exonic enhancers in normal limb formation.

2936T

Searching novel genes for hereditary hearing loss in multiplex families using next generation sequencing. *Y.H. Lin[1], C.C. Wu[1,2], Y.C. Lu[1], C.J. Hsu[1], P.L. Chen[2].* 1) Department of Otolaryngology, National Taiwan University Hospital, Taipei, Taiwan; 2) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan.

Despite the clinical utility of genetic diagnosis in addressing idiopathic sensorineural hearing impairment (SNHI), current strategy of mutation screening using Sanger sequencing suffers from the limitation that only a limited number of DNA fragments associated with common deafness mutations can be genotyped. Consequently, definite genetic diagnosis cannot be achieved in many families with obvious family history. To investigate the diagnostic utility of next generation sequencing (NGS) and to delineate the genetic epidemiology of uncommon deafness genes in an East Asian population, in the present study, we applied the NGS technique to 12 Han Chinese multiplex families (i.e. families with multiple affected members) with idiopathic SNHI. NimbleGen sequence capture array was designed to target all exons and 100 bp of flanking sequence from 79 common deafness-associated genes. NGS by HiSeq2000 using paired-end (2×100) protocol was performed to get a greater than 30-fold coverage across the targeted regions. We applied bowtie, samtools, GATK, Picard and IGV for the bioinformatics analyses. After variant calling, variant allele frequency > 5% in 5400 NHLBI exomes and in 1000 Genomes Project 2012 were filtered out. PolyPhen2 and SIFT were used to assess the effect of non-synonymous changes on the protein. Five indel (insertion/deletion) variants and 36 non-synonymous variants were identified in the 12 multipex families. After validation by Sanger sequencing and mutation effect assessment by PolyPhen2 and SIFT, twelve variants with high probability of changing the function of gene were observed in 5 autosomal dominant families, and 1 autosomal recessive family, respectively. Those variants include one known pathogenic variant (*GJB2* p.R75Q) and 11 novel variants (*GRHL2* p.K9R, *KCNQ4* p.S680F, *CCDC50* p.D295Y,*MYH9* p.E1256K, *MYO1A* p.E456G, *GJB4* p.C169W, *DIAPH1* p.R1146W, *GJB6* p.L76fs, *WFS1* p.V412A, *CDH23* p.D428N, and *CDH23* p.V858I). The assignment of causality for certain variants needs to be achieved by checking the segregation pattern in the pedigrees and possible functional study in the future. In conclusion, NGS enables a precise genetic diagnosis in certain multiplex families with idiopathic SNHI by identifying mutations in relatively uncommon deafness genes.

2937F

Combination of genomic technologies and consanguinity in order to identify pathogenic variants in recessive disorders. *P. Makrythanasis[1], M. Nelis[1], F.A. Santoni[1], M. Guipponi[2], F. Consanguinity and inbreeding increase the sharing of alleles among individuals; thus a considerable number of autosomal recessive phenotypes occur in offspring(s) of consanguineous couples. We have collected samples from consanguineous families with phenotypes of unknown etiology that are compatible with autosomal recessive transmission, in order to identify the functional genomic variation responsible for the disease. Any phenotype and family history compatible with autosomal recessive inheritance (and unknown molecular defect) was a candidate for participation in the study. 42 families of different ethnic background have been collected so far. From each family, blood DNA from the patient(s), all unaffected siblings and the parents is extracted. Samples are i/ analyzed by array-CGH for the detection of homozygous deletions; ii/ genotyped with a 720K SNP array in order to identify Runs of Homozygosity (ROH) and define the areas of the genome that could include the causative variant; iii/ exome sequenced (one affected individual per family). The variants within the targeted areas are selected for the downstream analysis. The mean coverage is 130x and 98.2% of the total coding region of RefSeq is covered at least 8x. By comparing the genotyping with the sequencing data, we found that the high throughput sequencing for Single Nucleotide Variants (SNV) that passed the quality threshold had a specificity of 99.95%, sensitivity of 97.7%, positive predictive value (PPV) 99.2% and negative predictive value (NPV) 98.6%. On average we identified 21901 variants per exome. So far we completely analysed 26 families and identified the causative variation in known genes in 3 of them: in *VLDLR*, causing disequilibrium syndrome, in *FKTN* causing Fukuyama muscular dystrophy and in *DMP1* causing hypophosphatemic rickets. In 12 further families 23 candidate genes/variants have been identified (more than 1 candidate genes were found per family). We present the genomic variants and the corresponding phenotypes of these families. In the remaining 11 families the likely molecular defect has not been identified using our experimental protocol. Consanguineous families provide an opportunity to identify pathogenic variants in known as well as candidate genes responsible for recessive phenotypes and rapidly fill in the gap between genotype and phenotype.

2938W

A single exome variant is the only expected variant by likelihood ratio for a rare heritable de novo dominant disorder in a three generation family with two affected. *S.M. Marchegiani[1,5], T.C. Markello[1,2,3], L.A. Wolfe[1], K. Fuentes-Fajardo[1], D.R. Adams[1,2,3], W.A. Gahl[1,2,3], J.C. Mullikin for NISC[4], T. Davis[1], J.P. Accardi[1], C.J. Tifft[1,3], C.F. Boerkoel[1,2,3].* 1) NIH Undiagnosed Diseases Program, Bethesda, MD; 2) Medical Genetics Branch, National Human Genome Research Institute; 3) Office of the Clinical Director, National Human Genome Research Institute; 4) NIH Intramural Sequencing Center, National Human Genome Research Institute; 5) Department of Pediatrics, National Capital Consortium, Bethesda, MD.

High throughput sequencing (HTS) refined the predicted mutation rate to 1.3 × 10-8 per base pair per generation, which yields approximately 1.3 (n= 0-4, P>0.95) mutations per diploid exome per generation. Given the known mutation rate and size of the exome, there is a P<0.05 probability that exome sequencing (ES) will identify more than one variant that is both deleterious and consistent with inheritance in the case where a de novo mutation occurred in a parent and correctly segregates into two offspring in a third generation. We illustrate this concept by identifying one novel variant in a de novo affected father and his affected daughter within a three generation family. The father and daughter carry the diagnosis ablepharon macrostomia (AMS), a rare presumed dominant disorder characterized by absent eyelids, dysmorphic facies, lax redundant skin and ambiguous genitalia. Exome sequencing identified a T>A substitution in the 5'UTR of TRIM23, a well-conserved ADP-ribosylation factor (ARF) gene on Chromosome 5 that has a role in vesicular trafficking. The variant from exome sequencing is only present in the affected father and daughter, and is absent in all unaffected family members, including both paternal grandparents. This variant is not reported in current databases. Consanguinity was excluded by high density single nucleotide polymorphism (SNP) array analysis. Pseudodominant inheritance is unlikely for a rare disease in an outbred family. Evidence of (non)penetrance was critically examined during clinical phenotyping, including comprehensive eye and skin exams with light and EM histopathology. We confirmed complete absence of features consistent with ablepharon macrostomia in the unaffected paternal grandparents, unaffected mother and unaffected brother, supporting a de novo dominant mutation in the father with subsequent inheritance by his daughter. We additionally established elastic fiber electron microscopy as another modality to clinically phenotype affected versus unaffected individuals in this family. The presence of a rare, heritable de novo dominant disorder in a three generation family provides an ideal model to propose that an identified and Sanger validated variant, like the one described for TRIM23 in this pedigree, is the only expected variant and thus likely causal for the condition in that family.

2939T

Whole-genome sequencing identifies mutations in known and novel genes for early infantile epileptic encephalopathy. *H.C. Martin[1], A.T. Pagnamenta[1], K. Hudspith[1], A. Rimmer[1], R. Copley[1], E. Sadighi Akha[1], J. Broxholme[1], A. Kanapin[1], J.-B. Cazier[1], D. Shears[2], H. Stewart[2], D. Bentley[3], J. Taylor[1], E. Blair[2], P. Donnelly[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Clinical Genetics, Oxford Radcliffe Hospitals National Health Service Trust, Churchill Hospital, Oxford, United Kingdom; 3) Illumina Cambridge, Chesterford Research Park, Little Chesterford, Cambridge, UK.

Early Infantile Epileptic Encephalopathy (EIEE) is a severe neurological disorder causing intractable seizures, intellectual disability and developmental delay. One subtype of EIEE, Ohtahara syndrome (OS), produces a characteristic “burst-suppression” pattern on the electroencephalogram. OS patients are routinely screened for mutations in several genes, including *ARX*,*CDKL5*, *SPTAN1* and *STXBP1*, as well as for large copy number variants, but most cases remain unexplained. As part of the WGS500 project at the Wellcome Trust Centre for Human Genetics, we used the Illumina HiSeq system to do high-coverage whole-genome sequencing (WGS) of six EIEE trios in which these standard tests had been negative: four OS cases and two girls with severe early-onset seizures. In each trio, we screened for rare or novel coding variants that would fit a *de novo*, simple recessive, compound heterozygous or X-linked model. Two OS cases had novel *de novo* nonsynonymous mutations in ion channel genes, one in *KCNQ2* and the other in *SCN2A*, both of which had previously been implicated in EIEE. Another OS case proved to have paternal isodisomy for chromosome 9, and, consistent with a recessive model on this chromosome, we identified a novel homozygous nonsynonymous mutation in an ion channel gene that has recently been linked to a similar epilepsy phenotype. In the fourth OS patient there were two strong candidates: compound heterozygous nonsynonymous variants in an ion channel gene that has been associated with muscular disorders, and a homozygous variant that affected splicing of a gene in the glycophosphatidyl inositol biosynthesis pathway. The two other epilepsy patients had *de novo* mutations in genes involved in Ras/MAPK and Wnt signalling. These three pathways have been previously linked to epileptogenesis (Bassuk et al. AJHG, 2008; Adachi et al. Seizure, 2012; Johnston et al. AJHG, 2012) and functional studies are underway to determine whether these variants are pathogenic. This work highlights the need to expand the panel of genes routinely screened in EIEE patients, emphasises the utility of WGS in elucidating unanticipated disease mechanisms and sheds new light on pathways important for neural development.

2940F

Novel intellectual disability genes identified by exome sequencing. *R. Rabionet[1], O. Drechsel[1], A. Puig[1], J. Gonzalez[1], I. Madrigal[2], M.I. Alvarez[2], N. Baena[3], M. Viñas[3], S. Ossowski[1], M. Guitart[3], M. Mila[2], X. Estivill[1].* 1) Genes & Disease programme, Center for Genomic Regulation, Barcelona, Spain; 2) Servei de Genètica, Hospital Clínic i Provincial de Barcelona, Barcelona, Spain; 3) Laboratori de Genètica, Corporació Sanitària Parc Taulí, Sabadell, Barcelona, Spain.

Intellectual disability (ID) is a genetically heterogeneous disorder affecting 1–3% of the population. In many cases, it presents as a sporadic disorder, although it can also show X-linked, AR and AD inheritance. About 30% of cases of ID can be explained by structural variants, and more than hundred genes have been implicated in its pathophysiology. Nevertheless, a large proportion of cases remains unexplained. A recent study has shown that *de novo* point mutations are a frequent cause of ID, which would make next generation sequencing technologies extremely powerful tools to identify rare *de novo* genetic causes of ID.

We recruited 35 trio cases of sporadic idiopathic ID, all of them negative for the fragile X expansion and without cytogenetically visible abnormalities. The exome was captured with Agilent sure select technology, multiplexed, and sequenced in an Illumina HISeq2000 lane. Potential damaging variants were detected by an in-house developed pipeline for variant annotation. Briefly, non-synonymous variants present in the case are selected and filtered based on their predicted functionality (*condel* score) and their frequency in known databases (EVS, 1000genomes, dbSNP). Then, *de novo* variants as well as potential X-linked or recessive genes (carrying homozygous or compound heterozygous variants in the case) were identified and annotated against a list of known ID-related genes. As a final step, the presence and *de novo* state of the identified variants were confirmed by Sanger sequencing. In the first 14 trios analysed, we detected an average of 8520 non-synonymous variants in the cases, of which an average of 27 were *de novo*. Frequency and functionality based filtering reduced the number of potential candidate ID genes harboring *de novo* variants to 0–10 per case. Two male cases carried X-linked variant in a known ID gene, two cases were compound heterozygous for two rare/novel potentially damaging non-synonymous variants in ID genes, and in one case we detected a *de novo* variant in a previously described ID gene. In two independent trios we identified a different *de novo* splicing variant in the same kinase gene. In four other cases we identified novel *de novo* variants in genes related with neurite outgrowth, gene silencing or epigenetic control of gene expression, which would be good candidates for novel ID genes.

2941W

Targeted deep resequencing identifies a mutation in MID2, as causal for X-linked intellectual disability with varied disease severity. *B. K. Thelma[1], S. G. Thenral[1], A. Michealraj[1], M. Kabra[2], G. Kaur[3], R. C. Juyal[4].* 1) Dept Genetics, Univ Delhi, South Campus, New Delhi, India; 2) Department of Pediatrics, All India Institute of Medical Sciences (AIIMS), New Delhi; 3) Department of Physiology, Government Medical College and Hospital, Chandigarh, India; 4) National Institute of Immunology, New Delhi.

Approximately 10% of X-linked intellectual disability (XLID) in males is contributed by copy number variants and monogenic causes account for an additional ~10–12% with >90 genes implicated in both syndromic and non-syndromic forms. Rapid technological advancement has aided the identification of several ID genes, but each of these account only for a small number of families with the exception of FMR1. However, many of these ID genes with diverse molecular functions cluster in specific cellular and molecular pathways. Ubiquitin- proteosome is one such emerging pathway involved in the regulation of proteins, notably during neuronal development and remodeling of the synapse. In the present study, by targeted resequencing of the linked region we report a novel missense mutation (NM012216.3 c.1040G>A; Q9UJV3 p.Arg347Gln) in MID2, which encodes ubiquitin ligase E3, as the likely cause of X-linked intellectual disability in a large Indian kindred. The mutation was observed in all affected and obligate carriers but not in any unaffected males of the family or in the population controls (n= 200). Screening of additional idiopathic individuals with intellectual disability subjects (n=250) did not reveal this or any additional mutations in the coding exons of this gene. When transiently expressed in HEK293T cell line, the mutation was found to abolish the function of the COS domain in the protein. The GFP tagged mutant protein accumulated in the cytoplasm instead of binding to the cytoskeleton resulting in altered the sub-cellular localization. This study highlights the growing role of the ubiquitin pathway in intellectual disability. The MID2 mutation, conferring a phenotype different from that of Opitz syndrome, is of considerable interest in ID etiology. It not only contributes to the literature on functional significance of TRIM proteins but also demonstrates the wide range of phenotypic variability caused by mutations in similar domains of paralogous proteins.

2942T

Exome sequencing and functional biology reveal novel genes causing Infantile Mitochondrial Encephalopathy. *P. Bonnen, A. Besse, T. Donti, S. Lalani, F. Scaglia, W. Craigen, B. Graham.* Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Mitochondrial disease is a diverse group of disorders that are estimated to occur with a combined incidence of 1/5,000. Approximately ninety percent of pediatric onset cases are caused by high penetrance recessive mutations in the nuclear genome, however after exhausting all available diagnostic tests most patients remain without a molecular diagnosis. Using a combination of sequencing, bioinformatics, and cellular and molecular biology we have discovered high-confidence pathogenic mutations. We identified pediatric patients who have been pre-screened and shown to be negative for mitochondrial and known nuclear gene candidates but have overwhelming evidence supporting a mitochondrial disease diagnosis. A battery of mitochondrial functional assays have been performed on all samples with available tissues including electron transport chain analysis, mitochondrial DNA copy number, FACS based analysis of relative mitochondrial membrane potential and reactive oxygen species. Exome sequencing has been completed on 20 patients. We have discovered and validated the pathogenic mutation in five patients. A causal relationship has been established using cDNA complementation and mitochondrial functional assays. This work has resulted in the discovery of novel disease genes, improved molecular diagnosis, and new insights into the pathogenetic mechanisms underlying mitochondrial encephalopathy.

2943F

***TIMM44* mutations identified by family-based WES cause severe mitochondrial respiratory chain disease due to defective mitochondrial protein import.** *M.J. Falk[1], S. Srinivasan[2], S. Dingley[1], J. Ostrovsky[1], M. Tsukikawa[1], E. Polyak[1], E. Place[1,3], M. Consugar[3], J.C. Perin[4], N. Avadhani[2], E.A. Pierce[3], X. Gai[5].* 1) Divisions of Human Genetics and Metabolic Disease, Department of Pediatrics, The Children's Hospital of Philadelphia and University of Pennslyvania Perelman School of Medicine, Philadelphia, PA; 2) Department of Animal Biology, School of Veterinary Medicine, University of Pennsylvania, PA; 3) Ocular Genomics Institute and Berman-Gund Laboratory for the Study of Retinal Degenerations, Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA; 4) Center for Biomedical Informatics, The Children's Hospital of Philadelphia, Philadelphia, PA; 5) Department of Molecular Pharmacology and Therapeutics, and Center for Biomedical InformaticsLoyola University Chicago Health Sciences Division, Maywood, IL.

Primary mitochondrial respiratory chain (RC) disease is a highly heterogeneous group of energy deficiency disorders, where mutations in more than 100 nuclear and all 37 mtDNA genes explain the genetic etiology for less than half of cases. To improve the diagnosis and understanding of pathogenic mechanisms in individual RC diseases, we have adopted a family-based whole exome sequencing (WES) approach. **METHODS:** We have completed WES analyses on 18 individuals from 6 kindreds, with multiple additional analyses currently ongoing. We employed a family-based WES approach using the Agilent 50 Mb “MitoExome” capture and Illumina HiSeq paired end sequencing with Sanger validation of variant segregation. **RESULTS:**Of the 6 kindreds in whom sequencing is complete, novel disease-causing recessive mutations were identified in one known gene (*RRM2B*). 1 to 2 lead candidate mutation(s) were identified for each of the other kindreds that involve novel genes not previously linked to human disease. One simplex case is a 7-year-old girl with severe multi-systemic manifestations of primary RC disease characterized by marked complex I-III deficiency, severe lactic acidosis, Leigh syndrome, GI dysmotility, and profound global developmental delay. WES analysis of the proband and her healthy parents revealed only a single gene, *TIMM44*, with biparental inheritance of rare, compound heterozygous, non-synonymous sequence variants (p.N251K and p.P308Q) predicted to be damaging by both Polyphen2 and SIFT. *TIMM44* encodes a key component of the TIM23 inner mitochondrial membrane (IMM) protein import complex. Functional analyses in fibroblast cell lines (FCLs) from the proband showed significantly impaired expression of a complex V matrix subunit that requires TIM23 complex import, as well as increased PINK1 expression, which typically occurs only by impairing its membrane potential-dependent TIM23 transport. Targeted IMM import assays in the proband's FCLs and isolated mitochondria confirmed defective mitochondrial import. Wild-type *TIMM44* cDNA rescue to ameliorate these functional abnormalities is underway. **CONCLUSIONS:** *TIMM44* is a novel cause of primary RC disease due to impaired mitochondrial protein import. A family-based WES analysis approach permits efficient determination of the precise genetic etiology for sporadic cases of mitochondrial disease, overcoming the substantial challenge of locus heterogeneity and rare individual gene contributions to disease burden.

2944W

A novel form of Limb Girdle Muscular Dystrophy caused by impairment of an ER-to-Golgi trafficking component. *N. Bögershausen[1], Y. Li[1], J.C. von Kleist-Retzow[2], R. Wirth[1], G. Nürnberg[3], H. Thiele[3], J. Altmüller[3], B. Schoser[4], P. Nürnberg[3], R. Heller[1], B. Wollnik[1].* 1) Institute of Human Genetics, University Hospital Cologne, Cologne, Germany; 2) Pediatrics Department, University Hospital Cologne, Cologne, Germany; 3) Cologne Center for Genomics, University of Cologne, Cologne, Germany; 4) Friedrich-Bauer-Institute, Ludwig-Maximilian-University Munich, Munich, Germany.

The Limb Girdle Muscular Dystrophies (LGMD) are a heterogeneous group of degenerative myopathies caused by functional alterations in the dystrophin-glycoprotein complex. Progressive proximal muscle weakness is characteristic of the disease and it may be associated with involvement of the heart and bulbar muscles, and/ or intellectual disability in a minority of cases. We examined a consanguineous Syrian family with three affected family members showing a hitherto undescribed form of LGMD. The clinical phenotype involved progressive muscle weakness of the proximal limbs, highly elevated serum creatine kinase (9–16 fold), hip dysplasia, scoliosis, and hypertrichosis in all three patients, along with eye abnormalities in two patients. There was no obvious cardiac or bulbar muscle involvement. We performed whole-exome sequencing in the index patient. There were no novel variants in any gene known to cause LGMD. Bioinformatic analysis of all known and novel exome variants for stretches of homozygosity drastically reduced the number of relevant variants. To refine the homozygous regions we performed genome wide homozygosity mapping for the whole family and found a significantly linked homozygous 1 Mb region on chromosome 4. Combination of mapping and exome data pointed to a single novel variant, a homozygous missense mutation in a gene encoding a component of a multi-subunit tethering complex that is involved in early ER-to-Golgi trafficking. Co-segregation of the mutation within the family was confirmed by Sanger sequencing. It was not found in 100 healthy Turkish controls or in any current database of human variation (including 10.000 alleles of the Exome Variant Server). We screened 32 patients with unexplained LGMD, but could not yet identify any further mutations in this gene. The mutation affects a highly conserved amino acid residue in a functional protein domain of this cargo protein and it is predicted to be probably damaging. Post translational modification of skeletal muscle proteins is important for their specific function during myogenesis and muscle regeneration, as exemplified by mutations in the Golgi resident glycosyltransferase fukutin that cause LGMD2I. We propose that the identified mutation might lead to alterations in post translational modification of muscle proteins and thereby cause a novel form of LGMD. Functional studies aiming to prove this mutational effect are in process.

2945T

Tackling giants with next-generation sequencing: homozygous or compound heterozygous truncating mutations of *TTN* from exome analysis define novel forms of cardiomyopathy with skeletal myopathy. *C. Chauveau[1, 2], C. Julien[2], H. Marks[3], R. Foley[4], A.L. Kho[5], B. Talim[6], MC. Arne-Bes[7], E. Uro-Coste[7], P. Maury[7], A. Vihola[8], B. Udd[8], H. Topaloglu[6], S. Moore[9], M. Gautel[5], C. Bonnemann[4], ME. Samuels[2], A. Ferreiro[7, 10].* 1) Groupe Myologie, U787 INSERM-UPMC paris VI, france, paris, France; 2) Centre de Recherche de l'Hôpital Ste-Justine, Université de Montréal, Montréal, Canada; 3) Section of Neurology, Department of Pediatrics, St. Christopher's Hospital for Children, Drexel University College of Medicine, Philadelphia USA; 4) National Institutes of Health, Bethesda, MD, US; 5) Cardiovascular Division and Randall Division for Cell and Molecular Biophysics, King's College London, London, United Kingdom; 6) Pediatric Pathology Unit, Child Health and Diseases Department, Faculty of Medicine, Hacettepe University, Turkey; 7) CHU Rangueil, Toulouse, France; 8) Folkhälsan Institute of Genetics and Department of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland; 9) University of Iowa, Iowa City, USA; 10) Centre de Référence des maladies neuromusculaires, GH Pitié-Salpêtrière, Paris, France.

Cardiomyopathies are potentially lethal conditions in which the muscular function of the myocardium is altered. They are frequent and can be associated with skeletal muscle disease. We describe the genetic analysis focusing on the titin gene (*TTN*, 363 exons) of 24 families with primary cardiomyopathy associated with congenital core myopathy. Titin plays a key structural and functional role in striated muscles. However, *TTN*'s size and complexity preclude full screening by Sanger sequencing, and until recently only a small number of mutations had been found. Since mutations in the titin M-line domain have been associated with cardiac and skeletal muscle phenotypes, we started with Sanger sequencing of the M line-encoding region encompassed by the last 6 exons of *TTN* (6.5% of the gene). We identified 4 novel nonsense (1 homozygous, 2 compound heterozygous, 1 heterozygous) and 1 heterozygous missense mutation in 4 families (16.6% of our cohort). The 2 heterozygous changes were inherited from healthy fathers. Subsequently we performed whole exome sequencing (WES) on one sample from those last two families using the current version of the Agilent 50Mb SureSelect targeting library and successfully captured and generated sequence for essentially all *TTN* exons (except a few alternative exons not targeted by the library). In each family, WES identified one new heterozygous mutation (missense and truncating); these were confirmed as compound heterozygotes by Sanger resequencing of the patients and parents. All 8 parents were heterozygous and healthy, suggesting that not all truncating *TTN* mutations, particularly if in the M-line, manifest unless associated with a second mutation. This can potentially explain the reported high prevalence of *TTN* truncating mutations in controls (3%) from a recent study which identified truncating *TTN* mutations in 27% cases of a series of dilated cardiomyopathy and which proposed a dominant negative effect of these mutations. The range of cardiological manifestations in our cohort was large and included previously unreported phenotypes. Our results expand the spectrum of TTN-related conditions and confirm that WES opens a new era for the study of giant and complex genes, of which *TTN* is the paradigm. We also propose that *TTN* is involved in an unexpectedly high proportion and large range of striated muscle phenotypes, and suggest that it should be considered and tested in any uncharacterized cardiac and/or skeletal muscle condition.

2946F

Exome sequencing for the molecular diagnosis of muscle disorders: successes and challenges encountered. *K.K. McDonald[1], J. Stajich[1], C.P. Blach[1], A.E. Ashley-Koch[1,2], M.A. Hauser[1,2].* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Department of Medicine, Duke University Medical Center, Durham, NC.

The molecular diagnosis of muscle disorders is challenging: genetic heterogeneity (>100 genes) precludes exhaustive clinical testing, and prioritizing sequencing of specific genes is difficult due to the similarity of clinical presentation. We have evaluated the usefulness of whole exome sequencing as a diagnostic approach for autosomal dominant muscular dystrophy by examining the extent of high quality sequence coverage of known muscle disease genes while searching for disease-causing variants. Exome sequencing was performed for 11 individuals from 4 families, using the Agilent SureSelect Human All Exon 50Mb kit and the Illumina HiSeq 2000 (2×100bp). Alignment was performed with BWA, and the Genome Analysis Toolkit was used for local realignment, quality score recalibration, and variant calling. After duplicate removal, the mean coverage per exome ranged from 42X to 84X, and 85.7%-91.8% of the expected capture region was covered at ≥10X. We created target intervals spanning the coding and splice regions of 102 skeletal and/or cardiac muscle disease genes, 499,520 bases total. For each exome, “failed” positions were identified that had <10 reads with QUAL scores ≥50. 4.9% of bases within the gene set failed in every exome. 11 genes (SMN1, FKRP, KBTBD13, DES, PABPN1, BIN1, COL6A1, PLEC, SEPN1, ISCU and POMT2) failed across ≥20% of their coding/splicing regions. Analysis of the exome data in one family resulted in the identification of a known nonsense mutation in filamin C, p.W2710X. If a minimum depth cut-off was applied as part of a quality filter, the mutation would not have been identified in one of the cases because only 5 reads were present at the position. In another family, we identified a known, functionally-tested, splice mutation in *desmin*, IVS3+3A>G. Interestingly, because it is not in a canonical splice site, the functional annotation fields in SeattleSeq 131 do not indicate that it is a splicing variant. Use of the “distancetosplice” field for filtering, however, did result in easy identification of the variant. In conclusion, while exome sequencing provides reliable, high-quality data for most exons in known muscle disease genes, gaps and low quality regions remain that must be evaluated on an individual basis. Additionally, filtering using distance to splice sites rather than disruption of canonical splice sites avoids potentially missing functional variants. To date, we have identified causative mutations for 2 of 4 families.

Usher-exome: an efficient diagnostic approach when used in combination with LSDB USHBases, Variant Manager USHVAM and USMA. *A.F. Roux[1, 2], T. Besnard[2, 3], G. Garcia Garcia[2, 4], D. Baux[1], C. Vaché[1], L. Larrieu[1], V. Faugère[1], J. Millan[4], M. Claustres[1, 2, 3].* 1) Molecular Genetics, CHU Montpellier, Montpellier, France; 2) INSERM U827, Montpellier, France; 3) Univ, Montpellier I, Montpellier, France; 4) Instituto de Investigación Sanitaria, Valencia, Spain.

Usher syndrome (USH) is a rare autosomal recessive disorder that associates sensorineural hearing loss (HL) and retinitis pigmentosa. Some patients will also exhibit vestibular areflexia (VA). Clinical and genetic heterogeneity is recognized as the 3 clinical subgroups, defined mainly on the degree of HL and VA, can be caused by mutations in one of the 9 known genes. If, in most cases clinical signs are in line with the defined causative gene, some patients will carry mutations in a gene responsible for a different subgroup (defined as atypical Usher). We have used so far Sanger sequencing, coupled with CGH-array to identify mutations in USH patients and the strategy was efficiently based on haplotyping followed by cascade sequencing of the candidate gene(s) according to their implication. We could show that the mutation detection rate was more than 90% but this approach remained laborious in terms of time and costs and inefficient for atypic USH patients. We have recently designed a targeted exome consisting of 330 kb of captured sequences (SeqCap EZ Choice, Nimblegen), sequenced using the GS Junior system (Roche 454). This design has been tested on 43 patients originated from France (22) and Spain (21), previously screened by Sanger in at least one USH gene (20 with 1 mutation, 23 with no mutation). This strategy was then applied to 8 patients for whom no analysis in any of the Usher genes had been performed. An average of 400 variants/patient has been identified. Successive filtering has been applied. An average of 20 variants/patient needed further analysis. In addition to central databases, studies were performed using tools dedicated to Usher syndrome (USHbases, USHVAM and USMA) in order to further assess the pathogenicity of each variant. By comparison with the variants previously identified by Sanger, we observed 3.5% of false negative among all the variants: 1% was due to poor coverage, the remaining was due to misreading in the homopolymeric regions. Ten additional mutations could be identified. The pathogenic mutations could be identified in 86% of the new USH cases, but that was possible thanks to the availability of dedicated tools and excellent knowledge on the Usher genes. The coverage was estimated to be > 40 reads for 92% of the covered regions, (minimum required for proper molecular diagnosis). Although an optimization of the design is necessary, these results are very promising for a future transfer to diagnostic facilities.

2948T

Loss of function mutations in *HINT1* are a major cause of autosomal recessive axonal neuropathy with neuromyotonia. *M. Zimon[1,2], J. Baets[2,3,4], L. Almeida-Souza[2,5], J. Nikodinovic[6], Y. Inherited Peripheral Neuropathies are a group of genetically and clinically heterogeneous disorders affecting 1 in 2500 individuals. Although more than 50 genes were associated with IPN, number of families still remains without genetic diagnosis pointing to novel genetic entities. Until recently, small family sizes hampered gene discovery however current technological advances present new opportunities for unraveling CMT molecular architecture.

In this study, we show that combined SNP genotyping, linkage analysis and whole genome sequencing were successful in discovering genetic cause in a small Belgian family diagnosed with autosomal recessive (AR) axonal neuropathy and neuromyotonia. After data filtering within the three linked regions, we identified two heterozygous mutations in *HINT1* (*histidine triad nucleotide binding protein 1*) - gene located on chromosome 5. Subsequent patient cohort screening allowed finding of 8 different mutations in a total of 32 families. Interestingly, the majority of patients carrying *HINT1* mutations were diagnosed with a motor greater than sensory axonal neuropathy associated with action myotonia in the hands and/or neuromyotonic and myokymic discharges on needle electromyography. Studies in yeast cells and patients lymphoblasts showed that mutations lead to either enzymatically inactive protein or to its post-translational degradation.

In conclusion, we present here combined genetic and functional evidences that the maintenance of functional HINT1 is crucial for the peripheral nervous system (PNS) physiology. Frequency of mutations in a cohort of patients diagnosed with autosomal recessive neuropathy was 11 % however in a specific group of patients with AR axonal neuropathy and neuromyotonia it raised to 76 %. Our findings are also of great importance for future molecular diagnostics and patient counseling.

Identification of novel genes in human primary immunodeficiency diseases using exome sequencing. *S. Khan[1], B. Wakeland[1], C. Liang[1], M. De la Morena[2], N. Van Oers[1], E. Wakeland[1].* 1) University of Texas Southwwestern Medical Center, Dallas, TX; 2) Children's Medical center, Dallas, TX.

Severe immunodeficiencies are rare in the human population (>1/70000) and their genetic etiology is very difficult to decipher. More than 150 genes have been linked to various forms of primary immunodeficiencies (PID) and most of these are the consequence of a monogenic defect and hence follow a simple mendelian inheritance. In this study we utilized whole exome sequencing strategy to identify the causative genetic lesions in patients with severe immunodeficiencies of unknown etiology. This strategy has proven to be a powerful, efficient strategy for identifying genes underlying rare mendelian disorder. We subjected five families with one or more children who have severe PID with an unknown genetic basis to whole exome sequencing using SureSelect Human All Exon Kit from Agilent technologies and sequenced in a single lane of an Illumina GAIIx. On average 4.5 Gbp of sequence data was generated per sample. Raw sequence data in fastq format were converted to BAM file format and aligned using the Genome Analysis Toolkit (GATK) which is a structured programming framework developed by the Broad Institute. GATK consists of robust analysis tools including depth of coverage analyzers, a quality score recalibrator, a SNP/indel caller and a local realigner. The data was further analyzed using Variant Call Format (VCF) tools package. On average individual genomes differed from the reference sequence by 67089 total SNVs. To distinguish potentially deleterious mutations from other variants, only nonsynonymous (NS) variants and short coding region insertions or deletions (indels; I) were considered. We will present the analysis for all the five families at ASHG 2012. The causative variants for the PID exhibited by the proband was sought using several filtering strategies that led to a list of candidate variations that were novel, deleterious mutations in affected child within a PID family. These variants are further processed through the PolyPhen 2 Gateway and SIFT to predict their potential effects on gene function and to generate a list of variants with potentially damaging SNVs. These mutations are now being validated using standard Sanger sequencing. The future studies will characterize the impact of these variants on their expression by RNA-SEQ analysis of PBMC from the parents and/or siblings that are heterozygous for the candidate variant. We hope that these data will identify novel genes and their functional role within the human immune system.

2950W

The ADAMTS18 gene is responsible for autosomal recessive syndromic retinal dystrophy. *S. Banfi[1, 5], I. Peluso[1], F. Testa[2], M. Pizzo[1], R. Collin[3], N. Meola[1], M. Mutarelli[1], G. Dharmalingam[1], M. Melone[4], I. Conte[1], F. Simonelli[2].* 1) TIGEM, Fondazione Telethon, Naples, Italy; 2) Ophthalmology, Second University of Naples, Naples, Italy; 3) Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 4) Clinical and Experimental Medicine and Surgery, Second University of Naples, Naples, Italy; 5) 5Medical Genetics, Department of General Pathology, Second University of Naples, Naples, Italy.

Inherited retinal dystrophies are a group of genetically heterogeneous disorders that lead to severe visual deficits. They can be caused by mutations in over 200 genes and there is evidence for the presence of as yet unidentified genes in a significant proportion of patients. By using homozygosity mapping and whole exome sequencing, we identified, in an Italian ARRD patient, a homozygous missense mutation in the ADAMTS18 gene, which was recently proposed to be linked to Knobloch syndrome, a rare developmental disorder that affects the eye and the occipital skull. In vivo gene knockdown and rescue assays performed in the medaka fish (Oryzias latipes) model organism confirmed the pathogenic role of the mutation. This study reveals that mutations in the ADAMTS18 gene can cause a broad phenotypic spectrum of eye disorders and contributes to shed further light on the complexity of ARRD.

2951T

Novel *PLP1* gene mutation discovered by whole genome sequencing in brothers with infantile onset dopa-responsive dystonia and delayed central nervous system demyelination. *R.L. Margraf[1], J. Durtschi[1], K. Mallempati[1], J. Bonkowsky[3], R. Lutz[4], K.V. Voelkerding[1,2], K.J. Swoboda[5].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, Utah; 3) Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, Utah; 4) Munroe-Meyer Institute for Genetics & Rehabilitation, University of Nebraska Medical Center, Omaha, Nebraska; 5) Departments of Pediatrics and Neurology, University of Utah School of Medicine, Salt Lake City, Utah.

Next-generation sequencing has provided a paradigm shift in our ability to identify causal variants in undiagnosed neurogenetic diseases and facilitated expansion of phenotypes associated with previously well-described neurologic disorders in which an atypical phenotype results in an expensive diagnostic odyssey. The male proband in this family presented in early infancy with generalized dystonia and normal brain MRI imaging in the first two years of life, and he was diagnosed with cerebral palsy. When his brother presented with a similar phenotype, further diagnostic workup revealed CSF neurotransmitter and biopterin deficiency thought to be consistent with a diagnosis of GTPCH1 deficiency, and dystonic symptoms were partially dopa-responsive. Several years later the diagnosis was revisited following sudden death of the proband in the setting of progressive spasticity and opisthotonic posturing. Repeat MRI neuroimaging in the younger brother revealed a previously undiagnosed leukodystrophy. To elucidate the genetic basis of these neurological symptoms, whole genome sequencing of family members was performed, including both parents, the two affected boys and an unaffected sister. Candidate gene variant discovery analysis involved heuristic filtering and probabilistic approaches facilitated by Golden Helix and VAAST software analyses, respectively, revealing an X-linked mutation in the *PLP1* gene (proteolipid protein 1 gene, c.617T>A, p.M206K) in the two affected male siblings and the mutation was heterozygous in their carrier mother, which was Sanger confirmed. This mutation was not found in the NCBI dbSNP135, 1000 Genomes, or HGMD databases and appears novel. The PLP1 protein is the predominant myelin protein present in the CNS, playing a role in the stabilization and maintenance of myelin sheaths and mutations in *PLP1* have been reported in the X-linked dysmyelinating disorders, Pelizaeus-Merzbacher disease (PMD) and spastic paraplegia type 2. PMD mutations have been reported that flank either side of the p.M206K variant found in our patients. While mutations in *PLP1* have been reported to cause both dystonia and leukodystrophy, the lack of early CNS dysmyelinating/demyelinating features and CSF studies indicating a possible diagnosis of dopa-responsive dystonia contributed to a substantial delay in diagnosis. This report emphasizes the value of whole genome sequencing for causal variant discovery in children with undiagnosed neurologic disorders.

2952F

Digenic inheritance in Autosomal Recessive Non-syndromic Hearing Loss cases carrying GJB2 heterozygote mutations: assessment of GJB4 and GJA1. *D. Kooshavar[1,2], M.R. Noori Daloii[1], M. Hashemzadeh Chaleshtori[2].* 1) Department of Medical Genetics, Faculty of medicine, Tehran University of Medical Science, Tehran, Iran; 2) Cellular and Molecular Research Center, Shahrekord University of Medical Science, Shahrekord, Iran.

Autosomal Recessive Non-syndromic Hearing Loss (ARNSHL), in up to 50 percent of the cases, is caused by mutations in the GJB2 gene which encodes the gap-junction (GJ) protein connexin (Cx) 26. Nevertheless 10 to 42 percent of patients with recessive GJB2 mutations are heterozygous carriers. Mutations of GJB4 and GJA1 encoding Cx30.3 and Cx43 respectively, can lead to hearing loss. Different connexins can integrate in heteromeric and heterotypic GJ assemblies. This study aims to determine whether variations in any of the genes GJB4 or GJA1 can be the second mutant allele in digenic mode of inheritance in the GJB2 heterozygous cases studied. We examined 44 unrelated GJB2 heterozygous ARNSHL subjects and 400 normal hearing individuals from different geographic and ethnic areas in Iran, for sequence variations in the two genes, using polymerase chain reaction followed by direct sequencing also Restriction Fragment Length Polymorphism (RFLP). Sequence analysis of GJB4 showed five heterozygous variations (c.451C>A, c.219C>T, c.507C>G, c.155_158delTCTG, c.542C>T) that the last one was not detected in any of control samples. The altered amino acid was highly conserved. There were three heterozygous substitutions (c.758C>T, c.717G>A, c.3*dupA) in GJA1 in five cases. We propose that GJB4 c.542C>T variation and with lower possibility other variations of GJB4 and GJA1, can be assigned to ARNSHL in a digenic pattern in GJB2 heterozygote mutation carriers. Further functional studies should be done to definitely enlighten the role of these variations in digenic form of ARNSHL.

Exocrine and endocrine pancreatic damage in cystic fibrosis are associated with SLC26A9. *D. Soave[1], T. Chiang[2], M. Miller[2], D. Su[2], K. Keenan[2], W. Li[1,2], W. Ip[2], F. Wright[3], S. Blackman[4], H. Corvol[5,6], M. Knowles[7], G. Cutting[4,8], M. Drumm[9], L. Sun[1], J. Rommens[2,10], P. Durie[2,11], L. Strug[1,2].* 1) Biostatistics, University of Toronto, Toronto, Canada; 2) Research Institute, The Hospital for Sick Children, Toronto, On, Canada; 3) Department of Biostatistics, University of North Carolina, Chapel Hill, North Carolina, USA; 4) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 5) AP-HP, Hopital Trousseau, Pediatric Pulmonary Department, Inserm U938, Paris, France; 6) Pierre et Marie Curie University-Paris 6, Paris, France; 7) Cystic Fibrosis-Pulmonary Research and Treatment Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA; 8) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 9) Departments of Pediatrics and Genetics, Case Western Reserve University, Cleveland, Ohio, USA; 10) Department of Molecular Genetics, Univ. of Toronto, Toronto, On, Canada; 11) Department of Pediatrics, Univ. of Toronto, Toronto, On, Canada.

Degree of lung and exocrine pancreatic damage (PD), and the occurrence of co-morbidities such as intestinal obstruction at birth (MI), varies in Cystic Fibrosis (CF) patients with the same CFTR gene mutations. This suggests involvement of other genes. In determining modifying genes related to early CF morbidity, we identified SLC26A9, SLC6A14 and SLC9A3 as associated with MI; SLC26A9 has also been reported as associated with CF-related diabetes (CFRD). Serum immunoreactive cationic trypsinogen concentration (IRT) acts as a marker of exocrine PD in CF patients. Using longitudinal IRT measurements we asked whether early PD is associated with the three MI modifiers, and whether early PD can predict CFRD later in life. CF patients enrolled in the Canadian CF Gene Modifier Study and in earlier studies of PD (Durie et al. 1986) were included. In 129 patients, there were 1 to 16 measurements per person, up to 23 years of age, with one measurement within 24 months following birth. CFRD was diagnosed in 37 of 129 patients. Genetic associations with IRT at birth and rate of decline were determined for 8 SNPs in the three MI genes. We used linear mixed effects (LME) modeling accounting for limits of detection of the IRT assay (less than 3 ng/mL). IRT and age were natural log transformed, each SNP and its interaction with age were then added to the model, adjusting for MI. To determine whether risk of CFRD was associated with IRT, similar LME modeling was used to estimate subject-specific IRT measurements at birth and rate of decline and these estimates were assessed as predictors of CFRD in a Cox proportional hazards model. Three of the four SNPs in the SLC26A9 gene were associated with IRT at birth (min p=0.003 at rs7512462; each C allele results in a 0.96 increase in log(IRT)) and its rate of decline (p=0.008). SNPs in SLC6A14 or SLC9A3 had p>0.05. Estimated IRT at birth, but not rate of decline, was associated with CFRD (p=0.004). A 46.7% decrease in the risk of CFRD is estimated for every one unit increase in log(IRT) at birth (log(IRT) interquartile range: 2.28 to 4.38). SLC26A9 is associated with MI, CFRD and IRT at birth and its rate of decline, suggesting potential for a common therapeutic intervention. Estimated PD at birth is a strong predictor of later-onset CFRD, suggesting the possibility of predicting CFRD risk at birth. These findings require confirmation in a second cohort and estimation of CFRD predictive models with a newborn-screened sample.

2954T

Clinical findings of a three-generation family with GLA nonsense mutation (W162X). *E. Severin[1], A. Stan[2], C. Dragomir[2], G.J. Sarca[3].* 1) Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; 2) Genetic Lab, Bucharest, romania; 3) Prof.Dr. C. Angelescu Hospital, Bucharest, Romania.

Background: The deficiency of α-galactosidase A, a lysosomal enzyme, is caused by different mutations in the GLA gene located on Xq22. Complete or partial deficiency of this enzyme results in the accumulation of globotriaosylceramide in cells throughout the body, leading to Fabry disease phenotype. Objectives: To describe and compare clinical findings, to confirm the diagnosis in male and female family members and to identify the mutation causing Fabry disease. Materials and Methods: 7 family members ranging in age from 8 to 56 years, 2 males and 5 females, were clinically assessed and also evaluated for enzyme activity. Genomic DNA was isolated from blood samples of all family members and analyzed for GLA gene mutation. Results: The proband, a 31-year-old male, first experienced symptoms onset at 7 years. He had a less severe phenotype with no cardiac or renal involvement. His maternal uncle had a severe classic form of Fabry disease (left ventricular hypertrophy, cerebrovascular manifestations, hearing loss, renal insufficiency). Both were found to have one copy of GLA mutation (c.485G>A). All five females were carrier with milder symptoms (acroparaesthesiae, pain or angiokeratomas). Conclusions: Fabry disease showed a wide range of clinical manifestations in this family. According to the results genetic testing should be considered especially for women and families in whom the diagnosis of Fabry disease is suspected based on early clinical signs and symptoms.

2955F

Targeted array-CGH analysis to identify copy-number changes underlying ciliopathies. *A. Lindstrand[1], C. Carvalho[2], D. Pehlivan[2], R.D. Clark[3], C.A. Johnson[4], H. Omran[5], B. Franco[6], H. Kremer[7], P.L. Beales[8], P.J. Scambler[8], E.R. Maher[9], J.R. Lupski[2,10], N. Katsanis[1].* 1) Center for Human Disease Mod., Duke University Medical Center, Durham, NC; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston TX, USA; 3) Division of Medical Genetics, Department of Pediatrics, Loma Linda University School of Medicine, Loma Linda, California; 4) Section of Ophthalmology and Neurosciences, Leeds Institute of Molecular Medicine, St James's University Hospital, Leeds, UK; 5) Department of Pediatrics and Adolescent Medicine, University Hospital Muenster, Muenster, Germany; 6) Telethon Institute of Genetics and Medicine (TIGEM), Napoli, Italy; 7) Departments of Otorhinolaryngology and Human Genetics, Radboud University Medical Centre, Nijmegen, The Netherlands; 8) Molecular Medicine Unit, University College London Institute of Child Health, London, UK; 9) Department of Medical and Molecular Genetics, Institute of Biomedical Research, University of Birmingham, Birmingham, UK; 10) Texas Children's Hospital, Houston TX, USA.

Disruption of ciliary and basal body function has been associated with a growing number of human genetic disorders, collectively termed ciliopathies. Although clinically distinct, ciliopathies manifest similar hallmark features including retinal degeneration, renal and pancreatic cysts, liver fibrosis, polydactyly and other skeletal abnormalities, situs inversus, and central and peripheral nervous system defects. Despite extensive sequencing efforts, 20–50% of the mutational basis for ciliary disorders remains unknown. In addition, genetic studies have indicated that ciliopathy genes can contribute both causal and modifying alleles across the ciliopathy spectrum, supporting the hypothesis that the mutational load in the ciliary proteome plays a critical role in defining disease penetrance and expressivity. To establish the genetic contribution of copy number variations (CNVs) throughout a spectrum ciliopathies we have developed a custom designed oligonucleotide array-CGH (aCGH) targeting the coding exons of 772 genes of interest. A total of 401 DNA samples from ciliopathy patients were evaluated using this targeted aCGH: Bardet-Biedl syndrome (BBS) = 92; Jeune syndrome (JS) = 52; Joubert syndrome (JBTS) = 4; Meckel-Gruber syndrome (MKS) = 87; Primary Ciliary Dyskinesia (PCD) = 83; Oral-facial-digital type I syndrome (OFD1) = 48; Usher syndrome (USH) =27; unknown ciliopathy = 8. We discovered one or more distinct CNVs in 43 (10.7%) unrelated individuals, including 33 deletions and 3 duplications in known ciliopathy associated genes. Interestingly, we detected an accumulation of the recurrent NPHP1 deletion in our BBS, OFD1 and PCD cohorts and 5 (18.5%) unrelated families with Usher syndrome harbored an identical 182 kb deletion of USH2A. In addition, eight contiguous gene deletions and duplications were detected which are likely to be deleterious. Deletion breakpoints have been confirmed in 16 cases by PCR and sequencing. None of the aberrations were detected in 229 control individuals. Our data suggest a major contribution of CNVs in ciliopathy disease burden. In addition, we found new candidate ciliopathy loci that are presently undergoing in vivo and in vitro validations.

2956W

Is the R202Q mutation clinically relevant in familial mediterranean fever, though? *S. Duzenli, A.O. Arslan.* Medical Genetics, Abant Izzet Baysal University, BOLU, BOLU, Turkey.

Familial Mediterranean Fever (FMF) is an autosomal recessive disorder characterized by recurring attacks of fever and serositis, affecting Arabs, Armenians, Jews and Turks. Up to date, determined disease causing mutations on the marenostrin/pyrin gene are 222, of which about 100 are said to cause clinical symptoms including amyloidosis. Most seen disease causing mutations in the Turkish population are M694V, V726A, A744S, E148Q, M694I, M680I, F497L and R202Q. We aimed to evaluate the phenotype-genotype correlation of MEFV gene mutation R202Q of exon 2, of which clinical effects are still debatable. Five hundred and eleven patients of Turkish origin with FMF symptoms, aged between one month and 65 years were screened for the eight mutations mentioned above. The molecular genetic testing was undertaken by using appropriate primers and probes on a Real-Time PCR system, after extraction of DNA from whole blood. Of the 511 clinically significant patients, 332 carried at least one of the mutations. Ninety nine patients were only heterozygote R202Q carriers. Compound heterozygosity with R202Q and another mutation was detected in 138 patients. In total, of the 511 patients, 332 had mutations on the MEFV gene, 32 were homozygous for R202Q and 138 had at least one R202Q mutation. According to Naimushin et al. the impact on the pyrin-protein structure of R202Q mutation is slightly higher than the E148Q mutation. It is further as good as accepted, that the E148Q mutation is associated with FMF symptoms. Accordingly, one could expect that both have a close-rangely effect on clinical outcome. When taken into account that MEFV mutation distribution and effect vary considerabely high among populations, we can conclude that the effect of the R202Q mutation on the phenotype of Turkish FMF patients can not be ignored. This rather should be discussed and studied further, to determine whether it is clinically relevant for the populations affected.

2957T

Molecular basis of microphthalmia/anophthalmia. *N. Chassaing[1], A. Causse[2], A. Delahaye[3], A. Vigouroux[1], P. Calvas[1].* 1) Service de Génétique Médicale, Hôpital Purpan, Université Toulouse III, Toulouse, France; 2) Service d'Ophtalmologie, Hôpital Purpan, Université Toulouse III, Toulouse, France; 3) Service d'Histologie, Embryologie, et Cytogénétique, AP-HP, Hôpital Jean Verdier, Bondy, France.

PURPOSE: Microphthalmia/Anophthalmia (M/A) are the most severe ocular developmental defects corresponding to a reduce size or an absence of the ocular globe. Incidence of M/A is estimated to be 1/10.000. Numerous genes have been implicated either in non syndromic and syndromic forms of M/A. The aim of this study was to evaluate respective responsibility of participation of the 7 major genes involved in M/A in human. METHODS: 135 patients suffering from M/A were included in this study. Among these patients, 35 displayed anophthalmia, 47 microphthalmia, and 53 colobomatous microphthalmia. The ocular involvement was isolated in 76 patients, and associated with other malformations in 59 patients. Most cases (110/135) were sporadic. Mutations screening was conducted in *SOX2*, *PAX6*, *OTX2*, *RAX*, *FOXE3*, *VSX2*, and *GDF6* entire coding regions and intron-exon borders by direct sequencing. Furthermore, we developed a semi-quantitative approach (QMPSF) in order to detect deletion or duplication events for *SOX2, PAX6*, *OTX2*, *RAX*, and *VSX2*. Mutated patients' phenotypes were examined in order to obtain a better delineation of each gene phenotypic spectrum. RESULTS: Molecular analysis allows identification of the causative mutation in 32/135 patients (24%). Mutations in*SOX2* represent the most common cause of M/A (18/135, 13%). *SOX2* mutations represent more than a half of the total of identified mutations (18/32, 56%) in this cohort. Interestingly, whole gene deletions account for 27% (5/18) of the identified *SOX2* mutations. *OTX2* and *RAX* are mutated in 4% (5/135), and 3% (4/135) of patients respectively. *FOXE3*, *PAX6*, *VSX2* and *GDF6*are only rarely involved. Most mutations were identified among anophthalmic patients (21/32, 65%). The mutation detection rate is of 24% in this cohort, but increases in the subgroup of anophthalmic patients (21/35, 60%). CONCLUSION: In this the large, molecular screening allows identification of the molecular defects in one quarter (32/135) of patients. We provide a rough evaluation of the frequency of these genes involvement in M/A and recognized some unusual phenotypes. Finally, these results underline the genetic heterogeneity of M/A and as the majority of patients do not harbour mutations in known M/A genes other genes remain to be.

2958F

Identification and functional investigation of non-coding NIPBL regulatory elements. *D. Braunholz[1], J. Wilde[4], L.D. Michelis[4], K.S. Wendt[2], E. Watrin[3], J. Eckhold[1], I.D. Krantz[4], G. Gillessen-Kaesbach[1], M.A. Deardorff[4], F.J. Kaiser[1].* 1) Institut für Humangenetik, Lübeck, Germany; 2) Dept. of Cell Biology Erasmus MC Dr. Molewaterplein 50 3015 GE Rotterdam, Netherlands; 3) Institut de Génétique et Développement de Rennes, CNRS Faculté de Médecine 2 avenue du Pr Bernard, 35043, Rennes, France; 4) Children`s Hospital of Philadelphia, Division of Human Genetics, Philadelphia, United States.

Cornelia de Lange Syndrome (CdLS) is a rare genetic developmental disorder with a variable severity of phenotype. Patients demonstrate morphological anomalies that include characteristic facial features, a range of malformations of the upper extremities, growth retardation and cognitive delays. Nearly 60% of classical CdLS patients carry mutations in NIPBL, compared with only 10% of mutations found in four other identified genes. Current molecular diagnostics, including whole exome sequencing, are restricted to the coding region of NIPBL. It is known that even small changes in NIPBL transcript levels have pathogenic effects in animal model systems, suggesting that mutations in NIPBL regulatory elements could also cause CdLS. To investigate this, we used in silico promoter prediction tools followed by reporter assays to identify a 2 kb-region that includes the first exon and 5' region of the first intron as the NIPBL promoter. Furthermore, we narrowed the core promoter to a 143 bp region upstream of exon 1. Sequencing analysis of the 2 kb NIPBL promoter in 110 mutation-negative CdLS patients identified two novel base substitutions. In vitro reporter gene assays and quantitative RT-PCR of blood samples or cell lines demonstrated that these mutations cause a significant reduction of the NIPBL transcript levels. In silico analysis also suggested a putative regulatory element within intron 9 that shows strong enrichment of the histone 3 lysine 4 monomethylation in various cell types, signifying a regulatory element. Reporter gene analysis demonstrates strong repression activity of this element toward the NIPBL promoter. As next step we will perform sequencing analysis of this regulatory element in a large cohort of patients with CdLS and related phenotypes as well as further molecular investigations, such as chromatin conformation capturing (3C), to examine the functional interaction of this cis-regulatory element with the NIPBL promoter. In summary, we identified and functionally characterized two regulatory elements within non-coding regions of NIPBL that influence NIPBL gene expression. Therefore, mutations within these elements may alter NIPBL-protein level to cause CdLS or related phenotypes.

Molecular genetic studies of nonsyndromic oculocutaneous albinism in the Pakistani population. *T. Jaworek[1], T. Kausar[1,2], N. Tariq[2], S. Sadia[2], M.I. Maqsood[2], A. Sohail[2], M.A. Bhatti[2], M. Ali[2], S. Riazuddin[1], R.S. Shaikh[2], Z.M. Ahmed[1,2].* 1) Cincinnati Children's Hospital Research Foundation, Cincinnati, OH. USA; 2) Institute of Biotechnology, Bahauddin Zakariya University, Multan, Pakistan.

Oculocutaneous albinism (OCA) is caused by a group of genetically heterogeneous inherited defects that result in the loss of pigmentation in the eyes, skin and hair. Mutations in the TYR, OCA2, TYRP1 and SLC45A2 genes have been shown to cause isolated OCA. No comprehensive analysis has been conducted to study the spectrum of OCA alleles prevailing in the Pakistani albino populations. We enrolled 75 large Pakistani families and screened them for OCA genes and a candidate gene, SLC24A5. Screening of the TYR gene revealed four known and three novel mutations in ten families. Ex vivo studies revealed the retention of an EGFP-tagged mutant tyrosinase in the endoplasmic reticulum (ER) at 37°C, but a significant fraction of two mutant proteins left the ER in cells grown at a permissive temperature (31°C). Three novel and two known mutations of OCA2 were found in fourteen families. Sequence analysis of the SLC45A2 gene revealed three novel probable pathogenic variants in three families. No mutation in TYRP1 and SLC24A5 was found in the remaining families, suggesting there may be an additional gene in which mutant alleles cause nonsyndromic OCA. Therefore, we performed a genome wide linkage analysis and mapped a novel locus for nonsyndromic OCA. Based on our results, it is tempting to speculate that OCA2 mutations are the most common cause of nonsyndromic OCA in the Pakistani population. We also report the clinical phenotypes of multiple affected individuals from each family. Overall, our study contributes to the development of genetic testing protocols and genetic counseling for OCA in Pakistani families. Details of these novel mutant alleles and a new OCA locus will be presented at the meeting.

2960T

A Case of Lymphedema with Microcephaly and Chorioretinopathy with a Mutation in the KIF11 Gene. *D. Finegold[1,2], E. Lawrence[1], K. Levine[1], R. Ferrell[1].* 1) Dept of Human Genetics University of Pittsburgh; 2) Childrens Hospital of Pittsburgh.

Ostergaard et al 2012 found KIF11 mutations in families with autosomal-dominant microcephaly associated with congenital lymphedema and chorioretinopathy. Subsequently, we carried out Sanger sequencing for all 22 coding exons in KIF11 in a set of 187 probands ascertained on primary lymphedema, identifying a heterozygous deletion in exon 20 in one family (Arg953fsX1012). This 17 bp deletion leads to a nonsense protein of 60 amino acids prior to a stop codon altering and truncating the normal protein. The family has been previously described as having Microcephaly-lymphedema-chorioretinal dysplasia syndrome, MLCRD OMIM #152950 (Crowe and Dickerman 1986 and Limwongse et al 1999). The proband also was diagnosed with ASD (atrial septal defect) at the age of 14. ASD was also noted in two of the patients in the Ostergaard et al paper. Potentially ASD could be part of the overall syndrome but with a lower penatrance. The mother also carried the heterozygous deletion and was affected with microcephaly and chorioretinopathy and mild lyphedema. This observation further confirms the findings of Ostergaard et al, expanding the molecular spectrum of mutation in KIF11.

miRNA-411 negatively regulates YAF2 and myogenic factors. *Y. Chen[1,2], N. Harafuji[1], P. Schneiderat[3], M.C. Walter[4].* 1) Center for Genetic Medicine Research, Children's National Medical Center, Washington DC; 2) Department of Integrative Systems Biology and Department of Pediatrics, George Washington University, Washington DC; 3) Department of Neurology, Ludwig-Maximilians-University of Munich, Germany; 4) Friedrich-Baur-Institute, Department of Neurology, Ludwig-Maximilians-University of Munich, Germany.

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant muscular dystrophy caused by de-repression of double homeobox protein 4 due to a contraction of the D4Z4 array at chromosome 4q35. Several studies suggest that defects in myogenesis are involved in the disease mechanisms. In this study, we hypothesized that misregulation of microRNAs (miRNAs) in FSHD is involved in the myogenic defects and disease progression. To identify misregulated miRNAs in FSHD myoblasts, miRNA expression profiling was performed using TaqMan microRNA arrays. Twenty-six and 11 miRNAs were differentially expressed in FSHD myoblasts during proliferating and 48 hours post-differentiation, respectively. The differential expression of miR-411 was validated by individual quantitative RT-PCR assay and additional arrays. In situ hybridization showed cytoplasmic localization of miR-411 in the myoblasts. The mRNA expression changes of the myoblasts were determined by mRNA expression profiling, and 4 potential miRNA-411 targets including YY1 associated factor 2 (YAF2) were identified. Over-expression of miR-411 in murine myoblasts, C2C12 cells, showed a reduction of YAF2 mRNA expression and myogenic factors myoD and myogenin. The findings suggest that the higher expression of miR-411 in FSHD primary myoblasts might be involved in the defects of myogenesis reported in FSHD.

Transcriptional profiling in facioscapulohumeral muscular dystrophy to identify candidate biomarkers. *F. Rahimov[1,2], O.D. King[3], D.G. Leung[4,5], G.M. Bibat[4,5], C.P. Emerson Jr.[3], K.R. Wagner[4,5], L.M. Kunkel[1,2].* 1) Genetics, Children's Hospital Boston, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Boston Biomedical Research Institute, Watertown, MA; 4) The Kennedy Krieger Institute, Baltimore, MD; 5) Neurology and Neuroscience, The Johns Hopkins School of Medicine, Baltimore, MD.

FSHD is a progressive neuromuscular disorder caused by contractions of repetitive elements within the macrosatellite D4Z4 on chromosome 4q35. The pathophysiology of FSHD is unknown and as a result, there is currently no effective treatment available for this disease. In order to better understand the pathophysiology of FSHD and develop mRNA-based biomarkers of affected muscles, we compared global analysis of gene expression in two distinct muscles obtained from a large number of FSHD subjects and their unaffected first-degree relatives. Gene expression in two muscle types was analyzed using GeneChip Gene 1.0 ST arrays: biceps, which typically shows an early and severe disease involvement, and deltoid, which is relatively uninvolved. For both muscle types, the expression differences were mild: using relaxed cutoffs for differential expression (fold-change $\geq$1.2 and nominal *P*-value <0.01), we identified 191 and 110 genes differentially expressed between affected and control samples of biceps and deltoid muscle tissues, respectively, with 29 genes in common. Controlling for a false-discovery rate <0.25 reduced the number of differentially expressed genes in biceps to 188 and in deltoid to 7. Expression levels of 15 genes altered in this study were used as a “molecular signature” in a validation study of an additional 26 subjects, and predicted them as FSHD or control with 90%; accuracy based on biceps and 80% accuracy based on deltoids. Genes and molecular pathways shown to be disrupted in FSHD should elucidate the underlying mechanisms of FSHD pathogenesis and facilitate development of novel therapies.

2963T

The second most prevalent mutation of *fukutin* in Japanese Fukuyama muscular dystrophy. *K. Kobayashi[1], R. Kato[1], E. Kondo[2], M. Osawa[3], K. Saito[2], T. Toda[1].* 1) Div Neurology/Molecular Brain Science, Kobe Univ Grad Sch Medicine, Kobe, Japan; 2) Inst Medical Genetics, Tokyo Women's Medical Univ, Tokyo, Japan; 3) Dept Pediatrics, Tokyo Women's Medical Univ, Tokyo, Japan.

Fukuyama muscular dystrophy (FCMD), one of the most common autosomal recessive disorders in Japan, is characterized by congenital muscular dystrophy combined with neuronal migration disorder and ocular abnormalities. Most of the Japanese FCMD patients are homozygous for a founder haplotype that carries the SVA-type retrotransposon insertion mutation in the *fukutin* gene causing abnormal splicing, whereas some other patients are compound heterozygous for the founder insertion and various kinds of less common mutations. However, no mutation that corresponds to the second most prevalent haplotype has been found so far. Here we show that this haplotype carries a deep intronic mutation (c.647+2084G>T), which is the same as the mutation found in Korean patients. It activates a pseudo-exon between exon 5 and 6, leads to frameshift and premature termination of fukutin synthesis, and causes hypoglycosylation of α-dystroglycan in the patients. This mutation seen in Japanese and Korean patients might have been derived from the same ancestor.

2964F

Molecular study of KRT14 mutations for making a screening panel test for Iranian patient affected with Epidermolysis Bullosa. *M. Mahdavi[1], M. Moghaddam[1], A. Kakavand[1], N. Hatamnejadian[1], B. Sedaghati khayyat[1], H. Dehghanpour[1], A. Ebrahimi[1,2].* 1) Parseh Medical Genetics Counsell, Tehran, Iran; 2) Shiraz medical science university.

Epidermolysis bullosa (EB) is a rare, heterogeneous, trauma-induced blistering disease. The identified genes include those that encode keratins 5 and 14 in epidermolysis bullosa simplex, collagen VII in dystrophic epidermolysis bullosa, and laminin 5 in Herlitz junctional epidermolysis bullosa.The subtypes have been classified according to skin morphology.The Simplex form is more common variation which has four subtypes.Although the Skin Biopsy is the first step in EB Testing strategy, direct molecular methods is needed to confirm and localize the mutations.We aimed to evaluate the KRT14 hot spot exons as a noninvasive, rapid and cost benefit panel test for first step screening of common mutations in EB affected patients.Methods: About 90 patients clinically diagnosed as EB, were collected and classified clinically. All DNA samples sequenced directly for selected exons of KRT14 .Result: about 30%of affected probands have mutation in KRT14 selected exons that most of the mutation were C to G convertion that changes Ser to Thr and CAG(Glutamin) deletion in first exon.These mutations were novel.KRT14 selected exons beside KRT5 and COL7A1 hot spots could show about 50% of EB types as a screening panel.Key words: EB, KRT14, Sequencing, KRT5, COL7A1,Hot spot.

Mutations in ANO5 in the Norwegian Limb Girdle Muscle Dystrophy population. *M. Van Ghelue[1,2], M. Ingebrigtsen[1], A. Skogstad[1], B. Hestholm[1], C. Wahl[3], S.I. Mellgren[4,5], F. Rasmussen[6], M. Rasmussen[7], B. Karimé[6], C. Jonsrud[1].* 1) Department of Medical Genetics, Division of Child, University Hospital of North Norway, Tromso, Norway; 2) Institute of Clinical Medicine, University of Tromsoe, Norway; 3) National Neuromuscular Centre, University Hospital of North Norway, Tromsoe, Norway; 4) Department of Clinical Medicine, University of Tromsoe, Tromsoe, Norway; 5) Department of Neurology, University Hospital of North Norway, Tromsø, Norway; 6) Department of Neurology, University Hospital, Oslo, Norway; 7) Department of Paediatrics, University Hospital Oslo, Norway.

Recently, recessive mutations in the ANO5 gene have been identified in two distinct phenotypes, non-dysferlin LGMD2B and distal non-dysferlin Miyoshi-like dystrophy families. Although heterogeneity in clinical features associated with ANO5 sequence variants, has been recognized, most patients presented with adult onset slowly progressive myopathy and high CK levels. In the current study, 26 Norwegian patients with high CK levels, presenting with myopathy of unknown etiology and with no mutations in the FKRP gene, were screened for ANO5 mutations. The most commonly found truncating c.191dupA mutation in exon 5 was identified in 4 patients. However, only a single patient was homozygous for this founder mutation. The other 3 patients were compound heterozygous with less common ANO5 variants. Although half of the investigated patients were females, mutations in ANO5 were exclusively found in male patients. In these patients, the clinical phenotype was heterogeneous and the severity of symptoms varied extensively between patients. Both, molecular results and the clinical findings retrospectively analyzed, of the 4 unrelated patients will be presented.

Mutation of the *EYS* gene implicated in autosomal recessive retinitis pigmentosa leads to abnornmal cellular aggregates and cell death. *W. Mustill[1], P. Kruczek[1], A. C. Zelhof[2], S. S. Bhattacharya[1].* 1) Institute of Ophthalmology, University College London, London, United Kingdom; 2) Department of Biology, Indiana University, Bloomington, USA.

Retinitis pigmentosa (RP) is a genetically heterogeneous disease leading to blindness due to photoreceptor degeneration. The condition can be inherited in a dominant, recessive, X-linked, or oligogenic fashion. Recessive and isolated cases account for 50–60 % of all forms of RP. In the early stages, rod photoreceptor function is predominantly impaired, leading to defective dark adaptation, night blindness, and constriction of the visual field, followed by impairment of visual acuity from the loss of cone photoreceptor cells and eventually complete blindness. Recent studies have demonstrated a significant prevalence of arRP patients with mutations in the EYS gene. However, little is known of the mechanism by which EYS mutations lead to RP. In this study we demonstrate that abnormal cellular aggregates are formed in cells transfected with mutant EYS DNA compared to WT DNA, and this leads to increased cell death. The WT construct was generated by cloning cDNA of the EYS gene into a GFP-tagged vector and the mutant constructs were generated from this using site directed mutagenesis. The mutant EYS DNA constructs were generated from previously identified sequence variants from arRP patients from France and Spain, and consisted of mis-sense and non-sense (truncating) mutations. This study is the first to investigate the effect of EYS mutations in vitro and is likely to play an important role in understanding the progression of RP.

Mitochondrial DNA variations in human ova and blastocyst and its clinical implications and IVF outcome. *M. Shamsi[1], G. Periyasamy[2], L. Chawla[3], N. Malhotra[3], N. Singh[3], S. Mittal[3], P. Talwar[4], K. Thangaraj[2], R. Dada[1].* 1) Anatomy, All India Institute Medical Sciences, New Delhi, India; 2) Evolutionary and Medical Genetics Laboratory, Centre for Cellular and Molecular Biology, Hyderabad, India; 3) Department of Obstetrics and Gynaecology, All India Institute of Medical Science, New Delhi, India; 4) ART centre, Army Research and Referral Hospital, New Delhi, India.

Background: Mitochondrial DNA (mtDNA) is maternally inherited and mutations in mtDNA of female germline determine oocyte function and may deteriorate indices of embryo quality and development. Hence, females having pathogenic mtDNA mutations are at high risk for conception difficulties, pre or post implantation loss, fetal anomalies or increased risk of transmission of mtDNA mutations in offspring. Therefore, we investigated the effect of mtDNA variations on the reproductive capacity of oocyte and early embryo (blastocyst) in idiopathic infertile females opting for assisted conception. Methods: Complete mitochondrial genome from single cell 49 oocyte and 18 blastocyst from 67 females was sequenced using long range PCR and analyzed. Findings: Samples (group A) with confirmed disease associated mtDNA mutations- T3396C (Non syndromic hearing loss), T10454C (hearing loss), G11696A (Lebers hereditary optic neuropathy), T12311C (chronic progressive external ophthalmoplegia) and T15908C (hearing loss) had lower fertilization rate and reduced embryo quality as compared to samples which did not have disease associated mtDNA mutations (group B). No difference in the implantation rate and clinical pregnancy rate observed was observed between the groups. Our analysis revealed 437 nucleotide variations most of which were in NADH Dehydrogenase (ND) genes that encode mitochondrial enzyme Complex I. 40.29 % samples had either a disease associated or non-synonymous novel or pathogenic mutation in the evolutionarily conserved region of mitochondrial genome. No association of any haplogroup with mtDNA-associated infertility was found in our study. Interpretations: Dependence of oocyte and embryo on mtDNA differ in various stages of development, therefore pathogenic affects of mtDNA variations manifest differentially during fertilization, implantation and embryonic growth. Screening mtDNA from oocyte or blastocyst offers a better diagnostic approach to understand the etiology of assisted reproduction technique failure or idiopathic infertility. It will help to reduce the risk of transmission of mtDNA diseases to the offspring and also to understand the dynamics of such transmission. MtDNA sequence analysis of oocyte is a simple, efficient and clinically reliable method, which can be used in diagnostic workup of infertile women.

2968T

Cumulus cell microRNA profiles are associated with oocyte aneuploidy. *B. R. McCallie[1], J. C. Parks[1], N. Treff[2], R. T. Scott[2], W. B. Schoolcraft[3], M. G. Katz-Jaffe[1,3].* 1) National Foundation for Fertility Research, Lone Tree, CO; 2) Reproductive Medicine Associates of New Jersey, Morristown, NJ; 3) Colorado Center for Reproductive Medicine, Lone Tree, CO.

Oocyte aneuploidy is a leading cause of miscarriage and age related infertility in human reproduction. MicroRNAs (miRNA) play critical roles in gene regulation and have been shown to be aberrantly expressed in human tumors with chromosome abnormalities. The aim of this study was to investigate a relationship between human oocyte aneuploidy and cumulus cell (CC) miRNA profiles. CCs were donated by couples undergoing infertility treatment with IRB approval and patient consent. Screening for all 23 oocyte chromosomes was performed on biopsied polar bodies using SNP microarray. Groups were classified according to oocyte chromosome constitution: (A) CCs from cumulus oocyte complexes with a euploid oocyte (n=6) and (B) CCs from cumulus oocyte complexes with an aneuploid oocyte (n=6). Expression profiling of 377 miRNAs was performed on individual human CCs using quantitative real-time PCR with the Taqman® Array Human MicroRNA Card (Life Technologies). Predicted target genes were identified with Pathway Studio (Ariadne Genomics) and validated by quantitative real-time PCR. MicroRNA profiling of human CCs identified the expression of 99 miRNAs, 10 (10%) which were differentially expressed in association with oocyte chromosome constitution ($P<0.05$). Six miRNAs showed increased expression with oocyte aneuploidy ($P<0.05$), including miR-29a, whose function when over expressed results in upregulated TP53 levels and the induction of apoptosis. This was confirmed by quantitative real-time PCR with increased TP53 expression observed in CCs of aneuploid oocytes compared to euploid oocytes ($P<0.05$). In addition, four miRNAs displayed decreased expression in association with aneuploid oocytes ($P<0.05$), including miR-16, whose function when decreased results in increased VEGF levels, critical for folliculogenesis. Elevated VEGF concentrations have been correlated with decreased pregnancy rates following infertility treatment. Quantitative real-time PCR validated higher VEGF gene expression in CCs of aneuploid oocytes compared to euploid oocytes ($P<0.05$). This study identified altered miRNA expression of human CCs in association with oocyte aneuploidy. Ongoing analysis may reveal critical roles in gene modulation and pathway regulation that reflect compromised follicular development and oocyte aneuploidy. Evaluation of miRNA expression and their target genes could allow for a non-invasive method for selection of euploid, developmentally competent oocytes.

Prenatal diagnosis of sirenomelia by combining two-dimensional ultrasound, new fetal skeletal rendering, three-dimensional helical computer tomography and magnetic resonance imaging. *X-l. CHEN[1], R. Liu[1], X-H. Yang[1], N. Zhong[2].* 1) Department of Ultrasound, HuBei Maternal and Children Health Care Hospital, Wuhan, Hubei, China; 2) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

To evaluate the value of prenatal diagnosis of skeletal abnormalities in sirenomelia, a prospective study was conducted for the period of September 2010 to February 2012. Fetal skeletal rendering, three-dimensional helical computer tomography (3D-HCT) and magnetic resonance imaging (MRI) were performed after two-dimensional ultrasound (2D-US) in seven cases of sirenomelia. Diagnostic skeletal detailed findings with each of the three techniques were compared with postnatal radiological findings and 3D-HCT. All cases performed postnatal autopsy, five cases performed chorionic villus and/or cord blood sampling. Six cases are singleton and one is conjoined twins. The abnormalities associated with seven siremomelia cases included different degrees of fusion of the lower extremities, bilateral renal agenesis, absent bladder, absent external genitalia and single umbilical cord. Five cases are associated with Oligohydramnios, five cases with partial absent ribs, seven cases with spine anomalies and five cases with cardiac anomalies. Karyotype and postnatal autopsy show that three cases are male and two are female. MRI can help to diagnose sirenomelia, it's less useful to skeletal abnormalities. Although 3D-HCT is a gold standard in diagnosis of skeletal abnormalities, the fetuses can't be X-rayed, so it is restricted. The new fetal skeletal rendering seem to be useful complementary method to 2D-US, and can quickly provide skeletal imaging just as 3D-HCT, and may improve accuracy of the prenatal diagnosis of skeletal abnormalities in sirenomelia.

Comparative Study on Quantitative Parameters of Blood Perfusion and Microvessel Density in Placenta of Rat model of Preeclampsia Evaluated with Contrast-enhanced Ultrasound. *Y-Q. Xu[1], X-L. Chen[1], X-J. Lu[1], X-H. Yang[1], P-W. Chen[1], J-H. Huang[1], C. Huang[1], Z-L. Lu[1], N. Zhong[2].* 1) Department of Ultrasound, Hubei Provincial Maternal and Children's Hospital, Wuhan, Hubei, China; 2) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Objective: To investigate the correlation between quantitative parameters with contrast-enhanced ultrasound (CEUS) and microvessel density (MVD). Methods: Twenty placenta of rat model of Preeclampsia underwent CEUS examination. The peak intensity time curves on the enhanced images were analyzed quantitatively with computer to get Quantitative Parameters (The mean transit time, the maximal peak intensity, the area under curve and the mean perfusion volume) . These parameters were compared with MVD counted with immunohistochemistry and the correlation was statistically studied. Results: The peak intensity time in the enhanced images was (28.55±11.45) s, the mean transit time was (134.77±56.45) s, the maximal peak intensity was (84.83±20.15) dB, the area under curve was (7102.61±245.76) dB,The mean perfusion volume was (58.01±23.56) dB, and the MVD of placenta of rat model of Preeclampsia was (230.98±34.78) in 20 rats. The maximal peak intensity was correlated positively to MVD of histological section ($r= 0.885, P < 0.01$). The area under curve was correlated positively to MVD of histological section ($r= 0.883$, $P < 0.01$). The mean perfusion volume was correlated positively to MVD of histological section ($r= 0.877$, $P < 0.01$). There was no correlation between the peak intensity time and MVD in lesions. There was no correlation between the mean transit time and MVD in lesions. Conclusions: The maximal peak intensity, the area under curve and the mean perfusion volume calculated with CEUS were correlated to MVD of placenta of rat model of Preeclampsia immunohistochemistry. These Parameters were valuable index for quantitative evaluation of placental blood perfusion.

2971T

Prenatal Ultrasound and Autopsy Findings in Simpson-Golabi-Behmel Syndrome. *K. Chong[1], J. Jessen[1], M. Injeyan[1], K. Fong[2], S. Salem[2], S. Keating[3], P. Shannon[3].* 1) Dept . of Obstetrics/Gynecology, The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hosp, Toronto, ON, Canada; 2) Dept. of Medical Imaging, Mount Sinai Hospital, Toronto, ON, Canada; 3) Dept. of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, ON, Canada.

Simpson-Golabi-Behmel (SGB) syndrome is an X-linked recessive genetic disorder characterized by prenatal and postnatal overgrowth, coarse facial features, polydactyly and an increased risk of embryonal tumors. Both a severe neonatal form with multiple anomalies and a less severe form have been described. There have been few reported cases of pregnancies affected with SGB syndrome prenatally and none with extensive pathological examination. We report two prenatal cases of congenital diaphragmatic hernia with multiple fetal anomalies that were diagnosed post delivery with SGB syndrome. Case 1 presented with normal nuchal translucency at 12 weeks gestation, but increased maternal serum AFP at 16 weeks gestation. There was on family history review, a maternal uncle who was “slow” and died in his teens. Case 2 presented with no previous antenatal screening in the pregnancy. This mother had a unilateral cleft lip and palate identified at birth. There was also a family history of male stillbirths. Upon identification of the multiple fetal anomalies including congenital diaphragmatic hernia on fetal ultrasound, both pregnancies were terminated after extensive counselling. Autopsy findings for both male fetuses revealed increased growth parameters, hypertelorism, congenital diaphragmatic hernia and some features not commonly observed in SGB syndrome: small omphalocele, renal anomaly and ovotestes. Follow up molecular analysis of the GPC3 gene confirmed a partial deletion of exon 3 (Case 1) and a splice site mutation in intron 7 (Case 2) confirming the diagnosis of SGB syndrome in both cases. Maternal DNA testing confirmed heterozygous carrier status for both mothers with X inactivation studies pending. These findings highlight the importance of family history, autopsy and molecular analysis in prenatal cases presenting with non isolated congenital diagphragmatic hernia on fetal ultrasound.

2972T

Testing the most frequent genetic diseases optimizes abnormal gene identity and test accuracy worldwide. *R. Lebo.* Dept Pathology, Akron Children's Hosp, Northeast Ohio Medical University, Akron, OH.

The most frequent worldwide genetic diseases have been selected to enable development and testing that identifies the largest proportion of disease alleles at the fewest number of disease sites analyzed. Targeted genomewide testing the most frequent genetic diseases provides the most reliable, conclusive results without testing relatives. Testing all the 145 most frequent genetic diseases each affecting at least 1 in 100,000 people among more than 1100 tested clinically in GeneTests would identify ~1 in 80 patients affected with a Mendelian disease and the 1 in 3 carriers of mutant alleles worldwide. The diseases on this list are further organized according to transmission category to enable selecting tests for any patient category including: patients selecting partners, pregnant couples, products of conception, fetuses, symptomatic patients of any age, and asymptomatic adults planning to optimize future medical interventions and lifestyle. Test platforms may be strengthened by also including the most frequent population-specific gene mutations. This approach will minimize confirmatory testing of known reported mutations as it optimizes test accuracy of the largest proportion of actionable positive and negative reports. The accompanying list can be analyzed by existing or to be developed targeted platforms that test all frequent disease categories and report only the appropriate category of patient results. Professionals who use this approach to develop, approve, order, test and/or report the most frequent diseases will facilitate genetic counseling and follow up patient care worldwide.

2973T

Single nucleotide polymorphism based method for fetal fraction quantification in maternal plasma using massively parallel sequencing (MPS). *G. Hogg[1], J. Tynan[1], M. Tang[1], S. Sovath[1], A. Maer[1], D. van den Boom[2], P. Oeth[1].* 1) Sequenom Center for Molecular Medicine (SCMM), 3595 John Hopkins Ct., San Diego, CA. 92121; 2) Sequenom, Inc. 3595 John Hopkins Ct., San Diego, CA. 92121.

BACKGROUND: The fraction of circulating cell-free (ccf) fetal DNA in maternal plasma can be measured by quantifying paternal Y chromosome markers or fetal specific methylation patterns of ccf fetal DNA. Here, we demonstrate the ability to detect and quantify ccf fetal DNA fraction in maternal plasma by measuring single nucleotide polymorphism (SNP) alleles using amplicon sequencing via MPS.

METHOD: ccf DNA was extracted from 4 mL plasma from 48 pregnant women using Qiagen ccf DNA extraction kit. A single-tube multiplex PCR was designed to amplify loci of 68 SNPs of high minor allele population frequency from the ccf DNA. A 2-step PCR approach was used to incorporate adapter and index sequences into the amplicons and allow direct capture of amplicon on the flow cell surface for sequencing using the HiSeq™ 2000 sequencer (Illumina, San Diego CA). Flow cells were clustered and sequenced according to the standard protocol for 36 cycles. Reads were aligned to the human genome (hg19) and matched read counts for expected SNP alleles were used to calculate the allele ratio of each SNP within each ccf DNA. Allele ratios based on sequencing counts above the homozygous maternal background were used to calculate the presence of paternal alleles from the fetal fraction not present in the maternal genome across multiple loci per sample.

RESULTS: 48 plasma samples were assayed. All 68 amplicons were detected in each sample. The average paternal allele frequency was used to calculate fetal fraction and ranged from 2 to 14%. These results correlated with a methylation based method of fetal fraction quantification of the same samples. The 68 amplicons were also used to sequence and accurately quantify fractions of a genomic DNA model system. Quantification was accurate using as little as 100,000 reads per sample.

CONCLUSION: This method allows accurate fetal fraction determination in maternal plasma by MPS and allows fetal fraction to be determined concurrently when multiplexed with other types of libraries. The low number of reads required to accurately quantify fetal fraction suggests high levels of sample multiplexing are possible.

The Pregnancy and Health Profile Pilot Project: Evaluating the impact of integrating a novel family history and genetic screening tool on patients, providers, and clinical practice. *E. Edelman[1], B. Lin[2], T. Doksum[3], B. Drohan[4], K. Hughes[4], S. Dolan[2], V. Edelson[5], J. O'Leary[5], L. Vasquez[6], S. Copeland[6], J. Scott[1].* 1) NCHPEG, Lutherville, MD; 2) March of Dimes, White Plains, NY; 3) Doksum Consulting, Boston, MA; 4) Partners Healthcare, Boston, MA; 5) Genetic Alliance, Washington, DC; 6) HRSA, Rockville, MD.

Effective patient-entered and EHR-compatible collection tools are needed to support translation of family health history (FH) into prenatal care. However, there are limited data about the impact of computerized tools on patient and provider acceptance and outcomes. “The Pregnancy and Health Profile,” (PHP) is a free prenatal genetic screening and risk assessment software for primary prenatal providers that collects FH during intake and provides point-of-care CDS for providers and education for patients. Our objective was to evaluate patient and provider outcomes of PHP in clinical practice. The study population included diverse prenatal providers and patients at 4 sites in IN, ME, NC, and NY. Evaluation included provider pre and post knowledge and usability surveys, pre and post chart audits to assess FH risk assessment, and patient satisfaction surveys. Quantitative survey results were entered into a SPSS database and analyzed using descriptive statistics, Fisher's exact test, and paired t-tests. Qualitative thematic analysis was used for responses to open-ended questions. 513/618 (83%) patients of diverse age and education levels provided feedback; 81% were white, 11% black, and 9% Latina. Patients felt PHP was easy to use (96%) and understand (98%). Ninety-six percent were not worried about the confidentiality of entering FH into PHP. Twenty of 65 providers (10 OBs and 6 family medicine physicians, 2 nurse midwives, 1 nurse, and 1 dietician educator) provided feedback. Providers felt the data collection and patient education aspects of PHP were useful (60%; 67%); there was mixed feedback on the usefulness of the CDS report. Provider confidence in identifying and managing genetic risks improved after using PHP in practice ($p<0.05$). In 2 of 3 sites with performance measure data, PHP improved documentation of a 3-generation FH ($p<0.001$). PHP improved documentation of race and ancestry for patient and/or father of the baby in all 3 sites ($p<0.001$). This study is one of the first to report on the integration of FH into primary prenatal practice. These data demonstrate that PHP is acceptable to patients and providers for providing FH and that PHP collects FH equal to or better than standard practice. Our results can inform future strategies that use point-of-care tools or online portals to improve patient participation around FH and provider management of genetic risks. Additional research is needed to validate patient-entered data in the prenatal setting.

Chromosomal Structural Abnormalities among Filipino Couples with Recurrent Pregnancy Losses. *E.C. Cutiongco-de la Paz[1,2], A.D. Berboso[1], E.G. Salonga[1], C.M. David-Padilla[1,2].* 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila, Manila, Metro Manila, Philippines; 2) Department of Pediatrics, College of Medicine, Philippine General Hospital, University of the Philippines Manila.

Introduction: Recurrent pregnancy loss (RPL) is a devastating reproductive problem that affects 5% of couples trying to conceive. RPL is classically defined as the occurrence of three or more consecutive pregnancy losses. However, several clinicians start evaluation with two or more because of the recent increase in childless miscarriages. Majority of the cases are due to cytogenetic errors. Objective : This study determines the prevalence of chromosomal structural abnormalities in Filipino couples who presented with 2 or more pregnancy losses. Methods: Results from chromosomal analysis of couples referred for 2 or more miscarriages done at the Institute of Human Genetics-National Institutes of Health-University of the Philippines, Manila on peripheral blood samples from 1991 to 2010 were retrospectively reviewed. Results and Discussion: There were 356 couples with a history of 2 or more miscarriages sent for chromosomal analysis from 1991–2010 included in this study. Among these 356 couples, 17 couples (4.8%) were found to be carriers of different chromosomal abnormalities, 1 of whom had both of them affected with chromosomal abnormalities. From a total of 18 cases, there were 13 (3.6%) translocations, 1 (0.3%) insertion, 2 (0.6%) with marker chromosomes, 1 (0.3%) pericentric inversion and 1 (0.3%) deletion. The results of this study are similar to that of previous large-scale studies which have demonstrated that parental chromosomal abnormalities are associated with RPL. Conclusion: The overall frequency of chromosomal structural abnormalities among patients with RPL in this study is 4.8% with translocations being the most common type detected. It highlights the recommendation that chromosomal analysis be an integral part of the evaluation of couples with two or more pregnancy losses because detection of chromosomal abnormalities is vital in genetic counseling and in the management of subsequent pregnancies.

2976T

Factor II G20210A and factor V G1691A mutations and methylenetetrahydrofolate reductase C677T polymorphism in 155 women with repeated pregnancy loss. *S. Seyedhassani[1,2], M. Houshmand[1], M. Neshan[2], F. Saeb[2].* 1) Medical Genetics, National Institute oF Genetic Engineering and Biot, Tehran, Tehran, Iran; 2) Dr. Seyedhassani Genetic Center, Yazd, Iran.

Introduction: pregnancy is the process from the fertilized ovum to the fetus with capability of extra uterine survival. Pregnancy loss is the most common complication of pregnancies. About 1 in 300 couples and 0.5–2% of women are involved in repeated pregnancy loss (RPL). Various etiological factors involve in RPL and the main part of them remains unknown. Among them the thrombophilic factors are important. Material and methods: Genetic counseling program was done for 158 couples suffering from RPL. Three molecular genetic variations were investigated in main thrombophilic agents: G20210A in factor II, G1691A in factor V and C677T in MTHFR gene. The method was PCR-RFLP. Results: No G20210A mutation was found in Factor II gene. Heterozygote G1691 mutation in factor V gene was found in 3 women (1.94%). But, C677T polymorphism in MTHFR gene was found in 33 women (21.3%). Among them, 4 cases (12.12%) were homozygote and 29 cases (87.88%) were heterozygote. Discussion: Assessment of variations in thrombophilic related genes can be useful in etiologic evaluation and planning of effective treatment in RPL women. Genetic counseling, clinical aspect of abortions and genotype-phenotype correlation should be considered for request of molecular thrombophilic tests in RPL.

Functional consequences of miscarriage Copy Number Variations (CNVs). *J. Wen[1], CW. Hanna[2], S. Martell[1], PCK. Leung[3], WP. Robinson[2], M. Stephenson[4], E. Rajcan-Separovic[1].*1) Pathology and laboratory medicine, University of British Columbia/Child & Family Res Inst, Vancouver, BC, Canada; 2) Medical genetics, University of British Columbia/Child & Family Res Inst, Vancouver, BC, Canada; 3) Obstetrics and gynecology, University of British Columbia/Child & Family Res Inst, Vancouver, BC, Canada; 4) Obstetrics and gynecology, University of Chicago, Chicago, IL, USA.

Our recent whole genome CGH array-based studies of sporadic and recurrent chromosomally normal miscarriages (N=43) identified unique CNVs in ~40% of miscarriages. The majority of the CNVs were small (<250kb) in size and inherited from either parent. We performed functional analysis of the TIMP2 gene, containing a unique maternal duplication (47kb), that was detected in 4/5 tested miscarriages from a couple with recurrent pregnancy loss (RPL). TIMP2 is of interest as it highly expressed in the placenta, pregnant endometrium and maternal-fetal interface, and plays a role in placental development and extracellular matrix (ECM) remodelling. The expression of TIMP2 was assessed using mRNA and protein extracted from primary cultures of placental tissue from miscarriage placentae (N=4) in comparison to cell cultures from elective abortions (N=4).As the TIMP2 gene has been proposed to be maternally expressed in the placenta, methylation of the promoter CpG island shore and an upstream enhancer was assessed using bisulfite pyrosequencing. Decreased mRNA and protein expression of TIMP2 was detected in miscarriages that carried the CNV. The TIMP2 promoter CpG island shore was 32% methylated in both blood and placenta, and showed no difference between CNV carriers and controls. The upstream enhancer was 96% methylated in blood and 56% methylated in placenta, suggesting a potential role as a tissue-specific enhancer. Similarly, no difference in DNA methylation at the TIMP2 enhancer was observed between CNV carriers and controls. However, there was a trend towards a negative correlation of enhancer methylation with mRNA and protein expression of TIMP2 ($r=-0.47$;$p=0.24$ and $r=-0.44$; $p=0.27$,respectively). Our analysis shows that miscarriage CNVs could result in abnormal RNA and protein expression for their integral genes. In the case of TIMP2 no dramatic methylation abnormalities were detected for the sites nearby the CNV examined in carriers. Aberrant expression of TIMP2 in the female carrier may impair ECM remodelling during decidualization, and/or in the embryo, it may affect placental development, trophoblast invasion or vascularisation. Both events could lead to miscarriage and possibly explain its recurrence. Microarray analysis and functional follow-up of CNVs could therefore enrich our knowledge of the genetic causes of miscarriage and potentially identify couples predisposed to RPL.As a consequence, CNVs are emerging as potential biomarkers for RPL.

The Fetal Fraction of cell-free DNA in Maternal Plasma is Not Affected by a priori Risk of Fetal Trisomy. *T. Musci[1], H. Brar[2], E. Wang[1], B. Brar[2], A.Y. Batey[1], A. Oliphant[1], M.E. Norton[3].* 1) Ariosa Diagnostics, San Jose, CA; 2) Riverside Perinatal Diagnostic Center, Riverside, CA; 3) Stanford University/Lucille Packard Children's Hospital, Stanford, CA.

Background: Non-invasive prenatal tests analyze cell-free DNA (cfDNA) for the detection of fetal trisomy. The amount of fetal DNA in a sample is a major determinant of the ability to detect trisomy. Objective: To examine possible clinical factors that might influence the fetal fraction of cfDNA in maternal plasma. **Methods**: A comparative analysis was performed on subjects from the multicenter Non-Invasive Chromosomal Evaluation (NICE) Study. Pregnant women 18 yrs and older, at 10 or more weeks gestational age with a singleton pregnancy who underwent invasive testing for any indication, were enrolled. Subjects with confirmed euploid pregnancies were stratified into a priori risk groups for having a fetus with trisomy. “Low-risk” (LR) subjects were less than 35 yrs of age and had low risk results based on serum screening. “High-risk” subjects were stratified by the most advanced maternal age (HR-MA), NT measurements >2.5mm (HR-NT), or those with the highest serum screening risk scores for fetal trisomy 21 or 18 (HR-SS). Fetal fraction was measured using the Ariosa Harmony™ test via targeted sequencing using 192 assays for polymorphic loci on chromosomes 1–12. Fetal percent comparisons were analyzed using analysis of variance (ANOVA) controlling for gestational age. **Results**: The median fetal fraction of cfDNA in each group was LR: 9.7% (n=208), HR-MA: 9.5% (n=208), HR-NT: 9.3% (n=152), and HR-SS: 10.6% (n=208). No significant differences for fetal fraction were observed when comparing women in the LR group to women in the HR-MA group (p=0.56) the HR-NT group (p =0.38) or the HR-SS group (p=0.29). **Conclusions**: Maternal age, serum screening and NT measurements show no significant effect on the fetal fraction of cfDNA in maternal plasma. These data suggest that the non-invasive Harmony™ test for aneuploidy detection is appropriate for a wide range of risk categories in the prenatal patient population.

Role of E2F1 in Testicular Descent and Fertility. *C. Jorgez[1,2], J. Addai[1], J. Newberg[3], V. Vangapandu[1], A. Sahin[1], J. Rosenfeld[4], L. Lipshultz[1,2], D. Lamb[1,2,3].* 1) Department of Urology, Baylor College of Medicine, Houston, TX; 2) Center for Reproductive Medicine, Baylor College of Medicine, Houston, TX; 3) Department of Molecular and Cell Biology, Baylor College of Medicine, Houston, TX; 4) Signature Genomic Laboratories, PerkinElmer, Inc., Spokane, WA.

E2F1 is a potent transcription factor required for DNA synthesis and cell proliferation. Mice lacking e2f1 are viable and fertile, yet display testicular atrophy with age, exocrine gland dysplasia and a spectrum of tumors. On the other hand, mice overexpressing e2f1 are infertile with testicular atrophy as a result of p53-independent apoptosis occurring within individual tubules resulting in germ cell, but not Sertoli cell depletion. After aCGH analysis of a series of men with non-obstructive azoospermia (NOA), we found a microduplication at 20q11.22 encompassing E2F1 in one NOA man. For confirmation E2F1-CNV-Taqman assays were performed that not only validated the aCGH finding, but also identified 10 of 86 (11.6%; p=0.002) NOA men with microduplications or microdeletions in E2F1. Sequence analysis of E2F1 revealed a SNP at position Ala102Thr in one infertile man that upregulates E2F1 expression in the human testis. Since humans lacking or having an extra copy of E2F1 are infertile, we reevaluated the phenotype of e2f1 deficient mice. The mice are subfertile with a decrease in the number of litters per month, although the number of pups per litter was not affected. By three weeks of age there is a significant decrease in testis weight. The declines in testicular weight, sperm count and motility continue throughout their lifespan. The mice have abnormal testicular histology with mislocalized cell associations, as well as a significant increase in circulating FSH levels. By five months of age fertility is significantly reduced. However, the most surprising finding is that these mice have unilateral (80%) and bilateral (10%) inguinal cryptorchidism. A search of the Signature Genomic Laboratories database of 26,706 individuals tested revealed an infant with an undescended right testis with a microduplication in 20q that includes E2F1. The DECIPHER database also contains a cryptorchid individual with a microdeletion encompassing E2F1 (of 5404 subjects deposited in this database). Additional analysis using E2F1-CNV-Taqman assays identified 2 of 60 (3.3%) cryptorchid individuals with microdeletions in E2F1. Our data suggest a role of E2F1, not only in spermatogenesis, but also in testicular descent. E2F1 plays an important role in male reproductive development and function.

Study of four SNPs in SLC6A14, INSR, TAS2R38 and OR2W3 genes for association with Iranian idiopathic infertile men. *E. Siasi[1], A. Aleyasin[2].* 1) microbiology, north tehran branch of azad university, Trhran, Iran; 2) molecular and clinical genetic, National institut of genetic engineering and biotechnology, Tehran, Iran.

Back ground- Genome wide SNP association study (GWAS) has reported several SNPs that had potential relevance to oligospermia and azoospermia in idiopathic infertile men in European population. Four of these releavant SNPs are in INSR (T132903C), SLC6A14 (C109869T), OR2W3 (T824C) and TAS2R38 (T886C) genes have reported to cause oligospermia and azoospermia in European populations. Objective- This is the first association study to evaluated their relationships with oligospermia and azoospermia in idiopathic infertile men in Iranian population. Methods- Their polymorphismshave been comparad in 96 male cases with idiopathic infertility and 100 normal control fertile men. SNPs analysis were performed using Real Time High Resolution Melt analysis (PCR-HRM) and confirmed by PCR-RFLP and sequencing analysis. Results- The frequency of two SNPs, T132903C in INSR gene and C109869T in SLC6A14 gene were statistically significant between infertile patients and fertile control groups. Their statistical analysis showed significant associations with idiopathic male infertility with P=0.02 and P= 0.04 respectively. The SNPs frequency for T824C in OR2W3 gene and T886C in TAS2R38 gene were approximately similar among case and control groups with P=0.2 and P=0.9 respectively. Conclusion- These results indicated that T132903C SNP in INSR gene and C109869T SNP in SLC6A14 gene play role in spermatogenesis defect in idiopathic infertility in Iranian case with oligospermia and azoospermia similar to that observed is Europian population.

2981T

NLRP7 subcellular localization in human oocytes and early cleavage stages. *E. Akoury[1,2], L. Zhang[2], M. Seoud[3], A. Ao[2], R. Slim[1,2].* 1) Department of Human Genetics, McGill University Health Centre, Montreal, Quebec, Canada; 2) Department of Obstetrics and Gynecology, McGill University Health Centre, Montreal, Quebec, Canada; 3) Department of Obstetrics and Gynecology, American University of Beirut, Beirut, Lebanon.

Hydatidiform mole is an abnormal human pregnancy with no embryo and cystic degeneration of placental villi. Maternal mutations in NLRP7, a gene that is expressed in oocytes, early cleavage embryos, and endometrial tissues, are responsible for recurrent moles and reproductive wastage. In addition, post-zygotic aneuploidies during early embryo development have been demonstrated in patients with NLRP7 mutations. However, to date the subcellular localization of NLRP7 in human oocytes and early developmental stages have not been reported. Using immunofluorescence experiments and confocal microcopy, we performed an extensive analysis to determine the subcellular localization of NLRP7 in leftover human oocytes and early cleave stage from patients undergoing pre-implantation genetic diagnosis. Our findings demonstrate that NLRP7 is indeed a maternal-effect gene and are in agreement with previous data about two other maternal genes characterized in mice, MATER (NLRP5) and Filia. In addition, our data shed new lights on the role of NLRP7 in postzygotic aneuploidies, implicate NLRP7 in early tissue differentiation, and will be presented at the meeting.

Human spermatogenic failure purges deleterious mutation load from the autosomes and both sex chromosomes, including the gene DMRT1. *D.F. Conrad[1], A. Lopes[2], K.I. Aston[3], F. Carvalho[4], J. Goncalves[5], R. Mathiesen[2], N. Huang[6], A. Ramu[1], J. Downie[7], S. Fernandes[8], A. Amorim[2,8], A. Barros[9], M. Hurles[6], S. Moskovtsev[10], C. Ober[11], J. Schiffman[7], P.N. Schlegel[12], M. De Sousa[13], D.T. Carrell[3, 14].* 1) Dept Genetics, Washington Univ School Med, St Louis, MO; 2) IPATIMUP, Institute of Molecular Pathology and Immunology of the University of Porto, R. Dr. Roberto Frias S/N, 4200-465 Porto, Portugal; 3) Andrology and IVF Laboratories, Department of Surgery; 4) Department of Genetics, Faculty of Medicine, University of Porto, Porto, Portugal; 5) Centre for Human Genetics, National Institute of Health Dr. Ricardo Jorge, Lisbon, Portugal; 6) Genome Mutation and Genetic Disease Group, Wellcome Trust Sanger Institute, Cambridge, UK; 7) Department of Oncological Sciences; 8) Faculty of Science, University of Porto, 4099-002 Porto, Portugal; 9) Centre for Reproductive Genetics Alberto Barros, Porto, Portugal; 10) Department of Obstetrics & Gynaecology, University of Toronto; 11) Department of Human Genetics, Department of Obstetrics & Gynecology, The University of Chicago, Chicago, IL 60637, USA; 12) Department of Urology, Weill Cornell Medical College, New York-Presbyterian Hospital, New York, USA; 13) Laboratory of Cell Biology, UMIB, ICBAS, University of Porto, Porto, Portugal; 14) Department of Physiology, Department of Obstetrics and Gynecology University of Utah School of Medicine, Salt Lake City, Utah, 84108, USA.

Gonadal failure, along with early pregnancy loss and perinatal death, may be an important filter that limits the propagation of harmful mutations in the human population. We hypothesized men with spermatogenic impairment, a condition with unknown genetic architecture and a common cause of male infertility, are enriched for rare deleterious mutations compared to men with normal spermatogenesis. We assayed genomewide SNPs and CNVs in 327 men with spermatogenic impairment and >1100 controls, and estimated that a rare autosomal deletion multiplicatively changes a man's risk for this condition by 10% (OR 1.10 [1.05–1.15], $p < 4 \times 10^{-5}$), a rare X-linked CNV by 29%, (OR 1.29 [1.16–1.43], $p< 3 \times 10^{-6}$) and a rare Y-linked duplication by 64% (OR 1.64 [1.28–2.10], $p < 9 \times 10^{-5}$). Based on the population frequency of potential risk alleles, extent of homozygosity, and evidence for dosage sensitivity of genes disrupted in men with spermatogenic impairment, we propose that the CNV burden is polygenic and distinct from the burden of large, dominant mutations described for developmental disorders. Our study also identifies focal deletions of the sex-differentiation gene *DMRT1* as likely recurrent causes of idiopathic azoospermia, and generates hypotheses for directing future studies on the genetic basis of male infertility and IVF outcomes.

2983T

A homozygous deletion of DPY19L2 gene is a cause of globozoospermia in men from the Republic of Macedonia. *D. Plaseska-Karanfilska[1], P. Noveski[1], S. Madjunkova[1], I. Maleva[1], V. Sotiroska[2], Z. Petanovski[2].* 1) Macedonian Academy of Sciences and Arts, Research Centre for Genetic Engineering and Biotechnology " Georgi D. Efremov", Skopje, Republic of Macedonia; 2) Private Hospital "Re-Medika", Skopje, Republic of Macedonia.

Globozoospermia is a rare but severe teratozoospermia, characterized by ejaculates consisting completely of round-headed spermatozoa that lack an acrosome or, in partial globozoospermia, containing a variable proportion (20%–90%) of acrosomeless spermatozoa. Men that are affected with total globozoospermia are infertile, and even the application of intracytoplasmic sperm injection (ICSI) has met with disappointingly low success rates. Several case reports of affected brothers suggested a genetic component to this disease. Homozygous mutations in *SPATA16* (spermatogenesis-associated 16) and *PICK1* (protein interacting with C kinase 1) genes were described as responsible for a complete form of globozoospermia in an Ashkenazi Jewish and a Chinese family, respectively. However, no mutations in these genes were detected in other men with globozoospermia, thus suggesting that*SPATA16* and *PICK1* genes are not the main loci associated with this condition. Recently, a homozygous 200 kb deletion on chromosome 12 encompassing only *DPY19L2* gene was identified in several patients from different origins, thus suggesting that deletions involving this gene might represent a major cause of globozoospermia. It was shown that the breakpoints of the deletions are located on a highly homologous 28 kb low copy repeat (LCR) sequence present on each side of *DPY19L2*, indicating that the identified deletions were probably produced by nonallelic homologous recombination (NAHR) between these two regions. Here we describe the presence of a homozygous deletion of the *DPY19L2* gene in two men with complete form of globozoospermia from the Republic of Macedonia. The deletion was detected by array CGH analysis, using 180K Agilent Human Genome CGH Microarrays and Genomic Workbench software. The results were confirmed with classical PCR using seven loci, of which three were intragenic, located in exons 1, 11, and 22 of the *DPY19L2* gene, while four were located in the LCR regions. PCR fragments were obtained only from the first centromeric and last telomeric locus in the LCR regions. Both patients are of Macedonian ethnic origin, live in the same town (Tetovo), but are not related. No consanguinity was reported in any of the two families. Four ICSI cycles were attempted in the two patients, but no pregnancy was achieved. In conclusion, our results support the notion that a homozygous deletion of *DPY19L2* gene represents a major cause of globozoospermia.

2984T

Decreased Puberty and Fertility Development in NELF KO Mice due to impaired GnRH neuron Migration. *S. Quaynor, L. Chorich, R. Cameron, L. Layman.* Institute of Molecular Medicine and Genetics, Georgia Health Sciences University, Augusta, GA.

Normal puberty and reproduction require the proper development and function of the hypothalamic-pituitary-gonadal axis controlled by gonadotropin-releasing hormone (GnRH) neurons. GnRH neurons develop in the olfactory placode region and migrate into the brain, where they project their processes to the median eminence. Lack of migration of these neurons results in diseases such as Idiopathic Hypogonadotropic Hypogonadism (IHH) and Kallmann syndrome (KS). Patients with IHH/KS present with absent puberty, low gonadotropins and sex steroids in addition to anosmia in KS. Nasal embryonic luteinizing hormone releasing factor (NELF) is an important protein that has been identified to contribute to GnRH neuron migration, and mutations of the gene have been demonstrated in IHH/KS patients. We previously confirmed *Nelf*'s role in GnRH neuron migration using immortalized mice GnRH cell lines; and to date all the studies regarding *Nelf* have been done using immortalized neuronal cells and zebrafish models. To extend these studies into mammals, we generated homozygous Nelf knockout (KO) mice to further understand the phenotypic effect with regard to GnRH neuron function in the whole animal. We hypothesized that *Nelf -/-* mice will have impaired pubertal development and compromised fertility. To assess puberty of *Nelf* KO animals, we measured hormone panels (LH, FSH, testosterone, and estradiol) and determined vaginal opening and estrus onset. To determine the effect of *Nelf* KO upon fertility, we measured estrus cycles, and determined the number of days between litters and the litter sizes of both homozygous males and homozygous females when they were mated with wild type animals. Finally, we confirmed the defects in GnRH neuron migration and cell number through the performance of immunohistochemistry on serial brain slices using GnRH antibody. Our preliminary results indicate that female *Nelf -/-* mice have delayed vaginal opening by five days compared with wild type mice. In addition, both male and female *Nelf -/-* mice have impaired fertility as manifested by a decreased litter size and increased time between litters. Preliminary evidence suggests that GnRH neuronal migration distance is decreased in *Nelf* KO mice compared to wild type. These data support our clinical findings of human NELF mutations and show that NELF plays an important role in both normal pubertal development and fertility.

Deficiency of PRSS37, a putative Trypsin-like serine protease, causes male infertility from mouse to human. *Z.G. Wang[1,3,5], C.L. Shen[2], J.B. Liu[3], J.S. Feng[4], Y. Kuang[5], H.X. Zhang[1], W.T. Wu[5], J. Chi[5], L.Y. Tang[3], J. Fei[5].* 1) State Key Laboratory of Medical Genomics, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine (SJTUSM), Shanghai, Shanghai, China; 2) Institute of Health Sciences, Shanghai Institutes for Biological Sciences of Chinese Academy of Sciences and SJTUSM, Shanghai, China; 3) Department of Medical Genetics, SJTUSM, Shanghai, China; 4) Department of Histology and Embryology, SJTUSM, Shanghai, China; 5) Shanghai Research Centre for Model Organisms, Shanghai, China.

PRSS37 is a putative Trypsin-like serine protease. Human serine proteases are involved in numerous physiological processes and pathological states. However, the physiological function of PRSS37 and its potential association with human reproductive capacity remain unknown to date. In the present work, we describe the crucial role of PRSS37 in male fertility. We show that Prss37 is exclusively expressed in adult testis, especially in developing elongating spermatids during spermiogenesis, and almost vanished in mature sperm. Mice deficient for Prss37 display significantly decreased male fertility, but their mating activity, testicular weights and histology, sperm counts, morphology and motility in vitro remain unaffected. In vivo fertilization assay reveals that Prss37-/- mice exhibit a markedly decreased fertilization rate (2.3% vs. 70% of that in control mice), accompanied by the defect in sperm transit from uterus to oviduct. In vitro study further shows incapability of sperm in sperm-egg recognition/binding when exposure of zona-intact eggs to Prss37-/- sperm, in which mature Adam3 was completely undetectable. These data indicate that Prss37-deficiency causes male infertility due to the defects of sperm migration from uterus to oviduct and sperm-egg binding via regulating Adam3 maturation. The infertile phenotypes in Prss37-/- mice perfectly reproduce the situation described as “unexplained male factor infertility (MFI)” in human. Thus, we further investigate the potential implication of PRSS37 in human male infertility. We show that human PRSS37 protein exists in the acrosome region of ejaculated human sperm, which is different from the mouse. Importantly, PRSS37 protein levels in 98 sperm samples from the patients with MFI (all normal semen parameters) are significantly decreased on average when compared to that in 30 healthy sperm samples (PRSS37/GAPDH ratio, 3.8 vs. 0.9, p<0.0001). Most strikingly, PRSS37 in 7 out of 98 patients (7%) is undetectable (ratio<0.01). In combination of the data acquired from the mouse and human studies, we summary our work as follows: Prss37 is a highly specifically expressed protein in late spermatids during spermiogenesis in mice. It is crucial for sperm migration from uterus to oviduct and sperm-egg binding through regulation of Adam3 maturation. Absence or decreased expression level of PRSS37 in human sperm could be one of the causes for “unexplained MFI”.

2986T

Changes in placental DNA methylation may be associated with karyotypically normal miscarriage. *CW. Hanna[1], DE. McFadden[2], WP. Robinson[1].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Pathology, University of British Columbia, Vancouver, BC, Canada.

Miscarriage, the spontaneous abortion of pregnancy before 20 weeks gestation, is the most common complication of pregnancy with a frequency of 15–20%. Chromosomal errors are observed in over 50% of miscarriages; however causes of karyotypically normal losses are less understood. Appropriate patterns of DNA methylation in the fetus and placenta are essential to maintain a healthy pregnancy. As altered DNA methylation may be a cause of pregnancy loss, we hypothesize that placental villi of karyotypically normal miscarriages will exhibit aberrant DNA methylation at imprinted loci and globally throughout the genome. DNA was extracted from 70 chromosomally normal first trimester placental villi samples: 33 miscarriages from women experiencing recurrent miscarriage (RM), 21 miscarriages from women with no history of miscarriage (M), and 16 control elective terminations (TA). DNA methylation at the imprinted loci*PLAGL1*, *H19/IGF2* ICR1, *SGCE*, *SNRPN*, *CDKN1C*, KvDMR1, *MEG3*, *AXL*, and *APC*, as well as at LINE-1 sequences, was assessed using bisulfite pyrosequencing. Ten of 33 (30.3%) RM placentae showed a loss/gain of methylation (defined as values greater than 1.5x the inter-quartile range) at any of the 9 imprinted loci, as did 1 of 21 (4.8%) M and 3 of 16 (18.8%) TA placentae (p=0.07). After correction for multiple comparisons, there was a significant difference in average methylation at *H19/IGF2* ICR1 (p<0.0001). Genome-wide DNA methylation was assessed in a subset of 20 samples (10 RM, 10 TA) using the Illumina Infinium HumanMethylation27 BeadChip array, which interrogates 27,578 CpG sites. Significance Analysis of Microarrays was utilized to identify candidate genes, using a <5% False Discovery Rate and >5% absolute difference between groups. Three of 14 candidate CpG sites, of functional importance, were followed up with pyrosequencing, including sites near the *CYP1A2* (cg04988473), *APC* (cg20311501) and *AXL* (cg14892768) genes. There was significantly increased methylation in RM (58.6%) and M (64.4%) compared to TA (50.8%) at *CYP1A2* promoter (p=0.002). We found no difference in DNA methylation at LINE-1 sequences or average array methylation between groups. This study suggests that altered DNA methylation at specific loci (*H19/IGF2* ICR1, *CYP1A2*) and not global dysregulation in the placenta, may contribute to karyotypically normal pregnancy loss in women, or be a consequence of placental insufficiency leading to miscarriage.

2987T

Co-culture of mouse embryonic stem cells with Sertoli cells promote in vitro generation of germ cells. *M. Miryounesi[1], K. Nayernia[2], M. Dianatpour[1], S. Savad[1], M. H. Modarressi[1].* 1) Department of Medical Genetics, School of Medicine, Tehran university of Medical Sciences, Tehran, Iran; 2) GENEOCELL, Advanced Molecular & Cellular Technologies, Montreal, Canada.

About 10 to 15 percent of couples worldwide have fertility problems, and half of them are infertile men. It seems that germ cells divide indefinitely to maintain sperm production in male. Sertoli cells support in vivo germ cell production; however the mechanism for this support has not been well understood. We designed the present study to analyze the effect of sertoli cells in differentiation of mouse embryonic stem cells (mESCs) to germ cells. Methods: To select differentiated mouse embryonic stem cells (mESCc) we used a fusion construct composed of the 1.4 kb promoter region of germ line specific gene Stra8 and Coding region of enhanced green fluorescence protein. Linearized vector (35 µg) was electroporated into ES cells. resistant colonies were selected and cultured 72 hours in the presence of Retinoic Acid (RA). GFP positive cells were selected by using fluorescence-activated cell sorting (FACS) and cultured for one month in non induced condition. To analyze sertoli cells effect in differentiation process, mESCs were separated in two groups: the first group was cultured on gelatin with retinoic acid treatment and the second group was co-cultured with sertoli cell feeder without retinoic acid induction. Expressions of pre-meiotic (Stra8), meiotic (Dazl and Sycp3) and post-meiotic (Prm1) genes were evaluated at different differentiation stages (+7, +12 and +18 days of culture). Results: In the first group, the expression of meiotic and post meiotic genes starts at 12 and 18 days after induction with RA respectively. In the second group, 7 days after co-culturing with Sertoli cells, expression of meiotic and post-meiotic genes were observed Discussion: In this study the effect of co-culturing of ESC and Sertoli cell line (TM4) in the process of differentiation of ESC was investigated. These results clearly show that differentiation process to germ cells is supported by Sertoli cells, which provide a novel effective approach for generation of germ cell in vitro and studying interaction of germ cells with their niche.

Androgen receptor CAG repeat length may influence the risk of polycystic ovarian syndrome (PCOS). *J. C. Silas[1,2], Singh. Rajender[3], S. Nirmala Sadasivam[4], M.N. Sadasivam[4], Singh. Lalji[5], K. Thangaraj[1].* 1) Centre for Cellular and Molecular Biology, Hyderabad, India; 2) Centre for Genetics and Inherited Diseases (CGID), Taibah University, Al- Madinah, Kingdom of Saudi Arabia; 3) Division of Endocrinology, Central Drug Research Institute, Lucknow, India; 4) Maaruthi Medical Centre and Hospitals, Erode, Tamil Nadu, India; 5) Banaras Hindu University, Varanasi, India.

Polycystic ovarian syndrome (PCOS) refers to an inheritable endocrine disorder in which the multiple fluid-filled sacs or cysts grow under the surface of one or both of the ovaries of women. Now PCOS is considered as an androgen excess disorder or hyperandrogenism. Since the effect of androgen is through the androgen receptor (AR), CAG triplet repeat length in the coding region of the AR gene could influence the risk of PCOS. It has been established in vitro that AR activity is inversely proportional to the length of the CAG repeats. We hypothesized that length of the CAG repeat could affect the androgenic response and hence the risk of PCOS. Methods used: In total, 169 patients following strictly defined inclusion criteria for PCOS were recruited. A total of 175 control samples were collected from ethnically similar normal women who volunteered for participation in the study. CAG repeat region of the AR gene was screened by PCR amplification followed by gene-scan and direct DNA sequencing methods. Distribution of the allele data and the mean allelic length was compared between cases and controls and between obese and non-obese cases. Along with the present study from India, we also conducted a meta-analysis on data from 11 studies including a total of 1777 cases and 1918 controls. Results: We found that the CAG repeat length was between 7 and 29 for both cases and controls. Mean and median CAG values were almost same for cases (17.4±3.3 and 18 repeats, respectively) and controls (17.4±3.31 and 18 repeats, respectively). CAG allele distribution pattern also looked similar between these two groups. Upon categorizing the cases into obese and non-obese groups, the allele distribution and mean repeat length looked indifferent. We observed a strong correlation between the DHEAS level and the presence of hirsutism; however, CAG repeat length was not associated with hyper-androgenism. Overall, meta-analysis showed no association between CAG length and PCOS; however, upon removal of two sensitive studies, data was almost homogenous (Q-value=8.727, df (Q) = 8.000, P-value=0.366, I-squared=8.330) and a strong association between CAG length and PCOS was seen. Overall, increased CAG length appeared to increase the risk of PCOS (fixed and random effect model p values, 0.001 and 0.002, respectively). Conclusion: CAG length does not associate with PCOS risk in the studied Indian population; however, overall, increased CAG length appears to increase the risk of PCOS.

2989T

An analysis of the initial experience offering cell-free fetal DNA testing to pregnant women. *J. Taylor[1], A. Ables[2], L. Hudgins[3].* 1) Perinatal Genetics, Lucile Packard Children's Hospital, Stanford, CA; 2) Master's Program in Human Genetics and Genetic Counseling, Stanford University School of Medicine, Stanford, CA; 3) Department of Pediatrics, Division of Medical Genetics, Stanford University School of Medicine, Stanford, CA.

Noninvasive prenatal testing (NIPT) for aneuploidy via maternal serum cell-free fetal DNA (cffDNA) recently became clinically available. In our Perinatal Genetic Counseling Clinic, NIPT is offered for indications including positive aneuploidy screening, ultrasound markers, and ultrasound abnormalities as well as to those who request a discussion of prenatal testing options including invasive procedures. Patients receive genetic counseling which includes a review of the cffDNA technology, and emphasizes the screening nature of this testing and limitation of screening to aneuploidy involving chromosomes 21, 18 and 13. The purpose of this report is to share our initial experience, highlighting the clinical utility and limitations of this novel test. Between 3/1/12 and 4/30/12, 76 women were offered NIPT. The test was accepted by 48 (63%) and declined by 28 (37%). For those who accepted NIPT, the median a priori Down syndrome (DS) risk was 1/94. For those who declined NIPT, the median a priori DS risk was 1/51. Of those patients who accepted testing, 43 (90%) had a “low risk” result (<1/10,000). Of those who had a low risk result, 4 continued on to have amniocentesis with normal results. Three patients (6%) received “high risk” results (>99% risk): 2 for trisomy 21 (T21) and 1 for trisomy 18 (T18). T21 was confirmed by amniocentesis in 1 patient and the other 2 patients declined confirmation but are using this information for delivery management. The 2 remaining patients (4%) received “no result” reports because of a low fetal fraction of DNA. Of the 28 patients who declined NIPT testing, 20 (78%) pursued diagnostic testing (median a priori DS risk: 1/29). Fourteen had amniocentesis and 6 had CVS. Of these, 7 (35%) were abnormal (median a priori DS risk: 1/5), including 5 cases of T21, 1 case of T18, and 1 case of tetrasomy 12p. Eight of the 76 (11%) patients declined all testing (median a priori DS risk: 1/510). In our initial experience the majority of women with relatively lower risk chose to pursue NIPT or declined all testing while women with relatively higher risk chose to proceed with diagnostic testing. In this initial review of our data, we find that NIPT is pursued by many women in place of diagnostic testing. However, it is essential that patients have genetic counseling to review the limitations of this technology, as illustrated by the tetrasomy 12p result that would not have been detected through NIPT.

Identification of messenger RNA of fetoplacental source in maternal plasma of women with normal pregnancies and pregnancies with intrauterin growth restriction. *P. Ayala Ramírez[1], R. García Robles[1], J. D. Rojas[2], M. Bermúdez[1], J. Bernal Villegas[1].* 1) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogotá, Colombia; 2) Department of Obstetrics and Gynecology Hospital Universitario San Ignacio, Pontificia Universidad Javeriana. Bogotá, D.C., Colombia.

Objective: to quantify placenta-specific RNA in plasma of women carrying foetuses with intrauterine growth restriction and pregnant women with normal pregnancies. Materials and methods: 8 pregnant women with foetuses with intrauterine growth restriction were studied as well as 18 women with uncomplicated pregnancies in the third pregnancy trimester. Total free RNA was quantified in maternal plasma by spectrophotometry and the gene expression of hPL (Human Placental Lactogen) at the messenger RNA level through technical Real Time-Chain Reaction Polymerase. Results: plasma RNA of fetoplacental origin was successfully detected in 100 percent of pregnant women. There were no statistically significant differences between the values of total RNA extracted from plasma ($p = 0.5975$) nor in the messenger RNA expression of hPL gene ($p = 0.5785$) between cases and controls. Conclusion: messenger RNA of fetoplacental origin can be detected in maternal plasma during pregnancy.

Instant familial haplotyping in conjunction with embryo analysis in preimplantation genetic diagnosis using DNA microarrays. *G. Altarescu[1], D. A. Zeevi[1], S. Zeligson[1], S. Perlberg[2], T. Eldar-Geva[2], E. J. Margalioth[2], E. Levy Lahad[1], P. Renbaum[1].* 1) Zohar PGD Lab, Medical Genetics Institute, Shaare Zedek Medical Center, Jerusalem, Israel; 2) IVF Unit, Shaare Zedek Medical Center, Jerusalem, Israel.

Introduction: PGD for molecular disorders involves development of gene and family specific protocols that are performed prior to the PGD cycle. Whole genome amplification (WGA) in conjunction with microarray platforms allows analysis of a very large number of SNPs. The aim of this study was to validate instant familial haplotyping in conjunction with blastomere analysis during PGD cycles. Methods: A PGD cycle was performed for a couple with paternal Charcot Marie Tooth type 1A disease using multiplex nested PCR for five informative STRs surrounding the duplicated 17p12 region. All mutant embryos from the case were blindly reanalyzed using WGA and microarray SNP analysis. WGA was performed on single blastomeres and blastocyst biopsies (2–5 cells) using the Repli-G kit. Genotype analysis was performed using Affymetrix Gene Chip Human Mapping 250K Nsp Arrays. Results: One blastomere and one blastocyst biopsy from two different embryos found to be mutant during the PGD cycle were reanalyzed along with genomic DNA samples from the CMT1A patient, his spouse, and affected mother using SNP microarrays. Wild type and mutant paternal haplotypes were assigned based on the affected mother. Out of 4844 total SNP probes on chromosome 17, 649 were identified as paternally informative, and 378 SNPs remained informative for the wild type or mutant allele when the maternal genotype was introduced. Qualitative analysis showed a 96% SNP call rate in blastocyst biopsies and 90% in blastomeres. Allele drop out (ADO) rates ranged between 3–18% (blastocyst) and 27–33% (blastomeres). After ADO analysis 103 to 137 SNPs were available for haplotype construction in blastocyst and 97 to 109 SNPs in blastomere. The whole chromosome haplotypes in both blastomere and blastocyst biopsies clearly showed that both embryos received the mutant paternal chromosome, reconfirming the initial analysis. Two recombination events were identified in all samples at +13.88 Mb and -54.94 Mb from the disease associated gene, and included 69–87 informative SNPs. Conclusions: Instant haplotyping using microarrays in conjunction with PGD analysis appears to be accurate and feasible during the time frame required for embryo transfer. This universal methodology drastically reduces pre-case haplotype preparation. Whole chromosome analysis allows fine-mapping of recombination events, thereby facilitating inclusion of a much larger number of genetic markers for haplotype construction.

Role of Cytokines in Recurrent Miscarriages. *F. Parveen, S. Agrawal.* Medical Genetics, Sanjay Gandhi PGIMS, Lucknow, Uttar Pradesh, India.

Introduction: Different single nucleotide polymorphisms within promoter and regulatory regions of different cytokines may influence the level of cytokines. It is now a well-established fact that during recurrent fetal losses there is a imbalance between Th1 and Th2 cytokines. Keeping this in mind we have studied the association of gene polymorphisms in the Th1 and Th2 cytokines i:e interferon-γ gene (IFN-γ +874 T/A), interleukin-4, interleukin-6, interlekin-10 gene (IL10; -1082 G/A,819, 592) and transforming growth factor-β gene (TGFB; +869 T/C) with RM cases and normal fertile women without the history of any fetal loss.. Materials and Methods: The polymorphism of the genes IFN-γ and TNF-α and interleukin IL-6, IL-4, IL-10 and TGF-β were assessed in 200 North Indian RM cases and 300 ethnically matched true negative controls by using RFLP and allele-specific oligonucleotides-polymerase chain reaction method. Results: We applied dominant and recessive model to test the above hypothesis. Our results revealed that there was no associations inTh2: IL-10(592 C/A) and the TGF-β gene anda significant association was observed inTh2: IL-4C590T, IL-6G174C, IL-10 (1082A/G&819 C/T) and Th1: IFN-γ +874 A/T between RM versus controls. Conclusions: This study indicates that both the Th2: IL-4C590T, IL-6G174C, IL-10 1082A/G and Th1: IFN-γ +874 A/T dominant cytokines are associated with RM.

Developmental neuropsychological assessment of 4–5 year old children born after preimplantation genetic diagnosis: A pilot study. *G. Sacks[1], J. Guedalia[3], T. Eldar-Geva[2], T. Gilboa[4], E. J. Margalioth[2], E. Levy-Lahad[1], G. Altarescu[1].* 1) PGD Lab, Medical Genetics Institute, Shaare Zedek Medical Center, Jerusalem, Israel; 2) IVF Unit, Shaare Zedek Medical Center, Jerusalem, Israel; 3) Neuropshychology Unit, Shaare Zedek Medical Center, Jerusalem, Israel; 4) Peiatric Neurology Unit, Shaare Zedek Medical Center, Jerusalem, Israel.

Introduction: Preimplantation genetic diagnosis (PGD) is a relatively new technique that enables the identification of affected embryos prior to transfer in couples at risk for a genetic disorder. Due to its relative invasiveness it is essential to identify any adverse outcomes and rule out potential insults to the long term development of children born as a result of PGD. The aim of this study was to measure and evaluate developmental neuropsychological profiles of 4–5-year-old children born after PGD and compare them to the norm. Materials and methods: Twenty seven, 4–5year-old, PGD children were recruited. Participants were subjected to a battery of neuropsychological assessments including: WPPSI - III (cognitive development), PLS-4-heb (language development), WRAVMA (visual motor abilities), CARS2 (a screening test for autistic spectrum disorders) and the Miles ABC Test (ocular dominance). Parental questionnaires included: BRIEF-P (executive function), CBCL and The CTS-BSQ (socio-emotional development). In addition, parents were interviewed to determine independent functional abilities of the children (VABS2-Interview edition). Subject's tests results were compared to each test's norms as provided by the test authors. Results: Children born after PGD showed scores within the normal range for all developmental outcomes. The mean WPPSI Full Scale Intelligence Quotient (FSIQ) was 102.7 (±13.3). Moreover, the children's mean Verbal Intelligence Quotient (VIQ) was 107.4 (±14.4); statistically significantly higher (P=0.013) than the general population, although not clinically significant (100±15). The mean total PLS-4 language score was 113.2 (±12.4), the mean WRAVMA scores for the visual-motor (drawing test), and fine-motor skills (pegboard test) were 104.4 (±13.4) and 97.7 (±15.5) respectively, the mean VABS Adaptive Behavior Composite was 106.1 (±11.4); all within normal test ranges. Socio-emotional development and executive function were all clinically normal. 40.7% of PGD cases were mixed eye-hand dominance. One of the subjects was found to show possible signs for autistic spectrum disorders and was sent for further evaluation, although a family history of autism was noted. Conclusions: This pilot study shows that children conceived after PGD show normal developmental neuropsychological outcomes at age 4–5 years when compared to the norms representing the general population of children of the same age.

2994T

Terminological clarification in PGD: Could reframe the debate? *S. Côté[1, 2], P. Hamet[1,2,3].* 1) Medical Genetic service, Montreal University health center, Montreal, Canada; 2) Biomedical sciences, faculty of medicine, University of Montreal, Montreal, Canada; 3) Canada Research Chair in predictive genomic, Montreal, Canada.

Although, most cases of preimplantation genetic diagnosis (PGD) are undertaken for medical reasons, as some authors specify, the choice of language in discussing the process is important in order to avoid stigmatization and discrimination of patients who use PGD (Bouffard et al. 2009). These authors add that when experts discussing PGD use terms such as eugenics or designer baby, there is a risk of shifting the debate and therefore preventing a deeper questioning about the possible misuse of PGD for social reasons. Therefore we are proposing a terminological clarification. Genetic diagnosis is originally defined as a genetic test to identify a genetic condition or predisposition to this condition. Actually, as the use of PGD goes far beyond the frameworks of medicine to better frame discussions and to respect parents seeking PGD for medical reasons, we propose that the term PGD be reserved exclusively for requests based on diagnostic indications. We suggest that PGD not be used in cases of social sex selection because identifying the sex of an embryo is not a genetic diagnosis and as such cannot, under any circumstances, be considered as a disease. Therefore, for social uses we suggest using terms that would be close to PSS (preimplantation social selection). However, should PGD be used in cases where sex selection is done in the context of an X-linked genetic disorder? If the embryo selected were a carrier of the mutation, would it not by definition be a generally healthy carrier? With regard to PGD used for the health benefits of a family member, we use the HLA typing as a component of genetic diagnosis. In this case, we could use PGD-HLA typing. Unfortunately, the vague terminology in this field risk to obscure objectives sought by a legitimate parental wish to avoid the burden of transmitting a genetic mutation. Echoes of these concerns can be heard not only in academic discussions but also in debates in the general population using terms designer baby and perfect child in a misguided fashion. Finally, in a context where social uses of PGD are increasing, we believe that a reflection on the use of a fair and appropriate terminology is necessary in order to could foster a climate of respect for patients who use PGD for medical reasons, facilitating health providers and insurances reimbursements.

2995T

A novel, generic, preimplantation genetic diagnosis protocol applied to cystic fibrosis involving mutation detection through high resolution melting analysis and simultaneous haplotype analysis through QF-PCR. *A. Destouni, M. Poulou, G. Kakourou, C. Vrettou, J. Traeger-Synodinos, I. Fylaktou, E. Kanavakis, M. Tzetis.* Medical Genetics, University of Athens, St.Sophia's Children's Hospital, Athens, Attica, Greece.

Cystic Fibrosis (CF) is the most common, autosomal recessive severe monogenic disease in Caucasians and a common indication for PGD. It is characterized by an extremely heterogeneous mutation spectrum (>1800 mutations http://www.genet.sickkids.on.ca/). Most PGD protocols to preclude CF described to date apply single-cell multiplex fluorescent PCR for analysis of linked polymorphic short tandem repeats (STR-linkage approach), including testing for the commonest CFTR mutation, p.Phe508-del, when indicated. This potentially has limiting application for cases with other mutations when phase analysis is unavailable. Here we report the development and successful clinical application of a novel, flexible, generic PCR PGD protocol to facilitate direct detection of any CFTR nucleotide variation(s) by HRM, and simultaneous confirmation of diagnosis through STR-haplotype analysis. A touch-down, multiplex PCR was optimized supporting co-amplifcation of any CFTR exon-regions, along with linked 6 STRs. The primers used for CFTR HRM analysis were previously described (Montgomery et al. 2007). Diluted (1/1500) 1st PCR products were used for a nested PCR to amplify separately the CFTR regions for HRM analysis (Idaho's LightScanner). CFTR genotypes were confirmed by STR analysis of the 1st PCR products. STR analysis provides an indication of embryo ploidy and facilitates contamination monitoring. The protocol was validated pre-clinically according to PGD guidelines, by testing single lymphocytes, isolated (by micromanipulation) from whole blood samples of candidate PGD patients. Four clinical PGD cycles were performed, for 4 CF carrier couples with the following CFTR genotypes: a) p.Phe508del and p.Phe508del, b) p.Phe508del and c.489+1G>T; c) p.Arg334Gln and c.489+3A>G; d) p.Phe508del and p.Leu732X, (HGVS CFTR reference sequences NM000492.3 and NG016465.1). 34 embryos were biopsied and a total of 34 blastomeres were analyzed. Five samples failed to amplify at all loci. Genotypes were achieved in 29/29 amplified samples, of which 17 were suitable for embryo transfer (unaffected CFTR genotypes). Transfer of 9 embryos led to 3 pregnancies (2 twin and 1 singleton). PGD genotypes were confirmed following conventional amniocentesis or trophoblast PND testing. The reported PGD method is a flexible and robust tool which facilitates direct CF genotype analysis, genotype confirmation and contamination detection in single cells, with minimal family work-up prior to PGD (generic).

PGD and heteroplasmic mitochondrial DNA point mutations: A systematic review estimating the chance of healthy offspring. *D.M.E.I. Hellebrekers[1], R. Wolfe[2], A.T.M. Hendrickx[1], I.F.M. de Coo[3], C.E. de Die[1,4], J.P.M. Geraedts[1,4], P.F. Chinnery[5], H.J.M. Smeets[1,4].* 1) Clinical Genetics, Maastricht University Medical Centre, Maastricht, Netherlands; 2) School of Public Health and Preventive Medicina, Monash University, Melbourne, Australia; 3) Pediatric Neurology, Erasmus MC-Sophia Children's Hospital, Rotterdam, The Netherlands; 4) Research Institute GROW, Maastricht University Medical Centre, Maastricht, Netherlands; 5) Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, UK.

Background: Mitochondrial disorders are often fatal multisystem disorders, partly caused by heteroplasmic mitochondrial DNA (mtDNA) point mutations. Prenatal diagnosis is generally not possible for these maternally inherited mutations because of extensive variation in mutation load among embryos and the inability to accurately predict the clinical expression. The aim of this study is to investigate if PGD could be a better alternative, by investigating the existence of a minimal mutation level below which the chance for an embryo of being affected is acceptably low, irrespective of the mtDNA mutation. Methods: We performed a systematic review of muscle mutation levels, evaluating 159 different heteroplasmic mtDNA point mutations derived from 327 unrelated patients or pedigrees, and reviewed three overrepresented mtDNA mutations (m.3243A>G, m.8344A>G and m.8993T>C/G) separately. Results: Mutation levels were included for familial mtDNA point mutations only, covering all affected (n=195) and unaffected maternal relatives (n=19) from 137 pedigrees. Mean muscle mutation levels were comparable between probands and affected maternal relatives and between affected individuals with tRNA- versus protein-coding mutations. Using an estimated a-priori prevalence of being affected in pedigrees of 0.477, we calculated that a 95% or higher chance of being unaffected was associated with a muscle mutation level of 18% or less. At mutation level 18%, the predicted probability of being affected is 0.00744. The chance of being unaffected was lower only for the m.3243A>G mutation (P<0.001). Most carriers of mtDNA mutations will have oocytes with mutation levels below this threshold. Conclusions: Our data show, for the first time, that carriers of heteroplasmic mtDNA mutations will have a fair chance of having healthy offspring, by applying PGD. Nevertheless, our conclusions are partly based on estimations and, as indicated, do not provide absolute certainty. Carriers of mtDNA should be informed about these constraints.

2997T

Successful pre-implantation genetic diagnosis in isolated sulfite oxidase deficiency: A happy end to the saga of a devastating neurogenetic disorder. *A. Kondkar[1], K. Abu-Amero[1,4], M. Salih[3], T. Bosley[2].* 1) Department of Ophthalmology, College of Medicine, King Saud University, Riyadh, Saudi Arabia; 2) Department of Ophthalmology and Pediatrics, College of Medicine, King Saud University, Riyadh, Saudi Arabia; 3) Department of Neurology, College of Medicine, King Saud University, Riyadh, Saudi Arabia; 4) Department of Ophthalmology, College of Medicine, University of Florida, Jacksonville, FL, USA.

Isolated sulfite oxidase deficiency (ISOD) is an autosomal recessive disorder that typically causes seizures shortly after birth followed by cystic cerebral cortical degeneration and death at an early age. This report presents a consanguineous Sudanese family who had three children who were biochemically diagnosed with ISOD. Another child died shortly after birth without definitive diagnosis; a fetus was aborted because of anencephaly; and a normal fetus aborted after diagnostic chorionic villus sampling. Sequencing revealed a novel two base successive deletion c.1232–1233 delTG in the sulfite oxidase gene on chromosome 12. Pre-implantation genetic diagnosis (PGD) and in vitro fertilization resulted in the birth of a healthy child. Patients with ISOD generally develop intractable seizures within days of birth followed by what appears on neuroimaging to be acute brain ischemia affecting predominantly cerebral white and grey matter, basal ganglia, and other deep grey structures. Various dietary manipulation and molybdenum cofactor treatment have been suggested as partial treatments for molybdenum cofactor deficiency for this type of genetic disorder but only OGD offers a definitive reproductive option for families with ISOD.

2998T

Outcomes of 687 in vitro fertilization (IVF) cycles and 5871 embryos evaluated using 23-chromosome single nucleotide polymorphism (SNP) microarray preimplantation genetic screening (PGS) for recurrent pregnancy loss (RPL). *K.J. Tobler[1], P.R. Brezina[1], A.T. Benner[2], L. Du[2], B. Boyd[2], W.G. Kearns[1,2].* 1) Department of Gynecology and Obstetrics, Johns Hopkins Medical Institutions, Baltimore, MD; 2) Genetics, Center for Preimplantation Genetics, Lab Corp, Rockville, MD.

Objective: We determined the pregnancy and miscarriage rates of patients undergoing IVF and dense microarray PGS for RPL.

Design: Retrospective review

Materials and Methods: A retrospective review was conducted of all embryos that underwent PGS by 23 chromosome SNP microarrays from January 2010 to April 2012. Patients underwent standard IVF and PGS primarily due to a history of ≥ 2 spontaneous miscarriages. Embryo biopsy was performed at either the cleavage or blastocyst stage. Sample DNA was amplified and analyzed using Human CytoSNP-12 DNA beadchips and GenomeStudio and KaryoStudio software. Embryos derived from parents with known translocations or inversions were excluded from the study. Data was split into four patient groups based on maternal age (<35, 35–37, 38–40, >40). Microarray data was also compared to previously published fluorescence in situ hybridization (FISH) PGS data from our laboratory (previously published). Binomial confidence intervals for proportions were calculated.

Results: A total of 5871 molecular karyotypes were obtained from 687 IVF cycles. The overall pregnancy rate per IVF cycle for women in this trial undergoing 23-chromosome SNP microarray PGS for RPL was 57% with a miscarriage rate of 9%. In blastocyst stage PGS, the pregnancy rate, 75%, was significantly (p<0.001) higher than the cleavage stage pregnancy rate, (47%). Miscarriage rates were significantly (p=0.002) higher in the cleavage stage (12%) than the blastocyst stage (5%). Both cleavage and blastocyst stage PGS yielded significantly (p<0.001) higher pregnancy rates than FISH PGS. Pregnancy rates decreased and miscarriage rates increased in all groups with advancing maternal age.

Conclusions: PGS using 23 chromosome SNP microarrays in women with RPL was superior to FISH PGS. Furthermore, performing the biopsy at the blastocyst stage was superior to cleavage stage biopsy. The application of dense microarray 23 chromosome PGS at the blastocyst stage may substantially improve pregnancy outcomes in couples suffering from RPL.

Cleavage-stage blastomere biopsy significantly impairs human embryonic reproductive potential while blastocyst-stage trophectoderm biopsy does not: A paired randomized controlled trial utilizing SNP microarray-based DNA fingerprinting. *N.R. Treff[1,2,3], K.M. Ferry[1], T. Zhao[1], J. Su[1], E.J. Forman[1,2], R.T. Scott Jr.[1,2].* 1) Reproductive Medicine Associates of New Jersey, Morristown, NJ; 2) Department of Obstetrics, Gynecology, and Reproductive Sciences, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ; 3) Department of Genetics, Rutgers-The State University of New Jesery, Piscataway, NJ.

Preimplantation genetic diagnosis (PGD) requires embryonic DNA which necessitates embryo biopsy. Despite the use of PGD for over 2 decades, the risks associated with embryo biopsy itself, and whether biopsy is safest at the cleavage or the blastocyst stage of embryo development, have not been well characterized. This study uses a novel paired randomized controlled trial (RCT) to accurately assess the impact of embryo biopsy at these 2 stages of development for the first time. Patients received routine care inclusive of embryo selection. Once the 2 best embryos were selected for transfer, one was randomized to biopsy and the other to control. Biopsy was performed with the most commonly used methodology involving a diode laser and gentle aspiration of either a blastomere (cleavage) or trophectoderm cells (blastocyst). The sibling biopsied and non-biopsied embryos were then transferred together. With resulting singleton deliveries, SNP microarray based fingerprinting of the embryo biopsy and newborn DNA was used to determine whether the child was derived from the biopsied (self) or non-biopsied (sibling) embryo. A McNemar paired test of proportions was used to evaluate significance. Results were obtained from 100% of blastomere and trophectoderm biopsies. 117 patients completed the study, including 55 cleavage stage and 62 blastocyst stage transfers. There was a significant reduction in delivery rates amongst biopsied compared to the non-biopsied cleavage stage embryos (29% compared to 46%, respectively; P=0.049); a loss of delivery potential of 39%. In contrast, the delivery rate of biopsied and non-biopsied blastocysts was not significantly different (47% and 48%, respectively; P=1.00). Optimizing clinical outcomes following any type of embryo genetic analysis (aneuploidy, single gene disorder, or translocation screening) might therefore be best realized by performing biopsies at the blastocyst stage. This is supported by the observation that the only RCTs to demonstrate a clinical benefit from aneuploidy screening utilized blastocyst stage biopsy. Potential explanations as to why blastocyst biopsy is safe when cleavage stage biopsy is not include the removal of a smaller proportion of the embryo, certainty that only extra-embryonic cells are biopsied, and better embryonic tolerance of manipulation after genomic activation.

Comparison of two whole genome amplification methods for preimplantation genetic diagnosis with HLA typing on beta-thalassaemia. *Q. Wang, J.F.C. Chow, W.S.B. Yeung, E.H.Y. Ng, P.C. Ho.* Dept. of Obs. & Gyn., The University of Hong Kong, Hong Kong.

Preimplantation genetic diagnosis (PGD) combined with HLA typing is a preventive and therapeutic approach allowing the birth of unaffected children who are also HLA identical to the affected siblings with life-threatening disorders such as beta thalassaemia. This study aimed to compare the performance of two whole genome amplification (WGA) methods used in PGD, SurePlex (BlueGnome) and REPLI-g (Qiagen) WGA kits for the HLA typing on single lymphocytes from HBB mutation carriers with known serological HLA types. HLA typing was determined by the CTS-PCR-SSP TRAY KITS (UCH). The genotype patterns of HLA regions A, B, and DRB1 obtained from patients' genomic DNA samples were used as references. WGA products generated through the SurePlex and REPLI-g kits were analyzed and the results of single cell HLA typing were compared. Our data revealed that following manufacturer's instructions, the Qiagen REPLI-g Kit was able to amplify DNA templates specifically, produce longer products, and detect the three mentioned alleles, while the SurePlex kit caused non-specific amplification in negative controls containing no DNA templates and failed to detect the HLA-DRB1 region properly. The detection failure of the HLA-DRB1 region with the SurePlex kit was also observed on the WGA products amplified from diluted genomic DNA samples (equivalent to the amount of DNA estimated in a single cell). These findings indicate that besides the well-known phenomena of allelic drop-out (ADO, PCR failure of one allele) and preferential amplification (PA, hypo-amplification of one allele), the inability of WGA kits to amplify target regions (i.e., amplification failure of both alleles) could occur, and might cause misdiagnosis. Therefore, a careful evaluation of the ability of WGA kits to amplify target regions is essential to ensure diagnostic efficacy and accuracy.

Preimplantation genetic diagnosis for a carrier of complex chromosome rearrangement resulting in a healthy offspring. *K. Writzl, A. Veble, B. Peterlin.* Institute of Medical Genetics, Ljubljana, Slovenia.

Complex chromosome rearrangements (CCR) are structural aberrations involving more than two breakpoints on two or more chromosomes. Carriers of CCR are at increased risk for infertility, miscarriages or chromosomally unbalanced offspring. Preimplantation genetic diagnosis (PGD) may avoid the transfer of embryos carrying unbalanced rearrangements, therefore increasing the chance of pregnancy. This is the first report for a live birth after PGD in the CCR carrier associated with translocation and inversion. A carrier of CCR was ascertained through the birth of an infant who had an unbalanced karyotype and died at 10 days. Using conventional cytogenetic methods the rearrangement was characterized as a translocation between the long arms of chromosomes 11 and 18. Whole chromosome paint fluorescent in situ hybridisation (FISH) analyses revealed additional rearrangement - paracentric inversion of derivative chromosome 11. Blastomeres were biopsied from 18 embryos in two PGD cycles, and 17 embryos (94.4%) were successfully diagnosed by FISH method. The probes were chosen to detect unbalanced translocated products and dicentric and acentric recombinant products in the event of recombination. The segregation mode most frequently found was adjacent - 1 (47%), followed by alternate (41%). No evidence for adjacent-2 segregation or 3:1 segregation mode was found. A pregnancy was achieved in the second PGD cycle, and the karyotype of amniocentesis was normal. A healthy baby was delivered. This report supports the benefit of PGD in CCR couples and adds to understanding of the mechanism of meiotic segregation in CCR. It also suggests that FISH method should be used to detect CCRs in apparently balanced translocation carriers.

Preimplantation genetic diagnosis (PGD) in Genomic Regions with Duplications and Pseudogenes: Long Range PCR in the Single Cell Assay. *D.A. Zeevi[1], R. Ron El[2], P. Renbaum[1], E. Kasterstein[2], D. Strassburger[2], D. Komarovsky[2], B. Maslanski[2], I. Ben-Ami[2], O. Bern[2], A. Komski[2], E. Levy Lahad[1], G. Altarescu[1].* 1) Medical Genetics Institute, Shaare Zedek Medical Center, Jerusalem, Israel; 2) IVF and Infertility unit, Assaf Harofeh Medical Center, Tel Aviv University.

Introduction: Long and short range nested PCR are generally employed for the analysis of disease-causing mutations in genes with homologous pseudogene copies. However, long range PCR is challenging when performed on single cells, as for PGD of monogenic disorders. PGD on single cells requires concurrent analysis of a mutation together with multiple linked polymorphic markers from close family members in order to reduce misdiagnosis. In PGD cases involving childless de novo mutation carriers, linkage cannot be performed based on family members but rather must first be identified in single gametes. However, if the mutation to be assayed lies in a duplicated genomic region, the design of an appropriate single cell assay, incorporating a long and short range-coupled multiplex PCR, can be an especially difficult task. Here we describe a novel method by which accurate PGD of de novo pseudogene-homologous mutations can be achieved. Methods: Whole genome amplification (WGA) was performed on single sperm using a multiple displacement amplification kit. Subsequently, the WGA samples were subjected to long range PCR followed by nested PCR and sequencing of a mutation in PKD1. In parallel, the samples were analyzed with gene-proximal polymorphic STR markers in order to determine allelic association. Results: Haplotypes were constructed around a pseudogene homologous mutation in PKD1 (c.701delC; de novo autosomal dominant male affected) in single sperm. Direct PCR mutation analysis could not be performed on the mutation carrier because the gene-specific allele was heavily diluted in 6 pseudogene copies. In contrast, WGA on 16 single sperm samples followed by long range PCR-mediated analysis clearly identified the PKD1 gene-specific locus and mutation. In addition, linkage analysis identified two distinct haplotypes; 11 sperm with haplotype A and 5 sperm with haplotype B. Surprisingly, this analysis showed that the PKD1 mutation carrier is a mosaic since only 3 out of 5 sperm with haplotype B possessed the mutation, unlike 11/11 sperm with haplotype A. Conclusions: Whole genome multiple displacement amplification enables the simultaneous analysis of short polymorphic marker, and long range gene-specific, PCR fragments. This original analytical scheme is universal and facilitates accurate PGD analysis in cases where mutation-linked haplotypes must be constructed from gametes (single sperm/polar body) of pseudogene-homologous mutation carriers.

TAR Syndrome Diagnosis Confirmed by aCGH Analysis. *S. Ceylaner[1], Y.K. Terzi[2], S. Kalyoncu[3], F.I. Sahin[2].* 1) Intergen Genetics Center, Ankara, Turkey; 2) Baskent University Faculty of Medicine Department of Medical Genetics, Ankara, Turkey; 3) Jineclinic Women's Health Center, Ankara, Turkey.

Thrombocytopenia-absent radius (TAR) is a rare congenital syndrome affecting less than 1 in 100,000 newborns, and is characterized by bilateral radial aplasia and thrombocytopenia. Also a number of additional features such as skeletal and cardiac anomalies, dysmorphic features, renal malformations, and intellectual deficit have been observed in TAR syndrome. In the present study we analyzed a 22-weeks-old male fetus with severe micrognathia, phocomelia of upper extremities, bilateral joint limitations of hip, knee and ankle of lower extremities and diastasis recti. Absence of the long bones of the upper extremities was also confirmed by X-ray imaging. Parents are healthy non-consanguineous individuals. To uncover the genetic cause of these findings array comperative genomic hybridization (aCGH) analysis was performed. DNA was isolated from amniotic fluid sample. Roche NimbleGen Human CGH 3×720K Whole-Genome Tiling v3.0 Array was used for aCGH analysis. The data were analyzed by using web based Genoglyphix program (Signature Genomics). As a result of aCGH analysis, variations in 12 regions were thought to be clinically significant, eleven of them were copy gain on chromosomes 2, 7, 11, 17, 19, 20 and X, and one of them was copy loss on chromosome 1. Deletion, located at 1q21.1, encompassed 346 kb of genomic DNA. This region comprises 16 genes, 9 of which are OMIM genes. Deletion in this region was found to be related to thrombocytopenia-absent radius syndrome. Chromosome analysis was also done from amniotic fluid and the result was normal constitutional karyotype (46,XY). Recent findings showed that deficieny of the RBM8A gene protein product Y14 may be responsible for development of TAR syndrome. Also other identified copy gains may have contributed to the accompanying dysmorphic findings. Array CGH analysis is a valuable tool in uncovering submicroscopic chromosomal rearrangements that cannot be discerned by conventional cytogenetic analysis.

Prenatal detection of anophthalmia in three cases with significantly different neonatal outcomes. *T. Bardakjian, D. Dorsainville, A. Schneider.* Dept Peds/Genetics, Albert Einstein Med Ctr, Philadelphia, PA.

Anophthalmia and microphthalmia can be detected prenatally via ultrasound. Genetic counseling after identification of this rare and severe birth defect is complicated given its etiological heterogeneity and phenotypic variability. We describe three prenatally identified cases where parents contacted the Anophthalmia /Microphthalmia Registry at Einstein Medical Center, Philadelphia after the 20 week “anatomy survey” ultrasound identified anophthalmia in the fetus. Two of the fetuses were identified with unilateral anophthalmia and the third with bilateral anophthalmia. All three had follow-up fetal MRI which confirmed the findings. Additional testing offered by the obstetrician varied. None were offered molecular testing for eye development genes. These cases demonstrate the variability seen in this condition and the difficulty encountered when a prenatal diagnosis of anophthalmia is made. We will propose a detailed prenatal work-up to help elucidate the situation for a family facing this diagnosis in utero and make genetic counseling more targeted.

Antenatal detection of a fetus with bilateral anophthalmia and pulmonary hypoplasia - a rare case report. *C.C. Albu[1,2], D.F. Albu[1,2,4], M. Dumitrescu[2,3], E. Severin[1].* 1) University of Medicine and Pharmacy Carol Davila Bucharest, Romania; 2) Alco San Clinic, Bucharest, Romania; 3) Marius Nasta Hospital, Bucharest, Romania; 4) Panait Sirbu Hospital, Bucharest, Romania.

Background: Matthew-Wood syndrome is a rare disorder including as main characteristics anophthalmia/microphthalmia, and pulmonary hypoplasia/aplasia, diaphragmatic hernia/eventration and cardiac congenital malformation. Case report: A 31-year-old Caucasian female, pregnant for the first time, was referred at 16 weeks' gestation for a routine prenatal ultrasound. The couple had normal general health and was not consanguineous. There was no family history of chromosomal anomalies. Methods: Routine ultrasonography at 16 weeks of pregnancy, triple test (AFP,uE3, hCG), selective ultrasonography for detection of fetal abnormalities and amniocentesis were performed. Results: Ultrasound examination revealed a single fetus with bilateral anopthalmia, pulmonary hypoplasia and diaphragmatic hernia. Triple test was not sensitive to the presence of trisomy 13, 18 and 21. The fetal karyotype indicated a normal cytogenetic female: 46,XX. Because of prenatal ultrasound detection of bilateral anophthalmia, the parents decided to terminate the pregnancy. An autopsy showed bilateral anopthalmia, pulmonary hypoplasia and diaphragmatic hernia. Conclusions: Matthew-Wood syndrome can be diagnosed prenatally by routine ultrasound examination. Prenatal ultrasound diagnosis of a sporadic case of Matthew-Wood syndrome was useful in the management of this case.

Outcomes following antenatal diagnosis of ultrasonographically isolated cleft lip with or without cleft palate. *A. Lehman[1], L. Burnell[1], C. Verchere[2], D. Pugash[3], S. Robertson[4], A. Loo[5].* 1) Dept Med Gen, Univ British Columbia, Vancouver, BC, Canada; 2) Dept Surgery, Univ British Columbia, Vancouver, BC, Canada; 3) Dept Radiology, Univ British Columbia, Vancouver, BC, Canada; 4) Cleft Palate / Craniofacial Program, BC Children's Hospital, Vancouver, BC, Canada; 5) Faculty of Dentistry, Univ British Columbia, Vancouver, BC, Canada.

Cleft lip with or without cleft palate (CLP) is one of the most common congenital malformations with an average incidence of 1 / 700 worldwide. Clefting of the fetal lip is routinely screened for during the second trimester detailed ultrasound scan. We reviewed postnatal outcomes following an antenatal diagnosis of ultrasonographically isolated CLP in a ten period between January 2000 and December 2009. All pregnancies in British Columbia referred to our tertiary care centre for a level III ultrasound were ascertained and then matched with the corresponding pediatric chart in our Cleft Palate / Craniofacial Program. Isolated CLP was defined as the absence of other fetal structural malformations on our level III scan. A minimum of 2 years of follow-up was reviewed. Ninety-seven cases were identified, 1 of which had no outcome data. Fifteen pregnancies led to termination and 13 had some amount of post-mortem examination or investigation recorded. Seventy-six of the 81 liveborn infants had at least 2 years of postnatal follow-up data available for review. The majority had no significant medical or developmental issues beyond effects from the clefting. Eleven of the 76 had a diagnosed or strongly suspected complex developmental disorder. Two of these children had inherited a clefting syndrome from a parent (Ectrodactyly ectodermal dysplasia and Blepharocheilodontic dysplasia). One had Trisomy 21. The other children had Noonan syndrome, Kabuki syndrome, autism with intellectual disability, autism, suspected autism spectrum disorder, a CNS malformation, and the last had a combination of short stature, minor anomalies, and significant behavioural difficulties. Another 11 children had minor anomalies not requiring any therapy (eg., transient hydronephrosis, non-closure of the fontanelle, small ventricular septal defect). With a normal karyotype and negative family history for a clefting syndrome, the frequency of an associated complex developmental disorder following an otherwise reassuring fetal ultrasound is around 10 percent. Combining our data with comparable studies on fetal karyotyping for isolated CLP, the yield is about 1 percent.

3007T

cfDNA is not compromised by temperature stress of maternal blood collected in Streck Cell-free DNA BCT. *A. Huang, A. Srinivasan, V. Nguyen, J. Cheng, J. Sprowl, R. Van Luchene, A. Aziz, D. Comstock.* Verinata Health, Inc., 800 Saginaw Drive, Redwood City, CA 94063.

Objective: Simulating temperature stresses that patient blood tubes endure during transit from a collection site to the clinical testing facility, this study examined the use of plasma cfDNA isolated from temperature-stressed maternal blood in massively parallel sequencing-based prenatal diagnostic screening assays. Methods: Four blood tubes each from 121 pregnant donors were received in Streck Cell-free DNA BCTs by overnight shipping. The first tube was the control (D1) while the remaining three tubes (D2, D4, D6) were subjected to repeat cycles of 24hr temperature stress (15hrs at 25C, 4hrs at 30C, 5hrs at 40C). The stress regimen mimicked typical “summer extreme” industry standard for shipping temperature profile. Plasma cfDNA was isolated from these samples, barcoded sequencing libraries generated and the libraries sequenced on the Illumina HiSeq2000. For each donor specimen, normalized chromosome ratios were derived from the sequencing data and compared across the four conditions. A normalized chromosome ratio is the number of unique tags aligning to a specific chromosome divided by the sum of tags aligning to one or more “normalizing” chromosomes. This ratio, with %CVs of less than one across hundreds of samples, is a quantitative metric for copy number variation that accounts for GC and sample-to-sample biases. Normalized chromosome ratio is very sensitive to small changes in copy number. Results: Plasma cfDNA quality was evaluated by comparing average Ratio data for Chrs 13, 18, and 21 for all conditions. Fetal fraction representation was evaluated by comparing R2 of linear correlation plots for Chrs X and Y for maternal samples with male fetuses. Average Ratio_18 and Ratio_21 from the 121 samples were largely unaffected by the temperature stress; average Ratio_13 showed a slight upward trend. Fetal fraction was not compromised by the temperature stress. Conclusion: Repeated temperature stress did not compromise cfDNA quality or fetal fraction in maternal blood collected in Streck BCT.

Effective epigenetic biomarker in first-trimester maternal plasma for non-invasive fetal trisomy 21 detection. *J. Lim[1], D. Lee[1], S. Kim[1], M. Kim[1], S. Park[1], Y. Han[2], M. Kim[2], M. Kim[2], K. Choi[2], H. Ryu[1,2].* 1) Laboratory of Medical Genetics, Medical Research Institute, Cheil General Hospital and Women's Healthcare Center, Seoul, South Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, KwanDong University college of Medicine, Seoul, Korea.

Purpose: Noninvasive prenatal diagnosis of trisomy 21 (T21) is being actively researched using epigenetic biomarkers for specific detection of fetal DNA in maternal plasma. The *HLCS*(holocarboxylase synthetase) and *RASSF1A* (Ras association domain family member 1) genes are located on chromosome 21 and 3, respectively. Their promoters have regions which are hypermethylated in the placenta and hypomethylated in maternal blood cells. We estimated the accuracy of non-invasive fetal T21 detection using a tissue-specific epigenetic characteristic of*HLCS* and *RASSF1A* during the first-trimester of pregnancy.

Methods: A nested, case-control study was conducted with maternal plasma collected from 40 pregnant women carrying 30 normal and 10 T21 fetuses. In this study, we used the methylated DNA immunoprecipitation (MeDIP) methodology for specific isolation of methylated DNA in maternal plasma. The maternal plasma levels of *HLCS* and *RASSF1A* were simultaneously measured by methylation-specific multiplex real-time quantitative PCR.

Results: The *HLCS* and *RASSF1A* levels were obtained in all cases. These levels were not different according to fetal gender (P>0.05 in both). The *HLCS* level was significantly increased in women with a T21 fetus compared with controls (P<0.05). The *RASSF1A* level was not different between the T21 cases and controls (P>0.05). The specificity of HLCS level and ratio of*HLCS* and *RASSF1A* levels for non-invasive fetal DS detection showed 66.7% and 90.0% at 90% sensitivity, respectively.**Conclusion:** The findings of this study suggest that ratio of *HLCS* and *RASSF1A* levels may be useful as potential biomarkers for non-invasive fetal T21 detection during the first trimester of pregnancy, regardless of fetal gender.

3009T

Prenatal diagnosis of a fetus with mosaic trisomy 18, omphalocele and severe intrauterine growth restriction: case report. *D.F. Albu[1,2], C.C. Albu[1,2], A. Oncescu[2,4], E. Severin[1], M. Dumitrescu[2,3].* 1) University of Medicine and Pharmacy Carol Davila, Bucharest, Romania; 2) Alco San Clinic, Bucharest, Romania; 3) Marius Nasta Hospital, Bucharest, Romania; 4) Panait Sirbu Hospital, Bucharest, Romania.

Background: Omphalocele is a midline abdominal wall defect with extrusion of abdominal viscera, covered by a membranous sac, into the base of the umbilical cord and is the one of the most common congenital malformation of the anterior abdominal wall. Omphalocele is frequently associated with other congenital malformations. However, the frequency of the reported associated malformations for omphalocele ranges from 27%; to 63%;. Objective: To determine wether omphalocele and intrauterine growth restriction (IUGR) are syndromic or non syndromic. Patients and methods: A 30 year old, Caucasian woman was referred at 17 weeks' gestation for a routine prenatal ultrasound. The couple had normal general health and was not consanguineous. There was no family history of congenital malformations and chromosomal abnormalities. Routine ultrasonography at 17 weeks of pregnancy, triple test (AFP,uE3, hCG), selective ultrasonography for detection of fetal abnormalities, and amniocentesis were performed. Ultrasound evaluation revealed severe intrauterine growth restriction (IUGR). Immediate amniocentesis was performed. It revealed the elevation of the AFP in the amniotic fluid. FISH analysis showed mosaic trisomy 18. The pregnancy was terminated one week later. Conclusions: Our case provides further evidence for the benefit of advanced imaging for prenatal diagnosis and the understanding of fetal condition. More important for our patient was her better understanding of fetal disorder due to 3D findings.

3010T

Chromosomal abnormalities in prenatal diagnosis: An Indian perspective. *B.B. Ganguly[1], N.N. Kadam[2].* 1) Genetics, MGM Center for Genetic & Diagnosis, New Mumbai, Maharashtra, India; 2) Department of Pediatrics, MGM Institute of Health Sciences, New Mumbai, India.

Statement of purpose: In cases with family history of mental retardation or suspected genetic illness, previous child with chromosome anomaly and advanced maternal age are generally considered for prenatal screening of double/triple/quadruple markers in maternal serum, which collects information about possibility of genetic abnormality in the fetus and calculates risk of Down syndrome, Edward syndrome and neural tube defects. The perceived risk directs prenatal chromosome analysis. Ultrasound imaging also prompts for prenatal diagnosis. Chromosome analysis is generally not considered as a straightforward approach for prenatal diagnosis in cases with significant background information. In the present paper, an analysis has been carried out for ascertaining the incidence of chromosomal anomaly in cases where screening result indicated high risk. Method: Amniotic fluid was cultured in replicate sets following standard technique for 140 cases. One of the primary cultures with 10–15 colonies was considered for harvesting and chromosome preparation approximately on day 8–10. Conventional G banding and chromosome analysis was carried out with the help of IKAROS software. Result: The cases registered in the study were comprised of 28.6% of 21–30 years of age, 69% of 31–40 years and 2% of 41–48 years. Of them, 65% had high risk of Down syndrome, 10% was with advanced age, 9% had family history, 4% with previous child carrying chromosome anomaly, and 1.4% each with IVF pregnancy, parental chromosome aberration, and cystic hygroma or echgenic bowel. Trisomy 21 was observed in 4.4% suspected cases only, though significant risk was detected in 65% cases on maternal serum screening. One case showed both inv(9) and t(15;16). Altogether, constitutive abnormality was observed in 9.2% cases. Other abnormalities, including inv(9), t(1;3), der(9)t(9;21)mat, der(22)t(9;22)mat, del(9q13), and polymorphic variability such as 14p+, 1qh+, 9qh+, 21p+, 22p+, etc. were recorded in 6% cases. Therefore, it has been realized that the practice of maternal serum screening is popular; however, traumatize patients with false positive result. And it may be imperative that false negative result may lead to delivery of chromosomally abnormal children. Chromosome analysis, in any circumstances, appears to be a more reliable and may be adopted as a direct approach for prenatal diagnosis.

A Powerful "Smart Tip" Method for Nucleic Acid Extraction and Enrichment of Cell-Free Fetal DNA from Maternal Plasma. *A. Gindlesperger, T. Stokes, P. Belgrader, R. Holmberg.* Akonni Biosystems, Frederick, MD.

Background: Non-invasive prenatal diagnostics (NIPD) is a much safer alternative to invasive techniques, but is more challenging due to the low concentration of highly fragmented fetal DNA in a high background of maternal DNA circulating in maternal plasma during early gestation periods. These conditions require the processing and concentration of large sample volumes to achieve adequate amounts of fetal DNA for analysis. The high ratio of maternal to fetal DNA can also confound the downstream detection method when trying to discern copy number variations such as aneuploidy. Akonni Biosystems' patented "smart-tip" technology, called TruTip®, uses a porous nucleic acid binding matrix inserted into a disposable pipette tip. This technology offers many advantages over the current extraction methods for this application, including the ability to process large volumes of plasma and enrich specific sized DNA. Its format is also amenable to automation to provide high-throughput processing capabilities. Methods: For this study, we designed a custom TruTip for large volume samples and developed a manual protocol demonstrating feasibility to extract circulating DNA from up to 10 mL of plasma. Conditions were optimized to maximize the yield of the male fetal DNA and minimize the recovery of the less fragmented female DNA in a final elution volume of 50 µL. Extraction yields were compared to Qiagen's Circulating Nucleic Acid Kit and assayed using a duplex quantitative real-time PCR assay to detect 1) male fetal DNA using a multi-copy Chrom Y assay and 2) total DNA, fetal and maternal, using a Chrom 1 assay. Results: The final optimized protocol provided for a 200-fold concentration of the plasma DNA in approximately 2.5 hrs. Real-time PCR data demonstrated similar recoveries of low levels of fetal DNA between TruTip and the Qiagen Circulating Nucleic Acid Kit, but TruTip exhibited a 3–4% higher enrichment of fetal DNA. This enrichment is highly significant when applied to detection methods, such as digital PCR and sequencing, and could allow for more accurate testing results earlier in the pregnancy than are currently available. Development is in progress to further enhance the enrichment and automate this TruTip application on the Hamilton liquid handling system for efficient, higher throughput processing.

Prenatal detection of a supernumerary dicentric chromosome 15 through cytogenetics and array CGH after fetal ultrasound findings of micrognathia and small stomach bubble. *J.L. Giordano, MS, L. Cohen, MD, MPH, V. Pulijaal, PhD, S. Gelber, MD, PhD.* Division of Human Genetics, Weill Cornell/NYP, New York, NY.

Array Comparative Genomic Hybridization (array CGH) is increasingly used in the prenatal setting to detect unbalanced chromosomal abberations in patients with abnormal ultrasound findings.A 35-year prima gravida had a routine fetal anatomy survey at 19+ weeks which suggested micrognathia and a small stomach bubble. There was normal growth, normal AFI, and no other anomalies noted. The sequential screening was within the normal limits. Pregnancy history was significant for IVF conception with ICSI using banked sperm given partner's history of Hodgkins lymphoma. Conventional cytogenetic analysis of amniotic fluid cells revealed an abnormal female karyotype with a supernumerary bisatellited marker chromosome. FISH analysis determined the marker was composed of chromosome 15 and included the Prader-Willi/Angelman critical region: 47,XX,+mar.ish idic(15)(q12)(D15Z1++,SNRPN+,PML-). Further characterization of the marker chromosome by whole genome oligonucleotide microarray confirmed a complex rearrangement consisting of a 5.70 Mb two-copy gain from the centromere of chromosome 15 to 15q13.1, comprising 39 genes including SNRPN and UBE3A, and a 1.96 Mb single copy gain, containing at least 19 genes:arr 15q11.2q13.1(20,410,890-26,106,556)x4,15q13.1q13.2(26,180,806-28,138,979)x3. Parental karyotypes were normal. This finding in the fetal DNA was consistent with a well-described idic (15) syndrome which is characterized by developmental delay and intellectual disability of moderate to profound degree, autistic behavior, epilepsy, early hypotonia, and some mild dysmorphic features. The family subsequently terminated the pregnancy after 21 weeks. While the idic(15) syndrome has been well described, this is the first report in which ascertainment occurred due to an ultrasound finding of micrognathia and a small stomach bubble. Accurate clinical interpretation of abnormal prenatal ultrasound findings requires comprehensive assessment and testing. This case illustrates the importance of using both conventional cytogenetics and aCGH to uncover atypical findings and provide information on the clinical heterogeneity of known genomic aberrations. Diagnostic information from prenatal aCGH earlier in pregnancy may improve genetic counseling and help parents make informed decisions.

Prenatal Diagnosis and Fetal Autopsy Findings in Aicardi syndrome. *M.C. Injeyan[1], I. Miron[1], P. Shannon[2], A. Malinowski[3], S. Blaser[4], D. Chitayat[1,3,5].* 1) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Canada; 2) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, Canada; 3) Department of Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, Canada; 4) Department of Diagnostic Imaging, Division of Neuroradioloy, The Hospital for Sick Children, Toronto, ON, Canada; 5) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, University of Toronto, Toronto, Canada.

Aicardi syndrome is a neurodevelopmental disorder purported to have an X-linked dominant mode of inheritance. The causative gene on the X chromosome has not been identified and diagnosis is based solely on clinical features. This disorder has been classically characterized by a triad of infantile spasms, agenesis of corpus callosum (ACC), and distinctive chorioretinal lacunae. Largely due to improved imaging techniques a number of additional cerebral features have been described, which together likely represent a specific malformation complex. Features include cortical abnormalities with heterotopias, cystic lesions, optic nerve hypoplasia, and hemispheric asymmetry. Patients with Aicardi syndrome may also have costovertebral anomalies, embryonic tumors and eye abnormalities such as colobomas. We report on a patient presenting at 19 weeks gestation with fetal ultrasound findings of a interhemispheric cystic structure in the region of the cavum septum pellucidum and third ventricle. Follow-up ultrasound at 21 weeks gestation showed ACC and one or more interhemispheric cerebral cysts. Fetal MRI performed at 24 weeks gestation found complete ACC, left cortical dysplasia, periventricular heterotopia, and an interhemispheric cyst. Amniocentesis was done and aCGH was normal and female. The couple elected to interrupt the pregnancy via induction of delivery. Autopsy showed a 27 week gestation female infant with ACC, interhemispheric cystic mass arising from tela choroidea, nodular periventricular and subcortical heterotopias, and abnormal cerebral gyration. The eyes showed numerous chorioretinal defects with absence of pigmentation of the overlying pigment epithelium, staphylomas and retinal dysplasia. X-rays showed T10 sagittal clefting, T7 wedged vertebral body and abnormal facies with flattened midface, prominent infraorbital creases, upturned nose, microstomia, and micrognathia. This constellation of cerebral, ocular and vertebral abnormalities was consistent with Aicardi syndrome. Prenatal diagnosis of ACC is a counselling challenge as the prognosis ranges between normal development to severe delay. A diagnosis of Aicardi syndrome may impact reproductive decision making due to low recurrence risk. Since the fetal ultrasounds/MRI findings are not specific, an autopsy including eye histopathology should be performed if the pregnancy is interrupted and ophthalmological examination should be done postnatally if parents decide to continue the pregnancy.

High-Throughput Massively Parallel Sequencing for Fetal Aneuploidy Detection from Maternal Plasma. *T.J. Jensen[1], T. Zwiefelhofer[1], R.C. Tim[1], Z. Dzakula[1], S.K. Kim[1], A.R. Mazloom[1], G. McLennan[2], C. Deciu[1], D. van den Boom[2], M. Ehrich[2].* 1) Research and Development, Sequenom Center for Molecular Medicine, San Diego, CA; 2) Research and Development, Sequenom Inc., San Diego, CA.

Background: Circulating cell-free fetal (ccff) DNA comprises 3–20% of all cell-free DNA present in maternal plasma. Numerous research and clinical studies have described the analysis of ccff DNA using next generation sequencing for detecting fetal aneuploidies with greater than 99% sensitivity and specificity. We sought to extend these studies using semi-automated library preparation, higher multiplexing during sequencing, and improved bioinformatics tools. This will enable a higher throughput and a more cost effective assay while maintaining optimal clinical performance. **Methods:** We performed initial studies to determine technical feasibility using an increased multiplexing level as well as a semi-automated library preparation method, following the processing of more than 3,000 maternal plasma samples. Subsequently,these processes were combined and we performed a clinical evaluation for detection of fetal aneuploidy using 1,269 samples and incorporating improved bioinformatic procedures for classification of fetal aneuploidy status. **Results:** Of the 1,269 clinical samples, 1,093 were confirmed by fetal karyotype analysis to be from a euploid fetus and 176 were confirmed to be from an aneuploid fetus (trisomy 21 = 134 cases; trisomy 18 = 36 cases; and trisomy 13 = 6 cases). Detection rates were 100% for all aneuploid cases. False positive rates were .08%, 0%, and .08% for trisomy 21, 18, and 13, respectively. **Conclusions:** These data suggest that increased multiplexing and semi-automated DNA library preparation methods in concert with improved bioinformatic procedures enable higher sample throughput without adversely impacting fetal aneuploid classification accuracy.

Isolation of selected, single chromosomes from the isolated circulating fetal cells for clonal expansion, molecular profiling, and next generation sequencing. *M. Malecki[1,2,4], R. Malecki[2,3].* 1) Phoenix Biomolecular Engineering Foundation, San Francisco, CA, USA; 2) Western University of Health Sciences, Pomona, CA, USA; 3) San Francisco State University, San Francisco, CA, USA; 4) University of Wisconsin, Madison, WI, USA.

Introduction. Circulating fetal cells (CFCs) present in the maternal circulation carry a great potential for diagnosis of genetic disorders, as well as for regenerative therapy after their clonal expansion. Although, their low concentrations - at 1 fetal cell per 10^7 maternal blood cells - makes them difficult to obtain through negative selection. The specific aim of this work was genetic engineering of the superparamagnetic and fluorescent, single chain variable fragments targeting the fetal cells, which would allow us to isolate circulating fetal cells. **Methods.** We have recently developed effective methods, including superparamagnetic and fluorescent chromosome-specific probes for isolating single chromosomes. We also engineered, based upon the cDNA library, the cell surface receptor targeting superparamagnetic and fluorescent scFvs (EGFR, TfR, SSEA-3 & 4, TRA-1-60 & -1-81) for isolating the selected cells [1]. For this study, we used these novel approaches of biomolecular engineering to generate the scFv targeting OSMR and COL1 proteins, which are present exclusively on fetal cells, but not on maternal cells [2].**Results.** With the native immunoblotting and fluorescence confocal, we demonstrated the high specificity of the scFv generated by biomolecular engineering. These scFvs allowed us to capture the fetal and stem cells with the FACS and MACS, as well as analyze them with FCM, XRF, and NMR. With the liquid phase FISH, we demonstrated the specificity of the engineered chromosome-specific probes (CSPs). Superparamagnetic and fluorescent properties of these CSPs allowed us to isolate single, selected chromosomes from single fetal cells. This followed by WCA and sequencing. **Conclusion.** The scFvs and probes generated by biomolecular engineering in this project create the solid foundations for prenatal diagnosis through molecular profiling of the circulating fetal cells. **Bibliography.** [1]. Noninvasive prenatal sex determination using massively parallel sequencing in samples from a large clinical validation study. *P. Oeth[1], A. Mazloom[1], T. Wang[1], G.E. Palomaki[3], J.A. Canick[3], A. Bombard[2], D. van den Boom[2], M. Ehrich[2], C. Deciu[1].* 1) Sequenom Center for Molecular Medicine, San Diego, CA; 2) Sequenom, Inc., San Diego, CA; 3) Women & Infants Hospital, Alpert Medical School of Brown University, Providence, RI.

Background: Early determination of fetal sex can be an important aspect of diagnosing and treating congenital X-linked disorders in the fetus including: hemophilia, X-linked mental retardation, Duchenne muscular dystrophy and congenital adrenal hyperplasia (where prenatal treatment of the female fetus can minimize or prevent virilization early in pregnancy). The current standard for fetal sex determination involves karyotyping of samples obtained via an invasive procedure (chorionic villus sampling or amniocentesis), which pose some risk of fetal loss. An equally accurate, but noninvasive approach is desirable. Many studies have demonstrated that noninvasive fetal sex determination using circulating cell-free DNA (ccfDNA) is highly accurate when using PCR-based assays or sequencing technologies. However, none have been conducted on a large clinical cohort. Materials and Methods: Plasma samples for the training cohort (Training Cohort) were part of a nested case-control study of pregnant women at high risk for fetal aneuploidy, collected between 10.5 and 20 gestational weeks (Palomaki, et al. GiM, 2011). Sequencing reads from a randomly selected subset of 1242 pregnancies, 623 male and 619 female fetuses, allowed for optimization of the classification algorithm based on normalized sequencing counts for select regions of the Y-chromosome. An independent blinded clinical validation cohort (Validation Cohort) consisting of another 397 samples was then tested (210 male and 187 female fetuses) using the Training Cohort classification algorithm. Results: The Training Cohort yielded a karyotype concordance rate of 99.4% (95% CI: 98.9–99.7%); eight discordant calls on 5 male and 3 female samples were made, respectively. The Validation Cohort yielded a karyotype concordance of 100% (95% CI: 99.0–100.0%). The combined concordance of all samples in both cohorts was 99.5% (95% CI: 99.0–99.8%) with a total of eight discordant classifications based on reported karyotypes. Conclusion: Noninvasive fetal sex determination using massively parallel sequencing on ccfDNA purified from maternal plasma demonstrated a high predictive rate compared to the reported karyotype in these clinical cohorts. This noninvasive molecular karyotyping methodology correctly classifies fetal sex for at least 99% of samples tested and can aid in the detection and management of inherited congenital sex-linked, X-linked, and autosomal recessive genetic disorders of the fetus.

MeDIP real time qPCR of maternal peripheral blood reliably identifies trisomy 21. *P. Patsalis[1], E. Tsaliki[1,2,3], C. Spyrou[2], G. Koumbaris[1,2], E. Kypri[2], S. Kyriakou[2], C. Sotiriou[2], E. Touvana[2], A. Keravnou[2], A. Karagrigoriou[4], K. Lamnissou[3], V. Velissariou[5], C. Sismani[1], E.A. Papageorgiou[1,2].* 1) Cytogenetics & Genomics, Cyprus Inst Neurology Gen, Nicosia, Cyprus; 2) NIPD Genetics Ltd, P.O.Box 27954, 2434, Nicosia, Cyprus; 3) Department of Genetics and Biotechnology, Faculty of Biology, School of Science, National and Kapodistrian University of Athens, Panepistimiopolis, 15771, Ilissia, Athens, Greece; 4) Department of Mathematics and Statistics, University of Cyprus, P.O. Box 20537, Nicosia, Cyprus; 5) Department of Genetics and Molecular Biology, Mitera Hospital, 15123, Athens, Greece.

Objective: One of the most promising technologies for non-invasive prenatal diagnostic (NIPD) of trisomy 21 is the application of the Methylated DNA Immunoprecipitation (MeDIP) real-time qPCR-based approach developed by Prof. Philippos Patsalis and his team. Thousands of Differentially Methylated Regions (DMRs) were generated and the best were used for the development and validation of the first universal non-invasive prenatal diagnosis for trisomy 21 (NIPD21), using MeDIP real-time qPCR for chromosome 21. To re-evaluate the efficiency of the 12 DMRs used in the MeDIP real time qPCR based approach, develop an improved version of the diagnostic formula and perform a larger validation study. Methods: Twelve selected DMRs were checked for CNVs in the DGV database. The DMRs located within CNVs were excluded from the analysis. One hundred and seventy five maternal peripheral blood samples were used to re-construct and evaluate the new diagnostic formula and for a larger scale blinded validation study using MeDIP real time qPCR. Results: Seven DMRs entered the final model of the prediction equation and a larger blinded validation study demonstrated 100% sensitivity and 99.2% specificity. No significant evidence for association was observed between cffDNA concentration and D value. Conclusion: MeDIP real time qPCR method for NIPD of trisomy 21 was confirmed and re-validated in a 175 samples with satisfactory results demonstrating that it is accurate and reproducible. We are currently working towards simplification of the method to become more robust and therefore easily, accurately and rapidly reproduced and adapted by other laboratories. Nevertheless, larger scale validation studies are necessary before the MeDIP real time qPCR based method could be applied in clinical practice.

3018T

Highly accurate non-invasive detection of fetal aneuploidy of chromosomes 13, 18, 21, X and Y by targeted sequencing. *M. Rabinowitz[1], G. Gemelos[1], M. Hill[1], B. Levy[2], S. McAdoo[1], M. Savage[1], Z. Demko[1].* 1) Natera, Inc., San Carlos, CA; 2) Department of Pathology and Cell Biology, Columbia, New York.

Objective: To develop a non-invasive prenatal aneuploidy test based on analysis of cell-free DNA in maternal blood that is capable of detecting all relevant whole chromosomal abnormalities of chromosomes 13, 18, 21, X and Y with high accuracy.

Materials and Methods: 176 maternal plasma samples (including 154 euploid and 22 aneuploid samples) were collected from patients at greater than 9 weeks of gestation under an institutional review board (IRB) approved protocol. Cell free DNA was isolated, and a targeted multiplex PCR amplification of 11,000 loci on 13, 18, 21, X and Y was performed. Sequencing data was analyzed using novel Parental Support (PS) technology that uses Bayesian statistics to analyze multiple copy number hypotheses and determine the Maximum likelihood a posteriori (MAP) hypothesis given the sequencing data. Unlike other reported methods, the PS method determines confidence, or estimated accuracy, for each sample. Similar confidences are produced for each of the five chromosomes, and can be incorporated into a DNA quality threshold metric to enable draws early in the pregnancy without increasing the probability of false positives or negatives.

Results: 155 samples passed a DNA quality threshold, and the PS approach yielded a call at all five chromosomes for these cases; all calls in this group were correct (775/775) including 12 trisomy 21, 3 trisomy 18, 2 trisomy 13, 1 monosomy X, and 2 XXY samples.Conclusions: The PS informatics approach is able to detect fetuses with a chromosomal abnormality from a maternal blood sample with high accuracy at chromosomes 13, 18, 21, X and Y. This method performs equally well at all chromosomes, does not require the use of a reference chromosome, and calculates a confidence call that is personalized for each sample.

Accuracy of prenatal diagnosis in elective termination of pregnancy. *J. Saraiva[1,2,3], F. Ramos[1,2], S. Maia[1], M. Branco[4], J. Raposo[5], J. Sá[1], S. Sousa[1], M. Venâncio[1,2], R. Pina[5], E. Galhano[4], L. Ramos[1].* 1) Servico Genetica Medica, Hospital Pediatrico, CHUC, Coimbra, Portugal; 2) Faculdade de Medicina da Universidade de Coimbra, Portugal; 3) Compete, Projecto PEst-C/SAU/UI3282/2011, IBILI, Coimbra, Portugal; 4) Centro de Diagnóstico Pré-natal, Maternidade Bissaya Barreto, CHUC, Coimbra, Portugal; 5) Serviço de Anatomia Patológica, Centro Hospitalar de Coimbra, CHUC, Coimbra, Portugal.

Objectives To evaluate the quality of the results of prenatal results in all cases of abortion due to fetal abnormalities. Method All 385 cases of therapeutic abortion due to fetal abnormalities recorded in a tertiary prenatal diagnosis centre from 2000 to 2007 were evaluated. Data from the prenatal results and post-mortem autopsy and genetics consultation was collected and compared regarding the abnormalities identified, the etiological diagnosis and its prognosis. The diagnosis were classified according to the etiology (Wellesley et al.) and the EUROCAT groups. Results In 81 of the 385 fetus (21%) there was full agreement between the prenatal data and the post-mortem examinations. In 81 fetus (21%) the etiologic diagnosis was changed, The results of the post-mortem examinations changed the prognosis in only 1 fetus. Conclusion In the 385 abortions due to fetal abnormalities the prenatal evaluation was excellent regarding the assessment of the prognosis as it was wrong in only 1 case. However the post-mortem examinations were useful as they identified further abnormalities in 79% and made possible a more precise or different diagnosis in 21% of the cases. [Compete, Projecto PEst-C/SAU/UI3282/2011].

Non-Invasive Chromosomal Evaluation (NICE) Study: Results of a Multicenter, Prospective, Cohort Study for Detection of Fetal Trisomy 21 and Trisomy 18. *K. Song[1], H. Brar[2], J. Weiss[3], A. Karimi[4], L.C. Laurent[5], A.B. Caughey[6], M.H. Rodriguez[7], J. Williams, III[8], M.E. Mitchell[9], C.D. Adair[10], H. Lee[11], B. Jacobsson[12], M.W. Tomlinson[13], D. Oepkes[14], D. Hollemon[1], A.B. Sparks[1], A. Oliphant[1], M.E. Norton[15], NICE Study Group.* 1) Ariosa Diagnostics, San Jose, CA; 2) Riverside Perinatal Diagnostic Center, Riverside, CA; 3) East Bay Perinatal Medical Associates, Oakland, CA; 4) Institute of Prenatal Diagnosis and Reproductive Genetics, San Gabriel, CA; 5) University of California - San Diego, San Diego, CA; 6) Oregon Health Sciences University, Portland, OR; 7) San Gabriel Valley Perinatal Medical Group, West Covina, CA; 8) Cedars-Sinai Medical Center, Los Angeles, CA; 9) Medical College of Wisconsin, Milwaukee, WI; 10) University of Tennessee, Chattanooga, TN; 11) University of California - San Francisco, San Francisco, CA; 12) Sahlgrenska University Hospital, Gothenburg, Sweden; 13) Northwest Perinatal Center, Portland, OR; 14) Leiden University Medical Centre, Leiden, Netherlands; 15) Stanford University/Lucile Packard Children's Hospital, Stanford, CA.

Background: Several groups have demonstrated in case-control studies, the ability to detect fetal trisomy 21 (T21) and trisomy 18 (T18) via analysis of cell-free DNA (cfDNA) using massively parallel DNA shotgun sequencing (MPSS). MPSS randomly analyzes cfDNA from the entire genome, resulting in higher cost and complexity than is currently practical for widespread clinical adoption. **Objective:** To evaluate performance of a directed cfDNA analysis method for detection of fetal T21 and T18. **Methods:** A multicenter, international, prospective cohort study was performed. Pregnant women of at least 10 weeks gestational age with a singleton pregnancy who underwent invasive testing for any reason were enrolled. A directed cfDNA analysis method was used to selectively analyze chromosomes 21 and 18 from maternal plasma of enrolled subjects. An algorithm was utilized that incorporated chromosomal cfDNA counts, fetal fraction, and maternal and gestational age to calculate a trisomy risk score for each sample. Samples were classified as High Risk or Low Risk for a given trisomy based on a 1 in 100 (1%) risk score cut-off. **Results:** All eligible subjects underwent analysis. Of the 81 T21 cases, all were classified as High Risk for T21 and there was one false positive among the 2888 normal cases, for a sensitivity of 100% (95% CI: 95.5–100%) and a false-positive rate of 0.03% (95% CI: 0.002–0.20%). Of the 38 T18 cases, 37 were classified as High Risk and there were 2 false positives among the 2888 normal cases, for a sensitivity of 97.4% (95% CI: 86.5%–99.9%) and a false-positive rate of 0.07% (95% CI: 0.02–0.25%). The presence of chromosomal abnormalities other than T21 or T18 did not affect the analysis of T21 or T18 risk. **Conclusions:** Directed cfDNA analysis and application of an individualized risk algorithm is an efficient and effective method for the detection of fetal T21 and T18.

3021T

Detection of fetal sub-chromosomal alterations in maternal plasma cell-free DNA (cfDNA) using massively parallel sequencing (MPS). *A. Srinivasan, X. Li, J. Sprowl, A. Huang, A. Sehnert, R. Rava.* Verinata Health, Inc., Redwood City, CA.

Objective: It has been well established that massively parallel sequencing (MPS) of cfDNA isolated from the plasma of pregnant women can be utilized to accurately detect whole chromosome fetal aneuploidies. The objective of this study is to further investigate and demonstrate detection by MPS of fetal chromosomal copy number changes at a sub-chromosomal level. Methods: To establish an algorithm to detect fetal sub-chromosomal aneuploidies, maternal-fetal DNA mixtures were generated by combining sheared genomic DNA (gDNA) from beta-lymphocytes of a child with Greig Cephalopolysyndactyl Syndrome caused by a 16 Mbp deletion in Chromosome 7 with sheared gDNA from beta-lymphocytes of the mother. Maternal-child mixtures containing 5% or 10% gDNA from the deletion sample were analyzed utilizing MPS with 36-mer sequence tags that were mapped to approximately 600 million unique sites on the hg19 build of the human genome. The sites were counted in non-overlapping 1 Mbp bins across the genome at approximately 190 thousand sites per bin. An algorithm was developed to quantitatively estimate a “fetal fraction” in each bin relative to the normalized counts from unaffected samples. Signal of the estimated fetal fraction above the background noise threshold was applied to detect amplifications or deletions at sub-chromosomal levels. The method was optimized on the prepared mixtures and then applied to clinically obtained samples from pregnant women with known fetal sub-chromosomal alterations. Results: The analyzed MPS data quantitatively identified the “fetal” 16 Mbp deletion on Chromosome 7 in the prepared maternal-child mixtures. The method was also able to detect an amplification of approximately 35 Mbp on Chromosome 6 in a clinical maternal sample where microarray data from chorionic villus sampling confirmed this finding in the fetus. Additional samples are now being tested. Conclusion: MPS data from cfDNA isolated from the plasma of pregnant women can be analyzed to detect fetal chromosomal alterations at a sub-chromosomal level and provide further karyotype information beyond whole chromosome aneuploidies.

Approach to prenatally diagnosed esophageal atresia/tracheoesophageal fistula. *B. Suskin[1,3], S. Klugman[1,3], T. Goldwaser[1,3], A. Roe[2,3], K. Bajaj[1,2,3].* 1) Obstetrics and Gynecology, Montefiore Medical Center, Bronx, NY; 2) Department of Obstetrics & Gynecology, North Bronx Health Network, Bronx, NY; 3) Albert Einstein College of Medicine, Bronx, NY.

BACKGROUND: Esophageal atresia (EA) describes a condition in which there is abnormal development of the upper gastrointestinal tract. EA can be isolated or associated with other anomalies including tracheoesophageal fistula (TEF), an abnormal connection between the esophagus and trachea. With an overall birth incidence of 1:3500 live births, only 44–56%; of cases are diagnosed prenatally. Management of prenatally diagnosed EA/TEF involves a multi-disciplinary approach. CASE: 31 year-old multiparous woman, without significant medical or family history, was found to have an appropriately grown female fetus with a small stomach at the time of anatomic survey at 19 weeks gestation. No other anomalies were seen. Subsequent sonograms, including a fetal echocardiogram, did not reveal additional structural anomalies. The patient underwent genetic counseling and opted to undergo an amniocentesis which revealed 46, XX, inv (4) (p12q21.1). The paternal karyotype demonstrated the same inversion. At 21 weeks gestation, polyhydramnios was present. The patient has been linked with an interdisciplinary team including clinical geneticists, neonatalogists and pediatric surgeons. [Patient has not yet delivered]. DISCUSSION: Esophageal atresia/tracheoesophageal fistula can be isolated or may be associated with other anomalies. When an absent or small fetal stomach is found, detailed ultrasound should be performed as up to 60% of EA's are seen with other anomalies. Thorough genetic counseling is indicated as EA can be associated with a wide range of genetic aberrations. The presence of additional anomalies and an underlying genetic etiology significantly impacts prognosis. We highlight the sonographic diagnosis of EA/TEF. Furthermore, we will also review common heritable etiologies as well as genetic counseling/management approaches to EA/TEF with an emphasis on currently available diagnostic testing.

3023T

Quantification of fetal DNA in maternal plasma by massively parallel sequencing using fetal-specific methylation markers. *M. Tang[1], J. Tynan[1], S. Sovath[1], A. Maer[1], G. Hogg[1], D. van den Boom[2], P. Oeth[1].* 1) Sequenom Center for Molecular Medicine, 3595 John Hopkins Ct., San Diego, CA 92121; 2) Sequenom, Inc., 3595 John Hopkins Ct., San Diego, CA 92121.

BACKGROUND: The presence of circulating cell-free (ccf) fetal DNA in maternal plasma allows for noninvasive prenatal diagnostic (NIPD) applications such as detection of fetal trisomies or monogenic diseases. Given the low fractional concentration of ccf fetal DNA in maternal plasma, metrics are needed to ascertain if sufficient ccf fetal DNA is present in order to accurately determine the fetal genetic status. We previously developed a MALDI-TOF Mass Spectrometry (MS) based fetal quantification assay (FQA), using fetal-specific methylation DNA markers (Nygren et. al., 2010, Clin Chem 56: 1627-35). Here we extended the FQA to its detection by massively parallel sequencing (MPS). **METHOD:** The unmethylated maternal fraction of ccf DNA was digested by methylation-sensitive restriction enzymes, and the undigested methylated fetal DNA fraction was amplified in the presence of synthetic oligonucleotides to permit competitive PCR. The amplicons were ligated to sequencing adaptors via two protocols. One directly ligated the 3' A-overhang amplicons to sequencing adaptors with 3' T-overhangs. The other utilized PCR primers containing deoxyuridine that were selectively cleaved by uracil glycosylase after PCR to generate specific overhangs, allowing sequencing adaptors to ligate with high efficiency. The resulting libraries were sequenced on HiSeq™ 2000 (Illumina, San Diego CA). Copy numbers of individual marker were calculated from the ratio of sequence reads uniquely mapped to the target regions with expected reference or competitor alleles, and fetal fraction was derived by comparing fetal DNA markers to total DNA markers. **RESULTS:** We sequenced FQA libraries from 48 maternal plasma samples. When compared to those detected by MALDI-TOF MS, copy numbers of individual markers were highly correlated (R^2>0.98), although platform-specific bias in allele ratio was observed in certain targets. Importantly, fetal fractions were consistent between MPS and MALDI-TOF MS detection. Furthermore, calculated fetal fraction did not change when FQA libraries were sequenced with other whole genome libraries in multiplex setting. **CONCLUSION:** We demonstrated feasibility of targeted sequencing of methylated DNA and its application to accurately detect fetal fraction in ccf DNA from maternal plasma. Combined sequencing of FQA and other NIPD application libraries allows NIPD test results be called with higher confidence.

Curated gene set outperforms GWAS Data on Pathway-Based Genetic Analysis. *J. Padbury[1,2], A. Uzun[1,2], A. Dewan[3], S. Istrail[2].* 1) Pediatrics, Women & Infants Hospital, Providence, RI; 2) Brown University, Providence, RI; 3) Yale University, New Haven, CT.

Genome-wide association studies (GWAS) have the potential of identifying novel genetic variants. They have become a popular approach to the investigation of complex diseases but they have had only a measured success. Complex mechanisms of gene-gene interactions underlie the pathogenesis of most complex diseases. We are interested in the genetic contribution(s) to preterm birth. Preterm birth is an important, poorly understood clinical problem. The incidence of preterm birth (PTB) in the United States is now 12.7%. Multiple genes, gene networks and variants have been associated with PTB. Simple patterns of inheritance are not sufficient enough to explain the pathogenesis of the majority of preterm births. We have developed an approach for identifying a parsimonious set of candidate genes for the study of preterm birth validated by a priori biological information. We took the genes involved in preterm birth from the published literature and from available expression arrays. In addition to these initial steps we included pathway analysis to impute additional genes likely to be involved in these pathways. Results from a genome-wide study of preterm birth, “GENEVA,” became available in dbGAP. The dataset includes phenotypic information (i.e. gestational age) and complete genotype data on nearly 4000 patients. We used our curated set of genes to analyze the GENEVA dataset. The results of the refined candidate genes were further analyzed by gene set enrichment analysis. We identified a total of 30 pathways with high confidence values (FDR<0.05) based on our curated set of genes. From a whole genome based pathway analysis 39 pathways with high confidence were identified. There were 17 shared pathways which were significant and the analysis based on curated genes showed greater significance in 15 out of the 17 shared pathways. Interestingly, most of the pathways involving inflammation were either shared or identified only by curated set of genes based pathway analysis. In conclusion the curated set of genes gave much stronger associations than the genome wide analysis in all but a few of these pathways. These results provide important confirmation of the role of genetic architecture in the risk of preterm birth. The results of the pathway analysis show highly significant associations and suggest several, important mechanistic implications.

3025T

Analysis of etiology and complications among 1,128, including 493 iatrogenic and 635 spontaneous, Chinese preterm births. *M. Xiao[1], W. Ren[1], N. Zhong[2].* 1) Dept. Obstetrics, Hubei Provincial Maternal and Children's Hospital, Wuhan, Hubei, China; 2) New York State Institute for Basic Research in Developmental Disabilities.

Objective: To investigate the singleton iatrogenic preterm birth and perinatal outcome. Methods: To retrospectively, from January 2007 to December 2011, analyze the etiology of iatrogenic preterm birth, which is compared to that of singleton spontaneous preterm birth, and to analyze the mode of delivery and perinatal outcome. A total number of 493 iatrogenic preterm births versus 635 cases of singleton spontaneous preterm birth in the same period were studied. Results: The etiology for the 493 cases of iatrogenic preterm birth studied is in an order of placenta previa (n=169, 34.3%), hypertensive disorders in pregnancy (n=152, 30.8%), intrahepatic cholestasis of pregnancy (n=74, 15%), placental abruption (n=47, 9.5%), fetal distress (n=35, 7.1%), and oligohydramnios (n=16, 3.2%). Compared to the singleton spontaneous preterm birth, the following rate among singleton iatrogenic preterm births was significantly ($p<0.05$ to $p<0.001$) increased: cesarean section (99.2% versus 11.7%), neonatal mortality (2.6% versus 0.9%), neonatal asphyxia (13.6% versus 6.8%), aspiration pneumonia (27.8% versus 15.4%),and neonatal respiratory distress syndrome (13.6% versus 6.8%). No statistical difference ($p>0.05$) was found in the rate of neonatal necrotizing enterocolitis (3.9% versus 3.6%) and of neonatal jaundice (44.4% versus 36.5%). Conclusion: iatrogenic preterm births is a severe condition that influences maternal and infant health. Active prevention and intervention of maternal health condition may have an important impact on the perinatal outcome.

Admixture Mapping Identifies Susceptibility Loci Associated with Preterm Birth in African Americans. *H. Tsai[1,2], X. Liu[1,3], X. Hong[4], G. Wang[4], T. Chang[2], Q. Chen[1], C. Pearson[5], D. Caruso[4], L. Heffner[6], B. Zuckerman[5], X. Wang[4].* 1) Dept Pediatrics, Northwestern Univ Sch Med, Chicago, IL, USA; 2) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Taiwan; 3) Department of Preventive Medicine, Feinberg School of Medicine, Northwestern University; Chicago, IL, USA; 4) Center on the Childhood Origins of Disease, Department of Population, Family and Reproductive Health, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA; 5) Department of Pediatrics, Boston University School of Medicine and Boston Medical Center, Boston, MA, USA; 6) Department of Obstetrics and Gynecology, Boston University School of Medicine and Boston Medical Center, Boston, MA, USA.

Objectives: Remarkable ethnic disparities have long been observed in preterm birth (PTB), particularly between African Americans (17.8%) and European Americans (11.5%). We screened and identified genomic regions associated with PTB using admixture mapping methods in 1,106 African American women among PTB cases and term controls. In addition, we also explored susceptibility loci associated with PTB subgroups, specifically spontaneous PTB. Methods: A total of 1,106 African American women were genotyped using the Illumina African American Panel, consisted of 1,509 ancestry informative markers. We performed admixture mapping analysis using the statistical methods implemented in the ANCESTRYMAP program. Results: The highest peak was observed on rs4782812 locating on the chromosomal region of 16q23.3 for PTB (LOD score = 1.80) and for spontaneous PTB (LOD score = 1.78), respectively. In addition, the chromosomal region of 7q22 with LOD score equal to 1.66 was observed in PTB. Fourteen known genes were found within the 7q22.1 region, including 2 genes, PDGFA (platelet-derived growth factor alpha polypeptide) associated protein 1 and ATP synthase, H+ transporting, mitochondrial Fo complex, subunit F2, which are potentially functional relevant to PTB. Similarly, fifteen known genes were found within the 16q23.3 region, including ATPase, Ca++ transporting, type 2C, member 2 and oxidative stress induced growth inhibitor 1, which are potentially functionally-associated with PTB. Conclusion: Our findings suggest that potential novel PTB related disease genes reside within the identified peak regions (7q22.1 and 16q23.3, respectively) in the inner-city study population. Further investigation of these promising regions, including fine-mapping and sequencing, is warranted.

3027T

Single Nucleotide Polymorphism in Toll-Like Receptor 6 is Associated with Risk for *Ureaplasma* Respiratory Tract Colonization and Bronchopulmonary Dysplasia in Preterm Infants. *A.H. Winters[1], T.D. LeVan[5,6], S.N. Vogel[2], K.L. Chesko[3], T.I. Pollin[1,4], R.M. Viscardi[3].* 1) Human Genetics, University of Maryland, Baltimore, Baltimore, MD; 2) Microbiology and Immunology, University of Maryland, Baltimore, Baltimore, MD; 3) Pediatrics, University of Maryland, Baltimore, Baltimore, MD; 4) Endocrinology, Diabetes and Nutrition, University of Maryland, Baltimore, Baltimore, MD; 5) Departments of Internal Medicine/Pulmonary and Epidemiology Nebraska Medical Center, Omaha, NE; 6) VA Nebraska-Western Iowa Health Care System Research Service, Dept. of Veterans Affairs Medical Center, Omaha, NE.

Introduction: Respiratory colonization with the genital mycoplasmas *Ureaplasma parvum* and *U. urealyticum* is associated with pulmonary inflammation and an increased risk for the chronic lung condition bronchopulmonary dysplasia (BPD) in preterm infants. We hypothesized that variants in genes regulating the inflammatory response, including toll-like receptors (TLRs), are associated with altered risk for *Ureaplasma* respiratory colonization and BPD. *Ureaplasma* is known to bind to TLRs, specifically heterodimers of TLR2 with TLR1 or TLR6, and cause downstream activation of the transcription factor NF-κB and upregulation of gene expression of pro-inflammatory mediators. *Methods:* 35 common SNPs from *CD14, IL6, IL8, MyD88, NOD2, TLR1, TLR2, TLR4,* and *TLR6* were assayed in 254 preterm infants <33 weeks gestation cultured for *Ureaplasma* species and evaluated for BPD. The majority of subjects (N=191[75%]) were African-American, and the remaining subjects were non-Hispanic Caucasian (N=63 [25%]). *Results:* SNPs in *NOD2* (rs2066844, OR=7.3 [1.46–36.52], total sample), *TLR2* (rs1439164, OR=3.7 [1.32–10.04] and rs3804099, OR=0.42 [0.18–0.96], non-Hispanic Caucasians), and *TLR6* (rs5743827, OR=0.54 [0.34–0.86], total sample and OR=0.55 [0.32–0.95], African-Americans; rs5743788, OR= 2.68 [1.11–6.43], non-Hispanic Caucasians) were significantly associated with *Ureaplasma* respiratory tract colonization. SNPs in *CD14, IL-8,* and *TLRs 2, 4,* and *6* were associated with BPD. *TLR6* SNP rs5743827 was associated with both *Ureaplasma* respiratory tract colonization and BPD, and there was evidence of an interaction between genotype and*Ureaplasma* colonization. Compared to infants without either risk factor, infants with both the risk genotype (GG) at rs5743827 and *Ureaplasma* colonization have a greater increased odds of BPD (OR=3.46 [1.58–7.61]) than would be expected from addition of the risks of genotype and *Ureaplasma* colonization (OR=1.33 [0.61–2.94] and OR=1.26 [0.46–3.45] respectively).*Discussion:* Polymorphisms in host defense genes may alter susceptibility to *Ureaplasma* infection and severity of the inflammatory response, which contributes to BPD. Specifically, the GG genotype at *TLR6* SNP rs5743827 was associated both with increased risk for *Ureaplasma* respiratory tract colonization and with BPD, particularly in *Ureaplasma*-colonized infants. These observations implicate host genetic susceptibility as a major factor in BPD pathogenesis in *Ureaplasma*-infected preterm births.

3028T

Genome-wide association study of preterm delivery in mothers. *F. Geller[1], B. Feenstra[1], M. Melbye[1], R. Myhre[2], S. Myking[2], The Early Growth Genetics Consort.[3], T. I. A. Sørensen[4], P. Magnus[2], M. L. Marazita[5], J. C. Murray[6], B. Jacobsson[2].* 1) Statens Serum Institut, Copenhagen, Denmark; 2) Norwegian Institute of Public Health, Oslo, Norway; 3) c/o M. McCarthy, Wellcome Trust Centre for Human Genetics, Oxford, UK; 4) Copenhagen University Hospital, Copenhagen, Denmark; 5) University of Pittsburgh, PA; 6) University of Iowa, IA.

Preterm delivery is a condition that puts mother and child at risk, additionally to the possible perinatal complications long term developmental problems are frequently observed. Based on two genome-wide association studies from Denmark and Norway, each starting out with 1,000 mothers with preterm delivery and 1,000 control mothers with term delivery, we tried to replicate SNPs with p-values below 0.0001 in additional cohorts of European descent from the Early Growth Genetics Consortium. We investigate five different phenotypes, preterm delivery (all deliveries before 37 weeks of gestation), premature rupture of membranes, spontaneous preterm labor without rupture of membranes, early preterm delivery (before gestational week 34), and gestational age as a quantitative trait. So far four additional cohorts have provided results based on more than 10,000 individuals. Preliminary results suggest that genetic regions relevant for fasting glucose levels, age at menarche and growth also play a role in preterm delivery.

3029T

Evidence of SNP variation in the folic acid metabolic pathway associates with preterm birth (PTB). *Y. Chen[1], B-J. Wang[1], M-J. Liu[1], Y. Wang[1], J. Mao[1], S-N. Wang[1], J-R. Dai[1], H. Li[1], N. Zhong[2].* 1) Ctr Reproduction and Genetics, Suzhou Municipal Hospital, Suzhou, Jiangsu, China; 2) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Preterm birth (PTB; birth before 37 weeks in humans) is one of the most common conditions in perinatal health. It is the leading cause for neonatal death. The rate of PTB is increasing globally. Presently, the etiology and pathogenesis are yet unclear. It has been proposed that metabolism of folic acid might have some pathophysiological role in the PTB and outcome of related pregnancy. We hypothesize that the genetic variation of folic acid metabolism may associate with PTB. To test which, a subset of single nucleotide polymorphisms (SNPs), selected from 12 genes/loci involved in the folic metabolic pathway, were subjected to SNaPshot analysis in a case-control study. Fourteen SNPs (CBS-C699T, DHFR-c594+59del19, FOLH1-T1561C, GST01-C428T, MTHFD1-G878A, MTHFD-G1958A, MTHFR-A1298C, MTHFD-C677T, MTR-A2756G, MTRR-A66G, NAT1-C1095A, NFE2L2-ins1+C11108T, RFC1-G80A, SHMT1-C1420T, TCN2-C776G and TYMS-1494del6) were simultaneously tested, within a single PCR reaction, among 527 DNA samples that include 340 from PTBs and 187 controls. Four SNPs from this subset of loci were found to associate with PTBs, with a p value significantly less than 0.05 to less than 0.001. Our study demonstrate that a panel of SNP variations related to the folic acid metabolism pathway could be screened through a flexible, fast and inexpensive procedure with a purpose of analyzing their association to PTB, as we described elsewhere. In addition to the fact that folic acid metabolism pathway is associated with birth defects including neural tube defects and congenital heart diseases, we further provided evidence here that SNP variations may also associate with PTB. Testing with a larger sample size of PTBs and controls are underway to validate the potential application that these loci may be applied as a clinical biomarker for prenatal screening for risk of PTB in a longitudinal cohort study.

Investigation of genetic risk factors for chronic adult diseases in preterm birth. *N. Falah[1], J. McElroy[1], V. Snegovskikh[2], C. Lockwood[2], E. Kuczynski[2], E. Norwitz[2], J. Murray[3], R. Menon[4], K. Teramo[5], L. Muglia[1], T. Morgan[1].* 1) Pediatrics, Div Med Gen & Genomic Med, Vanderbilt Univ, Nashville, TN; 2) Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT; 3) University of Iowa; 4) The Perinatal Research Center, Nashville, TN; 5) Departments of Obstetrics and Gynecology, University of Helsinki, Helsinki, Finland,.

Background: Preterm birth (PTB) is the leading cause of infant mortality. The putative pathogenetic pathways of preterm birth overlap with those of adult cardiovascular, immune and metabolic disorders (CIMD), with common mechanisms including inflammation, immunotolerance, thrombosis, and nutrient metabolism. Whereas many genetic factors for CIMD have been identified, progress in PTB has lagged behind. We hypothesized that highly validated genetic risk factors for CIMD (P < 1 × 10-30) may also be associated with PTB, via pleiotropic effects. Result: Case-control study of women with spontaneous preterm delivery (n=673) versus term delivery (n=1119). There were four diverse cohorts (US White, US African-American, US Hispanic, and Finnish). Of 35 independent SNPs genotyped, there were 13 statistically significant associations (P < 0.05), which was more than expected (binomial test; P = 0.02). In US White mothers (307 cases/342 controls), the G allele of HLA-DQA1 (A/G) rs9272346 was protective for PTB in the initial discovery cohort (P = 0.02; OR = 0.65; 95% CI: 0.46, 0.94). This protective association replicated (P = 0.02; OR=0.85(95% CI; 075- 0.97) nominally in the Danish National Birth Cohort (883 cases, 959 controls), but lost significance upon multiple testing correction. Conclusion: We observed more statistically significant associations between CIMD-related genetic risk variants and PTB than expected, suggesting that chance is an unlikely explanation for one or more of the associations. In particular, a protective association of the G allele of HLA-DQA1 was found in two independent cohorts of mothers, and in previous studies, this same allele was found to protect against type I diabetes (meta-analysis P value 5.52 × 10-219). Previous investigations have implicated HLA phenotypic variation in recurrent fetal loss as well as in chronic chorioamnionitis. Given the limited sample size in the present study, we suggest larger studies to further investigate possible HLA genetic involvement in PTB.

Maternal SNPs in the p53 pathway: risk factors for aneuploidy 21? *A.P.C. Brandalize[1, 2, 3], J.A. Boquett[1, 2, 3], L.R. Fraga[1, 2, 3], L. Schuller-Faccini[1, 2, 3].* 1) Genetics, UFRGS, Porto Alegre, Rio Grande do Sul, Brazil; 2) Instituto de Genética Médica Populacional, INAGEMP, Rio Grande do Sul, Brazil; 3) Programa de Pós-Graduação em Genética e Biologia Molecular, UFRGS, Porto Alegre, Rio Grande do Sul, Brazil.

p53 family and its regulatory pathway play an important role as regulators of developmental processes, limiting the propagation of aneuploid cells. Its dysfunction or imbalance can lead to pathological abnormalities in humans. Our working hypothesis was based on two evidences: 1) The loss of p53 function or genes that regulate this metabolic pathway may be related to the accumulation of aneuploid cells and then decrease the action of apoptotic mechanisms that would eliminate aneuploid embryos in women with wild alleles, increasing the risk of DS in women with these polymorphisms and; 2) Loss of p73 function due to polymorphisms in its encoding gene may interfere in the control of the meiotic spindle during oogenesis, increasing the risk of aneuploidy in the offspring. Based on these hypothesis we analyzed through real time PCR (using taqman probes) the role of TP53 R72P polymorphism (rs1042522), TP73 G4A (rs2273953) and C14T (rs1801173), MDM2 SNP309 (rs2279744), MDM4 T>C in intron 9 (rs1563828) and USP7 G>A in intron 25 (rs1529916) as maternal risk factors for 21 aneuploidy. A case-control study was conducted with 263 mothers of DS children and 196 control mothers. The distribution of these genotypic variants was similar between case and control mothers. However, the combined alleles TP53 C and MDM2 G, and TP53 C and USP7 A increased the risk of having offspring with DS (OR = 1.84 and 1.77; P < 0.007 and 0.018, respectively). These results indicate a synergistic effect between genes that act in the same pathway in a multifactorial way. The allele P72 reduces the efficiency of p53 to induce apoptosis. The G allele increases the expression of MDM2, degrading more p53 and negatively influencing the induction of apoptosis as well. It is known that a large amount of p53 protein is produced by the human placenta in abnormal pregnancies, so p53 can be an important factor in the pathogenesis of diseases through the induction of throphoblast apoptosis. The interaction of these polymorphisms could decrease the levels of the pro-apoptotic p53 protein, making it less functional in response to cell damage. As a consequence, the reaction would be attenuated by trophoblastic apoptosis and promote greater tolerance of aneuploidy. This work is the first to establish a relationship between polymorphisms in the TP53 gene family and its regulatory pathway as risk factor for aneuploidy of 21. Future studies in other populations should be conducted to confirm our findings.

3032T

Disomy 21 mosaicism in sperm. *E. Iwarsson[1], U. Kvist[2], M.A. Hultén[1,3].* 1) Dept of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden; 2) Centre for Andrology and Sexual Medicine, Karolinska University Hospital Huddinge, Stockholm, Sweden; 3) Warwick Medical School, University of Warwick, United Kingdom.

The mechanism underlying the low paternal origin of trisomy 21 Down syndrome (less than 10%) is still unknown. To elucidate this question we have now initiated fluorescent in situ hybridisation (FISH) studies to record the copy number of chromosome 21 at different stages of spermatogenesis. We here present data on the incidence of disomy 21 sperm mosaicism by FISH analysis in a sample of 11 men with normal spermiograms. Due to the risk of false positive and false negative signals using a single FISH probe we have applied two chromosome 21q probes. We review previous published work on the incidence of disomy 21 in sperm samples and conclude that all previous studies in this respect have been applying a single chromosome 21 probe only. Thus, our study is the first using more than one probe on chromosome 21 for the reliable establishment of disomy 21 in sperm. The average incidence of chromosome 21 disomy in the sperm samples from our cohort of 11 men was 0.13%, with a range of 0.00%–0.25%. On this score we may therefore expect around 1 per 1000 conceptions to be trisomic for chromosome 21 of paternal origin.

3033T

DiGeorge sequence due to uncontrolled maternal gestational diabetes. *A. Ludtke[1], T. Mucci[2], M. Aquino[2], E. Graber[3], L. Mehta[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Department of Allergy/Immunology, Winthrop University Hospital, New York, NY; 3) Pediatric Endocrinology and Diabetes, Mount Sinai School of Medicine, New York, NY.

DiGeorge syndrome is commonly defined by the presence of congenital heart defect, absent or hypoplastic thymus with immune deficiency and hypocalcemia due to hypoplastic or absent parathyroid glands. Additional features include craniofacial abnormalities such as velopharyngeal incompetence, facial dysmorphism, skeletal abnormalities, growth retardation, learning difficulty, and renal anomalies. The etiology of DiGeorge syndrome is heterogeneous, with 90 percent of cases due to microdeletion of chromosome 22q11.2 and rarely of chromosome 10p13. Non-genetic factors causing features of DiGeorge syndrome, referred to as DiGeorge sequence or anomaly, include fetal exposure to teratogens such as alcohol, Vitamin A, or maternal diabetes. We report a female infant delivered to a 26 year old mother with uncontrolled insulin dependent diabetes, who was non compliant with prenatal care. The infant was large for gestational age, with birth weight of 4.08kg and typical appearance of an infant of diabetic mother. She developed persistent hypocalcemia and was flagged by positive newborn screen for SCID. Evaluation revealed absent thymus. Lymphocyte panel revealed no T-lymphocytes but normal numbers of NK cells and elevated B cells. Cardiology evaluation showed no structural heart defect, but biventricular hypertrophy and PDA, both of which resolved at 2 weeks age. In addition, the infant had rib and vertebral anomalies. Chromosome analysis and FISH to detect a chromosome 22q11 deletion was unsuccessful due to absence of T cell lymphocytes. Array CGH was performed with a normal result. In the absence of 22q11 and 10p13 deletion, uncontrolled maternal diabetes was the most likely cause of these abnormalities. The increased risk of congenital malformations in infants of diabetic mothers is well documented. In particular, heart defects such as truncus arteriosus, caudal dysplasia, renal and musculoskeletal findings are well described with several reports of DiGeorge syndrome spectrum of branchial arch abnormalities. At least 9 individuals with DiGeorge anomaly including thymic aplasia are reported in association with maternal diabetes. Particularly noted in these cases is the associated presence of cardiac and renal defects. The mechanism by which maternal hyperglycemia causes birth defects is ill understood but is likely to be complex. Early and rigorous control of hyperglycemia is an important public health measure to prevent the occurrence of serious birth defects.

3034T

Investigation of telomere length in new newborns and correlation with gestation age and birthweight. *E.C. Tan[1], S.N. Lim[2], Z. Yahya[2], D. Zeegers[2], T. Moe[3], E.E.P. Kyaw[3], G.S.H. Yeo[3], M.P. Hande[2].* 1) KK Research Ctr, KK Women's & Children's Hospital, Singapore; 2) Department of Physiology, National University of Singapore; 3) Maternal-fetal Medicine, KK Women's & Children's Hospital, Singapore.

Telomeres are critical for genomic stability; they provide a means for chromosome replication and become shorter with each cell division. Telomere length appears to be a predictor of organismal fitness in the human population. Although there is some inter-individual variation in telomere length, shorter telomeres are associated with increased risk of some cancers and cardiovascular disorders. As there are only a few small studies on telomere lengths in newborns, we investigated the variability for newborns of different birthweight and gestation age in our hospital. Cord blood from births with Chinese parents was collected at delivery. Data was also collected on birthweight, gestation age, and mother's age. Terminal restriction fragment (TRF) assay was performed on genomic DNA extracted from whole blood to measure the telomere length of each sample. Variance analyses and correlation coefficients were calculated using SPSS. All study variables have normal distribution. The birthweight of the newborns in the study ranged from 2.2 kg to 4.2 kg with gestation age from 245 to 288 days. There was statistically significant correlation between mother's age with gestation age, and between birthweight and gestation age. Telomere length from 134 samples (68 males, 66 females) showed a wide range from 8.2 kb to 19.2 kb. The mean TRF length was 12.6 kb (males: 12.3 kb ± 2.6; females: 13.1 kb ± 2.4). Overall, there was marginal correlation of telomere length with gestation age with increased significance after controlling for maternal age. For males, the correlation was highly significant (r: -0.349; p: 0.004). This correlation of telomere length with gestation age is likely due to the result of telomere attrition in utero with increased growth.

A Case of Arthrogryposis and Mosaic Turner Syndrome. *L. Mora, A. Lopez, I. Zarante.* Instituto de Genética Humana, PontificiaUniversidad Javeriana, Bogotá, Colombia.

Arthrogryposis Multiplex Congenital is a heterogeneous condition defined as non-progressive contractures in more than two joints and in multiple body areas, the pathogenesis is impaired fetal movements. Arhrogryposis with central nervous system involvement includes chromosomal and other syndromes. The cause can be pathology in the peripheral or central nervous system, in muscles or in connective tissue, defects in neuromuscular transmission, compromised space in utero, maternal disease, external factors like medication or drugs, or compromised vascular supply to the fetus. Turner syndrome is a disorder of females, is a chromosomal aberration associated with partial or complete absence of one X chromosome. It is characterized by short stature, primary amenorrhea and some phenotypical features such as webbed neck, short stature, broad chest with widely spaced nipples, cubitus valgus, and lymphedema at birth. The most frequent chromosome constitution in Turner syndrome is 45,X without second sex chromosome. However, about 50 percent of cases have other karyotypes. About one quarter of Turner syndrome cases involve mosaic karyotypes, in which only a proportion of cells are 45,X. The most common karyotypes and their approximate relative prevalence are as follows; 50 percent of cases 45,X, 15 percent of cases 46,X,i(Xq), 15 percent of cases 45,X/46,XX, about 5 percent of cases 45,X/46,X i(Xq), about 5 percent of cases 45,X, other X abnormality and about 5 percent of cases other 45,X/? Mosaics. Contractures in multiple areas are quite rare in Turner Syndrome. Here is a case of newborn girl with Arthrogryposis multiplex congenital, and mosaic with a X chromosome monosomy 45,X/46,XX.

Paternal uniparental disomy 6 and 2q13 deletion detected prenatally in a patient with cardiac defects, transient neonatal diabetes mellitus, hydrocephalus and dysmorphic features. *D. Niyazov[1], C. Tillis[2], D. Feliperamirez[3], A. Robichaux[4].* 1) Dept Pediatrics, Div Med Genet, Ochsner Clinic Foundation, New Orleans, LA; 2) Dept Pediatrics, Div Neonatol, Ochsner Clinic Foundation, New Orleans, LA; 3) Dept Pediatrics, Div Endocrin, Ochsner Clinic Foundation, New Orleans, LA; 4) Dept Obst & Gynecol, Div Mat Fet Med, Ochsner Clinic Foundation, New Orleans, LA.

Introduction: Paternal uniparental disomy 6 (pUPD6) is associated with transient neonatal diabetes mellitus (TNDM), macroglossia and dysmorphic features. To our knowledge, pUPD6 was not reported with 2q13 deletion. We present a patient with multiple anomalies and prenatally ascertained pUPD6 and 2q13 deletion. We discuss mechanisms elucidating effects of pUPD6 and 2q13 deletion that resulted in patient's phenotype. Case Report: Fetal hydrocephalus and IUGR were detected at 18 weeks gestation. Karyotype showed 46,XX but SNP array revealed homozygosity of chromosome 6 which was paternal. SNP array also detected a 469 kb 2q13 deletion which was paternally inherited. NPHP1 sequencing showed a heterozygous deletion. Proband was born SGA at term and developed TNDM which resolved at 5 weeks. She had macroglossia, shallow orbits, infraorbital creases, low-set ears, micrognathia and long fingers. She also had ASD/VSD and hypotonia. Her brain MRI revealed hydrocephalus consistent with aqueductal stenosis requiring shunting. Discussion: Paternal UPD6 is associated with TNDM due to abnormal imprinting of 6q24 locus which may be due to overexpression of PLAGL1. The latter regulates pituitary adenylate cyclase-activating polypeptide receptor which stimulates insulin secretion. PLAGL1 is also an important member of a cellular network of imprinted genes involved in fetal growth. ZFP57 is another gene in 6q24 region which may play a role in structural brain abnormalities, developmental delay and CHD. It's unclear if the paternally inherited 2q13 deletion contributed to the phenotype. NPHP1 sequencing and MLPA did not detect another mutation along with the heterozygous deletion which could cause Joubert syndrome type 4. Positional and downstream effects of the 2q13 deletion could potentially modify expression of paternal UPD6 but there's no literature to support this. UPD6 was not described with 2q13 deletion. Our case underscores importance of chromosomal microarray in prenatal diagnosis. The SNP array in our patient appeared to have an advantage over oligonucleotide array because the latter cannot detect UPD. Prenatal identification of paternal UPD6 was crucial in diagnosis and management of TNDM and in estimation of prognosis and recurrence risks.

3037W

Congenital acquired mosaicism for monosomy 7. *J. Hiemenga, S. Klemm, J. Foley, H. Toriello.* Medical Genetics, Cancer Genetics, Spectrum Health, Grand Rapids, MI.

The molecular genetic etiology for Acquired Monosomy 7 and inevitable progression to myelodysplastic syndrome (MDS) or acute myelogenous leukemia (AML) is elusive, in part because of the rarity of affected individuals and families. We present the only reported congenital case of acquired Mosaic Monosomy 7. An infant male with a pregnancy complicated by polyhydramnios and antenatally diagnosed multiple congenital anomalies had a normal 46, XY prenatal karyotype. At birth he was found to be mosaic for monosomy 7 in 15% of peripheral leukocytes on a 180K oligonucleotide array, additionally he had an 11.6 Mb microduplication of the 9q33.3q-q34.3 region and a 5.18 Mb microdeletion of the 11q24.1-q24.3 region. He remained negative for mosaic monosomy 7 by FISH analysis on an alternate tissue source, a newborn buccal swab. This infant's 11q24.1 5.18 Mb deletion overlaps partially with that of Jacobsen syndrome, a contiguous gene deletion syndrome involving chromosome 11 distal to 11q23. This infant's clinical presentation was consistent with both Mosaic Monosomy 7 and Jacobsen syndrome. He had pancytopenia, was transfusion dependent, and supported with granulocyte-colony stimulating factor. He had multiple physical findings consistent with Jacobsen syndrome. Additionally, this infant had duodenal atresia, micro retrognathia, long thin neck, lumbar hemivertebrae with gibbus malformation, and a unilateral dysplastic kidney. Reports of acquired Mosaic Monosomy 7 in the literature are scant with a familial confirmation of the diagnoses made during bone marrow transplant screening of potential donor siblings. Affected parents have not been reported. The earliest reported onset is 9 months of age but acquired Mosaic Monosomy 7 presents most commonly throughout childhood into early adulthood. One of this infant's four elder siblings was found to have 3% monosomy 7 in peripheral leukocytes, below the reporting laboratory's control confidence interval range. She did not have thrombocytopenia; her initial bone marrow evaluation was normal and had no cells reported with monosomy 7. We have recommended close monitoring of this sibling and annual follow up with other family members.

3038F

Overgrowth as a presenting symptom of the 22q11.2 duplication syndrome - a novel association. *D.M. McDonald-McGinn[1], E. Bratton[1], K. Dickinson[1], A. Kohut[1], A. Bailey[1], A. Wilkens[1], I. Krantz[1], B. Emanuel[1], S. Saitta[2], M. Deardorff[1], E.H. Zackai[1].* 1) Div Human Gen, Children's Hosp Philadelphia, Philadelphia, PA; 2) Cedars Sinai Medical Center, University of California Los Angeles, Los Angeles, CA.

Introduction: 22q11.2 CNV's are well described entities involving deletions and duplications. Both are the result of non-allelic homologous recombination due to the presence of low copy repeats which flank the deletion/duplication and define the breakpoints. Although expected to occur with equal frequency we've found the deletion to be twice as prevalent as the duplication. Moreover, in several instances we and others have identified the duplication in seemingly unaffected adults, raising important questions regarding management, recurrence risk counseling, and prenatal diagnostic issues. Now, having previously evaluated 52 individuals with a 22q11.2 duplication, we report the novel association of overgrowth as a prominent feature - this following the identification of duplications in two children during routine evaluations for LGA. This new association may have important implications for ascertainment and further management. Methods: We retrospectively reviewed our database of 52 individuals with the 22q11.2 duplication syndrome following the identification of 22q11.2 duplications in two patients who were referred for evaluation to our overgrowth clinic. Results: 54 individuals (38 males; 16 females) with 22q11.2 duplications included 33 probands, 15 parents, 4 siblings, 1 aunt and 1 first cousin. Of these, growth data is reported on 34 children (27 males; 7 females) of whom 14/34 (41%) had a birth weight >90%. By gender, 11/27 (41%) males were >90% and 3/7 (43%) females were >90%. Birth length was >90% in 7/34 (21%) including 6/27 males (22%) and 1/7 (14%) females. 8/34 (24%) continued above the 90% beyond infancy including 6/27 (22%) males and 2/7 (29%) females. Head circumference mirrored height with 8/34 (24%) patients having macrocephaly including 7/27 (26%) males and 1/7 (14% females). Conclusion: Chromosome 22q11.2 is a hot spot for copy number variation with both deletions and duplications having similar structural and functional differences reported such as congenital heart disease, palatal differences, intellectual deficits and autism. However, recently published growth curves for the 22q11.2 deletion do not demonstrate overgrowth. Thus, here we report a novel finding in association with the 22q11.2 duplication. This may well be an important clue to the identification of the diagnosis. Moreover, it will be useful in providing appropriate care for these patients and perhaps in identifying candidate genes for overgrowth within this region.

Down syndrome patients nutritional evaluation at the Hospital Para El Nino Poblano outpatients. *M. Cortes[1], J. M. Aparicio[2,3], R. J. M. Perez[1], F. E. P. Romero[1].* 1) Nutrtion; 2) Genetics, Hospital para el Nino Poblano, Puebla, Puebla; 3) Estomatology, Benemerita Universidad de Puebla, Mexico.

From a total of 4617 karyotypes (100%) performed in 19 years period of time at a Pediatric Hospita, at Puebla city in Mexico; 33.6% (1553 patients) were diagnosed as chromosomal trisomy, were 32.8% (1511 patients) diagnosed as Down syndrome (trisomy 21). This alteration is usually caused by an extra copy of chromosome 21 (trisomy 21). Characteristics include decreased muscle tone, stockier build, asymmetrical skull, slanting eyes and mild to moderate developmental disability. 1127 patients have regular trisomy (47XX+21 or 47XY+21), caused by a meiotic nodisjunction event, also chromosomal translocations were observed; 260 patients 46XYt(14;21) or 46XXt(14;21q) were the long arm of chromosome 21 is attached to chromosome 14. 43 patients 46XYt(21;21) or 46XXt(21;21), and 81 patients with mosaicism. It was tried to determine nutritional status for growth, development and nutrition improvement in some Down patients . Looking at history, John Langdon Haydon Down identified and first described in 1866 the syndrome that now his name, it was not until 1932 when Davenport suggested that chromosomal irregularities could cause certain forms of mental retardation, including Down syndrome. Only in 1956 the available techniques allowed establish a definitive finding that the normal human chromosome number is 46. In 1959 Jerome Lejeune discovered that Down syndrome was extra chromosome belonging pair chromosomes 21 (HSA21). His finding was confirmed by Jacobs that year. After first cases of translocation and mosaicism. In 1970 Caspersson postulate genetic material that, when it tripled, causes appearance phenotypic characteristic of Down syndrome, is concentrated in distal long arm chromosome 21. Down Syndrome is principal cause of intellectual disability and the most common human genetic disorder: 1/600 to 1/1000 views. Approximately 40% children with Down syndrome born with congenital heart disease and 15% born with gastrointestinal malformations. Children with Down syndrome also at risk of other medical complications can affect nutritional status and their overall development. This study main goal carries assessment nutritional status in children with Down syndrome by determining nutritional status which may impact on growth, development and nutrition in children with this genetic alteration. Both rehabilitation therapy as nutritional evaluation, are both important for a better quality of life.

Follow-up of patient with non-supernumerary ring chromosome 7: Clinical manifestations, cytogenetic and molecular analysis. *C. Salas[1], P. Perez-Vera[1], D. Cervantes[2], R. Cruz-Alcivar[1], R. Daber[4], L. Conlin[4], L. Leonard[4], NB. Spinner[4], C. Duran-Mckinster[3], V. Del Castillo-Ruiz[2].* 1) Laboratorio de Cultivo de Tejidos, Instituto Nacional de Pediatria, Mexico city, Mexico; 2) Departamento de Genetica Humana, Instituto Nacional de Pediatria, Mexico city, Mexico; 3) Servicio de Dermatologia, Instituto Nacional de Pediatria, Mexico city, Mexico; 4) Department of Pathology and Laboratory Medicine of Children's Hospital of Philadelphia, PA.

Ring chromosome 7 (r7) is an uncommon cytogenetic finding that leads to variable phenotypes, resulting from variable terminal deletions, dynamic mosaicism and parental origin. The most frequent phenotype of the r7 patients are pre- and postnatal growth retardation, microcephaly, intellectual disability and dermatologic findings. Almost all reported cases present dynamic mosaicism, with the same apparent chromosomal breakpoints and ring structure, and in only two patients FISH analysis revealed cryptic subtelomeric or telomeric deletions. Here we report the clinical, cytogenetic and fine molecular mapping of a male child with a non-supernumerary r7. Clinical report. The propositus was the first child of healthy non-consanguineous parents. At 20 months of age, the patient had dysmorphic features, developmental delay and dermatologic lesions with variable pigmentation. We re-evaluated the patient at 6 years and physical examination showed hypogenitalism, lumbar dextroscoliosis, cerebellar and ophthalmological abnormalities and melanocytic congenital nevi (MCN). Methodology. Cytogenetic and molecular analysis was performed in peripheral blood (PB), fibroblasts of light (LS) and dark (DS) skin and in a MCN sample. Results. The cytogenetic analysis in PB showed a single cell line with r7; LS and DS revealed monosomy (-7) and r7 cell lines in different proportions. Almost 5 years later, a new cytogenetic analysis showed three different cell lines in PB: monosomy 7, r7 and duplicated r7 (idic r(7)); LS sample was similar to the previous study, with monosomy and r7 cell lines, and in MCN, monosomy, r7 and duplicated r7 cell lines were observed. FISH revealed subtelomeric loss in both chromosome arms in all tissues studied. Genome-wide SNP array showed a 0.8 Mb deletion in 7p22.3 (8 genes) and a 7.5 Mb deletion in 7q36 (29 genes). SNP array analysis also revealed low level monosomy 7 mosaicism in PB (less than 5%). Analysis of informative SNPs on chromosome 7 demonstrates the presence of maternal uniparental disomy (UPD) in the monosomy 7 cell line. This finding suggests that the r7 is paternally derived. Discussion. The SNP array analysis was useful to delineate the deleted r7 regions, which included genes related to genital and central nervous system development and for identification of the maternal UPD involving Silver-Russell region. The combination of all results obtained permits us to establish an accurate genotype-phenotype correlation.

MOWAT - WILSON SYNDROME: CASE REPORT. *J. Acosta Guio[1,2,3], A. Zarante[1].* 1) medical genetic, Pontificia Universidad Javeriana Instituto genética humana, Bogotá, Colombia; 2) Instituto de nutricion, genetica y metabolismo de la Universidad el Bosque, Bogotá, Colombia; 3) Instituto de Ortopedia Infantil Roosevelt, Bogotá, Colombia.

Mowat - Wilson syndrome (MWS), is a rare disease the prevalence is currently unknown approximately 180 cases have been reported until 2010. It is characterized by distinctive facial phenotype, moderate to severe mental retardation, epilepsy Hirschsprung disease and other congenital malformations. Case Report: We describe the case of 9 years old Colombian girl, second pregnancy, non-consanguineous marriage, born at term uncomplicated. Mother reports that the patient had hypotonia from birth. Later the patient present developmental delay, and epilepsy. Currently, low weight, microcephaly, triangular facies, bilateral ptosis, posteriorly rotated ears, short philtrum and full lips, hypothenar hypoplasia hands, cubitus valgus and joint hypermobility. The patient did not present Hirschsprung disease but she has a diagnosis of precocious puberty. The initial investigation included karyotype: the result was 46,XX and the comparative genomic hybridization (CGH) showed a microdeletion at chromosome 2q22.32-q22.3, for this reason the Fluorescent in situ hybridization (FISH) was made in her parents who had not the microdeletion. Finally, we concluded that the patient had a novo deletion. MWS is caused by mutations or deletion (≈ 17%) in that region is located the ZEB2 gene (zinc finger E-box-binding homeobox 2), who is involved in the development of neural crest derived cells, central nervous system and midline development. The majority of mutation are sporadic, therefore the risk of recurrence in the siblings is low or the same of the rest of population. The precocious intervention is necessary and it should include: physical therapy, occupational and speech therapy. We present the first case molecularly confirmed in Colombia.

The association of low socioeconomic status and the risk of having children with Down syndrome: a report from the National Down Syndrome Project. *J.E. Hunter, E.G. Allen, L.J.H. Bean, S.B. Freeman, S.L. Sherman*. Department of Human Genetics, Emory University, Atlanta, Georgia.

The majority of Down syndrome (DS) cases are due to the nondisjunction of chromosome 21 in oocytes. To date, advanced maternal age and altered recombination are the only well-established risk factors for the nondisjunction errors and these are known to differ in profile with respect to the type of error, meiosis I (MI) or meiosis II (MII). In this study, we examined the association between low maternal socioeconomic status (SES) and trisomy 21 stratified by the type of nondisjunction error among 1691 families recruited as part of the National Down Syndrome Project, a multisite, population-based case-control study of live births. Three potential SES risk factors (both mother and father had not completed high school, both maternal grandparents had not completed high school, and an annual household income of <$25,000) were used to calculate an SES index (0, 1, and ≥2 low SES factors present). We used logistic regression and adjusted for statistically significant confounders including maternal age, race, and parity. We detected an association of having a child with maternal MII error among families with one low SES factor (OR=1.81, 95% CI=1.07–3.05) and two or more low SES factors (OR=2.17, 95% CI=1.02–4.63) compared to families with no risk factors. We found that this association was driven primarily by having a low household income (OR=1.79, 95% CI=1.14–2.73). No association was found with maternal MI errors for 1 and ≥2 low SES factors (OR=1.11, 95% CI=0.80–1.56 and OR=1.31, 95% CI=0.81–2.10, respectively). Further studies are warranted to explore which aspects of low maternal SES, such as environmental exposures, may account for this association and why they influence this one type of nondisjunction error of chromosome 21.

Surgical Intervention for Esophageal Atresia in Patients with Trisomy 18. *E. Nishi[1,2], T. Nakamura[3], K. Iio[4], S. Mizuno[5], H. Kawame[6], Y. Fukushima[7], T. kosho[7].* 1) Dept Genetics, Nagano Children's Hosp, Azumino City, Nagano, Japan; 2) Department of Medical Genetics, Shinshu University Graduate School of Medicine, Matsumoto, Japan; 3) Department of Neonatology, Nagano Children's Hospital, Azumino, Japan; 4) Department of Surgery, Central Hospital, Aichi Human Service Center, Kasugai, Japan; 5) Department of Pediatrics, Central Hospital, Aichi Human Service Center, Kasugai, Japan; 6) Department of Genetic Counseling, Ochanomizu University School of Humanities and Sciences, Tokyo, Japan; 7) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan.

Trisomy 18 (T18) is the second most common autosomal trisomy characterized by multiple congenital anomalies and an extremly short life span, with the median survival time as 14.5 days and the survival rate at age 1 year from 5 to 10%. Esophageal atresia (EA) is a frequently observed and potentially letal complication in patients with T18. There has been no evidence about efficacy of surgical intervention for EA in patients with T18. To delineate the outcome of surgical intervention for EA with tracheoesophageal fistula (TEF) in T18, we reviewed detailed clinical data of 24 patients with full T18 who had EA admitted to the neonatal intensive care units of Nagano Children's Hospital from April 1993 to March 2008 and Central Hospital of Aichi Human Service Center from April 1982 to March 2009. They all underwent one or two operations for their EA. Nine of 24 patients (Groups 1 and 2, 37%) had only palliative surgery. Group 1 (n=6) had only gastrostomy or both gastrostomy and jejunostomy. Group 2 (n=3) had gastrostomy and TEF resection (TEFR). The other 15 patients (Groups 3 and 4, 63%) had radical surgery. Group 3 (n=10) had single-stage operation of esophago-esophagostomy and TEFR. Group 4 (n=5) had gastrostomy followed by esophago-esophagostomy and TEFR. Surgical complications included hemorrhage, chylothorax, pneumothorax, mediastinitis, respiratory infection, and insufficient suture requiring reoperation. No intraoperative death or anesthetic complications were noted. Enteral feeding was accomplished in 17 patients (71%), three of whom were fed orally. The median survival time was 29.5 days (range,1–1786): 12 days in Group 1 (1–133): 106 days in Group 2 (47–172): 23 days in Group 3 (2–694): and 518 days in Group 4 (32–1786). The survival rates at age 1 day, 1 week, 1 month, and 1 year were 100%, 92%, 58%, and 17%, respectively. Three patients could be discharged to home (12.5%), with the median hospital stay as 137 days (73–947). The common underlying factors associated with death were congenital heart defects and heart failure, followed by pulmonary hypertension. These data suggest that surgical intervention for EA in patients with T18, especially two-stage operation (gastrostomy followed by esophago-esophagostomy and TEFR), could contribute to longer survival, establishment of enteral feeding, and that EA might not always be an absolute poor prognostic factor in patients with T18.

Mosaic supernumerary ring chromosome 3: Does copy number gain of FOXP1 contribute to expressive speech impairment and intellectual disability? *I. Filges[1,2], A. Datta[3], E. Boehringer[3], L. Suda[4], B. Roethlisberger[4], P. Miny[1].* 1) Division of Medical Genetics, University Children's Hospital and Department of Biomedicine, Basel, Switzerland; 2) Department of Medical Genetics, Children's and Women's Hospital, Child and Family Research Institute, Vancouver, Canada; 3) Division of Neuropediatrics and Developmental Medicine, University Children's Hospital, Basel, Switzerland; 4) Medical Genetics, Center of Laboratory Medicine, Cantonal Hospital, Aarau, Switzerland.

Assessing the clinical significance of mosaic small supernumerary ring chromosomes (sSRC) still represents a major challenge in prenatal and postnatal diagnosis, and phenotype-genotype correlations are notoriously difficult. We report on the extremely rare finding of a mosaic sSRC of chromosome 3, initially identified prenatally, the current postnatal findings by array genomic hybridization (AGH) and the long-term clinical follow-up of the child. The now 7 year-old girl shows minor facial anomalies, microcephaly and is missing one upper central incisor. She has moderate intellectual disability and severe speech impairment, with an almost complete absence of expressive speech, uses simple sign language, whereas receptive speech is conserved. Motor development is within the normal range. She has repeated absences and had one generalized seizure. Cerebral MRI and basic metabolic investigations were normal. Repeated EEG and polysomnography recordings showed increasing epileptogenic activity of a spike and spike-wave type in the posterior region to currently generalized spike-wave activity continuing during slow- sleep (CSWS) but conserved sleep structure. High resolution AGH of DNA from stored cultured amniocytes confirmed a de novo gain (copy number state 2.5) of the genomic region 3p14.2q11.2 encompassing 35.1 Mb harboring 65 genes. The identical aberration was found in DNA from cultured fibroblasts but not from blood lymphocytes of the patient. Conventional karyotyping of fibroblasts showed a SRC in 25%, 2 SRC's in 25% and a normal result in 50% of cells reflecting array results. Due to the size of the aberration and developmentally relevant gene content we conclude that the mosaic SRC 3 may explain our patient's phenotype although we could not identify patients with the same duplication of the affected region for comparison. The region contains FOXP1 (3p13) haploinsufficiency of which causes ID with severe language impairment. FOXP1 encodes a transcription factor and is closely related to FOXP2, a gene also implicated in rare forms of speech disorders. Functional evidence of heterodimer formation and overlapping neural expression patterns suggests that FOXP1 and FOXP2 can co-regulate gene expression in the brain. We hypothesize that also increased levels of FOXP1 transcription may affect these interactions and thus contribute to speech and neurodevelopmental impairment in our patient.

Cat eye syndrome: Wide clinical variability in three patients from the same family. *M.I. Melaragno[1], S.I. Belangero[1], A.N. Pacanaro[1], F.T. Belucco[1], D.M. Christofolini[2], L.D. Kulikowski[3], R.S. Guilherme[1], A. Bortolai[4], A.R. Dutra[1], F.B. Piazzon[5], M.C. Cernach[1].* 1) Morphology and Genetics Department, Universidade Federal de São Ppaulo, São Paulo, São Paulo, Brazil; 2) Ginecology and Obstetricy Division, Faculdade de Medicina do ABC, Brazil; 3) Department of Pathology, Cytogenomics Laboratory, LIM 03, Universidade de São Paulo, SP, Brazil; 4) Genetics Division. Hospital do Servidor Público do Estado de São Paulo, Brazil; 5) Genetics Unit. Instituto da Criança, Universidade de São Paulo, Brazil.

A small supernumerary marker chromosome (sSMC) derived from chromosome 22 is a relatively common cytogenetic finding. The 22 sSMC can result in tetrasomy for a chromosomal region that spans the chromosome 22p arm and the proximal 2 Mb of 22q11.2. The majority of cases are sporadic, although some familial cases have been reported. Here, we report three patients from the same family (mother, daughter, and son), with sSMCs derived from chromosome 22, resulting in cat eye syndrome. There are no previous reports of this syndrome occurring within three patients in the same family. Classical cytogenetics and FISH with probes from chromosome 22 revealed a supernumerary dicentric and bisatellited chromosome derived from chromosome 22 in all metaphase cells analyzed. MLPA using the SALSA MLPA P250 DiGeorge Syndrome kit and high resolution array showed four copies of the proximal region of chromosome 22, described as arr 22q11.1q11.21(14,435,171-17,190,083)×4 (NCBI 36/hg 18), indicating a breakpoint at LCR-A. Thus, all patients presented as 47,XY or XX,+idic(22)(pter→q11.21::q11.21→pter), resulting in cat eye syndrome due to chromosome 22 partial tetrasomy 22pter-q11.21. Although all subjects presented the same chromosomal abnormality, they showed a wide range of phenotypic differences, even being from the same family. While the daughter presents a more severe phenotype than her brother and her mother, the mother presents only subtle abnormalities and was diagnosed only because of her children. Our findings emphasize the great clinical variability in CES even in familiar cases with the same marker chromosome and also highlight the importance of performing chromosome examination even in asymptomatic parents to determine the risk of recurrence and provide more conclusive genetic counseling for these families. Maternally inherited Xq26.2 duplication in a male offspring with severe prenatal and postnatal growth deficiency, dysmorphic facial features, hydrocephalus and developmental delay resembling Russell-Silver syndrome. *L. Tuzovic, J. Wynn, L. Rohena, K. Anyane-Yeboa, A. Iglesias.* Division of Clinical Genetics, Columbia University Medical Center, New York, NY.

Xq duplications in males are extremely rare. Less than 100 cases with different breakpoints on Xq have been described in the literature. To our knowledge, duplications in the distal region of Xq26.2 have been described in only a few patients. Madrigal et al. reported a similar duplication as the one in our case in two brothers with prenatal and postnatal growth deficiency and developmental delays, hypotonia, craniofacial disproportion and dental malocclusion. We further expand the clinical and molecular phenotype in a 5 year old male with severe prenatal and postnatal growth deficiency, hydrocephalus, dysmorphic facial features and developmental delay resembling Russell-Silver syndrome. He was born to a phenotypically normal 19 year old Hispanic female G1P0 at 35 weeks gestation via emergent cesarean section due to fetal bradycardia. Prenatal course was complicated with severe intrauterine growth restriction and oligohydroamnios which prompted induction of labor. Prenatal ultrasound revealed bilateral ventriculomegaly. Fetal echocardiogram showed mild muscular VSD. Amniocentesis was performed and showed 46, XY male karyotype. His birth weight was 1365 grams (<5th percentile). Exam at 2 months of age was significant for dysmorphic facial features including relative macrocephaly, frontal bossing, small and flat face, epicanthal folds, hypertelorism, down slanted palpebral fissures, small cupped ears, down turned corners of mouth and micrognathia. His postnatal course was further characterized by severe growth deficiency and motor and cognitive delay. MRI of brain at 2 years of age showed stable mild hydrocephalus secondary to partial aqueduct stenosis and thinning of the corpus callosum. Genetic workup included SNP-microarray which revealed a 3.9 MB microduplication in Xq26.2q26.3 region. Parental studies revealed that phenotipically normal mother is a carrier of the same duplication. Maternal X-inactivation studies showed 100 percent skewed X-inactivation pattern suggesting that the inherited duplication is likely pathogenic. At the age of 5 years, he remains below the 3rd percentile for height and weight. He shows mild developmental delay and attends special class in kindergarten where he receives speech and physical therapies. He now speaks in full sentences however still has problems with fine motor skills. This report will help to further expand the clinical and molecular phenotype associated with rare distal Xq duplications.

3047W

***De novo* translocation disrupting Mediator complex subunit in a patient with Pierre-Robin sequence and developmental delay.** *K.H. Utami[1,4], A.M. Hillmer[2], E.G.Y. Chew[2], C.L. Winata[1], V. Korzh[3], S. Mathavan[1], P. Sarda[5], S. Davila[1], V. Cacheux[1,4].* 1) Human Genetics, Genome Institute of Singapore, Singapore, Singapore, Singapore; 2) Genome Technology and Biology, Genome Institute of Singapore, Singapore, Singapore; 3) Fish Developmental Biology, Institute of Molecular and Cell Biology, Singapore, Singapore; 4) Cytogenetics Department, Genome Institute of Singapore, Singapore, Singapore; 5) Department of Genetics, Montpellier University Hospital, Montpellier, France.

Pierre-Robin sequence (PRS) is a clinically well-defined subgroup of cleft lip and palate, micrognathia, and respiratory distress with unknown etiology. Here we report a case of a girl diagnosed with Pierre-Robin sequence at birth. She was diagnosed with developmental delay by the age of 4, and shown to have dysmorphic features, strabismus, hirsutism and multiple contractures. Karyotyping analysis revealed a *de novo* translocation between chromosomes 12q24 and 19q12. By using long paired-end tag (DNA-PET) sequencing we narrowed down the breakpoint to a disrupted Mediator complex subunit gene, *MED13L* on chromosome 12. The breakpoint coordinate was confirmed by FISH analysis and refined by sequencing. Furthermore, transcript and protein expression levels were found to be reduced by >50% in the patient's lymphoblastoid cells. We checked the ortholog expression in the zebrafish and mouse embryo, and observed an enriched expression in the brain and branchyal arches, respectively. This was then supported by similar patterns of expression in the hippocampus and dentate gyrus (BrainAtlas) of mouse and human. Other mutations in the same gene have been reported previously in a patient with congenital heart defects and intellectual disability. In conclusion, *MED13L* might have a potential function that could be the underlying cause of phenotype observed in the patient.

3048F

614kb duplication at chromosome 9q22.32 encompassing PTCH1 gene in a family with reciprocal translocation (9;20)(q22;q13) and intrafamilial phenotypic variability. *C. Vinkler[1], D. Lev[4], A. Singer[3], A. Frumkin[1], M. Davidovich[2], M. Michelson[1], Y. Michaeli-Yossef[2].* 1) Inst Med Gen, Wolfson Med Ctr, Holon, Israel; 2) Child Developmental Center, Maccabi Health Services, Rishon LeZion, Israel; 3) Medical Genetics Unit, Baezilai Med Ctr, Ashkelon, Israel; 4) Department of Genetic Research, The Department of Genetic and Metabolic Diseases, The Hebrew University Medical Center, Jerusalem, Israel.

Several previously unidentified, clinically significant, submicroscopic chromosome abnormalities, have been discovered since the widespread clinical use of comparative genomic hybridization microarray technology. Specifically, there have been reports of clinically significant microduplications found in regions of known microdeletion syndromes. These microduplications have distinct features from those described in the corresponding microdeletion syndromes. Deletions or loss-of-function mutations of the PTCH1 gene, result in basal cell nevus syndrome (Gorlin syndrome), while gain-of-function mutations were proposed to cause holoprosencephaly (HSE). We report on a familial translocation t(9;20)(q22;q13) in three cases with variable phenotypes. A 614kb duplication at chromosome 9q22.32 harboring the PTCH1 gene, was found in one of the cases by array CGH. This is a 2y old boy, who carries a t(9;20)(q22;q13) translocation. He has microcephaly, short stature, failure to thrive, dysmorphic features and developmental delay. His brain MRI is normal. He inherited the translocation from his father who has microcephaly, short stature, dysmorphic features and normal intelligence. Family history discloses a pregnancy that was terminated at 16w gestation due to holoprosencephaly. Fetal karyoytype revealed the paternal t(9;20)(q22;q13)translocation. We postulate that in this family, all three cases may have the same 614kb duplication near the site of the translocation breakpoint which was found in the 2y old boy. The duplicated region harbors two genes FANCC and PTCH1. No clinical significance is known to be associated with FANCC duplication. However, duplication of the region encompassing the PTCH1 gene has been previously described in two families with microcephaly, short stature, and intellectual disability. This is the first report of HSE in a family with PTCH1 duplication. Gain of function of the PTCH1 together with modifier genes involved in the sonic hedgehog signaling pathway, may be responsible for the variable expression in this family causing also an HSE phenotype.

3049W

Case report: A boy with 49, XXXXY Syndrome, diagnosed by karyotype and a characteristic phenotype. *A. Zarante, J.C Prieto, O. Moreno.* Insituto de Genetica, Universidad Pontificia Javeriana, Bogotá, Colombia.

49,XXXXY Syndrome, is a rare sex chromosome aneuploidy ocurr in 1:85,000 - 1:100,000 male births. That conditions are characterized by the growth deficiency with multiple congenital malformations: microcephaly, facial dysmorphism, heart, genitourinary and skeletal defects (limited pronation elbow, radioulnar synostosis, clynodactyly of fifth finger) also present developmental delays, cognitive impairments and behavioural disorders. We present case of a child of 17 months with developmental delay. The positive findings found on the physical examination were: hypertelorism, upward slant to palpebral fissures, inner epicanthal fold, auricular anomaly, micrognathia, radioulnar synostosis, clynodactyly of fifth finger, cryptorchidism and hypoplasic scrotum. The nuclear magnetic resonance brain showed : increased supratentorial ventricles and incipient signs of volume loss with enlarged subarachnoid spaces. The band R karyotype reported 49,XXXXY. We made a a literature review and discussed the case with additional phenotypic manifestations mainly in the brain.

6p25 Interstitial Deletion in Two Dyzigotic Twins with Gyral Pattern Anomaly and Speech and Language Disorder. *M. Bozza[1], L. Bernardini[2], A. Novelli[2], P. Brovedani[1], E. Moretti[1], R. Canapicchi[1], V. Doccini[1], T. Filippi[1], A. Battaglia[1].* 1) Stella Maris Clinical Research Institute, Calambrone (Pisa), Italy; 2) Mendel Laboratory, IRCCS Casa Sollievo della Sofferenza-Hospital, San Giovanni Rotondo (FG), Italy.

Submicroscopic 6p25 deletion is now recognized as a clinically identifiable syndrome, characterized by intellectual disability, language impairment, hearing deficit, craniofacial, ophthalmologic, cardiac, and varying central nervous system anomalies. We report on two dizygotic twins with a maternal segregating hemizygous interstitial deletion on chromosome 6p25.1, spanning 0.9 Kb; the smallest ever reported. Both had dysmorphic features (prominence of the metopic suture, synophrys, hypertelorism, down-slanting palpebral fissures, tented mouth), and a distinct brain MRI, showing a focal significant increase of the right peri-frontal subarachnoid space, with shallow sulci and a mild anomaly of the gyral pattern. Such brain anomaly has never been reported in association with del 6p25. Both propositi had a borderline-mild intellectual disability, speech and language difficulties, and behavior abnormalities. Their mother, formally tested, had a borderline cognitive impairment. Although none of the genes mapping to the deleted region are apparently related to the phenotype, LYRM4 resulted down-regulated in the cerebellar cortex of schizophrenia patients compared with controls, and Lyrm4 was down-regulated in the prefrontal cortex of mice with microdeletions in the locus syntenic to human 22q11.2 patients affected by schizophrenia. These data are in agreement with the emerging concept that similar CNVs are pathogenic in patients affected by distinct neurological diseases, and that these loci are more general risk factors for different disorders. The resemblance of our patients to those with the more extensive 6p25.1p25.3 terminal deletion suggests that the gene/s responsible for the physical phenotype should reside in the 6p25.1 genomic region.

3051W

Microdeletion of 19p13.3 in a girl with Peutz-Jeghers syndrome, intellectual disability, hypotonia, and dysmorphic features. *Y. Kuroda[1], T. Saito[2], J. Nagai[2], K. Ida[1], T. Naruto[1], M. Masuno[3], K. Kurosawa[1].* 1) Devision of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Kanagawa, Japan; 2) Department of Clinical Laboratory, Kanagawa Children's Medical Center, Yokohama, Kanagawa, Japan; 3) Genetic Counseling Program, Kawasaki University of Medical Welfare, Kurashiki, Japan.

The Peutz-Jeghers syndrome (PJS) is a rare autosomal-dominant disease characterized by gastrointestinal polyposis and mucocutaneous pigmentation. Germline point mutations in STK11 have been identified in about 70% of patients with PJS. Only a small number of large genomic deletions have been identified. We report a girl with PJS and multiple congenital anomalies. The girl was the second child of non-consanguineous and healthy parents. She was delivered at 35 weeks 2 days. Her birth weight was 1821g, length 42cm, and head circumference 27cm. She had umbilical hernia, bilateral inguinal hernia, scoliosis, strabismus, and malformed ears. She had conductive deafness secondary to middle ear disease. Hypotonia was noted at the first year of age. She started controlling head at 6 months, sitting at 10 months, standing 33 months, and walking at age 43 months. She started speaking several words at age 3 and went to junior school with special class. She developed lip pigments at age 12. Oligonucleotide-based array CGH revealed an approximately 610kb deletion at 19p13.3 including STK11 gene and other 21 RefSeq genes. Most of the PJS patients with partial or whole STK11 deletion were revealed smaller than 200kb deletion at 19p13.3. These cases had a typical PJS and no other phenotype. Le Meur [2004] reported a patient with PJS and intellectual disability associated with 250kb deletion of 19p13.3. The patient had a deleted allele of PJS derived from his mother and also had paternally derived NF-1 mutation allele. Our patient is the second case of smaller than 1Mb deletion with PJS, intellectual disabilities, and other anomalies. Several studies have determined the prevalence of congenital anomalies in children with cancer. Cancer development would share the etiology of congenital malformations. These results indicated that the application of array CGH for MCA/DD is a clue to understand cancer risk and surveillance.

3052F

Maternal mosaicism for deletion of 22q13.3 resulting in siblings with Phelan-McDermid syndrome. *K. Phelan[1], B.R. DuPont[2], R.C. Rogers[2].* 1) Hayward Genetics Ctr and Dept of Pediatrics, Tulane Univ Health Sci Ctr, New Orleans, LA; 2) Greenwood Genetic Center, Greenwood, SC.

We report a phenotypically normal mother with a deleted, dicentric chromosome 22 resulting from a translocation between 22q13 and an unidentified acrocentric chromosome. Two of her three children inherited the deleted 22 and have Phelan-McDermid syndrome. EH was born in 1993 and presented with neonatal hypotonia and failure to thrive. Physical features included ptosis, long eyelashes, full cheeks, flat midface, small jaw, narrow philtrum, and slight syndactyly between toes two and three. Chromosome studies at age 2 were reported as normal. She spoke a few words at age 1 year then lost her speech. Her receptive language skills were better than her expressive skills. She was diagnosed with autism at age 5. Her brother TH was born in 1996 and was diagnosed with autism at age 2. Physical features included dolicocephaly, bitemporal narrowing, flat midface, pointed chin, high arched palate, long eyelashes, and lax ligaments with hyperextensible joints. His hands were slightly large with mild 5th finger clinodactyly. Chromosome studies at age 4 detected a dicentric chromosome designated dic(22;?)(22pter->22q13.3::?cen->?pter). Chromosomes were repeated on EH and identified the same dicentric 22 as seen in her brother. Parental chromosome analyses was performed and revealed that the dicentric was present in 6% of maternal (CH) peripheral blood cells. In 2006, chromosome analysis, FISH, and microarray studies were performed on CH and TH. Custom OGT 22q microarray on TH determined that the deletion size was 3.5 Mb and extended to the terminal region of chromosome 22. Chromosome structure and mosaicism was further characterized in CH with G-banding and FISH. The low level of mosaicism in CH was not detected by microarray analysis. This case demonstrates the challenge of diagnosing parental mosaicism for structural chromosome abnormalities. Typically, a parental rearrangement can be identified by screening a minimal number of metaphase spreads by G-bands or FISH. In individuals with mosaicism, screening a low number of spreads may fail to detect the abnormal cells so the study must be expanded to screen a greater number of cells. The use of microarray analysis is this case was not helpful as it failed to detect the mosaicism in the mother. If not for the birth of a second affected child in this case the study for mosaicism may not have been pursued and genetic counseling based on minimal screening would have provided inaccurate recurrence risks.

3053W

De Novo Interstitial Deletion of 3q22.1-q22.3 in Two Patients- a New Microdeletion Syndrome. *Y. Wilnai[1], W. Wilson[3], C. Jett[3], M. Manning[1,2].* 1) Division of Medical Genetics, Department of Pediatrics, Stanford University Medical Center, Stanford, CA; 2) Department of Pathology, Stanford University Medical Center, Stanford, CA; 3) Division of Pediatric Genetics, Department of Pediatrics, University of Virginia, Charlotteville, VA.

With improved cytogenetic techniques, sub microscopic chromosome deletions and duplications are being identified with increased frequency. We report two unrelated patients who exhibit a distinct behavioral pattern and dysmorphic features that were found to have deletion of chromosome 3 at band q22.1-q22.3. Patient 1-microarray analysis was performed using 135k whole genome oligonucleotide array, UCSC hg 18. Patient 2-microarray analysis was performed using 180k whole genome oligonucleotide array, UCSC hg 19. Patient 1 is a 13-yo male with a 4.5 Mb deletion of 3q22.1q22.3 (43 genes, 2 of which code for OMIM disorders). One gene, SLCO2A1, is associated with hypertrophic osteoarthropathy; the second, PCCB, is associated with propionic acidemia. Patient 2 is a 9-yo male with 4.1 Mb deletion of 3q22.1q22.3 (39 deleted genes, four of which code for OMIM disorders). Two deleted genes are mentioned above; the other two are the TF gene associated with atransferrinemia and BFSP2 associated with cataracts. Both boys' development followed a parallel behavioral pattern. They were diagnosed with autism in toddler years and received intensive behavioral therapy, with progress in speech and socialization. Later they developed attention deficit hyperactive disorder. Both boys had normal birth parameters, however, later developed microcephaly and failure to thrive. Patient 1 developed central obesity during his second decade. The two boys suffered from seizure like episodes with normal EEGs and brain MRI. Both patients have a recognizable pattern of facial features including ptosis, beaked nose, low set posteriorly rotated ears, smooth philtrum and thin upper lip. We report 2 patients with deletion of chromosome 3q22.1-q22.3. The patients presented with a distinct and recognizable behavioral pattern and physical features. After a thorough literature review, it appears that this is the first report describing this microdeletion syndrome. About 40 genes are deleted in this region, less than 5 are associated with recognized disorders. Deletion of the disease associated genes does not seem to explain our patients' features. By delineating the clinical and behavioral features of this new micro deletion syndrome, we can provide information that may lead to a better understanding of the functions of the deleted genes.

Chromosomal microarray analysis of individuals with autism or learning deficits presenting for genetic services. *J. Roberts[1], J. Hayes[1], N. Dzidic[2], K. Hovanes[2], M. Dasouki[1], M.G. Butler[1].* 1) Department of Psychiatry and Behavioral Sciences, Kansas University Medical Center, Kansas City, KS; 2) Combimatrix Diagnostic, Irvine, CA.

Chromosomal microarray analysis is now in common practice in the clinical setting for identifying deletions and duplications in the human genome. We report our experience with the use of 105K or 180K oligonucleotide microarrays (performed at CMDX laboratory, Irvine, CA) in consecutive patients with autism or autism spectrum disorders (ASD) and/or developmental delay or learning problems presenting for genetic services at Kansas University Medical Center during the past 4 years. Of the 214 patients [139 males and 75 females (male/female ratio=1.85) with average age of 10.3 years and range of 9 months to 52 years; 64 (or 30%) with autism or ASD and 150 (or 70%) with learning deficits], 44 (or 21%) had either a known anomaly detected on the microarray in 30 patients or a non-diagnostic copy number variant (CNV) in 14 patients contributing to the clinical presentation. Six patients with ASD showed a recognized anomaly by microarray analysis while 6 had non-diagnostic CNV findings. The most common chromosome involved in the microarray anomaly in the ASD subgroup was chromosome 15 (3 of 12 microarray findings). For the learning deficit subgroup, chromosomes 2 (5 of 32 findings) and 22 (5 of 32 findings) were most involved. For those with learning deficits, 24 patients showed a recognized microarray anomaly of which 18 had a deletion while 8 patients had a non-diagnostic CNV which was usually a duplication. Twelve out of 64 patients (19%) with ASD had a microarray finding compared with 32 out of 150 patients (21%) with learning deficits. Clinically, no patient with ASD and a microarray finding had seizures compared with 4 patients (12%) with learning deficits. Four patients (33%) with ASD and a microarray finding had dysmorphic features usually craniofacial compared with 18 patients (56%) with learning deficits. No patient with ASD had microcephaly compared with 8 patients (25%) with learning deficits. Three patients (25%) with ASD had macrocephaly compared with 1 patient (3%) with learning deficits. Three patients (25%) with ASD and a microarray finding had a family history of ASD compared with 9 patients (28%) with learning deficits and a family history of learning deficits. In conclusion, our study would further support a significant yield in identifying genetic factors contributing to ASD and learning deficits in patients presenting for genetic services and the usefulness of microarray analysis in the clinical setting.

3055W

A Wolf Hirschhorn - like phenotype in a patient with a *de novo* 6q26-q27 deletion and 20p13-p12.1 duplication. *F. Faucz[1,2], H. Salomão[2], R.B. de Alexandre[1,2], A. Bonalumi[2], J. Souza[2], J.A. Rosenfeld[3], S. Raskin[2,4], V.S. Sotomaior[2].* 1) Section on Endocrinology & Genetics, PDEGEN, NICHD, NIH, Bethesda, MD; 2) Laboratory of Molecular Genetics, NIMA, PPGCS, Pontificia Universidade Catolica do Parana, Curitiba, PR, Brazil; 3) Signature Genomics, Spokane, Washington, DC; 4) 3Genetika - Centro de Aconselhamento e Laboratório de Genética, Curitiba, PR, Brazil.

Wolf-Hirschhorn syndrome (WHS [MIM 194190]) is a chromosome deletion syndrome with a well delineated phenotype. The vast majority of cases are the result of hemizygosity of 4p16.3. Many patients carry a deletion of several megabases that results in severe mental and growth retardation, major malformations and seizures, and a characteristic facial appearance with wide forehead, large and protruding eyes, hypertelorism, prominent glabella, down-turned mouth, and micrognathia. Here we report the case of a seven-year-old girl, child of a non-consanguineous and a healthy 24-year-old mother and 33-year-old father, that was initially referred to medical examination with clinical suspicion of Wolf-Hirschhorn syndrome. Pregnancy was unremarkable, she was born at 40 weeks of gestation with a birth weight of 2760 g (5^{th}-10^{th} percentile), a length of 47 cm (5^{th}-10^{th} percentile). Apgar scores were 1 and 3, and cardiac arrest was reported at birth. She has facial dysmorphia, microcephaly, thin upper lip, epicanthic fold, strabismus, enlarged nasal base, posterior cranial fossa anomaly, recurrent urinary tract infections, right urinary lithiasis, horseshoe kidney, vesicoureteral reflux, intestinal volvulus,hip dislocation, vertebral scoliosis, butterfly vertebrae, syndactyly of 2nd and 3rd toes, right thumb without movement, and generalized hypotonia. Seizures were reported at three years of age. Motor development and language development were delayed. Karyotype was normal and Array CGH analysis of 1543 loci using 4685 BAC clones detected two abnormalities: a single copy loss of 29 BAC clones from the terminal region of the long arm of chromosome 6 at 6q26-q27 (7.5Mb - 18 genes); and a single copy gain of 46 BAC clones from the terminal end of the short arm of chromosome 20 at 20p13-p12.1 (16.3 Mb - 65 genes). FISH analysis confirmed a derivative chromosome 6 that shows deletion of 6q26-6q terminal and the presence of a hybridization signal from the chromosome 20pter-20p12.1 clone. This derivative chromosome 6 results in partial monosomy of 6qter and partial trisomy of 20pter. Both parents had normal aCGH. Thus the derivative chromosome identified in this patient is *de novo*. The clinical manifestations and phenotype-genotype correlation in our patient match no known syndrome described in the literature, therefore, this description is of importance for characterization of a new syndrome.

3056F

Submicroscopic chromosomal rearrangements in patients with an Angelman syndrome-like phenotype. *K. Hosoki[1], T. Ohta[2], N. Niikawa[2], S. Saitoh[3].* 1) Pediatrics, Hokkaido Univ Grad Medicine, Sapporo, Japan; 2) RIPHS, Health Sciences Univ of Hokkaido, Tobetsu, Japan; 3) Pediatrics and Neonatology, Nagoya City Univ Grad School of Medical Sciences, Nogoya, Japan.

Angelman syndrome (AS) is characteristic by severe developmental delay, seizure, ataxic movement and inappropriate laughter. AS is caused by loss-of-function of maternally inherited*UBE3A* located in 15q11-q13. Although clinical features of AS are clinically discernable, AS-like features are seen in other genetic disorders including Rett syndrome and Pitt-Hopkins syndrome. In a series of genetic investigation of patients suspected to have AS, we have collected 33 patients with an AS-like phenotype for whom routine genetic tests for AS (*SNRPN* DNA methylation test, FISH analysis, *UBE3A* mutation screening test) revealed negative results. We performed whole genome microarray analysis using Genome-Wide Human SNP Array 5.0 (Affymetrix) to these patients. We identified three patients with copy number variation (CNV) larger than 300kb (0.3Mb 6q13 deletion, 5.6Mb 10q11 deletion, 0.3Mb 21q22.3 deletion). 10q11 deletion was proven to be *de novo*, but parental samples were not available for 6q13 deletion and 21q22.3 deletion. Recently 10q11 rearrangements were reported in patients with variable clinical features including developmental delay, intellectual disability, epilepsy and ataxia. Our results further confirmed that 10q11 deletion could cause intellectual disability, epilepsy and ataxia resembling AS. Pathogenicity of 6q13 deletion and 21q22.3 deletion are not conclusive but these deletions contain several functional genes. Therefore, these deletions may be associated with AS-like phenotype. In conclusion, we detected three submicroscopic deletions in 33 patients with an AS-like phenotype. Submicroscopic chromosomal rearrangements may be associated with an AS-like phenotype although the frequency appears to be low.

3057W

Twenty-two year follow up of identical twins with discordant phenotype due to a ring 13 chromosomal mosaicism in one of them. *Y. Lacassie.* Dept Ped/Div Clin Gen, LSU Hlth Sci Ctr, and Children's Hospital, New Orleans, LA.

At the 43rd Annual Meeting of the ASHG in 1993 we reported identical twins with discordant phenotype due to a ring 13 chromosomal mosaic syndrome in one of them. Her major manifestations included IUGR, FTT, developmental delay/intellectual disability, hemihypotrophy of the left side of the body with leg length discrepancy, profound hearing loss at left due to inner ear malformations, dental anomalies mainly on the left side, dislocation left hip, distinctive left hand with mbd/clinodactyly of the 5th finger, short left 3rd metatarsal, and telecanthus, congenital torticollis due to Klippel-Feil anomaly, 13 ribs, scoliosis and wider halluces and short 5th toes. At 3 months hypotonia and developmental delay were first noticed. Chromosomes on blood at age 31\2 years were normal and a possible Silver-Russell syndrome was diagnosed. Since our first evaluation and establishment of diagnosis in 1990, at age 4, through chromosomal studies on skin fibroblasts from both sides of the body, we have had the chance to follow up this patient annually for 22 years. Early intervention programs, posterior transpedicular hemi-epiphysiodesis of cervical spine performed at age 61\2, epiphysiodesis of the right distal femur at age 101\2, and Bone Anked Hearing Aid (BAHA) implanted at age 24 for her severe/profound sensory neural hearing loss at left, have allowed her a relative normal life with better prognosis than predicted early in life. She had her menarca at age 138/12 years and stopped growing at age 17. The periodic follow up of her normal identical twin has allowed the physical, mental and dysmorphological comparisons along the years. Her normal twin is 16 cm taller, her OFC is 1 cm larger being in the 50th centile, and has normal superior intelligence. However, streaks of hypopigmentation in the right shoulder and arm, fibular deviation of halluces and 2nd toes and minor clinodactyly of the 5th toes have suggested the possible transfer of abnormal cells during gestation. The detection of a ring 13 chromosomal mosaicism with greater involvement on fibroblasts from the left side of the body, in agreement with the clinical manifestations, and not found on peripheral blood using standard chromosomal analysis and aCGH, stresses the importance of detailed clinical dysmorphological evaluation.

12p micro RNA expression in Fibroblast Cell Lines from Probands with Pallister-Killian Syndrome. *K. Izumi[1], Z. Zhang[2], M. Kaur[1], I. Krantz[1].* 1) Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Center for Biomedical Informatics, Children's Hospital of Philadelphia, PA.

Pallister-Killian syndrome (PKS) is a multi-system developmental disorder caused by tetrasomy 12p that exhibits tissue-limited mosaicism. The spectrum of clinical manifestations in PKS includes craniofacial dysmorphisms, cleft palate, congenital diaphragmatic hernias, congenital heart defects, involvement of the audiologic, musculoskeletal, gastrointestinal and genitourinary systems, cutaneous anomalies, intellectual disability and seizures. In an attempt to understand the molecular basis of the developmental differences observed in PKS, we performed genome-wide expression analysis on skin fibroblasts from probands and demonstrated a unique gene expression pattern for PKS. As a potential molecular driver of such a globally dysregulated gene expression pattern, we evaluated the potential contribution of micro RNAs. There are 6 micro RNAs (miR-141, miR-200c, miR-613, miR-614, mir-920 and miR-1244) located on 12p. The expression levels of 5 of these micro RNAs (excluding mir-920) were examined using the Nanostring n-Courier system. The gene expression levels of computer-predicted target genes for each of these micro RNAs were measured concurrently. Micro RNA expression was measured using skin fibroblast cell lines obtained from 12 probands with PKS and 5 control individuals. All micro RNAs located on 12p were overexpressed in PKS fibroblasts, although the fold difference of the expression level was 1.07 to 1.29, and is less than that of the genomic copy number difference. Among the 12p micro RNAs, miR-1244 had the highest fold difference of 1.29. One of the computer-predicted targets of miR-1244 is the MEIS2 gene (located on chromosome 15q14), whose haploinsufficiency is associated with congenital heart defects and cleft palate. The expression level of MEIS2 was significantly down regulated in PKS probands. The fold difference of miR-200c was 1.25, and its known targets include ZFPM2 (located on chromosome 8q23.1), whose haploinsufficiency is associated with congenital heart disease and congenital diaphragmatic hernia. The expression level of ZFPM2 was also downregulated in PKS probands. Given that the degree of differential expression of these micro RNAs was rather mild, the contribution of extra copies of micro RNAs may be small, however, overexpression of miR-1244 and miR-200c due to tetrasomy 12p may contribute to the pathogenesis of congenital heart defects, cleft palate and diaphragmatic hernia via modulating the expression of MEIS2 and ZFPM2.

Genetics of precocious puberty: A proband with Klinefelter syndrome, maternal uniparental disomy 14 and precocious puberty. *K. Reddy, H. Bass, J. Keni.* Kaiser Permanente Southern California, Los Angeles, CA.

Genetics of precocious puberty: A proband with Klinefelter syndrome, maternal uniparental disomy 14 and precocious puberty. Reddy KS1, Bass HN1, Keni J2 Medical Genetics1 and Pediatric Endocrinology2, Kaiser Permanente Southern CA kavita.s.reddy@kp.org A 9-year-old boy with precocious puberty and learning difficulties was found to have a 47,XXY karyotype. Parental peripheral blood chromosome studies identified a Robertsonian (Rob) 13/14 translocation in the father. An oligonucleotide and SNP array CGH study on the proband uncovered mixed maternal uniparental disomy (matUPD) for chromosome 14. Two large blocks of maternal isodisomy in the pericentromeric and terminal regions with intervening heterodisomy were detected and corresponded with a meiosis II non-disjunction error with a double crossover and subsequent trisomy rescue or gamete complementation. Since the father carries a Rob 13/14 translocation, he has an increased risk for producing nullisomy 14 sperm, supporting the possibility of gamete complementation. The clinical work-up of the patient demonstrated a hormone profile for central precocious puberty, a microadenoma of the pituitary by MRI, normal chest CT, normal serum alpha-fetoprotein and hCG, premature growth spurt and obesity. Klinefelter syndrome, upd14mat, obesity, pituitary macro- or microadenoma, and hCG-producing intracranial or mediastinal germ-cell tumors, either independently or in combination, have been associated with precocious puberty. It is probable that these genetic mutations predispose to precocious puberty through tumor formation and obesity. Management of the patient involves treatment with a GnRH analog (leuprolide) and dietary changes to control obesity.

3060F

Molecular genetic testing of recurrent anencephaly in a family without partial trisomy 2p22-pter. *C. Sergi[1], J. Gekas[2], D. Kamnasaran[3].* 1) Department of Laboratory Medicine and Pathology, University of Alberta, Edmonton, Canada; 2) Human Genetics Research Unit, Centre de recherche de l'hôpital Saint-François d'Assise, Québec, Canada; 3) Department of Pediatrics, Laval University, Québec, Canada.

Background: Human neural tube closure involves a complex interplay between genetic and environmental factors. In fact, failed closure of the anterior region by day 28 results in anencephaly. The incidence of anencephaly is estimated to be as high as 1/1000 pregnancies, and about 1.2/10 000 live births in North America. Unfortunately, fetal loss, still births or early neonatal deaths are the prognostic consequences of anencephalic pregnancies. We present a family with recurrent anencephaly and genetic testing of the *VANGL1* and *FOXN1* as candidate genes for anencephaly. **Methods and Results:** The mother, currently 28 years old with 4 gravida, 3 abortus, had a history of recurrent pregnancy losses and with three anencephalic fetuses in separate pregnancies. Both parents are clinically normal and with an unremarkable family history. Standard high G-banding cytogenetic studies performed on the chromosomes of the family members' peripheral blood lymphocytes and/or prenatal amniocytes did not identify any numerically and structurally abnormalities. Genes of the planar cell polarity pathway are implicated in neural tube defects. We examined the coding regions and intron-exon boundaries of *VANGL1* on human chromosome 1p13.1 and *FOXN1* on human chromosome 17q11-q12, genes which have phenotypes within the anencephaly spectrum. However, despite our rigorous testing, no DNA variations or mutations were identified among these genes.**Conclusion:** Familial recurrence of anencephaly is extremely rare and has been previously associated with a structural abnormality of human chromosome 2p. We suggest that other Planar Cell Polarity genes are an intriguing research avenue to further investigate families with recurrent neural tube defects in search of a genetic etiology.

Urethrocystoscopy, diagnostic laparoscopy, versus testicular descent gonadectomy in a patient with ambiguous genitalia: A case report. *F. Cuellar-López[1], J. M. Aparicio[2,4], I. de la Torre[3].* 1) Pediatric Urology; 2) Genetics; 3) Surgery, Hosp Para el Nino Poblano, Puebla, Puebla; 4) Estomatology, Benemerita UNiversidad Autonoma de Puebla, Mexico.

A pediatric patient with normal male caryotype, where ambiguous genitalia was observed, evaluated and corrected by surgery at the Hospital Para El Nino Poblano in Mexico. Disorders of sexual development (DSD), formerly termed intersex conditions, are considered a rare clinical event and it is important an early genetic and clinical diagnosis in order to counsel parents on therapeutic options. However, the problem of early gender assignment has been challenged by the results of clinical and basic science research, which show that gender identity development likely begins in uterus. Here the techniques for surgical genital reconstruction have been associated to psychological, interfamilial and social implications of gender assignment which in some cases became a real problem for surgical reconstruction. Recently, the Lawson Wilkins Pediatric Endocrine Society, (LWPES, 2008) and the European Society for Pediatric Endocrinology, (ESPE, 2009) have published proposed changes to the nomenclature and definitions of disorders in which the development of chromosomal, gonadal, or phenotypic sex is atypical. They proposed to change the nomenclature to reflect advances in our understanding of the pathophysiology of these sexual disorders in order to the help to the concerns of affected patients. Previous terminology and revised nomenclature of disorders of sexual development (DSD) based on a new nomenclature. Results:The patient with normal chromosomal study, 46 XY, was evaluated in a medical and surgical multidisciplinary manner due to ambiguous genitalia. It was confirmed the presence of vagina and cervix by vaginoscopy and urethrocystoscopy. The vagina size of 7 centimetres of length. by ureteral catheter, the cervix was observed andhysterosalpingography was performed. By laparoscopy process, intra-abdominal testis, left testicular descent effected video-assisted was observed, achieving distal third take up only channel is where ipsilateral. Inguinal testicular biopsy was done. In relation to the right side, a remanent tissue bulk form was found. Resection was performed where histopatological studies reported uterine horn. Resection of vagina, uterus and fallopian tubes by posterior sagittal approach with lifting and moving straight. Moreover, testicular hypotrophy was detected at left order to assess after its resection and testicular prosthesis was used. Make consequential within mixed plastia hypospadias, Snodgrass and Duckett.

Congenital association VACTERL at the Hospital Para El Nino Poblano, Mexico: Fourteen cases report. *A. Garcia-Guzman[1], J. M. Aparicio-Rodriguez[2,3].* 1) Pediatrics; 2) Genetics, Hospital para el Nino Poblano, Puebla; 3) Estomatology, Benemerita Universidad Autonoma de Puebla, Mexico.

INTRODUCTION. VACTERL association has been described in the literature since 1982. At the beginning only four clinical characteristics were described in comparison with six described nowadays; (V) Vertebral, (A) anal Atresy, (C) cardiac anomalies, (TE) Traqueal-Esophagic fistula, (R) Renal malformations, (L) limbs anomalies. This congenital association has 0.3 to 2.1 cases per 10,000 new born incidences. In México, few clinical cases have been reported, the main goal of this study is to analyze the different clinical patterns among 14 patients with this genetically disease in a third level pediatric Hospital in Mexico. MATERIAL AND METHODS. A Descriptive, retrospective and transversal study was performed among 14 patients diagnosed with VACTERL (with a minimal of three clinical features). RESULTS AND DISCUSSION. The male gender was observed to have an increased incidence if compared to females patients (6;1). 79% was diagnosed at new born stage. The main clinical features founded among the studies population were; 1. Anal atresy (83%) associated to ano-rectal malformation with fistula. 2. Cardiovascular malformations (92%) like Inter Auricular Communication (67%) 3. No VACTERL association as Ambiguous genitalia was also observed (57%) with carytotype in all cases. 4. Annular pancreas (14.28%) The VACTERL association in this study was observed with several different clinical symptoms: A. Three and four clinical symptoms 35.71% B. Five clinical symptoms 21.42% C. Six clinical symptoms 7.14% It is important to have a earlier diagnosis with a medical and surgical treatment to ensure a better quality of life for all patients with these congenital malformations.

3063W

Orthodontic correction in malformated unilateral teeth structure in a patient with pseudoachondroplasia: A case report. *S. Ochoa[1], J. M. Aparicio[2,4], D. D. A. Camarillo[3], S. S. Cabrera[1].* 1) Orthodontics; 2) Genetics; 3) Pediatric Estomatology, Hospital para el Nino Poblano, Puebla, Puebla, Mexico; 4) Estomatology, Benemerita Universidad Autonoma de Puebla.

Pseudoachondroplasia is a genetic disease characterized by a growth factor alteration, is a disorder of bone growth; is characterized by severe growth deficiency and deformations such as bow legs and hyperlordosis. Prevalence is estimated at around 1/60,000. The disorder is usually discovered during the second year of life with the onset of slow growth and walking difficulties. The short stature becomes more prominent with age and the hands and feet appear short and wide. Joint laxity is a general clinical feature, but predominantly affects the hands. Defective epiphyseal growth causes early arthrosis. The limb deformation is caused by metaphyseal lesions. Genetic transmission is autosomal dominant, but most isolated cases are due to de novo mutations. The disorder is caused by small mutations or deletions in the COMP gene (19p13.1) coding for the cartilage oligomeric matrix protein. Diagnosis is made on the basis of epiphyseal and metaphyseal anomalies detected on radiographs during the second year of life. The principle differential diagnosis is achondroplasia, the meaning of the word (a=without; chondro=cartilage and plasia=development), literally means “without cartilage formation,” but the craniofacial anomalies present in this disorder are absent in patients with pseudoachondroplasia and radiographic findings differ significantly. Forms of multiple epiphyseal dysplasia may also be included in the differential diagnosis. Genetic counseling may be proposed and the recurrence risk is 50%. Prenatal diagnosis is feasible if the mutation has been detected in an affected parent. Treatment is based on physiotherapy, management of the spinal deformation and corrective orthopedic surgery. Intensive physical activity should be avoided.

3064F

Hearing loss frequency in a pediatric patient group at a third level hospital. *A. Romero[1], J. M. R. Aparicio[2], L. P. C. Gallegos[1].* 1) Audiology; 2) genetics, Hospital Para el Niño Poblano, Puebla, puebla, Mexico.

The hearing is the usual way to acquire spoken language; one of the most important human attributes and means of communication in all cultures. Language is the main way of learning in children and plays a key role in thinking, knowledge, and intellectual development. The ear is an active sense detected used through our lives, even where sleeping. 75% of the information is received by both ears. Hearing loss is particularly dramatic in childhood, as the intellectual and social development of the child is intimately linked to the cortices of the central nerve system, which allow us to acknowledge of the surrounding word and the correct language acquisition. In modern times, in 1945 Carhart and Canfield coined the word “Audiology”, thus, it was born the modern science of hearing. Just eight years later, in 1953, the National Institute of Audiology was founded. By the fact that the foundation of this institution marked a historic milestone to be advanced to any similar in developed countries. it has been investigated the association between hearing loss and low weight at birth. With the implementation of potential evoked auditory brain stem in infants graduates of neonatal intensive care (NICU) units Hecox and Galambos in the early 1970s offers 100% sensitivity and specificity of 86%. Currently, hearing in infants, pre-school and school sieve is something quite unknown in our country, even among the medical staff, and is limited to very few institutions, some of them belongs to a private sector. The initial experiences in this area date back to 1987, when he placed an cochlear implant at the General Hospital ;Dr. Manuel Gea González; in which these operations continue carrying out. This operational experience are considered important for scientific contributions in Mexico. Also, aware of the realization of single channel and multichannel, Guadalajara and Monterrey cities in Mexico, implants initiated between the years 1996 and 1998. In some hospitals in Mexico, the Neonatal auditory sieve is performed, This causes the vast majority of cases of hearing loss and deafness which is generally detected late; In addition, the staffing of auditory prosthesis covers sparsely to people who need them; and only benefit with cochlear implants a minimum percentage of them. Today among the child population, hearing loss (decrease of the level of below-normal hearing) is the more frequent defect, beating Down syndrome and infantile.

Diagnostic Exome Sequencing Reveals a de novo Mutation in the DYNC1H1 Gene in a Sporadic Case of Developmental Delay, Seizures, and Polymicrogyria. *K.D. Gonzalez[1], J. Wei[1], X. Li[1], H.M. Lu[1], H. Lu[1], J.S. Cohen[2], R. McClellan[2], S. Naidu[2], W. Zeng[1].* 1) Ambry Genetics, Aliso Viejo, CA; 2) Department of Neurogenetics, Kennedy Krieger Institute, Baltimore, MD.

Clinical diagnostic exome sequencing has rapidly made its way from research to the clinical setting and has been instrumental in successfully providing a molecular diagnosis for families who had previously been unsuccessful in their pursuit of the underlying disease etiology. We sequenced protein-coding regions of the genome (exome) in a 2 1\2 year old female with global developmental delay, microcephaly, seizures, hypotonia, behavioral difficulties, and MRI findings of polymicrogyria. The family history was negative for similar phenotypes. The patient had evaded diagnosis through clinical evaluation and extensive testing over many years including negative *MECP2, TUBB2, WDR62*, and *GPR56* gene sequence analyses, as well as uninformative biochemical and SNP-array results. The patient was heterozygous for a missense mutation (c. 4700G>A; p.R1567Q) in exon 22 of the *DYNC1H1* gene and co-segregation analysis showed that her mother and father did not carry the mutation, indicating a *de novo* mutation occurrence. The amino acid is completely conserved throughout vertebrates. *DYNC1H1*interacts with the LIS1 gene in which mutations cause gross disorganization of cortical neurons leading to lissencephaly. Mutations in *DYNC1H1* lead to neuronal degeneration. *DYNC1H1*mutations have been identified in patients with central and peripheral neuronal defects including mental retardation, speech and motor developmental delay, hypotonia, and microcephaly, Charcot-Marie-Tooth (CMT2), epileptic seizures, brachycephaly, dysmorphic features, and lower extremity spinal muscular atrophy (SMA). The identified mutation is highly consistent with the patient's clinical symptoms and, after years of unsuccessful analyses, led to a molecular diagnosis for the family. Additionally, the findings further delineate the phenotypic spectrum of patients with mutations in the *DYNC1H1* gene.

Congenital poikiloderma, fatty infiltration of muscles and pulmonary fibrosis: a new syndrome. *S. Mercier[1,2], S. Kury[3], JM. Mussini[2,4], A. Magot[2,5], B. Isidor[1], S. Barbarot[6], A. David[1], S. Bezieau[3].* 1) Service de Génétique Médicale, Unité de Génétique Clinique, CHU de Nantes, Nantes, France; 2) Centre de Référence des Maladies Neuromusculaires Nantes-Angers, CHU de Nantes, Nantes, France; 3) Service de Génétique Médicale, Unité de Génétique Moléculaire, CHU de Nantes, Nantes, France; 4) Laboratoire d'Anatomie Pathologique A, CHU de Nantes, Nantes, France; 5) Laboratoire d'Explorations Fonctionnelles, CHU de Nantes, Nantes, France; 6) Service de Dermatologie, CHU de Nantes, Nantes, France.

Congenital poikiloderma is a key feature in Rothmund-Thomson syndrome (RTS). We report a sporadic case of congenital poikiloderma, hypopigmentation, hypotrichosis and hypohidrosis in a 7 year-old boy, initially diagnosed with RTS-like. At the age of 6 years, he presented with distal lymphoedema of the four limbs. Simultaneously, a rapidly progressive muscle weakness occurs with primary distal lower limb predominance, and secondary clinical extension to proximal upper and lower limbs. Wheel chair use was required at the age of 7 years. Serum creatine kinase level was normal and electromyographic examination showed a myogenic pattern in lower limbs. Muscle MRI showed a very diffuse fatty infiltration of lower limbs, which was confirmed by the quadriceps muscle biopsy. Microscopy of the skin revealed elastic tissue degeneration with alterations of the elastic network in the superficial and deep dermis. Respiratory function tests revealed a mild restrictive impairment. RTS was excluded on clinical evolution and normal *RECQL4* gene analysis. A similar report with poikiloderma, tendon contracture, pulmonary fibrosis and identical histological anomalies has been described in a South African family with autosomal dominant inheritance suggesting a *de novo* mutation in our patient. Array-CGH was normal and trio-based exome sequencing is pending. This second report highly supports that this syndrome should be considered as a distinct entity.

3067W

Prenatal diagnosis of a fetus with a rare association of a multiple heart and renal malformations: case report. *M. Dumitrescu[1,3], D.F. Albu[2,3,4], C.C. Albu[2,3], A. Oncescu[2,3], E. Severin[2].* 1) Marius Nasta Hospital, Bucharest, Romania, Bucharest, Romania; 2) University of Medicine and Pharmacy Carol Davila Bucharest, Romania, Bucharest, Romania; 3) Alco San Clinic, Bucharest, Romania; 4) Panait Sarbu Hospital, Bucharest, Romania.

A 32-year-old pregnant Caucasian woman was reffered for prenatal ultrasound examinations. The sonoghraphic fetal monitoring demonstrated a rare association of a multiple heart and renal malformations: absence of valve of Vieussens, common arterial trunk, unilateral atrial enlargement, severe bilateral hidronephrosis and polyhidramnios. Amniocentesis was performed during the 18th week of pregnacy. Fetal chromosomal analysis showed abnormal karyotype: 46XX,add 12(p13.3). The parents decided to continue the pregnancy. Unfortunately the baby died two weeks later. Postnatal ultrasounds and autopsy confirmed our sonographic findings. Conclusion: Prenatal evaluation both sonographic and genetic was very useful for the pregnancy management. In this family case, any future pregnancy should be be karyotyped for further evaluation. The necessity of routine ultrasound examination for the prenatal diagnosis of chromosomal abnormatities to all pregnancies.

3068F

Complex chromosomal translocation leading to a dual diagnosis of Prader-Willi Syndrome and Cri-du-chat in a 14 year old boy illustrating the importance of re-evaluation in an individual with atypical Prader-Willi phenotype. *J.A. Gold[1, 2], S. Ramanathan[1].* 1) Pediatrics, Loma Linda University Medical Center, Loma Linda, CA. Dept. Pediatrics Division Genetics and Metabolism; 2) University California Irvine University Medical Center Dept Pediatrics Division Genetics and Metabolism.

Introduction: Prader-Willi syndrome (PWS) affects 1/15,000-1/30,000, individuals. It is characterized by prenatal-onset hypotonia, infantile poor feeding and failure to thrive. This is followed by hyperphagia, childhood-onset obesity, short stature, facial dysmorphic features, psychomotor delay, and a distinct behavioral phenotype. Lack of expression from the paternally inherited copy of the PWS/Angelman (AS) critical region on chromosome 15 at 15q11–q13 region causes PWS. Three molecular subtypes of changes include paternal deletion, maternal uniparental disomy (UPD) and imprinting center defects. Cri-du-chat Syndrome or 5p minus syndrome affects 1/20,000-1/50,000 individuals. It is associated with the deletion of short arm of chromosome 5 of varying sizes from extremely small to the complete p arm of chromosome 5. It is characterized by a typical cat like cry at birth, microcephaly, hypertelorism, epicanthic folds, low-set dysplastic ears, hypotonia and severe psychomotor and developmental delay. Case Report: 14 year old boy presented with features of Prader-Willi syndrome due to an unbalanced chromosomal translocation between chromosome 15 and chromosome 5. It has resulted in a deletion of the PWS region on chromosome 15q and a small deletion on chromosome 5p Cri-du-chat region. Microarray result: 8.9 Mb proximal deletion of 15q11.2-q13.1, consistent with Type I deletion for the PWS/AS syndrome region; 6.533 Mb terminal deletion of 5pter-p15.31, consistent with Cri-du-chat syndrome. We will discuss the overlapping features of Prader-Willi and Cri-du-chat syndromes as well as any unusual features for either condition. We do not know how the patient's genotype will affect or modify the expression of the phenotypes for these disorders in him. To our knowledge this is the first patient described with both conditions. Unfortunately this has made it extremely difficult to give accurate information on the natural history and long term out comes with any complications.

3069W

MOLECULAR CHARACTERIZATION OF SHOX GENE AND REGULATORY REGIONS IN PATIENTS WITH IDIOPATHIC SHORT STATURE FROM THREE MEDICAL CENTERS IN OF BOGOTA, COLOMBIA. *T. Vinasco[1], G. Jaimes[2], M. Coll[3], C. Cespedes[4], H. Velasco[5].* 1) Morfology, National University, Bogota, Cundinamarca, Colombia; 2) Central Military Hospital, Bogota, Colombia; 3) Hospital de la Misericordia, Bogota, Colombia; 4) San Ignacio Hospital, Bogota, Colombia; 5) MD, MSc, E. Genetic Institute, National University, Bogota, Cundinamarca, Colombia,.

Short stature is a concept that encompasses normal variants and pathologic variants. One of these variants is Idiophatic Short Stature (ISS) where patients do not have corporal asymmetry, growth defiency, nor chromosomal anomalies or any syndromatic sign. Although several genes have been described in ISS, mutations in SHOX gene has been found in a high frequency in these patients (around 3 to 15%). Our study evaluated 52 patients with ISS from three national referral medical centers and sought any type of deletion / duplication of SHOX gene and conserved non-coding regions (CNE) by MLPA (MRC Holland, SALSA MLPA KIT P018-E1 SHOX y P018-F1 upload version). We found that 9.6% patients had mutations in SHOX, 4 patients had deletions (Exon 1, Exon 2, Exon 6 and Intron 6b) and one had duplication (CNE 9). Two of these mutatios were new (Exon 6b deletion and CNE 9 duplication), one was de novo, 3 mutations were inherited from one of the parents and in the remainder, we could not confirm the source. All patients had height below -2.5 SD and some patients were on growth hormone therapy. This is the second Latin American study reporting SHOX mutations for ISS patients. Sequencing is desirable in negative cases (47) looking for punctual mutation.

Clinical and molecular characterization of non-syndromic craniosynostosis: an International Consortium Approach. *M.L. Cunningham[1], P.A. Romitti[2], C.M. Justice[3], A.F. Wilson[3], T. Roscioli[4], E. Oláh[5], B. Bessenyei[5], M.R. Passos-Bueno[6], B. Wollnik[7], A.O.M. Wilkie[8], S.A. Boyadjiev Boyd[9], International Craniosynostosis Consortium.* 1) Dept of Pediatrics, Division of Craniofacial Medicine, University of Washington and Seattle Children's Research Institute, Seattle, WA, USA; 2) Department of Epidemiology, College of Public Health, The University of Iowa, Iowa City, IA; 3) Genometrics Section, IDRB, Division of Intramural Research, NHGRI, NIH, Baltimore, MD; 4) School of Women's and Children's Health, Sydney Children's Hospital, University of New South Wales, Sydney, Australia; 5) Department of Genetics, Debrecen, Hungary; 6) Department of Genetics, University of Sao Paolo, Brazil; 7) Institute of Human Genetics, University of Cologne, Germany; 8) Craniofacial Unit, Oxford University Hospitals NHS Trust, John Radcliffe Hospital, Oxford, United Kingdom; 9) Department of Pediatrics, Section of Genetics, University of California Davis, Sacramento, CA.

Non-syndromic craniosynostosis (NSC), the premature closure of one or more of the cranial vault sutures is a common congenital malformation, affecting approximately one out of 2,000 newborns. Rare mutations in the FGFR2, TWIST1, FREM1, LRIT3, EFNA4, ALX4, and RUNX2 duplications have been reported in a minor fraction of NSC cases; however, the etiology of this birth defect is not well understood. In an attempt to better characterize the clinical phenotype and to identify susceptibility loci and contributing environmental factors we have established an International Craniosynostosis Consortium (ICC) coordinating the effort of physicians and researchers at 10 sites in the United States, 4 craniofacial units in the United Kingdom, the Hungarian National Registry for Birth Defects and several major craniofacial centers in Australia, Brazil and Germany. A total of 741 families have been recruited and characterized and clinical databases with sample repository were created. A study website allows collaborators, referring physicians and members of the affected families to contribute to the goals of ICC (https://genetics.ucdmc.ucdavis.edu/icc.cfm). As a result, RUNX2, ALX4, FREM1, and LRIT3 variants predisposing to NSC were identified and reported by our group. The findings of the first genome-wide association study suggested a role for BMP2 and BBS9 in sagittal NSC. The goal of this paper is to present our current approach and to inform the genetics community of possible ways to contribute to the mission of the ICC (contact: simeon.boyd@ucdmc.ucdavis.edu).

Molecular prenatal diagnosis of a sporadic alobar holoprosencephalic fetus: Genotype-phenotype correlations. *J. Gekas[1], C. Sergi[2], D. Kamnasaran[3].* 1) Human Genetics Research Unit, Centre de recherche de l'hôpital Saint-François d'Assise, Québec, Canada; 2) Department of Laboratory Medicine and Pathology, University of Alberta, Edmonton, Canada; 3) Department of Pediatrics, Laval University, Québec, Canada.

Background: Holoprosencephaly (HPE) is principal defect in the developing prosencephalon with an incidence of 1 in 250 conceptuses and 1 in 10-16,000 live newborn infants. Current prenatal diagnostic protocols on the clinical management of holoprosencephaly involve combined fetal imaging analyses with cytogenetic and molecular genetic testing on suspected cases. To date, mutations are identified in 5–10% of nonsyndromic, non-chromosomal cases in at least 12 genes. We report the molecular prenatal diagnosis of a fetus with alobar holoprosencephaly. **Methods and Results:** CTG band karyotyping and array CGH genome-wide cytogenetic screenings were done, in conjunction with DNA sequence analyses of the *SHH*,*ZIC2*, *SIX3* and *TGIF* genes in search of a molecular etiology. Our proband was conceived by a 37-year-old healthy mother (2 Para, 1 Abortus) and is the second child of non-consanguineous parents with an unremarkable family history. At 18 gestational weeks, transabdominal 2D ultrasonography detected a gestational age appropriate fetus with an alobar holoprosencephalic brain that died in-utero. Post mortem examination disclosed findings of a male alobar holoprosecenphalic fetus with facial findings of cyclopia and absence of the nasal structures. Standard CTG band karyotyping and array CGH did not disclose any plausible findings. However, by using a candidate gene approach, we identified the proband with a sporadic, non-polymorphic, heterozygous c.298 C_T substitution non-sense mutation in the first exon of the *SHH* gene. No mutations were detected in other HPE associated genes: *ZIC2*, *SIX3* and *TGIF*. The proband mutation is predicted to encode a non-functional protein (p.Gln100Ter) which truncates before the cholesterol mediated autoproteolytic cleavage site. A comparison of these findings to the literature identifies three previous nonsyndromic HPE cases with heterozygous substitution mutations in the same codon 100 of the *SHH* gene, but with extreme variability in the holoprosencephaly phentoypes. **Conclusion:** We report a new fetal case manifesting alobar holoprosencephaly with codon 100 of the *SHH* gene having a hotspot for loss-of-function mutations. Mutations in codon 100 of SHH are identified in both sporadic and autosomal dominant inherited cases and with demonstrative evidence of variable expressivity and penetrance of the prosencephalon development deficiency spectrum.

3072F

Sonic Hedgehog (SHH)regulatory region deletion in a patient with Holoprosencephaly. *L. Ribeiro-Bicudo[1], R. Quiezi[1], M. Ansari[2], K. Williamson[2], A. Richieri-Costa[1], D. FitzPatrick[2].* 1) Genetics, Hospital for Rehabilitation of Craniofacial Anomal, Bauru, Sao Paulo, Brazil; 2) MRC Medical Center Research, Edinburgh, UK.

The craniofacial development is a complex and dynamic process which involves diverse stages of embryonic life. Holoprosencephaly (HPE) is one of the most common craniofacial malformations characterized by the incomplete separation of the cerebral hemispheres into distinct right and left halves. Clinical expression is extremely variable ranging from minor facial signs to complexes craniofacial anomalies such as ciclopia. Structural chromosomal anomalies previously compiled from chromosomal HPE data predicted at least 12 different HPE loci that include SHH, SIX3, TGIF, PATCH1, TGF1, FOXH1, ZIC2, SIX3, GAS1 e GLI2, and among these genes, SHH appears to be the major one, accounting for 50% of the identified mutations. We report a Brazilian patient presenting a mild form of lobar HPE associated with eye anomalies who presented microcephaly, neurodevelopmental delay, bilateral microphthalmia, more severe in the right eye, convergent strabismus, pendular nystagmus, nasal septum agenesis, flat face, cleft lip/palate surgical scars, an upper placed pre-maxilla with a single maxillary central incisor, bilateral ungueal hypoplasia of the 5° toe. Ophthalmological evaluation showed right microcornea and left retinal coloboma. G-banded chromosomes in peripheral lymphocytes were normal. Mutation analysis for the genes SOX2, OTX2, PAX6, SHH, SIX3, TGIF, ZIC2 and BMP4 were unremarkable. Array-CGH analysis showed a submicroscopic microdeletion of 540 kb at 7q36.3, the deletion occurred approximately between 150 kb up to 694 kb upstream of the SHH promoter, encompassing the SHH regulatory region and affecting transcription of this gene. This study was approved by the Ethics Committee of the Hospital de Reabilitação de Anomalias Craniofaciais, Bauru/Brazil (HRAC). In mice, the Shh gene has six enhancers that regulate Shh transcription in the embryonic forebrain. The Shh floorplate enhancers (SFPE2) and Shh brain enhancer (SBE1) are localized approximated 200 kb downstream from Shh promoter, the other enhancers, SFPE1, SBE4, SBE2 and SBE3 are approximated 400 kb upstream from Shh promoter, and three of these enhancers are highly conserved in human. The microdeletion found in our study affected at least three of these enhancer elements (SBE2, SBE3 and SBE4) and suggests that the HPE phenotype is probably casual for loss of SHH enhancers. Grants: Fapesp Proc. n° 2011/07012-9.

3073W

Associated malformations among infants with radial ray deficiency. *C. Stoll, B. Dott, Y. Alembik, M. P. Roth.* Faculte de Medecine, Genetique Medicale, Strasbourg, France.

Infants with radial ray deficiencies very often have other associated congenital anomalies. The reported frequency and types of associated malformations vary between different studies. The purpose of this investigation was to assess the frequency and types of associated malformations among infants with radial ray deficiencies in a geographically well defined population from 1979 to 2004 of 346,831 consecutive births. Of the 73 infants with radial ray deficiencies born during this period (prevalence at birth of 2.1 per 10,000), 75 % had associated malformations. Infants with associated malformation were divided into recognizable conditions (16 (22%) infants with chromosomal and 20 (27%) with non chromosomal conditions), and non recognizable conditions (19 (26%) infants with multiple malformations). Trisomies 18 and autosomal deletions were the most frequent chromosomal abnormalities. VACTERL association, thrombocytopenia absent radii syndrome, Fanconi anemia and Holt-Oram syndrome were most often present in recognizable non chromosomal conditions. Malformations in the musculoskeletal, cardiovascular and urogenital systems were the most common other anomalies in infants with multiple malformations and non recognizable conditions. The frequency of associated malformations in infants with radial ray deficiencies emphasizes the need for a thorough investigation of these infants. Routine screening for other malformations especially musculoskeletal, cardiac and urogenital systems anomalies may need to be considered in infants with radial ray deficiencies, and referral of these infants for genetic evaluation and counseling seems warranted.One should be aware that the malformations associated with RRD can be often classified into a recognizable malformation syndrome or pattern (in 49 % of the cases).

3074F

Orofaciodigital syndrome in a group of patients who attended Operation Smile Foundation in Colombia, between 2005 and 2012. *J. Martinez[1], I. Briceno[1,2], A. Venegas[2], S. Bohorquez[1], M. Montiel[1], A. Patiño[1], L. Arias[1,2].* 1) Universidad de La Sabana, Chia, Colombia; 2) Universidad Javeriana. Bogota Colombia.

Oral-facial-digital syndrome is a group of related conditions that affect the development of the oral cavity (the mouth and teeth), facial features, and digits (fingers and toes).13 potential forms of oral-facial-digital syndrome. The different types are classified by their patterns of signs and symptoms. However, the features of the various types overlap significantly, and some types are not well defined. The classification system for oral-facial-digital syndrome continues to evolve as researchers find more affected individuals and learn more about this disorder. Abnormalities of the oral cavity that occur in many types of oral-facial-digital syndrome include a split (cleft) in the tongue, a tongue with an unusual lobed shape, and the growth of noncancerous tumors or nodules on the tongue. Affected individuals may also have extra, missing, or defective teeth. Another common feature is an opening in the roof of the mouth (a cleft palate). Some people with oral-facial-digital syndrome have bands of extra tissue (called hyperplastic frenula) that abnormally attach the lip to the gums. Distinctive facial features often associated with oral-facial-digital syndrome include a split in the lip (a cleft lip); a wide nose with a broad, flat nasal bridge; and widely spaced eyes (hypertelorism). Abnormalities of the digits can affect both the fingers and the toes in people with oral-facial-digital syndrome. These abnormalities include fusion of certain fingers or toes (syndactyly), digits that are shorter than usual (brachydactyly), or digits that are unusually curved (clinodactyly). The presence of extra digits (polydactyly) is also seen in most forms of oral-facial-digital syndrome. Other features occur in only one or a few types of oral-facial digital syndrome. These features help distinguish the different forms of the disorder. Other forms of oral-facial-digital syndrome are characterized by neurological problems, particular changes in the structure of the brain, bone abnormalities, vision loss, and heart defects. Oral-facial-digital syndrome has an estimated incidence of 1 in 50,000 to 250,000 newborns. We conducted a study among 2500 patients attending “Operation Smile” in Bogota, 8 cases of orofaciodigital syndrome were diagnosed, which corresponds to 0.3% of the population studied. This result indicates a frequency significantly higher than that reported in the literature for general population. The Clinical description is presented.

3075W

A New type of Acrofacial Dysplasia. Prenatal diagnosis and autopsy findings. *K. Millar[1], A. Toi[2], S. Keating[3], P. Shannon[3], S. Unger[4], D. Chitayat[1,5].* 1) Department of Obstetrics and Gynaecology, The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) Department of Diagnostic Imaging; Mount Sinai Hospital, Toronto, Ontario, Canada; 3) Department of Pathology; Mount Sinai Hospital, Toronto, Ontario, Canada; 4) Service of Medical Genetics, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 5) Department of Paediatrics, Division of Clinical and Metabolic Genetics, The Hospital for Sick Children; University of Toronto, Toronto, Ontario, Canada.

Acrofacial dysostosis (AFD) is a clinically and etiologically heterogeneous group of disorders characterized by craniofacial and limb anomalies. Various sub types of AFD have been described and the types de Macena Sobreira, Bates and Rodriguez are among the lethal. We report on a new type of lethal AFD. The mother was a 23-year-old G1P0 woman of English/Irish decent and the father was 22 years old and of Hungarian/English decent. The couple was healthy, non-consanguineous and the family history was non-contributory. The fetus presented at 20.2 weeks gestation with ultrasound findings of ventriculomegaly and short femur lengths consistent with 16 weeks gestation. A repeat fetal ultrasound done by us revealed severe micromelia, absent bilateral fibula, bilateral talipes and bilateral abnormal position of both knees. The facial profile was flat with micrognathia and there was moderate cerebral ventriculomegaly. The heart was thought to be anatomically normal. Fetal MRI confirmed severe micromelia, cerebral ventriculomegaly with hypoplasia of the corpus callosum, partially fused fornices and abnormalities of the cerebellum. Chromosome analysis and microarray analysis were normal and female. The couple was counselled and decided to continue the pregnancy. Delivery was at 33.0 weeks gestation and induced for severe maternal gestational hypertension. The baby died two hours following delivery of respiratory failure. The autopsy showed facial dysmorphism including a flat philtrum with protruding lower lip, small cleft in alveolar ridge with tooth like structure and tethered tongue. She had severe micromelia, bilateral axillary pterygia, hypoplastic thumbs, camptodactyly with only two flexion creases on most fingers, possible ventricular septal defect and hydrocephalus with partial rhombencephalosynapsis and fused thalami. There are a number of genetically and phenotypically distinct conditions with mandibulofacial dysplasia with acral anomalies. The anomalies in our case are different and may represent a new AFD syndrome.

Development of a Visit Assessment Tool to Address Birth Defects and Dysmorphology. *O.A. Abdul-Rahman[1], L. Hayes[2], B. Loyola[2], D.A. Stevenson[2], S. Astley[3], C. Chambers[4], K.L. Jones[4], H.E. Hoyme[5], F. Waffern[6], J.C. Carey[2].* 1) Dept Pediatrics, Univ Mississippi, Jackson, MS; 2) Dept Pediatrics, Univ Utah, Salt Lake City, UT; 3) School Public Health, Univ Washington, Seattle, WA; 4) Dept Pediatrics, UCSD, San Diego, CA; 5) Dept Pediatrics, Univ South Dakota, Sioux Falls, SD; 6) Dept Pediatrics, Univ California Irvine, Irvine, CA.

Introduction: The National Children's Study (NCS) is a longitudinal study of various aspects of children's health including genetic, epigenetic, and environmental effects. However, detailed phenotypic information on these children is not comprehensively collected. The current NCS protocol includes study visits at birth, 6 months, and 12 months of age. Several institutions collaborated to develop, evaluate, and implement an assessment tool to be used by NCS field workers to document physical features by digital photography and physical assessment during these visits. Methods: Clinical geneticists from the participating institutions used the Elements of Morphology definitions and illustrations on over 400 phenotypic features as a guide for variations and anomalies needing documentation to design the dysmorphology assessment instrument (DAI). The DAI is composed of two components. The first component is the Photographic Protocol made up of 15 photographic images (8 views of craniofacies and 7 views of the hands and feet), and three 10-second videos for newborns to capture 332 features. The second component is the Physical Assessment list, which was the result of identifying features that are not captured sufficiently on the Photographic Protocol. Results: As of April 2012, the DAI has been administered to 60 participants. The images and videos from the Photographic Protocol for three participants at each age range were randomly selected for case review by three of the authors (OAR, DAS, JCC). Of the 332 features assessed, the rate of agreement on the presence or absence of a feature was 91.6% for the newborn, 92.2% for the 6 moth-old, and 91.9% for the 12 month-old. There was also general agreement regarding photo quality with some differences on the more subjective features and those difficult to define. Conclusions: The DAI is a comprehensive and valid tool able to be implemented by trained staff to capture dysmorphology in the field. This data will provide the complement to genetic and environmental information so that genotype-phenotype correlations can be determined. Further validation and modification of the DAI is needed prior to implementation with the NCS. The DAI may also be a tool to be used by other population-based studies requiring reliable capture of phenotypic information in the field by staff with limited genetics training.

3077W

A NEW CASE OF CRANIOFACIAL MICROSOMIA AUTOSOMAL DOMINANT ASSOCIATED WITH COMPLETE RIGHT SIDE TESTICULAR AND SCROTAL ECTOPIA. *J. Rojas Martínez[1], J.C. Prieto Rivera[1,2].* 1) Pontificia Universidad Javeriana, Instituto de Genetica Humana, Bogota, Colombia; 2) Hospital La Victoria, Genetica, Bogota. Colombia.

Craniofacial microsomia includes a spectrum of malformations primarily involving structures derived from the first and second branchial arches. The severity of the findings range from subtle facial asymmetry with apparently normal ears, to a typical asymmetry with microtia / anotia, atresia of the ear canals, microphthalmia, and respiratory compromise from severe mandibular hypoplasia. Other associated malformations include cleft lip and/or palate, abnormal vertebrae, cardiac, limbs, central nervous system and genitourinary abnormalities, within the latter has never reported the complete scrotal and testicular ectopia unilateral. We present the case of a nine-month-old boy born in Bogotá (Colombia), product of fifth pregnancy maternal, nonconsanguineous parents, born preterm by cesarean section at 35 weeks due to placenta previa, at 2 days of birth, distal functional colostomy was performed for imperforate anus. Normal neurodevelopment. Background in the family of father, aunt and paternal cousin with microtia. Physical examination found facial asymmetry by right hemifacial microsomia with microtia grade III, left small skin tag of 4 mm of sessile base, bilateral epicanthic folds, infantile male genitalia with complete right scrotal and testicular ectopia and nonfunctioning anal sphincter with imperforate anus. Radiographic findings include decreased height of 3 and 4 dorsal vertebrae that resemble platyspondyly and suspected atlanto-odontoid dislocation. CT of the abdomen with absent right kidney, normal left kidney. Skull radiography shows right side mandibular, maxillary and zygomatic arch hypoplasia. Q Banding karyotype was normal: 46, XY. Brainstem evoked response audiometry: abnormal study consistent with right conductive hearing loss. Most cases of craniofacial microsomia correspond to sporadic cases; there are few reports of autosomal dominant inheritance as in this case, the association with complete scrotal and testicular ectopia unilateral has not been reported in the literature.

A replication study of genome-wide significant Rheumatoid Arthritis susceptibility loci in the Pakistani population. *S.F. Jalil[1,2], A. Bhatti[1], F.Y. Demirci[2], X. Wang[2], I. Ahmed[1], M. Ahmed[3], M.M. Barmada[2], J.M. Malik[4], P. John[1], M.I. Kamboh[2].* 1) Atta-Ur-Rahman School of Applied Biosciences (ASAB), National University of Sciences and Technology (NUST), Islamabad, Pakistan; 2) Department of Human Genetics, GSPH, University of Pittsburgh, Pittsburgh, PA; 3) Rheumatology Unit Military Hospital Rawalpindi, Pakistan; 4) Rehmat Noor Arthritis Research Center Rawalpindi, Pakistan.

Rheumatoid arthritis (RA) is a common, systemic and multifactorial autoimmune disease. The etiology of RA is very complex and is suggested to be the outcome of various environmental, hormonal and genetics factors. Genome-wide association studies (GWAS) have identified several genome-wide significant SNPs associated with RA. In this study, we sought to replicate the association of 32 reported genome-wide significant SNPs residing outside the MHC locus in a unique Pakistani population. We genotyped 32 SNPs in a sample of 366 Pakistanis that comprised related and unrelated cases and controls. All SNPs were genotyped using TaqMan assays and data were analyzed using family case-control (FamCC) ver 1.0 software. Twelve of the 32 SNPs were replicated in this sample with significant p-values ranging from 1.01E-05 to 4.80E-02, the most significant being the *CD28*/rs1980422 SNP. Suggestive associations were seen with additional 6 SNPs (P - 8.97E-02 to 1.93E-01). These observations suggest that different populations share the genetic background and susceptibility loci for RA.

3079W

A novel missense mutation in *PARD3* is associated with class III malocclusion. *T. Nikopensius[1,2], M. Kals[2], T. Annilo[1], T. Jagomägi[3], M. Saag[3], A. Metspalu[1,2].* 1) Institute of Molecular and Cell Biology, University of Tartu, Estonia; 2) Estonian Genome Center, University of Tartu, Estonia; 3) Dept of Stomatology, Faculty of Medicine, University of Tartu, Estonia.

Class III malocclusion is clinically heterogeneous facial phenotype associated with varying combinations of skeletal and dental components. The familial aggregation rates and recurrence risks provide evidence that genetic factors play an important role in its etiology. Moreover, research in multiplex kindreds has indicated that class III malocclusion may represent a monogenic dominant phenotype. We report a novel mutation that underlies class III malocclusion in an Estonian family. Employing whole-exome sequencing in three affected individuals (grandfather-father-son), we identified a heterozygous missense mutation (c.2677C>T [p.Ala893Thr]) in *PARD3* that segregated with this disorder in three generations. The previously undescribed mutation was validated by Sanger sequencing in all patients whereas two unaffected siblings did not carry this mutation. *PARD3* (par-3 partitioning defective 3 homolog) encodes a protein which similarly to other PARD family members is essential for asymmetrical cell division and direct polarized cell growth. PARD3 interacts with several members of the SMAD family of signal transduction and transcriptional modulator proteins that mediate multiple signaling pathways including transforming growth factor beta (TGF-beta) receptor signaling pathway. The TGF-beta family members have a crucial role in craniofacial morphogenesis, particularly in regulation of epithelial differentiation and epithelial-mesenchymal interactions in extracellular matrix remodeling, and recent evidence suggests that their function during craniofacial development is largely mediated through the SMAD signaling system. SMAD proteins are phosphorylated and activated by transmembrane serine-threonine receptor kinases in response to TGF-beta signaling. TGF-beta has been shown to alter cell polarity via a SMAD-dependent signaling mechanism where SMADs can directly interact with proteins involved in cell polarity, such as PAR proteins. This finding underscores the importance of other yet unknown genes and developmental factors in the etiology of dental anomalies.

Genotype/Phenotype correlation in Smith-Magenis Syndrome with abnormal 17p deletions. *T. Vilboux[1], A.C.M Smith[2], S. Chandrasekharappa[3], C. Ciccone[1], J. Blancato[4], W.J. Introne[2], W.A. Gahl[1,2], M. Huizing[1].* 1) Medical Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 2) Office of the Clinical Director, National Human Genome Research Institute, NIH, Bethesda, MD; 3) Cancer Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 4) Department of Oncology, Georgetown University Medical Center, Washington, DC.

Smith-Magenis syndrome (SMS) is a complex developmental disorder characterized by an interstitial deletion of chromosome 17p11.2. This syndrome includes variable symptoms such as cognitive impairment, craniofacial dysmorphia, height-growth delay, infantile hypotonia, brachydactyly, attention deficit, decreased sensitivity to pain, self-injury, maladaptive behaviors, speech delay, hearing loss, and sleep disturbance. Most SMS patients have the same approximately 3.7Mb interstitial 17p11.2 genomic deletion. Haploinsufficiency of the *RAI1* gene is likely responsible for most of the SMS features, but haploinsufficiency of other genes within the deleted region may also contribute to the phenotype of SMS patients with 17p11.2 deletions. To further investigate the molecular basis of the SMS phenotype we studied phenotype/genotype correlation of 10 SMS patients with abnormal 17p deletions. We identified exact deletion sizes by multiple genomic techniques, including FISH (fluorescent in situ hybridization), MLPA (Multiplex Ligation-dependent Probe Amplification) and quantitative PCR analyses. Furthermore, each patient's DNA was analyzed on a SNP-microarray (Illumina chip) to define the exact 17p breakpoints. With these data we refined the minimal Smith-Magenis syndrome critical region to an approximately 500-kb interval on 17p11.2 that includes RAI1 and 6 other genes. A deeper analysis of the genes in or outside this minimal critical region provided us with candidate genes for some of the unusual phenotypes of certain patients, including, obesity, severe speech delay, hearing-loss or immune defects. Analysis of genotype/phenotype correlations in patients with unusual deletions in complex syndromes like SMS may provide candidate genes for specific phenotypes within the syndrome. These findings may not only benefit the studied syndrome, but may also assist in molecular analysis of more common phenotypes (e.g. for SMS: autism, sleep abnormalities, obesity, speech delay, maladaptive behaviors).

MiR-133a and MiR-422a in Human Circulating Monocytes are Potential MicroRNA Biomarkers Underlying Postmenopausal Osteoporosis. *Y. Wang[1], L. Li[1], B.T. Moore[1], X.H. Peng[1], X. Fang[2], J.M. Lappe[1], R.R. Recker[1], P. Xiao[1].* 1) Osteoporosis Research Center, School of Medicine, Creighton University, Omaha, NE; 2) Biostatistical Core, Office of Research and Compliance, Creighton University, Omaha, NE.

MicroRNAs (miRNAs) are a class of short non-coding RNAs (~ 22 nt) that involved in posttranscriptional gene regulation, which regulate gene expression by targeting mRNAs. Circulating monocytes play important roles in osteoclastogenesis by acting as osteoclast precursors and secreting osteoclastogenic factors, such as IL-1, IL-6 and TNF-α. This study aimed to find significant miRNA biomarkers in human circulating monocytes underlying postmenopausal osteoporosis. We used ABI TaqMan® miRNA array followed by qRT-PCR validation in human circulating monocytes to identify miRNA biomarkers between 10 high BMD and 10 low BMD postmenopausal Caucasian women. MiR-133a and miR-422a were up-regulated (P = 0.007, P =0.065) in the low compared with the high BMD groups in the array, which were also validated by qRT-PCR (P = 0.044, P =0.029). We performed bioinformatic target gene analysis and found three potential target genes, CXCL11, CXCR3 and SLC39A1 of miR-133a and five potential target genes (CBL, CD226, IGF-1, PAG1, and TOB2) of miR-422a, which are able to inhibit osteoclastogenesis. In addition, we performed Pearson correlation analyses of the expression levels of miR-133a and miR-422a with the expression levels the potential target genes in the 20 postmenopausal women. We did find negative correlations though not significant. Many studies demonstrated that miR-133a is important in the development of muscle, such as skeletal and cardiovascular muscle. In bone, particularly, miR-133a has been found to regulate osteoblastogenesis by targeting and regulating Runx2 expression. A recent study also demonstrated that miR-133a was up-regulated in osteoblast-like periodontal ligament stem cells treated with ibandronate, a nitrogen-containing bisphosphonate that inhibits bone resorption and is widely used to treat osteoporosis. Only one study demonstrated that miR-422a was down-regulated in osteoblast-like cell line (MG-63) treated with peptide-15. However, our study for the first time suggests that in vivo miR-133a and miR-422a in osteoclast precursors, circulating monocytes, are potential miRNA biomarkers underlying postmenopausal osteoporosis.

3082F

Genome-wide Mosaic Paternal Uniparental Isodisomy. *J. Kalish[1,2], A. Wilkens[1], S. Mulchandani[3], E. Zackai[1], N. Spinner[3], M. Bartolomei[2], L. Conlin[3], M. Deardorff[1].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Cell & Developmental Biology, Perlman School of Medicine, The University of Pennsylvania, Philadelphia, PA; 3) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA.

The growing number of identified imprinted genes in humans underscores the need for biparental inheritance of the genome; however, 8 cases of live-born genome-wide mosaic paternal uniparental isodisomy (GWpUPiD) have been reported. We describe four additional cases diagnosed by genome-wide SNP array analysis. All four patients presented with persistent neonatal hypoglycemia caused by hyperinsulinism (HI). Three of the four presented with hemihyperplasia as well as placentomegaly. Given the increased risk for hepatoblastoma and Wilms tumor in patients with paternal uniparental disomy (UPD) 11, we initiated screening with alphafetoprotein (AFP) levels and abdominal ultrasounds. Patient 1 developed large cystic liver hamartomas requiring resection. She is currently 26 months old with near normal cognitive development. Patient 2 had severe HI requiring a 95% pancreatectomy. She had persistently elevated AFPs and serial imaging followed by biopsy revealed bladder polyps, adrenal cortical hyperplasia, and hepatic hemangiomas. At 13 months, she has some mild motor delays. Patient 3 was born at 27 weeks gestation with a unilateral multiloculated cystic suprarenal mass and had severe HI. Patient 4 was born at 24 weeks gestation, had severe HI, and had an adrenal mass concerning for neuroblastoma. Patients 3 and 4 died of complications of HI and prematurity. An autopsy of patient 4 revealed adrenal cortical and pancreatic hyperplasia. The clinical features in these patients partially derive from alteration of the 5 known paternal UPD disease loci in humans. These include UPD 6q24 (transient neonatal diabetes), 11p15 (Beckwith-Wiedemann syndrome; BWS), 14q32 (hypotonia and bell-shaped thorax), 15q11.2 (Angelman syndrome), and 20q13 (pseudohypoparathyroidism). The predominant phenotype in all GWpUPiD patients reported to date is BWS. All reported GWpUPiD patients developed adrenal, renal, and/or hepatic tumors. This 100% incidence of tumorigenesis suggests that the UPD11 phenotype is augmented in GWpUPiD. This may be due to additional less well-characterized imprinted regions involved in cell growth. Alternatively, these patients have isodisomy that may uncover recessive loci, which contribute to the increased incidence of tumors. Given the rapidity of tumor growth and the prolonged age of onset seen in GWpUPiD patients, we recommend vigilant ultrasound screening of these patients in the first years of life and consideration of tumor surveillance into adolescence.

The Catalase: influence of C-262 T polymorphism on Keratoconus. *S. Torabi Dalivandan[1], Z. Salehi[1], S. Saboohi[1], M.J. Mohammadi Fatideh[2, 3], H. Yourdkhani[2].* 1) Biology Department, Science Faculty, University of Guilan, Rasht, Iran; 2) Ophthalmology Department, Amiralmomenin Hospital, Rasht, iran; 3) Guilan University of Medical Sciences, Rasht, iran.

Keratoconus (KC) is an eye disorder in which the cornea assumes a conical shape because of thinning and protrusion, with the possible involvement of both genetic and environmental factors. It has been reported that oxidative damage contributed to pathogenesis of this disease. To inactivate stress oxidative there are several antioxidant enzymes, one of them is catalase which contributes H2O2 to H2O and O2. Given the role of oxidative damage in causing this condition, the aim of this study was to investigate the association of Catalase C-262 T polymorphism with KC. Blood samples were obtained from 30 Iranian patients (mean age of 25.65±2.115 years) with KC and 30 healthy controls (mean age of 23.87±1.125 years). To determine genotype frequencies genomic DNA was extracted from the blood samples and subjected to the allele- specific PCR (AS-PCR) technique. Statistical analyses were performed using MedCalc v.12.1.4.0 software. Results has not emerged significance differences from the comparison of either genotype (P > 0/05). We conclude that the catalase gene C-262 T polymorphism can not be a risk factor in KC.

3084F

Metabolic abnormalities in Williams-Beuren syndrome patients and candidate genes. *M.G. Palacios[1], R. Flores[1], V. Campuzano[1,2], M. del Campo[1,3], M. Segura-Puimedón[1], L.A. Perez-Jurado[1].* 1) Genetics Unit, DCEX, Universitat Pompeu Fabra & Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Barcelona, Spain; 2) Neurosciencies Program, Mar Institute of Medical Research Foundation (IMIM), Barcelona, Spain; 3) Program in Molecular Medicine and Genetics, Hospital Universitari Vall d'Hebron, Barcelona, Spain.

Background: Williams-Beuren syndrome (WBS, MIM 194050) is a neurodevelopmental disorder with multisystemic manifestations caused by a 1.55–1.83Mb deletion at 7q11.23 including 26–28 genes. Reported metabolic abnormalities in WBS include transient hypercalcemia of infancy, subclinical hypothyroidism in ≈30% of children, and impaired glucose tolerance in ≈75% of adult individuals. We have studied several biochemical and hormonal parameters in a cohort of 100 WBS individuals, half of them participating in a pilot clinical trial to evaluate the efficacy and safety of angiotensin II receptor blockers in reducing oxidative stress and blood pressure in WBS. **Results**: 1) Triglyceride plasma levels were significantly decreased in WBS, with a median at the 15th percentile and 24.5% cases with hypotriglyceridemia, while cholesterol levels were above the normal range in 1/3 of cases. Haploinsufficiency at *MLXIPL*, documented by RTPCR expression quantification in patient cell lines and liver samples of Wbs mouse models, is likely related to the lipid abnormalities. 2) Bilirubin levels were significantly increased, with 24.1% of cases showing indirect hyperbilirubinemia, preferentially females (p=0.026) with homozygous hypomorphic *UGT1A1*-promoter alleles. Decreased triglyceride and increased bilirubin levels were also observed in Wbs mouse models. Interestingly, expression of *Ugt1A1* was significantly increased in murine Wbs livers. 3) Additional abnormalities included elevated total protein (30.9%), albumin (26.7%) and transferrin (66.1%) plasma levels. Subclinical hypothyroidism (TSH elevation with normal T3/T4) was found in 44.6% but did not correlate with the biochemical abnormalities. 4) Following therapy with angiotensin II receptor blockers for 12 months (n=16), a significant reduction in protein plasma levels (p=0.015), as well as uric acid (p=0.018) and creatinine levels (p=0.001) was observed. **Conclusions**: Our data indicate that several unreported biochemical alterations are relatively common in WBS and should be studied in greater detail in order to better prevent potential long-term complications. These biochemical alterations can be related to haploinsufficiency for specific genes at 7q11.23. Angiotensin II receptor blockers might contribute to improve some biochemical abnormalities through controlling oxidative stress and blood pressure.

3085W

Bilateral radioulnar synostosis and vertebral anomalies in a child with a 16p13.3 interstitial deletion. *T. Slavin[1, 2], A. Tam[3], K. Lee[3], S. Lee[2], W. Burkhalter[1,4,5].* 1) Department of Pediatrics, University of Hawaii, John A. Burns School of Medicine, Honolulu, Hawaii; 2) Kapiolani Medical Specialists, Hawaii Community Genetics, Honolulu, Hawaii; 3) University of Hawaii, John A. Burns School of Medicine, Honolulu, Hawaii; 4) Kapiolani Medical Specialists, Kapiolani Orthopedic Associates, Honolulu, Hawaii; 5) Department of Surgery, University of Hawaii, John A. Burns School of Medicine, Honolulu, Hawaii.

We describe an 8-year-old boy with developmental delay, bilateral radial ulnar synostosis, Klippel-Feil anomaly and multiple other vertebral deformities who was found to have a de novo, previously unreported, deletion of 114.5kb of 16p13.3. On physical exam he was nondysmorphic, but had myopathic facial features with a small jaw. His mouth displayed dental crowding with ankyloglossia, a large thick tongue and a bifid uvula. He had prominent ear crus bilaterally. He had wide nipple spacing. He displayed limited range of motion in his neck, mild scoliosis, complete loss of forearm rotation on the right and limited pronation and supination on the left. He had a right transverse single palmar crease. He displayed hypoplasia of thenar and hypothenar musculature bilaterally. He had some prominence of the medial aspect to the top of his knees. His gait was mildly uncoordinated and he was not able to run. The remainder of his physical exam was unremarkable. Fanconi anemia testing by chromosome breakage was normal. Renal ultrasound was normal. Full skeletal survey and echocardiogram were recommended but not done at the time of this report. There are only 5 known genes contained in the deletion and one miRNA. Interestingly, none of the genes have any known involvement with skeletal regulation to explain the striking boney defects seen in the patient presented herein. ABCA3 and DCI are involved in surfactant and beta-oxidation of unsaturated fatty acids, respectively. MIR940 is a novel miRNA with little known function that is reported to be expressed in the cervix and renal cell carcinoma. E4F1, DNASEIL2, RNPS1 are expressed in bone marrow and hematologic cell lines and have broad functions and therefore may have a role in bone regulation. Nonetheless, even though we cannot find a specific genotype-phenotype correlation to explain the boney findings in this patient, we believe this deletion is causative, given that it was de novo and that this patient cannot be easily explained as having any other specific recognizable pattern of human malformation. As this is the first case report involving this particular gene deletion, additional case reports and functional studies regarding the genes and regulatory elements involved will be valuable in better understanding the regions role in skeletal regulation.

ASTN2 deletions in autism spectrum disorder and related neuropsychiatric phenotypes. *M.T. Carter[1], A.C. Lionel[2], A.K. Vaags[2], B.A. Fernandez[3], W. Roberts[4], P. Szatmari[5], C.R. Marshall[2], S.W. Scherer[2].* 1) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 2) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, ON, Canada; 3) Disciplines of Genetics and Medicine, Memorial University of Newfoundland, St. John's Newfoundland, Canada; 4) Autism Research Unit, Hospital for Sick Children, Hospital for Sick Children, Toronto, ON, Canada; 5) Department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton, ON, Canada.

Astrotactin-2 (ASTN2) encodes a cell adhesion molecule widely expressed in the developing brain. The protein, in complex with ASTN1, facilitates glial-guided neuronal migration. Previous studies have implicated disruption of ASTN2 in attention deficit-hyperactivity disorder (ADHD), schizophrenia, and autism spectrum disorder (ASD). We present two unrelated males referred for clinical genetics assessment with autism spectrum disorder and prominent behavioral issues, each with a deletion involving ASTN2. Patient 1 is a 16 year old male with high-functioning autism, ADHD, language-based learning disability, obsessive compulsive disorder (OCD), oppositional defiant disorder (ODD), scoliosis, micrognathia, pectus excavatum, and pre and postnatal symmetric growth retardation. There is a positive family history of Asperger syndrome. Array comparative genomic hybridization (aCGH) showed a 194 kb deletion at 9q33.1, involving three RefSeq genes including ASTN2. The ASTN2 deletion was confirmed by FISH. It was not present in the father, and the mother was unavailable for testing. Patient 2 is a 12 year old male with Asperger syndrome, above average IQ, and a history of escalating behavioral outbursts (swearing, violent threats, sexual inappropriateness). He has dysmorphic features (short and upslanted palpebral fissures, long face, prominent nose, bilateral sandal gap) and both height and head circumference are at the 98th percentile. aCGH showed a 291 kb deletion at 9q33.1, involving exonic sequences of the ASTN2 gene. The deletion was not present in the mother, and the father was unavailable for testing. We found three additional males with deletions within the ASTN2 gene in our autism cohort, as well as one family with an intragenic ASTN2 duplication which segregates with Asperger syndrome diagnoses in a mother and her two sons (and not in the third unaffected son). No copy number variants at this locus are found in 2357 population controls. We present the clinical and molecular features of these six probands, and suggest that ASTN2 disruption is highly penetrant for autism and related neuropsychiatric disorders.

3087W

Atypical deletions of the Williams-Beuren syndrome region implicate genes involved in mild facial phenotype, epilepsy and autistic traits. *G. Merla[1], L. Micale[1], C. Fusco[1], B. Augello[1], P. Alfieri[2], M.C. Digilio[3], D. Menghini[2], S. Vicari[3].* 1) Medical Genetics Unit, IRCCS Casa Sollievo Della Sofferenza, San Giovanni Rotondo, Italy; 2) Child NeuroPsychiatry Unit, Neuroscience Department, IRCCS Children Hospital Bambino Gesù, Rome, Italy; 3) Medical Genetics, IRCCS Children Hospital Bambino Gesù, Rome, Italy.

Interstitial deletions of multiple contiguous genes at chromosome band 7q11.23 are responsible for Williams-Beuren Syndrome (WBS; OMIM # 194050), a genomic disorders with multi-system involvement and variable expressivity, caused by a hemizygous deletion of 1.5 Mb on chromosome 7q11.23 spanning 28 genes. A few patients with larger and smaller deletions have been reported. They show clinical features that vary between isolated SVAS to the full spectrum of WBS phenotype, associated with epilepsy or autism spectrum behavior, infrequently diagnosed in WBS patients with common deletions. In this report, we describe clinical, cognitive, and genetic features of four patients with atypical 7q11.23 deletion. Two of them carry an approximately 3.5 Mb larger deletion towards the telomere that includes also two genes implicated in neuropsychiatric disorders as Huntingtin-interacting protein 1 (HIP1) and tyrosine 3-monooxygenase/tryptophan 5-monooxigenase activation protein gamma (YWHAG). The others two individuals carry two shorter deletions of approximately 1.2 Mb at centromeric side that does not include the BAZ1B and FDZ9 genes. The description of these additional cases further helped us to refine the genotype-phenotype correlations in WBS. Our data suggest, indeed, that HIP1 and YWHAG cause the severe neurological dysfunctions, including epilepsy and autistic traits, seen in the two WBS patients with larger deletion. Mild facial features and moderate neurocognitive profile of patients with the smaller deletions may be related in part to the preservation of BAZ1B and FZD9 gene. This report highlights the importance to identify and characterize further patients with atypical deletions of 7q11.23 region to shed light on the pathogenic role of genes within and outside the WBS region.

3088F

Morphogenesis of the face in Wolf-Hirschhorn syndrome: three elucidative patients. *J. Carey[1], A. Calhoun[1], P. Hammond[2], A. Lortz[3], S. South[1].* 1) Dept Ped/Div Med Gen, Univ Utah Hlth Sci Ctr, Salt Lake City, UT; 2) Molecular Medicine Unit, UCL Institute of Child Health, London, UK; 3) The 4p- Support Group, Sunbury, OH.

Wolf-Hirschhorn syndrome (WHS) is a contiguous gene deletion syndrome caused by deletions of the distal short arm of chromosome 4. Patients with WHS have growth delay, developmental delay, and the distinctive “Greek warrior helmet” craniofacial appearance. Key features include hypertelorism, prominent eyes, arched eyebrows, prominent nasal bridge, downturned corners of the mouth, micrognathia, and a short philtrum. Historically, the typical facial gestalt has been felt to be due to deletion of the gene WHSC1, found within both of the two overlapping putative critical regions for the syndrome, WHSCR1 and WHSCR2. However, recent published reports and assessment of previously unpublished photos reveal 3 informative individuals, whose findings suggest that the facial gestalt of WHS is due to deletion of multiple genes on distal 4p. Summaries of the 3 cases follow: 1: Girl with growth failure, developmental delay, seizures, and facial features including prominent forehead, mild telecanthus, and long palpebral fissures. She had a 1.78MB terminal deletion of 4p, which involves LETM1, but does not include WHSC1 or WHSC2. Dense surface modeling (DSM) fine-grained computerized facial analysis was consistent with a partial WHS phenotype and was right on borderline for WHS face. 2: Boy with growth delay, poor feeding, ASD, and developmental delay. He showed a subtle WHS facial gestalt. He had a 4.3 MB interstitial deletion including LETM1, WHSC1 and WHSC2. DSM showed some difference from control faces, and on DSM was right at the borderline for WHS. 3: Boy with poor growth, feeding difficulties, developmental delays, hypertelorism, mild syndactyly, and prominent eyes. He had a 432kb deletion proximal to the both the putative WHS critical regions which does not include LETM1, WHSC1, or WHSC2. DSM classified his face as more WHS-like than control-like and not borderline like Cases 1 & 2. Although WHSC1 has long been felt to be the key to the gestalt of WHS, these 3 patients point to a more complex picture. By DSM, Patients 1 and 3 have features more consistent with WHS than Patient 2, despite the fact that patient 2 is the only one of the three who carries a deletion of the two overlapping WHS critical regions. Analysis of these patients argues that genes outside of the purported critical regions impact the morphogenesis of the face in WHS.

3089W

Growth hormone receptor gene polymorphism and Prader-Willi syndrome. *M. G. Butler, J. Roberts, J. Hayes, X. Tan, A. Manzardo.* Psychiatry & Behavioral Sci, Univ Kansas Med Ctr, Kansas City, KS.

Prader-Willi syndrome (PWS) is characterized by infantile hypotonia; failure to thrive; a poor suck and feeding difficulties; hypogonadism with genital hypoplasia; growth hormone deficiency with short stature, small hands and feet; hyperphagia leading to early childhood obesity; mental deficiency and behavioral problems. PWS is due to loss of paternally expressed genes from the 15q11-q13 region usually from a de novo paternally derived deletion. When treated with growth hormone (GH), PWS individuals respond favorably in stature and body composition (decreased fat, increased muscle mass). The exon-3 deletion polymorphism (d3) in the growth hormone receptor (*GHR*) gene occurs in about 50% of Caucasians in the general population and has been associated with an increased growth response to GH therapy in non-PWS patients. The aim of our study was to assess the association of the GHR alleles with height, weight, head circumference and body mass index (BMI) at baseline and prior to GH treatment, as well as, gender and PWS genetic subtypes. We examined 69 genetically confirmed individuals with PWS (30 males, 39 females; average age ± SD = 20.1 ± 12.8y). Thirty-nine individuals had the 15q11-q13 deletion and the remaining subjects had maternal disomy 15 or an imprinting defect. The vast majority (i.e., 95%) of our subjects were Caucasians. The distribution of alleles (fl/fl, n=36 or 52%; fl/d3, n=25 or 36%; d3/d3, n=8 or 12%) in our PWS subjects was similar to reported data in Caucasian control subjects. There were no gender or PWS genetic subtype differences identified in the distribution of *GHR* alleles. We found a negative correlation ($p<0.05$) with age for height standard deviation scores and a positive correlation ($p<0.05$) with age for weight and BMI. Adjusting for effects of age and gender, we found that individuals with PWS carrying the d3 allele showed a significant increase in BMI compared with those having the full length allele ($F=3.9$, $p<0.02$). This model explains ~35% of the shared variance in BMI with ~5% of the unique variance attributed to *GHR* alleles. No differences in height, weight or head circumference standard deviation scores were found. In summary, the d3 allele was associated with significantly increased BMI in our cohort of PWS subjects prior to GH treatment but not for height or weight. The presence of the d3 allele and its impact on BMI and the care of individuals with PWS while on GH therapy should be addressed.

Molecular characterization and genotype/phenotype correlation of ten patients with structural rearrangements in the *NIPBL* gene. *YW. Cheng, C. Tan, K. Arndt, S. Das, D. del Gaudio.* Human Genetics, University of Chicago, Chicago, IL.

Cornelia de Lange syndrome (CdLS) is a genetically heterogeneous disorder characterized by severe growth retardation, intellectual disability, upper-limb abnormalities, hirsutism and characteristic facial features. Heterozygous mutations in the *NIPBL, SMC1A* and *SMC3* cohesin-associated genes account for approximately 60–65% of patients with a diagnosis of CdLS; the majority of them have been found in *NIPBL*. Recent studies have shown that intragenic deletions and duplications in *NIPBL* are present in approximately 2–5% of patient with CdLS. To explore the occurrence of intragenic deletions and duplications in the *NIPBL* gene we analyzed a cohort of 430 patients referred to our laboratory for CdLS clinical testing and that had previously tested negative by standard *NIPBL* sequence analysis. Deletion/duplication analysis was performed by MLPA and custom exon-targeted oligonucleotide array-CGH. *NIPBL* copy number changes were detected in 10 out of 430 (2.3%) patients, including 8 intragenic single- or multi-exon alterations (7 deletions, one duplication), a full *NIPBL* gene deletion and a paternally inherited large duplication involving *NIPBL* exons 32 to 47 and including downstream genes *FLJ13231*, *NUP155* and *WDR70*. Preliminary analysis of the clinical phenotype of these patients suggest that the majority have facial features consistent with CdLS and include synophyrs (6/9), long thick eyelashes (6/9), upturned/anteverted nares (6/9), thin upper lip (6/9) and a long smooth philtrum (7/9). The patient with the large duplication involving partial *NIPBL* and downstream genes was also determined to have a *PTPN11* sequence change and a phenotype consistent with Noonan syndrome. Additional clinical information on all ten patients is being gathered and will be presented. Our experience contribute to the growing amount of data on*NIPBL*-related copy number variations in patients with CdLS, and support the clinical usage of *NIPBL* deletion/duplication analysis in patients with negative *NIPBL* results by sequencing.

***TSC2-PKD1* Contiguous Deletion Syndrome with Aortic Stenosis and Severe Myopia.** *K. Enomoto[1,2], Y. Sugawara[2], M. Hotate[2], Y. Motoyoshi[2], Y. Hatai[3], S. Mizutani[2], K. Kurosawa[4].* 1) Division of Pediatrics, JA Toride Medical Center, Toride, Ibaraki, Japan; 2) Department of Pediatrics and Developmental Biology, Tokyo Medical and Dental University Graduate School, Tokyo, Japan; 3) Division of Pediatrics, Tokyobay Urayasulchikawa Medical Center, Urayasu, Chiba, Japan; 4) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan.

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder characterized by (1) brain lesions, including subependymal nodules, cortical tubers, and subependymal giant cell astrocytomas, (2) skin lesions, including hypomelanotic macules, facial angiofibromas, and shagreen patches, and (3) renal lesions. Approximately 70% of probands has *TSC2* identifiable causative mutation mostly detected by sequence analysis, rarely exonic-deletion/duplication analysis including multiplex ligation-dependent probe amplification (MLPA) or micro-array. Although the whole-gene deletion of *TSC2* is very rare, it usually involves contiguous gene of *PKD1*, characterized to cause, in case of mutation, autosomal dominant polycystic kidney disease (ADPKD), directly downstream to the *TSC2* separated by only a 60-bp region. We herein present a young case of 16p13.3 microdeletion extending to 700kb involving *TSC2* and *PKD1*identified by micro-array CGH examination. He presents some clinical and dysmorphic features including congenital heart defect, aortic stenosis (AS) and patent ductus arteriosus (PDA), pectus excavatum, severe myopia, and facial dysmorphism which are inconsistent with typical TS, ADPKD or simple addition of them. Therefore, we suggest that the haploinsufficiency of the genes involving the deleted region excepting *TSC2* and *PKD1* contributes to the above mentioned some characteristic features.

3092F

Jacobsen syndrome: Cognitive-behavioral profiles, developmental trajectories, and IQ related to deletion size. *G. Fisch.* NYU College of Dentistry 250 Park Ave. S., 6th fl. New York, NY.

Jacobsen syndrome [JBS] is caused by a subtelomeric deletion at chromosome 11q25. Prevalence is estimated at 1/100,000 births. In addition to its clinical features, JBS causes intellectual disability [ID]. ID severity in patients with JBS is variable. To our knowledge, this is the first comprehensive cognitive-behavioral evaluation of children with JBS. Our purpose is to: (1) ascertain cognitive-behavioral profiles and develop trajectories in children with JBS; and (2) examine IQ related to deletion size. Method Subjects: Ten children with JBS were recruited from various sites in the US and Europe. All were English-speaking. Five were male, 5 were female. Ages ranged from 5–20 years (Mean=11.25 years). Materials: Children were administered a neuropsychological battery that included cognitive assessment with the Stanford-Binet (4th Edition) [SBFE] and adaptive behavior [DQ] with the Vineland Adaptive Behavior Scale [VABS]. Procedure: At initial testing [T1] children were administered the SBFE, and parents interviewed with the VABS. Eight children were available for retesting 2 years later [T2]. Results IQ at T1 ranged from 36–80 [Mean IQ=59.2 ± 16.2]. DQ ranged from 31–68 [Mean DQ=52.1 ± 13.1]. Four children exhibited behaviors consistent with a diagnosis of mild autism. Cognitive-behavioral profiles were relatively flat, with relative strength in quantitative reasoning and significant weakness in short-term memory. Cognitive-behavioral profiles at T2 remained relatively stable. IQ scores ranged from 43–79 [Mean IQ=62 ± 14.2], DQ scores ranged from 40–68 [Mean DQ=54.6 ± 11.8]. The correlation between deletion size and IQ was (r=-0.20; p=ns) and DQ (r=-0.18; p=ns). Discussion The cognitive-behavioral profile is significantly different from children with other microdeletion disorders, e.g. Williams syndrome [WS] or Wolf-Hirschhorn syndrome [WHS], who show relative strengths in verbal and quantitative reasoning. Children with JBS show strengths in quantitative reasoning only. Children with WS or WHS show relative weaknesses in both abstract / visual reasoning and short-term memory. Those with JBS show relative weakness in short-term memory only. Previously, Colden et al [2009] examined 14 individuals with JBS and found a strong negative correlation [r=-0.82] between IQ and deletion size. We find a significantly lower correlation not different from zero. Results will be discussed in the context of sampling and sample size.

3093W

Concurrent Deletion of BMP4 and OTX2 Genes: Clinical Evidence of Synergistic Effect of the Two Master Genes in Ophthalmogenesis. *R. Kosaki[1], T. Takenouchi[2], C. Torii[3], S. Nishina[4], K. Kosaki[3].* 1) Div Med Genet, Natl Ctr Child Hlth & Dev, Tokyo, Japan; 2) Dept Pediatr, Keio Univ, Tokyo, Japan; 3) Center Med Genet, Keio Univ, Tokyo, Japan; 4) Div Ophthalmol, Natl Ctr Child Hlth & Dev, Tokyo, Japan.

BMP4 and OTX2 are master genes in ophthalmogenesis. Mutations of BMP4 and OTX2 often lead to eye defects, including anophthalmia-microphthalmia. A significant degree of variable expressivity has been reported in heterozygous individuals with BMP4 or OTX2 mutation. Interestingly, both BMP4 and OTX2 reside on 14q22, being only 2.8 Mb apart. Previous studies reported that among three patients with 14q22 deletion involving BMP4 and OTX2, all had severe eye defects. The minimal degree of variable expressivity among these individuals who were doubly heterozygous for BMP4 and OTX2 could be attributed to the combinatorial relationship of the two genes observed in animal models. We herein report a patient with a concurrent deletion of BMP4 and OTX2 who exhibited bilateral microphthalmia, more specifically, anterior segment dysgenesis with microcornea. The presence of severe microphthalmia in the propositus supports the notion of functional complementarity between BMP4 and OTX2 in humans. Evolutionarily conserved physical linkage of BMP4 and OTX2 loci may suggest an advantage of the proximal alignment of the two genes. Another striking feature in the propositus was the progressive white matter loss observed by serial neuroimaging. A review of nine previously reported patients with 14q22 microdeletion revealed decreased white matter volume in half of the patients. It remains to be elucidated whether the white matter lesion is age-dependent and progressive. In conclusion, anterior segment defects of the eyes, especially when accompanied by decreased white matter volume on neuroimaging, should raise the clinical suspicion of 14q22 microdeletion.

Interstitial deletion of 3.8 Mb in chromosome 6q25.2-6q25.3 in a patient with Coffin-Siris syndrome. *S. Mizuno[1], E. Nishi[1], Y. Muramatsu[1], M. Tominaga[2], K. Kurosawa[2].* 1) Dept Pediatrics, Central Hosp, Aichi Human Service Ctr, Kasugai, Aichi, Japan; 2) Dept Clinical Genetics, Kanagawa Childrens Medical Center, Kanagawa, Japan.

We describe the case of a 5-year-old girl with 3.8Mb interstitial deletion of chromosome 6q25.2-5q25.3 identified by oligonucleotid array-CGH. The patient was born to healthy parents at the gestational age of 39 weeks with average height and weight. She presented with psychomotor developmental delay, absent speech, progressive postnatal growth restriction, hypertrichosis,hirsutism of the back, and a distinctive facial appearance with thick lips. The most noteworthy finding was the nails of her fingers and toes were thin, malformed and hypoplastic. These feature of the nails are diagnostic characteristics of Coffin-Siris syndrome, which is also known as “Fifth digit syndrome” Tsurusaki et al. reported germline mutation in one of six SWI/SNF-A chromatin-Remodeling complex subunit genes, *SMARCB1*, *SMARCA4*, *SMARCA2*, *SMARCE1*, *ARID1A* and *ARID1B*, causes Coffin-Siris syndrome. The chromosomal deletion in our patient involved *ARID1B*, the haploinsufficiency of which resulted in the development of Coffin-Siris Syndrome. Although the chromosomal deletion in this case involoved 12 genes other than ARID1B, psychomotor development and physical manifestation of the patient were almost identical to those in other reported cases with Coffin-Siris syndrome caused by mutation in ARID1B. Further studies on interstitial deletions in this region are required to describe the precise phenotype of Coffin-Siris Syndrome caused by chromosomal deletion.

3095W

Detailed Neurodevelopmental Phenotype of a Child with a 22q11.2 Distal Deletion. *S. Mosca[1], L.M. Langevin[2], A.C. Lionel[3,4], C.R. Marshall[3,4], B. Argiropoulos[1,2], A.M. Innes[1,2], S.W. Scherer[3,4], D. Dewey[1,2], J.S. Parboosingh[1,2], F.P. Bernier[1,2].* 1) Medical Genetics, University of Calgary, Calgary, Alberta, Canada; 2) Alberta Children's Hospital Research Institute, Calgary, Alberta, Canada; 3) The Centre for Applied Genomics and Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

Microdeletions mediated by non-allelic homologous recombination (NAHR) between flanking low-copy repeats (LCRs) at 22q11.2 are highly variable, as is the phenotypic presentation in individuals harboring deletions within this region. Eight major LCRs are located in 22q11, and recombination between LCR_{22-3} and LCR_{22-4} results in a common ~3Mb deletion responsible for a range of phenotypes now recognized as 22q11.2 deletion syndrome. Recently, distal deletions resulting from NAHR between LCR_{22-4} and LCR_{22-5} have been associated with a novel disorder which appears to be distinct from the more proximal 22q11.2 deletion syndrome. Common features include developmental delay, microcephaly, pre- and post-natal growth delay, cardiovascular malformations, prematurity, and mild dysmorphic features. While an increased incidence of neurodevelopmental disorders, such as Autism Spectrum Disorder (ASD) and Attention Deficit Hyperactivity Disorder (ADHD), have been described in children with typical 22q11.2 deletions, details on the neurodevelopmental phenotypes seen in children with distal 22q11.2 deletions are lacking. The analysis of copy number variants (CNVs) using Illumina 2.5M genotyping microarrays in a cohort of 91 children recruited as part of a study on the genetics of Developmental Coordination Disorder (DCD) identified an ~1.3Mb distal 22q11.2 deletion flanked by LCR_{22-4} and LCR_{22-5} in an individual with severe DCD and ADHD. This deletion was validated by quantitative real-time PCR and was not inherited from the mother. The participant was born at 37 weeks and was small for gestational age. He went on to have failure to thrive and speech delay. We present detailed neurodevelopmental test results for this participant who had an IQ score at the lower range of normal (IQ of 80), and met diagnostic criteria for both DCD (1st centile on the Movement Assessment Battery for Children) as well as ADHD (Diagnostic Interview for Children and Adolescents). This case demonstrates the variability seen in the clinical presentation of individuals with 22q11.2 distal deletions. It is increasingly recognized that rare CNVs are an important cause of neurodevelopmental disorders with both reports of recurrent as well as rare variants in patients with ASD as well ADHD. We add distal 22q11.2 deletions to the list of CNVs that may contribute to pediatric neurodevelopmental phenotypes although further validation in replication cohorts will be required to confirm this association.

3096F

A *de novo* 163 kb interstitial 1q44 microdeletion in a boy with thin corpus callosum, psychomotor delay and seizures. *K. Selmer[1,2], E. Bryne[3], O. Rødningen[1], M. Fannemel[1].* 1) Dept Medical Genetics, Oslo Univ Hospital, Ullevaal, Oslo, Norway; 2) Institute of Medical Genetics, University of Oslo, Oslo, Norway; 3) Habilitation Center, Vestfold Hospital, Tønsberg, Norway.

The 1q44 deletion syndrome has shown to be a recognizable phenotype with developmental delay, short stature and corpus callosum abnormalities as relatively consistent features. However, the disorder is still clinically heterogeneous and a genotype-phenotype correlation has been challenging to establish. In particular, a delineation of a critical region for the corpus callosum development has turned out to be difficult, and many candidate genes have been proposed. We present here a patient boy with a clinical picture of the 1q44 deletion syndrome, including a thin corpus callosum, and the hitherto smallest 1q44 deletion reported in this syndrome. The deletion spans a maximum of 163 kb and includes only the two genes *FAM36A* and*HNRPU*. This finding supports the previously suggested hypothesis that the *HNRPU* is an essential gene to the development of corpus callosum. However, as patients with deletions outside this interval also have been reported to have corpus callosum abnormalities, other mechanisms are probably also involved. We identified two conserved non-coding regions in the deleted region of the patient, and speculate that also other elements interfere with the complex interplay and spatiotemporal gene expression during embryonic development.

3097W

Genotype phenotype correlation study of 2q23.1 microdeletion syndrome and characterization of three new patients. *L. Zhang[1], H.T. Bjornsson[2], D. Batista[3], G. Wiesner[1], T. Wang[2], A. Parikh[1].* 1) Dept Med/Human Gen, Case Western Univ SOM, Cleveland, OH; 2) IGM, Johns Hopkins Univ, Baltimore, MD; 3) Kennedy Krieger Inst, Baltimore, MD.

2q23.1 microdeletion syndrome is a newly characterized syndrome with 20 patients described in clinical detail to date. Haploinsufficiency of *methyl CpG-binding domain protein 5 (MBD5)* is implicated to account for the core features of this syndrome including intellectual disability, severe speech impairment, epilepsy, behavioral problems, mild craniofacial dysmorphism, small hands and feet, and broad based ataxic gait. We have previously reported a patient with de novo 210 kb deletion at 2q23.1 involving 5'-UTR regions of *MBD5* and *ORC4L (origin recognition complex, subunit 4-like)*. We now report two new patients with de novo deletions at 2q23.1, one with a 110kb deletion involving only the 5'-UTR of *MBD5* and *ORC4L* and another with a 2.7 Mb deletion involving multiple genes including *MBD5*. We compared the genetic and clinical findings in our patients with those reported in the literature and conducted a genotype phenotype correlation study on the genes within these deletions and clinical features of the three patients. Heterozygous deletion of *ORC4L* does not contribute significantly to the clinical phenotype. Haploinsufficiency of *EPC2 (enhancer of polycomb homolog 2)* is likely associated with microcephaly and short stature. Studying the spectrum of clinical phenotype in patients with different sizes of microdeletions provides an opportunity to delineate gene functions at 2q23.1 and understand the pathophysiology of complex neurodevelopmental phenotypes including autism and intellectual disability in 2q23.1 microdeletion syndrome.

3098F

Polycystic kidney disease and a 2.5Mb duplication on chromosome 3p22.1. *K. Dahan[1], M. Madhoun[2], M. Gilliaux[3], V. Benoit[1], B. Grisart[1].* 1) Ctr Human Gen, Institut de Pathologie et de Génétique, Gosselies, Belgium; 2) Nephrology Departement, CHU de Charleroi, Montigny-le-Tilleul, Belgium; 3) Gynecology Departement, CHU de Charleroi, Montigny-le-Tilleul, Belgium.

The use of high-resolution microarray technology for investigation of patients with intellectual disability or congenital anomalies provided the unique possibility to identify new microdeletion/microduplication syndromes and discover the dosage sensitive genes, which are implicated in the manifestation of various genetic conditions. We report 3p22.1 microduplication, 2.5 Mb in size, detected in a 19.5-year-old woman with enlarged cystic kidneys and slight facial dysmorphism, . There are 20 RefSeq genes included in this duplication. In comparaison with transgenic mice models, CTNNB1 gene looks to be a strong candidate gene for the renal phenotype strongly mimicking autosomal dominant polycystic kidney disease. Further cases with similar duplications will contribute to the delineation of a potential new microduplication syndrome of 3p22.1.

3099W

Subtelomeric deletion including the WHSC1 gene located in the critical region of the Wolf-Hirschhorn Syndrome. *A.L.S. Ludmila Serafim, J.M. Pina Neto, I.F. Mazzucatto.*Genetic, Universidade de São Paulo, Ribeirão Preto, SP., Brazil.

We report here a patient with severe intellectual disability, who initially showed a deficit of intrauterine growth. The proband was born premature and hypotonic. After was observed short postnatal stature, dysmorphic facial characteristics suggestive of Pitt-Rogers-Danks Syndrome (PRDS), such as microcephaly, high forehead, frontal hair line high, facies significantly abnormal, triangular face, hypertelorism with telecanthus, eye prominent, high and arched eyebrow, midface hypoplasia, thin lips, high palate, abnormal helix, appendix preauricular, and a small hand. It was also reported that convulsive crisis started at six months of age. After performing classical cytogenetic examination which did not detect any changes, we used the MLPA (Multiplex Ligation Probe Amplification) technique with kit P036-E1 to investigate the presence of submicroscopic chromosomal abnormalities in subtelomeric regions and also the P245-A2 Kit which identifies 21 microdeletion syndromes. The P036 kit detected a deletion in the gene PIGG, located in the chromosomic region 4p16.3. While P245-A2 kit showed a deletion in the gene WHSC1, confirming the alteration in the 4p16.3 region previously detected by the kit P036-E1. The critical region of Wolf-Hirschhorn syndrome (WHSCR) is located at 4p16.3. The WHSC1 gene is located in this. Despite of the deletion of the WHSC1, the proband has phenotypic characteristics slightly different of the WHS. Although previously described as distinct disorders, it is now known that WHS and PRDS represent the clinical spectrum associated to a single syndrome. Some evidences show that PRDS represents a variant of WHS, since the occurrence of deletion in the 4p16.3 region occurs in both sydrome. It has also been found a deletion in the PIGG gene, supposing that the deletion in the region 4p has a minimum size of 1.4 Mb. In this clinical case, besides the use of different sets to confirm the existence of specific alteration, it has been also possible provide a better understanding of the extent of this change. It is believed that the combination of kits with additional probes may eventually offer the best solution for routine diagnostic screening of the submicroscopic chromosomal aberrations, since it allows a precise identification and better delineation of these alterations.

3100F

Atypical Form of Osteopathia Striata with Cranial Sclerosis and Increased Mineral Density in an Adolescent Female with Mosaic Chromosome 2 Rearrangement. *R. Mendoza-Londono[1,2], A. Howard[2,3], E. Sochett[2,4], L. Dupius[1,2], D.J. Stavropoulos[5], R.C.C. Wong[6], S. Robertson[7], A.M. Joseph-George[5,6].* 1) Div Clinical & Metabolic Gen, Hosp Sick Children, Toronto, ON, Canada; 2) The Bone Health Centre, The Hospital for Sick Children and University of Toronto; 3) Department of Orthopaedic Surgery, The Hospital for Sick Children and University of Toronto, Canada; 4) Division of Paediatric Endocrinology, The Hospital for Sick Children and University of Toronto, Canada; 5) Cytogenetics Laboratory, Division of Molecular Genetics, Department of Paediatric Laboratory Medicine, The Hospital for Sick Children and University of Toronto, Toronto, Canada; 6) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto; 7) Department of Women's and children's health, Dunedin school of Medicine, University of Otago, Otago New Zealand.

Osteopathia Striata with Cranial Sclerosis (OSCS-MIM 300373) is a rare disorder of bone mineralization caused by mutations of *WTX*, a protein that regulates WNT signaling. Females with this disorder usually present with macrocephaly, learning disability, sclerosis of the base of the skull, and longitudinal striations of the long bones. We present a 17 year old female with mild learning disabilities, significantly increased bone mineral density (Z score +8.1 at the level of L2–L4), and radiological findings reminiscent of OSCS. Family history was negative for other similarly affected individuals and both parents have normal bone mineral densities. On physical examination, the patient presented with long and narrow face with prominent jaw, marfanoid body habitus (arm span to height ratio of 1.06) and arachnodactyly. Sequencing of *WTX* single coding exon did not reveal any pathologic mutations. ArrayCGH on a 44K oligo platform did not reveal any copy number variations that could explain her phenotype. Chromosome analysis on lymphocytes and fibroblasts revealed a *de novo* mosaic karyotype with two apparently balanced cell lines in both tissues: ~32% of metaphases had an altered chromosome 2, while the remaining cells had a normal karyotype. By G-band analysis the derivative chromosome 2 has two separate intrachromosomal rearrangements that involve five breakpoints. The first is an interarm insertion of material from 2q13-2q21.1 into band 2p11.2 and the second, a paracentric inversion in the long arm with breakpoints estimated at 2q22.2 and 2q33.1. FISH using genomic BAC clones have confirmed this interpretation. Studies are underway to further define the breakpoints and determine which gene(s) are disrupted by the rearrangement and may be responsible for different aspects of the phenotype. Identification of the responsible gene may allow the identification of an autosomal regulator of WNT signaling on chromosome 2.

3101W

Further evidence of the role of HOXA genes in anatomical development. *P.A. Mowery-Rushton[1], R.A. Schultz[1], J.B. Ravnan[1], J.E. Burton[2,4], J. Kussmann[3,5], J.A. Rosenfeld[1], B.C. Ballif[1], L.G. Shaffer[1].* 1) Signature Genomic Laboratories, PerkinElmer Inc, Spokane, WA; 2) Carle Foundation Hospital, Urbana, IL; 3) University of Missouri, Columbia, MO; 4) Current affiliation: University of Illinois College of Medicine at Peoria, Peoria, IL; 5) Current affiliation: Children's Mercy Hospital, Kansas City, MO.

Introduction: The HOXA gene cluster encodes transcription factors that play a role in regulating patterns of anatomical development during embryogenesis. Mutations of specific HOXA genes and deletions of the entire cluster have been described in the literature associated with autosomal recessive Athabaskan brainstem dysgenesis syndrome (HOXA1), autosomal recessive microtia, hearing impairment and cleft palate (HOXA2), autosomal recessive radio-ulnar synostosis with amegakaryocytic thrombocytopenia (HOXA11), and autosomal dominant hand-foot-genital syndrome and Guttmacher syndrome (HOXA13). Here we describe two patients with small overlapping deletions of a portion of the HOXA gene cluster with similar phenotypes in order to further delineate the role of HOXA genes during embryogenesis. Materials and Methods: We analyzed the results of oligonucleotide-based microarrays on over 23,000 patients stored within the Genoglyphix® database. Results: We identified two patients with relatively small deletions (54.8 and 80.7 kb), which include part of the HOXA gene cluster. Both children had hypospadias with kidney abnormalities and mild dysmorphic features. One child had multiple heart defects, fifth finger clinodactyly, tapered digits, and hallux varus. The other child had hypotonia, developmental delay, movement disorder, and laryngomalacia, but not abnormalities of his digits. The smallest region of overlap is 30.2 kb and includes HOXA10, HOXA11, and the 3' end of HOXA13. Conclusion: These results reinforce the role of the HOXA genes in genitourinary tract development and suggest that haploinsufficiency of HOXA10 and/or HOXA13 contributes to renal and genital abnormalities. The additional anomalies noted in each child may be due to deletion of additional genes in the non-overlapping regions or disruption of expression of other HOXA genes within the cluster, due to the deletion.

3102F

4p16.3 deletion limited to WHSCR2. *N. Okamoto[1], K. Shimojima[2], T. Yamamoto[2].* 1) Dept Medical Genetics, Osaka Med Ctr/Res Inst, Osaka, Japan; 2) Tokyo Women's Medical University Institute for Integrated Medical Sciences, Tokyo, Japan.

Wolf-Hirschhorn syndrome (WHS) is a contiguous gene deletion syndrome associated with growth retardation, developmental disabilities, epileptic seizures and distinct facial features resulting from a deletion of the short arm of chromosome 4. Two critical regions for WHS have been narrowed to a 200kb region about 1.9Mb from 4p telomere. Wolf-Hirschhorn Syndrome Critical Region 1 (WHSCR1) is a 165kb region proximal to the *FGFR3* and *LETM1* genes. WHSCR1 includes the 3' part of *WHSC1*and the *WHSC2*. WHSCR2 is distal to WHSCR1 and directly adjacent to it. WHSCR2 includes the *LETM1* and 5' end of the *WHSC1*.*WHSC1* is one of the nuclear receptor binding SET domain protein is a family of three histone-methyltransferase. The haploinsufficiency of *WHSC1* is believed to be responsible for a number of WHS characteristics. *LETM1* has been suggested as a candidate gene for the seizures in WHS. We report on a patient with severe growth retardation, microcephaly and a characteristic facial appearance reminiscent of WHS. The 2-year-old male propositus was the first-born child of healthy and nonconsanguineous parents. Fetal echogram revealed severe intra uterine growth retardation. He fed poorly and his physical growth was severely retarded from early infancy. However, his developmental mile stones were not so delayed. His development quotient was 79 at 2 years of age by Japanese standard method. Physical examination identified dysmorphic features, including a triangular face, prominent glabella, a high nasal bridge, bilateral low set ears, down slanting palpebral fissures, a high arched palate and pointed chin. Hearing and visual acuity were normal. His weight was 5.7 kg (-4.8SD), his length was 70.1 cm (-4.8SD) and head circumference was 41cm (-4.8SD). He was free from seizures. His karyotype by G-banded analysis was 46,XY. By array-CGH analysis, loss of genomic copy numbers was identified in the region 4p16.3, which included *FGFR3*, *LETM1* and *WHSC1*. The size of the deletion was only 101Kb. This is the minimal deletion of 4p16 so far reported. The deletion was compatible with WHSCR2. From these studies, we suspect that haploinsufficiency of *WHSC1* is the most probable cause of growth deficiency, microcephaly and characteristic facial features in our patient. Studies from his clinical manifestations will be a good help to delineate the role of *WHSC1*.

Array CGH in 190 Korean patients with developmental delay and/or intellectual disability: a single tertiary care university center study. *Y. Sohn[1], C. Lee[1], S. Park[2], J. Yun[1], E. Jung[1], H. Kim[1], S. Yim[3].* 1) Medical Genetics, Ajou University Medical Center, Ajou University School of Medicine, Suwon, South Korea; 2) MG MED, Inc., Seoul, Republic of Korea; 3) Physical Medicine and Rehabilitation, Ajou University Medical Center, Ajou University School of Medicine, Suwon, Republic of Korea.

This study analyzed demographic, clinical, and cytogenetic data (G-banded karyotyping and array CGH) of patients with unexplained DD/ID in Korean single institution. We collected clinical and cytogenetic data based on retrospective chart in Ajou University Medical Center, Suwon, Korea from April 2008 to March 2012 A total of 190 patients identified. The mean age was 5.1 ± 1.87 years. Array CGH yielded abnormal results in 26 of 190 patients (13.7 %). Copy number losses were about 2 folds more frequent than gains. A total 61.5% patient had copy number losses. The common deletion disorders are 22q11.2 deletion syndrome, Angelman syndrome and 18q deletion syndrome. Copy number gains were identified in 34.6% patients and common diseases are Potocki-Lupski syndrome, 15q11-13 duplication syndrome and duplication 22q. Abnormal karyotype with normal array CGH was exhibited in 2.6% patients; balanced translocation (n=2), inversion (n= 1) and low-level mosaicism (n=1). Craniofacial dysmorphic features (P = 3.53 × 10-4) and failure to thrive were also more frequent in group of abnormal CGH. We expected that array CGH complemented by karyotype analysis is useful diagnostic tool, in selected patient groups, especially ID/ DD combined with craniofacial anomaly or failure to thrive.

3104F

Diagnostic investigation in Rwandan patients with MR/MCA. *A. Uwineza[1,2], J. Hitayezu[1], L. Mutesa[1].* 1) Medical genetics, National University of Rwanda, Huye, Rwanda; 2) Center for Human Genetics, CHU Sart-Tilman, University of Liège, Belgium.

Multiple congenital anomalies and mental retardation (MCA/ MR) affect approximately 3% of newborns. There is no available data on genetics of MR and MCA in Central Africa. The aims of this study was to detect chromosomal abnormalities such as submicroscopic microdeletion/microduplication and subtelomeric imbalance in this group of patients. Newborn, children and young adults were recruited from the Teaching University Hospitals of Kigali and Butare, Rwanda. All individuals were clinically examined and karyotype was done in Rwanda and a blood sample was obtained for genetic testing in Belgium (Center for human genetics, Liege). All patients with trisomy 21, 13 and 18 and were excluded from the study. Karyotype analysis of the remaining 52 patients was normal. Fragile-X was excluded in all these patients and we found premutation in 2 male patients. Thus the MLPA was performed and identified (SALSA MPLA P245 Microdeletion and MLPA P0 36 and P070 Human Telomere, MRC Holland) one chromosome 10q duplication, one chromosome 9p duplication, one deletion of the 22q11.2 region and one 7q11.23 microdeletion (William-Beuren syndrome). For the remaining cases array-CGH will be performed. This study will allow to identify the etiology of MR/MCA in Rwandan patient and will show the importance of genetic testing in developing countries.

3105W

Clinical features and genomic characterization of two subjects with a pure duplication of 9q34. *H. Yoshihashi[1], M. Ikegami[2], C. Torii[3], K. Kosaki[3].* 1) Division of Medical Genetics, Tokyo Metropolotan Children's Medical Center, Fuchu-shi, Japan; 2) Department of Pediatrics, Tokai University Hachioji Hospital, Tokyo, Japan; 3) Center for Medical Genetics, Keio University, School of Medicine, Tokyo, Japan.

Introduction: Duplications of 9q34 have been rarely described in the literature. New molecular techniques allow the identification of subtelomeric chromosomal rearrangements, but additional subjects of a duplication of 9q34 have not been increasingly reported. In the previous reports of the duplication 9q34, several clinical features were in common, including a distinctive face, arachnodactyly, hypotonia and developmental delay. However, the additional phenotypic spectrum and genomic critical region remained unclear. We presented two subjects with a pure duplication of 9q34 and compared with the clinical features of previously reported those using array CGH analysis. Materials and methods: Case1. 8y-female. 42w0d, 2294g. She had a distinctive face, laterality of ear malformations, long fingers, clinodactyly, hypotonia during infancy, mild intellectual disability and atlantoaxial rotatory subluxation. The analysis of G-banding, FISH and SKY indicated a distal interstitial duplication of 9q34. The karyotype was 46,XX,dup(9)(q34.1q34.3). Case2. 10mth-male. 40w5d, 3075g. He had a distinctive face, hypospadias, VSD, long fingers and toes, adducted thumb, camptodactyly, hypotonia, hip joint abduction, developmental delay. On the basis of findings of G-banding and FISH, the karyotype was 46,X,der(Y)-t(Y;9)(q11.2;q33). Array CGH analysis was performed using the ISCA 180K microarray platform (Agilent Technologies) to determine the precise breakpoints of 9q34 segments and identify any other genomic abnormalities. Results: The size of segments in the Case1 and Case 2 were 7.7Mb(130.7–138.4 Mb; from the pterminus) and 12.8Mb(127.4–140.2Mb), respectively. No other chromosomal rearrangements were significantly detected. Discussion: The phenotype observed in our subjects with a pure duplication of 9q34 represented a variety of clinical features depending on the size of an individual duplication. These detected segments included the approximately 4.1Mb(131.7–135.8Mb) of 9q34 as the overlapping region documented in the current report, which was highly suggestive of critical region of 9q34 duplication syndrome. Further genetic study may provide insight into the clinical characterization of 9q34 duplication syndrome.

Osteopathia Striata with Cranial Sclerosis and Developmental Delay in a Male with a Mosaic Deletion in Chromosome region Xq11.2. *S. Chenier[1], A. Noor[1], L. Dupuis[2], D.J. Stavropoulos[1,3], R. Mendoza-Londono[2].* 1) Department of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) The Hospital for Sick Children, Department of Pediatrics, Division of Clinical and Metabolic Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Ontario, Canada.

Osteopathia striata with cranial sclerosis (OSCS) is an X-linked disease caused by mutations involving *WTX* (*FAM123B*), a tumor suppressor protein with dual functions. OSCS typically affects females whereas males generally have fetal or neonatal lethality. Surviving affected males have characteristic facial dysmorphisms, skeletal features such as macrocephaly and short stature, neurodevelopmental disabilities and a high prevalence of neuromuscular anomalies. On imaging, hemizygous males display more marked cranial and peripheral skeletal sclerosis without the metaphyseal striations that are seen in women with OSCS. Observations of striation in males may be indicative of a somatic mosaic mutation in *WTX*. To date only two cases of surviving males haves been confirmed with mosaic point mutations in *WTX*. We report the first case of a male with mosaic deletion of the whole *WTX* gene. We show that a mosaic deletion in a hemizygous male patient can cause a mild phenotype of OSCS, including facial and skull base bone striations, nasal stenosis, conductive hearing loss, global developmental delay and mild facial dysmorphology without short stature or macrocephaly.

Keratoconus associated with Williams-Beuren Syndrome: new case report. *M.C. Frasson[1], M.M. Viana[2], L.L. Leao[2], M. Stofanko[3], H. Goncalves-Dornelas[3], P.S. Cunha[4], M.J.B. Aguiar[2].* 1) Serviço de Retina, Hospital São Geraldo, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 2) Serviço Especial de Genética Médica, Hospital das Clínicas, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 3) Núcleo de Genética Médica (GENE), Belo Horizonte, Minas Gerais. Brazil; 4) Departamento de Bioquímica e Imunologia, Instituto de Ciências Biológicas, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil.

Background: Williams-Beuren syndrome is a multisystemic genetic disorder caused by the contiguous gene deletion at 7q11.23. Keratoconus is a complex disease and it is suspected to have a genetic origin, although the specific gene responsible for keratoconus has not been identified. Although there are several ocular features in Williams-Beuren syndrome, keratoconus is not regularly described as part of this syndrome. Purpose: To report a new patient with keratoconus and Williams-Beuren syndrome. Discussion: This is the third case of an association between Williams-Beuren syndrome and keratoconus. The authors believe that the Williams-Beuren Syndrome Chromosome Region can be a possible target for further investigation as the genetic basis of keratoconus.

3108F

Minimal interstitial deletion in a patient with de novo 15q24 microdeletion syndrome presenting with severe scoliosis. *X. Gao[1], C. Johnston[2], S. Sparagana[3], C.A. Wise[1,4].* 1) Sarah M. and Charles E. Seay Center for Musculoskeletal Research, Texas Scottish Rite Hospital for Children, Dallas, TX; 2) Department of Orthopedic Surgery, Texas Scottish Rite Hospital for Children; 3) Department of NeurologyTexas Scottish Rite Hospital for Children; 4) Department of Orthopaedic Surgery and McDermott Center for Human Growth and Development, University of Texas Southwestern Medical Center Dallas.

Early onset “infantile” or juvenile onset idiopathic scoliosis (IS) cases comprise less than 10% of all IS patients, yet deserve special attention because of their high risk of progressive deformity. Respiratory compromise is particularly problematic in this population. We report a Hispanic male patient who presented at our institution at ten years of age with a diagnosis of IS. The family reported onset of deformity at three years, with brace correction from five to ten years of age. Prior genetic studies were reportedly normal. Re-evaluation at age 13 revealed hypotonia, large low set ears, flat nasal bridge, decreased sensitivity to pain, mild sacral dimpling, mild intellectual disability, and a severe left thoracic spinal deformity measuring 75 degrees. Brain MRI findings showed mild cerebral atrophy. Scoliosis was surgically corrected with instrumentation and fusion to avoid further deformity and respiratory compromise. Repeat chromosomal studies using array-CMA-HR+SNP revealed del15q24.1q24.2, spanning approximately 1.6 Mb (74.5–76.1 MB, hg19) in the patient and normal CMA in the father. Normal chromosomes were subsequently confirmed in both parents by Illumina OmniExpress-12 v1.0 beadchip arrays. These findings are consistent with de novo 15q24 microdeletion syndrome and may represent the smallest deletion yet described. 15q24 microdeletion syndrome was first described in 2005 in three patients with hypotonia, dysmorphic facial features, and genital anomalies in males. More recently, a review of thirteen cases in the literature noted three with scoliosis, and no mention of skeletal involvement in the remaining ten. We subsequently reviewed our database of 548 idiopathic scoliosis (IS) cases (66 EOS, 482 adolescent IS) and 744 healthy controls screened by Illumina OmniExpress-12 v1.0 beadchip arrays to assess the frequency of copy number variation in the 15q24 region. We found no other deletions (>10 kb) within the 15q24 region in patients or controls, suggesting that interstitial deletion of this region is not frequently associated with IS. Our patient helps to further delineate genotype/phenotype correlations in 15q24 microdeletion syndrome. We suggest that 15q24 microdeletion syndrome patients should be closely monitored for progressive scoliosis. Our findings also illustrate the potential utility of molecular genetic re-evaluation using updated platforms for patients with aggressive “idiopathic” scoliosis and other non-specific findings.

3109W

Microdeletions in 9q33.3-q34.1 may constitute a contiguous gene deletion syndrome characterized by developmental delay, microcephaly, mild dysmorphisms, strabismus, and seizures of incomplete penetrance. *J.A. Lee[1,2], J.K. Ehret[1], E. Wohlleber[1], S. Vogt[1], A.M. Zink[1], E. Rossier[3,4], M. Bonin[3,5], U. Grasshoff[3], A. Bevot[6], M. Mathieu-Dramard[7], G. Plessis[8], A. de Broca[9], S. Kanafani[7], B. Röthlisberger[10], M. Holder-Espinasse[11], I. Simonic[12], L. Willatt[12], P. Miny[13], I. Filges[13], J. Andrieux[14], H.V. Firth[12], A. Dufke[3], H. We report six patients with overlapping microdeletions of chromosome 9q identified by molecular karyotyping. Their common clinical features include psychomotor developmental delay with delayed or absent speech, strabismus, and microcephaly. *De novo* deletions ranging from 1.23 to 4.13 Mb in 9q33.3-q34.11 were detected, whereas the smallest deletion was detected in patient 4, whose 432-kb deletion was inherited from her mother who is reported to have mild intellectual disability. The smallest region of overlap (SRO) concerning the common clinical features is defined by the deletion in patient 4, and includes only three RefSeq genes. Interestingly, the larger deletions have 29 genes in common including *STXBP1*. *STXBP1* loss-of-function mutations and deletions have been associated with early infantile epileptic encephalopathy (EIEE, or Ohtahara syndrome), and were previously identified in patients with intellectual disability and non-syndromic epilepsy. In our cohort, however, the seizure phenotype appears to be incompletely penetrant (two of six patients). Notably, patient 4 has seizures, although her deletion excludes *STXBP1*. Thus, although one or more of the SRO genes may likely contribute to the phenotype, the involvement of *STXBP1* and/or possibly other genes due to deletion of long-range regulatory elements cannot be ruled out. Compared to patients with *STXBP1* mutations, our microdeletion patients are clinically similar except for distinctive microcephaly and strabismus. Publications by Saitsu and colleagues and Mignot and colleagues support this genotype-phenotype correlation, and may help to further define the SRO. Taken together, this suggests the possibility of a contiguous gene deletion syndrome involving several genes contributing to the phenotype. Sequencing of the three SRO genes in a cohort of 192 unrelated patients with mild to severe idiopathic intellectual disability, as well as gene expression analyses in our patients, is underway to identify the causative gene(s). Thus far, no causative mutations have been identified, arguing against mutations in these genes being a common cause for intellectual disability. We suggest that microdeletions of this region on chromosome 9q cause a clinical spectrum including developmental delay especially concerning speech, microcephaly, mild dysmorphisms, strabismus, and seizures of incomplete penetrance, and may constitute a new contiguous gene deletion syndrome.

Identification and diagnosis of Williams-Beuren syndrome in a public genetic center in Brazil. *M. M. Viana[1], M. Stofanko[2], P. S. Cunha[3], H. Goncalves-Dornelas[2], M. J. B. Aguiar[1], S. D. J. Pena[2, 3].* 1) Serviço de Genética Médica, Hospital das Clínicas, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; 2) GENE (Núcleo de Genética Médica), Belo Horizonte, Minas Gerais, Brazil; 3) Departamento de Bioquímica e Imunologia, Instituto de Ciências Biológicas, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil.

Introduction: Brazil is considered one of the emerging economies in the world. It has a public health system (SUS - Sistema Único de Saúde) that covers medical expenses for 80% of the population and demands cheaper diagnostic approaches when compared to developed countries. For instance, the cost of aCGH techniques is prohibitive for our reality. Thus, genetic diagnosis based on clinical data and testing focused at specific targets is more appropriate than genome wide screening procedures. To test our hypothesis we selected patients with suspected Williams-Beuren Syndrome (WBS), a multisystem disorder with well delineated phenotype, which is caused by microdeletions at 7q11.23. Purpose: To describe our experience in identifying and confirming WBS through a simple and inexpensive targeted diagnostic method. Methods: Between 2005 and 2010, 2,399 patients were evaluated for the first time at a public genetic center in Minas Gerais, Brazil. The medical charts were analyzed and a total of 26 patients were selected because of suggestive clinical features of WBS; 17 accepted to take part of the trial. Three (3) more patients were evaluated in 2011 and accepted to participate. DNA was extracted from oral mucosa cells and submitted to a simple and inexpensive novel technique developed called Microdeletion Fluorescent Quantification by Polymerase Chain Reaction (MFQ-PCR). All results were confirmed by loss of heterozygozity assessed by multiple microsatellites or real-time PCR. Results: A total of 20 samples were collected. Twelve tested positive for WBS. As expected, the main characteristics of positive cases were friendly personality (83%), prominent lips (83%), slanted palpebral fissures (75%), microcephaly (58%), long philtrum (50%), anteverted nares (42%), stellate pattern of the iris (33%). The main cardiac abnormalities were pulmonary stenosis (42%), mild to moderate aortic regurgitation (33%) and supravalvular aortic stenosis (33%), 2 patients had normal echocardiograms (17%). Discussion: In emerging economies, it is necessary to take into consideration the cost of diagnostic tests. Our report shows that it is possible to adequately make precise diagnosis using clinical expertise together with simple, targeted, cost appropriate diagnostic techniques. This experience can be extended to other genetic syndromes.

Implementation of molecular karyotyping in routine diagnostics provides new insights into the pathophysiology of Silver-Russell syndrome. *S. Spengler[1], M. Begemann[1], N. Ortiz Brüchle[1], P.M. Kroisel[2], B. Oehl-Jaschkowitz[3], G. Raabe-Meyer[4], C. Spaich[5], P. Blümel[6], U. Moog[7], K. Zerres[1], T. Eggermann[1].* 1) Institute of Human Genetics, RWTH Aachen University, Aachen, Germany; 2) Institute of Human Genetics, Graz, Austria; 3) Gemeinschaftspraxis für Humangenetik, Homburg, Germany; 4) Praxis für Humangenetik, Hannover, Germany; 5) Institute of Clinical Genetics, Stuttgart, Germany; 6) G v Preyer Childrens` Hospital, Wien, Austria; 7) Institute of Human Genetics, Heidelberg, Germany.

Silver-Russell syndrome (SRS) is a clinically and genetically heterogeneous disorder characterized by severe growth retardation, relative macrocephaly, a triangular face and asymmetry of body and/or limbs. The clinical spectrum is broad and the diagnosis is rather subjective. Therefore a comprehensive molecular diagnostic workup is needed. Unfortunately, the currently applied diagnostic algorithm leaves about 50 % of patients without molecular diagnosis: (epi)genetic disturbances in 11p15 can be detected in ~40% of patients and maternal uniparental disomy of chromosome 7 in further ~10% (upd(7)mat). By implementation of molecular karyotyping (Affymetrix SNP Array 6.0) in our diagnostic algorithm for SRS we could significantly improve the detection rate for genetic disturbances and thereby contribute to a more personalized clinical management: 19.5% of patients without the characteristic (epi)genetic disturbances on chromosomes 7 and 11 showed pathogenetic copy number variants. As some of them were associated with known microdeletion syndromes, our results illustrate the broad genetic heterogeneity of SRS and the difficulty in clinical diagnosis. Furthermore, the application of molecular karyotyping helps us to get new insights in the molecular aetiology of SRS, either by identifying new genetic regions or by precise characterisation of genetic disturbances affecting the known SRS loci. By analyses of imbalances affecting the imprinting control regions (ICRs) in 11p15 and 7q we obtained relevant data on the complex regulation mechanisms and interactions between the different loci illustrating that the clinical outcome is influenced by the size, the breakpoint positions and the parental origin of the imbalances. In conclusion, implementation of molecular karyotyping in the diagnostic algorithm for patients with SRS features is urgently needed because: a) causal (sub)microscopic imbalances can be found in a significant proportion of patients without the characteristic (epi)genetic disturbances, b) detailed analysis of CNVs in 11p15.5 allows insights in the complex regulation of the imprinted factors localised in this region, c) SRS candidate regions can be discovered, d) based on the molecular findings risk figures can be delineated.

3112F

Clinical, molecular cytogenetic evaluation and genotype-phenotype correlation of a patient with partial Jacobsen syndrome without thrombocytopenia caused by an 13 Mb deletion of del(11)(q24.1). *J. Moon[1], J. Kim[1], J. Kim[2], M. Nam[1], S. Yoon[1].* 1) Laboratory Medicine, Korea Univ. Ansan Hosp., Ansan, Gyeonggi, South Korea; 2) Laboratory Medicine, Korea Univ. Anam Hosp., Seoul, South Korea.

Clinical manifestations of Jacobsen syndrome (JBS) depend on the size of the 11q deletion, which usually varies between ~5 and 20 Mb. Typical JBS features include developmental delay/mental retardation, congenital heart defects, thrombocytopenia, and characteristic dysmorphic craniofacial features. We present a patient with de novo terminal deletion of chromosome 11q24.1q25. The clinical phenotype in our patient, born prematurely, includes mild neonatal thrombocytopenia, neonatal jaundice, short stature, and feeding difficulties. She has mild facial abnormalities, including epicanthal folds mimicing simian crease right hand and both toe deformities and a sacral malformation. The patient did not show any abnormalities in hearing screening tests, brain and abdominal ultrasonography, and heart echocardiogram except for persistent foramen ovale of prematurity, but no substantial congenital heart defect. Cytogenetic analyses revealed the karyotype of 46,XX,del(11)(q23.3). Using fluorescence in situ hybridization (FISH) for *MLL*, located on 11q23 showed normal signals, in contrast with 11q subtelomere FISH, showing one signal deletion. Utilizing whole-genome cytogenetic array analyses, we identified an ~13 Mb deletion of the terminal part of chromosome 11q in the patient. The deletion breakpoint was mapped between 121,560,927 and 134,926,021 bp. This includes multiple genes including LOC. Interestingly, the patient's intact hearing and abscence of heart and kidney abnormalities is suggestive of incomplete penetrance, but relatively mild facial defects support previous data that relatively smaller deletions not involving 11q23 usually have less number of facial dysmorphisms. The patient's parents' karyotypes and 11q subtelomere FISH results were normal, revealing the patient's abnormality as de novo. Notably, neither thrombocytopenia nor congenital anomalies were detected in this family, including the patient's brother. Our data can be compared with previous cases patients with deletion of similar region and multiple anomalies including strabismus and toe abnormalities.

3113W

Triplication of 7q11.23 distal to the critical region for the Williams-Beuren syndrome. *J.G. Pappas[1], R.D Nass[2], E. Ward[1], I.K. Gadi[3].* 1) Dept Pediatrics, Clin Genet Svcs, New York Univ, Sch Med, New York, NY; 2) Dept Neurology, Pediatrics, Child and Adolescent Psychiatry, New York Univ, Sch Med, New York, NY; 3) Cytogenetics, Laboratory Corporation of America, Research Triangle Park, NC.

We present a 14 year old boy with autism spectrum disorder and 1.1 Mb interstitial triplication of 7q11.23 distal to the critical region for the Williams-Beuren syndrome. He presented at age 3 with global developmental delays especially no speech development. Peripheral blood chromosome analysis and fragile-X test by PCR were reported normal. At age 13 he had a neurodevelopmental evaluation which revealed mild intellectual disability, autism with significant apraxia. At age 14 his height was 163 cm, his weight was 52.7 kg and his head circumference 55 cm; all around the 50% centile. He had normal puberty development, sloping forehead and facial asymmetry with right face larger than left, up-slanted eyes with inverted lower eyelids, attached earlobes, down turned corners of the mouth and tapering fingers with fetal pads. Whole genome SNP microarray analysis was performed using the Affymetrix 6.0 platform which uses over 900,000 SNP probes and 900,000 NPCN probes with a median spacing of 0.7 Kb. This microarray revealed triplication 7q11.23 [arr 7q11.23(74,882,566–75,981,763)x4]. This interstitial triplication was confirmed by the region specific BACs RP11-951G4 and RP11-107L23 on 50 interphase and 10 metaphase cells. These BACs were used for parental testing which showed normal hybridization signals on both chromosome 7 homologues in all nuclei of the parental blood samples. These results were consistent with a de novo origin of the triplication. The OMIM annotated genes included in the triplication interval were: *TRIM73*, *HIP1*, *CCL26*, *CCL24*, *POR*, *MDH2*, *HSPB1*, *YWHAG*, *SRCRB4D*, *ZP3* and *DTX2* (NCBI36/hg18). There is no report in the medical literature with the triplication seen in our case. Ramocki et al. (2010) reported cases with 1.2 Mb deletion and two siblings with the reciprocal 1.2 Mb duplication of a segment overlapping the triplicated segment in our case. Common features of the reported cases with the deletion included epilepsy, mild intellectual impairment, neurobehavioral abnormalities including autism. The reported siblings with the duplication had behavioral disorders and no epilepsy. Ramocki et al (2010) studied cases with smaller deletions and concluded that copy number variations of *HIP1* contributed to the neurological abnormalities in their cases. *HIP1* is included in the triplicated segment in our case. Our case shares the neurodevelopmental phenotype attributed to copy number variations of *HIP1* and further supports this association.

3114F

A *de novo* 9.0 Mb Deletion at Chromosome Region 10q21.3-q22.3 associated with severe psychomotor Delay and mild Noonan Phenotype: a Case Report. *S. Baffini[1], G. Scarselli[2], L. Castiglia[3], M. Vinci[3], S. Amata[3], M. Fichera[3,5], J.D. Barp[4], E. Gambineri[4], E. Chiappini[4], M.L. Giovannucci Uzielli[1,4].* 1) Genetic Science, Florence, Italy; 2) Neuroscience Department, University of Florence, Italy; 3) Laboratory of Genetic Diagnosis, IRCCS Maria Santissima, Troina (Enna), Italy; 4) Science of Mother and Child Health Department, University of Florence, Italy; 5) Medical Genetics, University of Catania, Italy.

We report a clinical and molecular study in an 8-year-old child, observed by a periodical follow-up since birth, with severe intellectual disabilities, short stature, mild facial dysmorphisms, reminiscent of Noonan phenotype, thinning and sparse hair, and mild hearing loss. Q- and G- banding karyotyping was normal. PTPN11 gene screening did not reveal any mutations. Utilizing an oligonucleotide array CGH (Agilent 60K) we identified a genomic, interstitial, microdeletion at 10q21.3-q22.3: the deleted segment is approximately 9.0 Mb, and involves a contiguous region of single copy loss of over 23 genes, including NODAL and C10orf11 (http://genome.ucsc.edu). The breakpoints were at 70,288,248 and 79,331,739 (GRCh37). Deletions of the long arm of chromosome 10 are very rare: to our knowledge, the two first cases were only cytogenetically analyzed and associated with abnormal clinical phenotype [46,XX, del (10)(q21.2q22.1)(Glower et al., 1987) and 46,XY,del (10)(q22.1q22.3)(Cook et al. 1999)]. Three further cases [46,XX,del(10)(q21.3q22.2), 46,XY,del(10)(q22.2q22.3) and 46,XX,del(10)(q22.2q22.3)] were also studied at the molecular level (Tzschach et al. 2010). Mutations of NODAL gene, a member of TGF-b gene family, have been associated with heterotaxia and cardiovascular problems. NODAL gene is involved in Activin/Nodal signaling that is interconnected to the Ras-pathway. Moreover, Rap-2, a member of the Ras GTPase family, directs internalized Activin/Nodal receptors into a recycling pathway, thereby preventing their degradation and maintaining their levels on the cell surface (Choi et al. 2008). Tzschach and colleagues (2010) hypothesized a correlation between C10orf11 gene haploinsufficiency and mental retardation. Further study is needed in order to evaluate whether the haploinsufficiency of NODAL and C10orf11 and possibly other genes within the deleted 10q region can be considered responsible for our patient's clinical phenotype.

3115W

A first reported case of a microdeletion in 8q22.22q23 in Colombia. Phenotypic and genotypic correlation. *P. Paez[1,2], S. Perdomo[1], X. Rojas[2].* 1) Dept Cundinamarca, Universidad el Bosque, IINGM Facultad de Medicina,Bogota, Colombia; 2) Hospital Universitario Clinica San Rafael, Bogotá, Colombia.

We present a Colombian seven year old girl referred to a clinical genetics setting because of developmental delay, microcephalia, epilepsy, severe short stature, impaired speech, delayed attention, facial dismorphism, neurosensorial deafness and skeletal abnormalities. She is the second of two born children of healthy non consanguineous parents. She was born at 34 weeks due to intrauterine growth restriction and oligohydramnios. She presented severe short stature (< 3DS), microcephalia, triangular palpebral ptosis, bilateral blefarophimosis, sparse eyebrows, flat philtrum, thin upper lips, low set ears, small hands, short thumbs, bilateral fifth finger clinodactyly. Cognitive impairment, distractibility and poor attention. Normal karyotype: 46,XX[25], Normal brain images. Array CGH (comparative genome hybridization) suggested a minimal/maximal deletion of 5.238 Mb and 5.374Mb respectively at 8q22.2q22.3. Deletion of this region has been associated with a clinical recognizable condition described worldwide in only five patients. This region comprises at least 25 clinical relevant genes including the KCNS2 gen (which could explain epilepsy in this case). Ptosis and blepharofimosis are very frequent signs in all reported patients including our patient. There is no complete molecular explanation for these two signs but there is a critical zone related to blepharofimosis (NMLF) and a candidate locus related to ptosis(ZFHX4) which are out of the zone affected in this patient but that could play a positional effect on the deleted region. This is the first report of this interstitial deletion in Latin-America. This patient shares the majority of the features described in the previous 5 patients except for the neurosensorial deafness not previously described. This report is an example of how high resolution microarray technology facilitates the detection of submicroscopic chromosome alterations in the context of clinical genetics settings in Latin-America.

3116F

A microdeletion of about 831 kb in a young woman causes a loss of more than 30 genes on the long arm of chromosome 17 including a copy of the BRCA1-gene. Implications for genetic counselling and clinical management. *P.M. Kroisel, J.B. Geigl, M. Mach, C. Pischler, E. Vallant, M.R. Speicher, K. Wagner.* Institute of Human Genetics, Medical University of Graz, Graz, Austria.

By CGH analysis using a 60k Agilent oligonucleotide array a de novo microdeletion was identified, leading to a haploinsufficiency of the important tumour suppressor gene BRCA1. These unintended findings in the patient were obtained because cytogenetic results did not provide any clue for presence of her congenital moderate mental impairment and dysmorphic facial features which on the other hand suggested that a small genomic imbalance might be responsible which finally could be confirmed. Besides this dn microdeletion (chr17:40869151–41700815) also a microduplication of about 332 kb at 1q25.1 (chr1:172199642–172532314) inherited from her phenotypically normal mother was found. Because of that latter fact and since the microduplication only affects 4 genes without any known important function, we assume that the microduplication is presumably without any additional clinical relevance. The observations made in this particular case certainly demonstrate again that accidental or coincidental findings in specific subsets of patients should seriously be considered and councelling has to be performed accordingly. The list of well defined inherited cancer predisposition syndromes, which can be attributed to a hereditary susceptibility and having far reaching implications for all family members, is steadily growing. De novo mutations or even microdeletions of such tumour suppressor genes are rather rare events, which for different gene loci obviously will show a remarkable variable probability. We recently identified the first patient with a contiguous gene syndrome due to microdeletion of 17p that also caused a loss of the entire TP53 gene as well as several flanking genes in a mentally retarded person. The current patient is now 28 years of age. Her length is 153.5 cm and weight is 38 kg. A microcephaly with an OFC of 51 cm was noticed and distinct dysmorphic facial features like ear anomalies and bilateral ptosis were recognized. No comparable microdeletions also causing a loss of the entire BRCA1-gene as well as up- and downstream flanking genes is reported thus far or included in databases like ISCA or Decipher. Because of the achieved diagnosis the patient and her family were already subjected to an additional extented genetic councelling with information about results and recommenations and specialists in breast cancer screening and prevention will be included in continued medical surveillance and maintenance as requested.

Williams-Beuren syndrome (WBS) is a multisystemic developmental disorder caused by hemizygous deletion of a segment on chromosome 7q11.23, spanning 1.55 Mb or 1.8 Mb, and encoding 28 genes. A few individuals have smaller deletions of the region. Their phenotypic features varies from supravalvular aortic stenosis syndrome (OMIM 185500) to classic Williams-Beuren Syndrome. We report a family, a mother and 3 sibs, with history of dominant supravalvular stenosis. The youngest daughter was diagnosed at birth with severe supravalvular aortic and pulmonary stenosis, requiring surgery, and facial dysmorphism. Caryotype and FISH of the 7q11.23 region was negative. Her two brothers present cardiovascular abnormalities, with for the youngest, aged 5 years, supravalvular aortic stenosis, involvement of the pulmonary branch, and mesenteric, coeliac and renal stenosis, and the eldest, aged 10 years, supravalvular pulmonary and aortic stenosis. They both had surgery for bilateral inguinal hernia, no classical WBS facial dysmorphism when seen, and impulsivity and short attention span (ADHD). Mother have supravalvular aortic stenosis, facial dysmorphism, and history of school difficulties, ADHD and still show strong anxiety. MLPA analysis of the 7q11.23 region found an atypical deletion, confirmed by array-CGH (Agilent 244k), of the entire ELN gene and part of the LMK1 gene. Although the loss of an ELN allele produces the cardiovascular pathology of WBS, the phenotypic consequences of losing other alleles within the WBS chromosome region are much less clear. More precise phenotypical data will be shown, and compare to the literature.

3118F

12q21 deletion syndrome with intellectual disability and facial dysmorphism. *A. Matsumoto, T. Yamagata, Y. Nozaki, E. F. Jimbo, M. Y. Momoi.* Jichi Medical University, Shimotsukeshi, Tochigi, Japan.

Interstitial deletion of 12q21 was reported in four patients, who presented intellectual disability (ID) and facial dysmorphisms. We report a patient with 12q21 deletion and tried to nominate these patients as 12q21 deletion syndrome. (Patient report) The patient was a 18-month-old boy. His father had karyotype of mos 46, XY/46, XY, inv(12)(q12q21) of 74:6 cells without abnormal phenotype. The patient's growth parameters were normal. At 18 months of age, the patient had ID (DQ 46) without meaningful words and with mild spastic diplesia. Other phenotypes of the patient included prominent forehead, hypotelorism, short upturned nose, long philtrum, small mandible, high-arched palate, low set ear, sparse hair and internal strabismus. Cranial magnetic resonance imaging (MRI) showed ventriculomegaly and mild hypoplasia of the corpus callosum. (Result) The patient's karyotype was 46,XY, del(12)(q21.2q21.33)inv(12)(q13.1q21.2). On his array CGH analysis using Agilent Human genome CGH 180K, a deletion at 12q21.2-q21.33(77. 2Mb ~91.2Mb)of 14 Mb was detected. (Discussion) Concordant clinical features of 12q21 deletion shared by previously reported four patients and our patient were ID, low set ear, sparse hair, prominent forehead and hyper- or hypotelorism. Other phenotypes observed in three or four patients were short upturned nose, small mandible, and cutaneous findings such as hyperkeratotic papular eruption and atopic dermatitis. On neuroimaging, ventriculomegaly was detected in three patients, and delayed myelinaization and mild hypoplasia of the corpus callosum was detected in one patient each. These findings are considered to be the phenotype of 12q21 deletion syndrome. The deletion in our patient was the shortest in 5 patients, that suggested the presence of responsible genes for the concordant feature should be localized in this region. Several important genes relating to neuronal development and function such as *ZDHHC17*, *NAV3*, *SYT1*, *PAWR*, *LIN7A*, *ALX1*, *DUSP6* and *ATP2B1* are localized at the deleted region. Further analysis for the responsible genes for 12q21 deletion syndrome should be interesting.

Autism, mild facial dysmorphism, abnormal EEG, sleep problems and language impairment in interstitial duplication 15q11-q13 syndrome. *N. Urraca[1], C. Cleary[2], E. Pivnick[3], K. McVicar[3], V. Brewer[3], R. Thibert[4], N.C. Schanen[5], M.C. Esmer[6], D. Lamport[7], L.T. Reiter[1,3].* 1) Neurology, UTHSC, Memphis, TN; 2) Speech and Language Pathology, University of Memphis, Memphis, TN; 3) Pediatrics, UTHSC, Memphis, TN; 4) Neurology, Mass General Hospital, Boston, MA; 5) Human Genetics Research Laboratory, Nemours Biomedical Research, Wilmington, DE; 6) Genetics, Hospital Central “Dr. Ignacio Morones Prieto”, SLP, MEX; 7) Psychology, University of South Alabama, Mobile, AL.

Chromosomal copy number variants (CNV) are the most common genetic causes of autism. As many as 1–3% of autistic cases are the result of duplications of the 15q11-q13 region. Advances in molecular detection of CNVs have had a significant impact on the detection of 15q duplication cases. Chromosome 15 has a number of low copy repeats that predispose the region to deletion/duplication events. This region has a cluster of genes preferentially expressed from one parental allele in the nervous system that clearly influence phenotypic outcome in deletion cases, but have been difficult to analyze in individuals with interstitial 15q duplications. Most cases that present clinically are de novo and of maternal origin, but paternal duplications can present phenotype as well. We performed an in depth phenotype/genotype analysis of individuals with interstitial 15q duplications to determine if maternal duplication is required for autism diagnosis. We used dysmorphology, neurological examination, neuropsychological, language, sleep, neurophysiology and ASD diagnostic tools for phenotypic analysis. Methylation Sensitive High Resolution Melting analysis of the maternally methylated SNRPN was used to determine the parent of origin of the duplication. 14 int dup(15) subjects were selected for analysis: 10 maternal and 4 paternal cases. Eleven are de novo. Six cases are PWS/AS Class I and 8 are Class II. The most frequent facial features found were long philtrum with a short bulbous nose. 60% also had hypotonia. 8/14 subjects had excessive 18–22 Hz beta activities on EEG throughout the waking record regardless of the parental origin of the duplication or the presence/absence of ASD. All subjects with maternal and 2/4 with paternal duplications scored on ASD for ADOS/ADI-R analysis. Most subjects had a low-moderate adaptive functioning score on the Vineland II test with no differences among groups. All subjects performed below age corrected average for receptive language. On average all subjects had reported-sleep problems, but in subjects with paternal duplications sleep problems were more severe, though they have better sleep habits. In conclusion, the majority of int dup(15) cases found were maternal in origin, most likely due to the coincidence of ASD with maternal duplication, the size of the duplication did not correlate with the severity of the phenotype, and subjects had mild facial anomalies, autism, language impairment, sleep problems and unusual EEG variant.

Mucolipidosis III gamma, tuberous sclerosis, and polycystic kidney disease caused by a contiguous gene deletion on chromosome 16p13.3. *J. Barea[1], L. Bird[1,2].* 1) Genetics Dept, UCSD, San Diego, CA; 2) Dysmorphology/Genetics, Rady Children's Specialists of San Diego, San Diego, CA.

We present the first known report of a patient with Tuberous Sclerosis 2, Polycystic Kidney Disease 1, and Mucolipidosis III gamma. This patient was noted to have clubfeet and developmental dysplasia of the hips from infancy. At 9 months old, she had a prolonged episode of unresponsiveness with an abnormal EEG and was diagnosed with a seizure disorder. At age 4 the patient was noted to have facial angiofibromas and hypopigmented macules, leading to the diagnosis of Tuberous Sclerosis. The patient later had a brain MRI that showed cortical tubers and subependymal nodules, and a renal ultrasound that showed renal cysts. However, the patient developed a variety of worsening orthopedic problems; including genu valgum, stiffness of finger joints, decreased shoulder mobility, scoliosis, pain on back and upper legs, and decreased exercise tolerance. She also had abnormal radiologic findings including bony deformities involving the wrists and distal forearms; thoracolumbar scoliosis with malformed and irregular appearing vertebral bodies, with spondylolisthesis of L5 on S1; and bilateral hip dysplasia with femoral head irregularities. Microarray analysis was done showing a 1.9 Mb deletion of chromosome 16p13.3. This deletion contains at least 96 genes, including TSC2 and PKD1. Other genes in the region were examined for their possible relationship to the orthopedic symptoms of the patient. The GNPTG gene, which encodes the gamma subunit of UDP-N-acetylglucosamine: lysosomal hydrolase N-acetylglucosamine 1-phosphotransferase enzyme, is within the deleted interval. Mutations in the GNPTG gene cause Mucolipidosis III gamma, and the patient's clinical and radiographic presentation was compatible with this condition. The diagnosis was confirmed by lysosomal hydrolase assay, which showed very high plasma enzyme levels and normal enzyme levels in leukocytes. ML III can be due to deficiency of the alpha/beta subunit encoded by the GNPTAB gene located on chromosome 12q23.3 or due to deficiency of the gamma subunit encoded by GNPTG. Given that ML III gamma is an autosomal recessive condition, a point mutation in GNPTG on the intact chromosome 16 was assumed and GNPTG sequencing revealed Gly126Ser mutation in a highly conserved residue. Further understanding of the differences between ML III gamma and ML III alpha/beta will be enhanced by determining the subclass of ML III patients.

3121W

GH deficiency and epilepsy in a patient with a 19q13.3 duplication encompassing the pth2, kcnc3 and kcna7 genes. *M. Vincent[1], C. Jeandel[2], J. Puechberty[1,3], C. Coubes[1], F. Dallavale[2], F. Rivier[4], A. Schneider[1,3], M. Girard[3], N. Ruiz[5], M. Tournaire[3], I. Touitou[5], G. Lefort[1,3], P. Sarda[1], D. Genevieve[1,6].* 1) Génétique médicale, CHU de Montpellier, Montpellier, Languedoc Roussillon, France; 2) Département de pédiatrie spécialisée endocrinopédiatrie, Hôpital Arnaud de Villeneuve, CHRU Montpellier, France; 3) Plate-forme Puce à ADN, Laboratoire de Génétique Chromosomique, CHRU Montpellier, France; 4) Service de Neuropédiatrie, Hôpital Gui de Chauliac, CHRU Montpellier, France; 5) Unité médicale des maladies autoinflammatoires, Hôpital Arnaud de Villeneuve, CHRU Montpellier, France; 6) Unité Inserm U844, Institut des Neurosciences de Montpellier, France.

GH deficiency of genetic origin can be observed either as an isolated feature due to mutation in the GHRH-R, GH1, GHS-R and BTK genes, or in a malformation context which is sometimes due to a genetic syndrome. The aim of this study is to report a patient with GH deficiency and PTH2 duplication and to discuss the potential role of this gene as a novel genetic etiology of GH deficiency. A young French boy presented with short stature, seizures, intellectual disability and peculiar facial features. Endocrinological tests performed because of moderate short stature revealed GH deficiency without failure in the rest of the pituitary axis, and a good response to GH treatment. Genetic investigations including SNP array showed a 6.8 Mb duplication on the long arm of chromosome 19 (19q13.33). We discuss the co-relation between the features observed in our patient and the genetic content of this chromosomal region. GH deficiency could be due to the PTH2 duplication and seizures due to KCNC3 and KCNA7 duplication. The other patients reported in the literature with distal 19q duplication encompassing the PTH2, KCNC3 and KCNA7 genes also presented with short stature and epilepsy. Based on data from the literature, in this report GH deficiency could be due to increased gene dosage of PTH2, resulting in an excess of PTH2 peptide, which plays a role in the regulation of the hypothalamic-pituitary-adrenal axis by down-regulation of GH secretion. This report suggests that PTH2 is a novel gene involved in GH deficiency in humans.

3122F

A large deletion confined to *COL4A5* causes Alport syndrome and diffuse leiomyomatosis. *M.JN. Sá[1,2], R. Sousa[3], FT. Costa[4], F. Carvalho[5], S. Alves[1], F. Carvalho[1], JP. Oliveira[1,2].* 1) Department of Genetics, Faculty of Medicine, University of Porto, Porto, Portugal; 2) Research and Development Unit of Nephrology (FCT-725), Faculty of Medicine, University of Porto, Porto, Portugal; 3) Department of Gastroenterology, Hospital Garcia de Orta, Almada, Portugal; 4) Department of Nephrology, Hospital Garcia de Orta, Almada, Portugal; 5) Department of Nephrology, Hospital Curry Cabral, Lisboa, Portugal.

Alport syndrome and diffuse leiomyomatosis (MIM#308940; ATS-DL) is a contiguous gene deletion syndrome involving the *COL4A5* and *COL4A6* genes. These genes are localized head-to-head in close proximity on chromosome Xq22.3 and share a common promoter region. Previous studies have suggested that the minimal deletion region associated to ATS-DL includes exon 1 of COL4A5 and exons 1, 1' and 2 of *COL4A6*. Herein, we report the molecular genetic analysis of an affected male with ATS-DL in whom a deletion confined to *COL4A5* was identified. The proband is a 25 years old male with Alport syndrome diagnosed at the age of five years, on the basis of typical electron microscopy findings on a kidney biopsy. Hearing loss became apparent at the age of seven years and anterior lenticonus was diagnosed at the age of 18 years. Renal replacement therapy by hemodialysis was started at the age of 20 years and the patient eventually received a cadaveric kidney transplant six months later. Esophageal leiomyomatosis was diagnosed at the age of 25 years on the investigation of persistent upper gastrointestinal symptoms, including dysphagia. Direct sequencing of *COL4A5* gene showed a large hemizygous deletion, encompassing exons 2 to 51. Direct sequencing of the first three exons of *COL4A6*gene was normal. These results were confirmed by multiplex ligation-dependent probe amplification (MLPA Alport syndrome kit, SALSA P191/P192). His mother and a sister, also affected with ATS-DL, are heterozygous for the same deletion. To our knowledge, this is the first time a family with ATS-DL is shown to have a large deletion confined to *COL4A5*. This observation suggests that deletion of exons 1, 1' and 2 of *COL4A6* is not required for the development of diffuse leiomyomatosis in association with Alport syndrome. Further investigation is needed to confirm the absence of mutations affecting the common promoter region of the two genes and to determine the extent of the deletion towards the telomere, to substantiate this remarkable finding.

3123W

Genetic study of a family segregating Waardenburg-Shah syndrome. *L. Cui[1], H.M. Wong[1], J. Zhu[1], F. de Almeida M[2], P.H. Tam[1], M. Garcia-Barcelo[1].* 1) The University of Hong Kong, Hong Kong, China; 2) Faculdade de Medicina de Ciências Medicas de Minas Gerais, Brazil.

Waardenburg-Shah syndrome (WS4, MIM_277580) is a congenital developmental disorder characterized by pigmentary abnormalities of the skin, eyes and hair, sensorineural deafness and intestinal aganglionosis (HSCR; Hirschsprung disease). Mutations in EDN3, EDNRB, or SOX10 account for approximately 65–85% of the WS4 patients. The disorder is clinically and genetically heterogeneous with either autosomal recessive or autosomal dominant inheritance with incomplete penetrance. EDN3, EDNRB, and SOX10 were sequenced in a three-generation family (14 individuals; 3 members affected with HSCR and 1 with WS4). A novel heterozygous missense mutation in the EDNRB (chromosome 13) was identified in four affected and three unaffected family members. The mutation changes the translation initiation codon Met1 of the EDNRB receptor isoforms 1 and 2 (M1V; predicted damaging) or the residue Met91 of the EDNRB isoform 3 (M91V; predicted benign). Importantly, the three EDNRB isoforms are expressed in the gut of newborns. Functional analyses coupled with confocal microscopy revealed the presence of a shorter EDNRB isoform 1 (M1V) as a result of alternative translation initiation site usage (Met46). Small quantities of this shorter protein were observed in the cellular membrane. Both EDNRB isoform 3 wild-type and the mutated (M91V) counterpart were only found in the cytosol, apparently not being implicated in the receptor-ligand relationship necessary for the differentiation of the neural crest cells from where both enteric neurons and melanocytes derived. Reduced amounts of a shorter form of the EDNRB receptor can indeed account for the disease phenotype. Yet, given the reduced penetrance of M1V, additional loci contributing to this disorder may exist in this family. To identify those, family members were genotyped using Illumina Human Omni2.5-quad BeadChip. After quality control and SNP pruning the Merlin software was used for parametric and non-parametric linkage. A susceptibility locus on chromosome 4q13.3-q24 (28.35 cM) was identified by both nonparametric and parametric linkage analysis. Haplotype analysis refined the linkage region to a 27.76 cM interval (between rs13146209 and rs17033669) encompassing two biologically plausible genes: MAPK10 and PPP3CA which are currently being sequenced in these individuals.

Founder effect of Spinocerebellar ataxia type 7 (SCA7) in a Mexican population. *Y. Tapia-Guerrero[1], O. Hernández-Hernández[1], M. Maldonado-Rodríguez[1], C. Cerecedo-Zapata[1], N. Leyva[1], L. Velázquez-Pérez[2], B. Cisneros[3], J.J. Magaña[1].* 1) Genetics, National Rehabilitation Institute, Mexico City, Mexico City, Mexico; 2) Center for the Research and Rehabilitation of the Hereditary Ataxias (CIRAH), Holguín, Cuba; 3) Genetics and Molecular Biology, CINVESTAV-IPN, 07360 Mexico City, Mexico.

Spinocerebellar ataxia type 7 (SCA7) is a polyglutamine (polyQ) neurodegenerative disease characterized by progressive cerebellar ataxia and retinal degeneration with ophthalmoplegia, hyperreflexia, sensory loss, dysarthria, and dysphagia. SCA7 is caused by expansion of the CAG trinucleotide repeats within the coding tract of the ATXN7 gene, which encodes ataxin-7, a subunit of protein complex involved in transcriptional regulation. This repeat is polymorphic in normal individuals with alleles ranging from 7 to 36 repeats. Alleles exceeding a threshold of approximately 37 repeats and reaching up to a number of 460 CAGs result in disease. Due to that SCA7 shares practically the same symptomatology with the other ataxias, its accurate diagnosis is based on identification of the genetic mutation that produces it. In this study, we analyzed a group of 62 patients with autosomic dominant cerebellar ataxias characteristics from the central region of Veracruz State, Mexico, applying a multiplex fluorescent PCR method (for SCA1, 2, 3, 6 and 7) in combination with capillary electrophoresis analysis of the amplified products. Furthermore, we analyze the variability at the SCA7 gene polymorphism in 300 unrelated Mexican healthy subjects. We identified SCA7 expanded alleles in 52 out of 61 patients (87%) and 9 patients with SCA2 (13%). We found twenty SCA7 mutant alleles, ranging from 37 to 72 repeats. Preliminary data indicated that in a region of 428.27 miles of Mexico southeast, unlike in other populations studied, SCA7 is by far the most common of all genetically verified dominant ataxias, suggesting the existence of a founder effect for the SCA7. Specifically, we found a preliminar prevalence in a Mexican population (Tlaltetela) of approximately 817 cases per 100,000 people. To investigate this possibility we performed an extensive haplotype study (3145G/A/)/D3S1287/D3S3635/D3S1228) including all SCA7 families available in these populations. In the general Mexican healthy population a total of ten alleles were found, ranging from 7 to 16 repeats. The most common allele had 10 repeats (59.5%) followed by the 12 and 11 repeats alleles (17.2% and 11.94% respectively). Alleles greater than 16 repeats had a frequency of 0.17. We conclude from this study that the relatively high frequency of SCA7 in this region could be the result of a founder effect. Until now this is one of the largest series of cases in specific geographical region around the world.

3125W

Study of GJB2, GJB6 and MT-RNR1m.1555A>G in Mexican hearing loss patients. *M. Arenas-Sordo[1], I. Menendez[2], E. Hernández-Zamora[1], A. Simarci[2], D. Gutierrez[1], P. Murphy[1], X. Leyva[1], F. Huesca[1], J. Dominguez-Aburto[1], M. Tekin[2].* 1) Genetics, INR, Av.Mexico-Xochimilco 289. Mexico DF, Distrito Federal, Mexico, 14389; 2) Hussman Institute of Human Genomics. University of Miami. 1501NW 10th Ave. Miami. Florida 33136.

Objective: The aim of this study was to elucidate the involvement of three common deafness genes in 76 unrelated Mexican probands with prelingual non-syndromic hearing loss. Methods: We screened GJB2, GJB6, and mitochondrial MT-RNR1 genes for mutation analysis in 76 (71 simplex; 5 multiplex) unrelated Mexican probands with prelingual non-syndromic hearing loss from the Department of Genetics at Instituto Nacional de Rehabilitacion in Mexico City. Results: We identified 8 different mutations and two polymorphic variants in GJB2. Eight cases were found to have bi-allelic mutations in GJB2 (10.6% prevalence) and six were found to have only one GJB2 mutation. c.35delG was the most frequent pathological GJB2 allele. The p.V27I polymorphism was frequently detected (allele frequency: 24%). The evaluation of the hearing severity showed that individuals with bi-allelic GJB2 mutations were affected mostly profound. DFNB1 carriers were severely or profoundly affected and non DFNB1 patients were among the three groups (moderate, severe and profoundly affected hearing loss). Asymmetric hearing loss were absent in the DFNB1 group, but it was identified mostly in non DFNB1 patients. Two screened GJB6 deletions and m.1555A>G mutation were not detected. Conclusions: This study showed that GJB2 mutations were an important cause of prelingual deafness in Mexican population.

3126F

A family with an OPA1 mutation and associated hearing loss. *C. Williams[1], H. Stalker[1], S. Schimpf-Linzenbold[2], B. Wissinger[2].* 1) Philips Unit, Dept Pediatrics, Genetics and Metabolism, Univ Florida, Gainesville, FL; 2) Molecular Genetics Laboratory, Centre for Ophthalmology, University of Tuebingen, Germany.

Mutations of OPA1 are the most common cause for familial dominant optic atrophy. This gene encodes a dynamin-like large GTPase that localizes to mitochondria and plays a crucial role in mitochondrial dynamics and cristae junction stabilization. We identified a novel mutation in exon 12 (Pro400Ser) of OPA1 that segregates through at least three generations. The 5-year-old proband had severe visual impairment with optic atrophy (OA) since infancy and a tremulous movement disorder without weakness. She developed sensorineural hearing loss (SNHL) at age 10 years requiring cochlear implants at age 14. An affected sibling with OA is now 19 years old but has no apparent hearing loss. The affected mother has OA with severe vision loss and has severe SNHL with onset at age 15 years (now with cochlear implants). The affected maternal grandmother has mild SNHL with onset at age 40: there is variable expression of SNHL in the kindred. Most individuals with OPA1 mutations (typically truncating or splice type) do not have associated hearing loss. The multisystem features in this family are therefore possibly related to a dominant-negative effect of the missense mutation. Exon 12 is located within the GTPase domain of OPA1 and previously reported families with Arg445His mutations have had OA and SNHL. The hearing loss in those families was attributed to auditory neuropathy (Amati-Bonneau et al., Ann Neurol 2005; 58:958–963).

3127W

Cerebrocostomandibular syndrome: clinical features of three new cases and preliminary analysis of exome sequencing data. *D.C. Lynch[1], E. Lemire[2], B. Chodirker[3], A.M. Innes[1], J.S. Parboosingh[1], F.P. Bernier[1] FORGE Canada Consortium.* 1) Department of Medical Genetics, Alberta Children's Hosp, Calgary, Alberta, Canada; 2) Department of Pediatrics, University of Saskatchewan, Saskatoon, Canada; 3) Departments of Biochemistry and Medical Genetics and Pediatrics, and Child Health, University of Manitoba, Winnipeg, Manitoba, Canada.

CCMS (OMIM 117650) is characterized by posterior rib-gap defects, reduction in rib number, and micrognathia. CCMS is clinically variable, ranging from mildly affected adults who present after the birth of an affected child, to presentation in infancy with absent ribs, respiratory distress, severe microcephaly, and other anomalies. Approximately 40% of affected individuals die within the first year of life due to respiratory insufficiency. Here we describe four new cases of CCMS, including a 13 yo male and his affected brother who died in infancy, and two sporadic cases (a 17 yo male and a 15 yo male). The mode of inheritance is unclear in this cohort, especially given previous reports of both autosomal dominant and autosomal recessive inheritance. All cases had typical features of CCMS include rib anomalies and micrognathia. We have sequenced the exomes of the three surviving patients patients and four unaffected parents or siblings. No variants in a common gene or gene family have been identified, raising the possibility of genetic heterogeneity in CCMS. It is also possible that the causative mutation has been missed in some or all patients due to the technical limitations of exome sequencing, or because CCMS is caused by mutations in non-coding regions. As autosomal recessive mutations in COG1 have been reported in CCMS-like patients, COG1 mutations were ruled out in this cohort through exome data analysis.

Dandy Walker Malformation in a boy with Ellis-van Creveld dysplasia. *J. Davis[1], E. Carter[2], P. Brill[3], C. Raggio[2].* 1) Dept Pediatrics, NY-PH Hosps - Weill Cornell, New York, NY; 2) Ctr. for Skeletal Dysplasias, Hosp for Special Surgery, New York, NY; 3) Dept Radiology, NY-PH Hosps - Weill Cornell, New York, NY.

Ellis-van Creveld syndrome (EvC; MIM:225500) is an autosomal recessive skeletal dysplasia characterized by short limb dwarfism, narrow chest, post-axial/axial hexadactyly, dysplastic teeth and hypoplastic nails. Approximately 60% of patients have congenital heart disease. Intellectual development is usually normal. Mutation of EVC and/or EVC2 (mapped to chromosome 4p16) has been detected in 2/3 of cases. Three patients with EvC have been reported to also have a Dandy Walker malformation (DVM), characterized by hypoplasia of the cerebellar vermis and cystic dilatation of the 4th ventricle. A 9+8yr-old male was referred to our service for management and evaluation of progressive genu valgum. He is the product of a spontaneous fraternal twin pregnancy discordant for EvC. His parents are 1st cousins of Mexican ancestry. Family history revealed no one else with similar findings. Following NSVD at 36wks, Twin A weighed 4lbs11oz. She has followed a normal course of growth and development. Twin B (our patient) weighed 4lbs10oz. He had natal teeth, a narrow thorax, and a heart murmur. Echocardiogram showed a common atrium with total anomalous pulmonary venous return. He had respiratory difficulties, epispadias, and short limbs with hexadactly of each hand. Congenital hypothyroidism and seizures have resolved. He has GE reflux and is fed through a G-tube. At 9+8yrs his height (106cm) plots at the 5th percentile on EvC growth charts. His head circumference (55cm) plots at the 98th percentile on growth charts developed for males his age. He has dysmorphic facies, posterior bossing, and two hair whorls. His teeth are dysplastic. His arms and legs are short, with short, broad hands and feet and dysplastic nails. There is polydactlyly involving the 2nd and 3rd digits of both hands. He has developmental delay. Molecular genetic studies are pending. Radiographs are consistent with EvC. MRI of the brain at 2mos showed enlarged ventricles with cortical atrophy. Follow-up MRI at 9+8yrs showed a large 4th ventricle, a small/hypoplastic cerebellar vermis and corpus callosum dyspgenesis (DVM). This is the 4th reported patient with EvC and DWM. In some cases, consanguinity may be responsible for two, separate recessive traits. However, it is tempting to speculate that DVM is a rare manifestation of EvC, especially given the demonstration of Evc and Evc2 proteins localizing to the basal bodies of primary cilia in mice, with involvement in moderating hedgehog signaling pathways.

3129W

***NEK1* and *DYNC2H1* are both involved in short rib polydactyly Majewski type but not in Beemer Langer cases.** *J. El Hokayem[1], C. Huber[1], A. Couve[1], J. Aziza[2], G. Baujat[1], R. The lethal short rib polydactyly syndromes include four distinct conditions (SRP I-IV), characterised by autosomal recessive inheritance and short ribs, short limbs, polydactyly, and multiple anomalies of major organs. Among them, SRP type II (Majewski; MIM 263520) is characterised by short ovoid tibiae or tibial agenesis and is radiographically closely related to SRP type IV (Beemer-Langer; MIM 269860) which is distinguished by bowed radii and ulnae and relatively well tubulated tibiae. *NEK1* mutations have been recently identified in SRP type II. Double heterozygosity for mutations in both *NEK1* and *DYNC2H1* in one SRP type II case supported possible digenic diallelic inheritance. The aim of our study was to screen *DYNC2H1* and *NEK1* in thirteen SRP type II and seven SRP type IV cases. All cases were either terminated pregnancies (15–28 week gestation) or neonatal death (32–35 week gestation). Among the SRP type II cases, five belonged to consanguineous families from Lebanon, India (with recurrent sibs), Pakistan, and France and the eight remaining cases were from Madagascar, France, Brazil (with recurrent sibs), Vietnam, Haiti, and Belgium. Among the SRP type IV cases, two were consanguineous from Tunisia and Turkey, and five were non-consanguineous cases from France, Algeria, Italy and UK. We identified homozygous *NEK1* mutations in 5/13 SRP type II with 2/5 being missense mutations, 1/5 frameshift mutation and 1/5 nonsense mutation. We also identified nine novel compound heterozygous *DYNC2H1* mutations in 4/12 cases with 7/9 being missense mutations; 1/9 was a frameshift mutation and 1/9 a splicesite mutation. *DYNC2H1*mutations have been previously identified in Asphixyating Jeune dysplasia and SRP type III but no correlation between the nature or the location of the mutation and the severity of the phenotype could be established. Finally, *NEK1* and *DYNC2H1* were excluded in 3/12 SRP type II and in all SRP type IV cases. The main difference between the mutation positive SRP type II group and the mutation negative SRP type II group was the presence of holoprosencephaly and polymycrogyria in the mutation negative group. This study confirms that *NEK1* is one gene causing SRP type II but also reports *DYNC2H1* as another SRP type II disease gene expanding the phenotypic spectrum of *DYNC2H1* mutations. The exclusion of *NEK1* and *DYNC2H1* in 3/12 SRP type II and in all SRP type IV cases further support genetic heterogeneity.

3130F

Refsum Disease: Genotype-phenotype correlation of a novel PHYH mutation in a brazilian patient. *L.A.R. Gabriel[1], J. Chiang[3], R.C.C. Filho[2], L.G. Freitas[2], M.P. Avila[2].* 1) Ocular Genetics Department, UFG, Goiania, GO, Brazil; 2) Retina and Vitreous Department, UFG, GO, Brazil; 3) Director, Casey Eye Institute Molecular Diagnostic Laboratory, Portland, OR, USA.

Herein we present a case report of Refsum Disease (RD) in a male brazilian patient with the p.R329X:c.985C>T mutation in the PHYH gene. The patient entered the Department of Ocular Genetics of the UFG with a previous diagnosis of retinitis pigmentosa. After the clinical examination, metatarsal and metacarpal alterations were noted; the alcohol sniff test revealed a severe anosmia; and retinitis pigmentosa was confirmed. Thus RD was suspected and the phytanic acid high levels corroborated the clinical diagnosis. While waiting for the molecular diagnosis, the patient was referred to the Cardiology and Neurology Department where exams were normal. The genetic testing included PHYH and PEX7 sequencing, where PEX7 showed no mutations and PHYH showed the mutation above. Right now the patient is under a low phytanic acid diet.

Description of sclerocornea in a patient with Van den Ende Gupta syndrome and homozygous mutation in *SCARF2*. *M. Migliavacca[1], N. Sobreira[2], G. Antonialli[1], M. Moysés[3], M. Melaragno[3], D. Valle[2], D. Brunoni[1], A. Perez[1].* 1) Clinical Genetics, Federal University of São Paulo, São Paulo, São Paulo, Brazil; 2) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Laboratory of Cytogenetics, Genetics, Department of Morphology and Genetics - UNIFESP-São Paulo- S.P. - Brasil.

Van den Ende-Gupta Syndrome (VDEGS) (OMIM - 600920) is a rare autosomal recessive disease characterized by blepharophimosis, beaked nose, hypoplastic maxila, skeletal abnormalities (hooked clavicles, gracile ribs, bowed long bones) and normal psychomotor developmental. Using homozygosity mapping Anastasio et al. (2010) identified homozygous mutations in *SCARF2* in 4 VDEGS patients from three consanguineous Qatari families. Bedeschi at al. (2011) described a VDEGS patient with sclerocornea and cataracts, features not described previously, due to compound heterozygosity for the common 22q11.2 microdeletion and a hemizygous *SCARF2* splice site mutation. They suggested that the ocular abnormalities were caused by the 22q11.2 microdeletion since sclerocornea has been described in patients with DiGeorge syndrome. Here we report a 21 year-old male who presented with mild developmental delay but normal cognitive function. He had microcephaly, high and broad forehead, hypertelorism, short palpebral fissures, bilateral sclerocornea, nystagmus, strabismus, hypoplastic alae nase with prominent columela and depressed nasal tip, malar hypoplasia, prominent everted lips, prominent, low set and posterior angulated ears, pectus escavatum, arachnodactyly, bilateral adduction of his thumbs, camptodactyly, bilateral hallux valgus with long overlapping toes. His skeletal survey showed retrognathia, mild thickening of skull, sclerosis of mastoid cells, thoracic and lumbar scoliosis, gracile ribs, narrow iliac, slender long bones, mild bowing of femur and fibula, shortened ulna not articulated with the radius, long metatarsus, bilateral valgus deformity of the halluces and osteopenia. Brain MRI and echocardiogram were normal. Karyotype and SNP genotyping array were normal. To identify the cause of his malformations, we performed whole exome sequencing in the proband and his unaffected brother. We identified a homozygous 17 bp deletion in exon 4 of *SCARF2* in the proband that was not present in his unaffected brother and led us to the diagnosis of VDEGS. This patient has bilateral severe sclerocornea, a feature previously described in only one VDEGS patient and thought to be secondary to a 22q11.2 microdeletion. Our patient expands the VDEGS phenotype and implicates *SCARF2* as the causative gene of sclerocornea in these patients.

3132F

Two brothers with autosomal-recessive primary hypertrophic osteoarthropathy caused by homozygous deletion in HPGD gene: Neonatal findings and long-term follow-up. *B. Tüysüz[1], S. Yilmaz[2], K. Bilguvar[2], O. Kasapçopur[3], E. Gül[1], M. Günel[2].* 1) Department of Pediatric Genetics, Istanbul University, Cerrahpasa Medical School,, Istanbul, Turkey; 2) Department of Neurosurgery, Program on Neurogenetics, Yale School of Medicine, New Haven, Connecticut, USA; 3) Department of Pediatric Rhematology, Cerrahpaşa Medical School, Istanbul University,Istanbul-Turkey.

A 8-month-old boy who is the first child of first cousin parents was referred to our department due to coarse face. He also had large anterior fontanelle, high-arched palate, hypertrichosis, inguinal hernia and large hands and feet. Radiographs showed osteopenia, wormian bones, subperiosteal ossification and expanded diaphysis and metaphysis. The patient has been followed up to the age of 7.5 years. Re-evaluation of the patient at the age of two revealed pain, enlargement and hyperhidrosis of hands and feet. Methotrexate 7.5 mg once a week intravenously was started, resulting in decrease of swelling and pain. He gained walk at 19 months. At the age of 3.5, swelling of knee joints, digital clubbing and decreased joint mobility were developed. Cold induced swelling of hands and feet was noticed by parents. Mild palmoplantar hyperkeratosis was observed at 6 years of age. IQ was normal. The patient was diagnosed as autosomal recessive primary hypertrophic osteoarthropathy (PHO), is a very rare disorder characterized by delayed closure of the cranial sutures and fontanels, digital clubbing, arthropathy, and periostosis. Mutations in HPGD gene, which encodes the NAD-dependent 15-hydroxyprostaglandin dehydrogenase caused PHO type 1. The patient had 2 bp homozygous deletion in exon 3 (c.310_311delCT) of HPGD gene leading to frameshift, premature truncation (p.L104Afsx2) of the polypeptide. A prenatal diagnosis was rejected during the subsequent pregnancy by parents. The second boy was born with large hands and feet and also typical radiological findings of PHO. This is the first report of detailed neonatal findings and longitudinal observation of a patient with PHO.

3133W

Germline Mosaicism for a 12q24 Deletion Identifies Haploinsufficiency of *MED13L* as a Cause of Hypotonia and Moderate Developmental Delay. *R.C. Gallagher[1], S. Scrivner[1], K. Brown[1], A. Collins[2], M. Saenz[1].* 1) Clinical Genetics and Metabolism, Department of Pediatrics, University of Colorado Anschutz Medical Campus; 2) Neurology, Department of Pediatrics, University of Colorado Anschutz Medical Campus.

Purpose: To report the identification of two siblings with moderate developmental delay, dysmorphic features and hypotonia who share a deletion of the *MED13L* gene, initially reported in association with transposition of the great arteries and developmental delay, as further evidence for the role of haploinsufficiency of *MED13L* in intellectual disability. Background: *MED13L*, previously described as *PROSIT240/THRAP2*, was reported to be deleted or mutated in individuals with transposition of the great arteries (TGA) at a high frequency of 3%. The initial affected individual with TGA had a translocation that disrupted the gene. Other clinical features included intellectual disability, ataxia, and nearly absent speech (Muncke N et al, Circulation, 2003 108:2843). The role of mutations of *MED13L* in intellectual disability without cardiac defects is unknown. Case report: Two maternal half-siblings presented with similar features of moderate developmental delay, hypotonia and strabismus. One is non-verbal; the other has mild to severe, bilateral, high frequency sensorineural hearing loss, and is verbal. Each has mild craniofacial dysmorphisms, though these differ in the two. One had minimal, the other mild, ataxia. There is no known cardiac defect in either. One sibling had a brain MRI that showed mild hypomyelination of the posterior periventricular white matter. Both were found to have a 200 kb deletion at 12q24.21 that encompasses the *MED13L* gene. The deletion was not identified in the peripheral blood of the mother. Conclusion: Haploinsufficiency of *MED13L* is a cause of intellectual disability, and is not always associated with cardiac defects. Elucidation of the phenotypic spectrum of disorders that present as new dominants will be increasingly important as whole exome and whole genome strategies are pursued for individuals with intellectual disability.

Genetic analysis of the *GBA* gene in Japanese familial Parkinson's disease. *Y. Li[1], M. Funayama[1], T. Sekine[2], L. Li[1], H. Yoshino[1], K. Nishioka[2], H. Tomiyama[2,3], N. Hattori[1,2,3].* 1) Research Institute for Diseases of Old Age, Graduate School of Medicine, Juntendo University, Tokyo, Japan; 2) Department of Neurology, Juntendo University School of Medicine, Tokyo, Japan; 3) Department of Neuroscience for Neurodegenerative Disorders, Juntendo University School of Medicine, Tokyo, Japan.

Background and Objectives: Gaucher's disease is an autosomal recessive lysosomal storage disease caused by glucocerebrosidase (*GBA*) mutation. Recent studies suggest that *GBA*mutation is a strong risk factor of Parkinson's disease (PD). We aim to investigate whether there is an association between familial PD (FPD) and *GBA* mutations. **Methods:** All coding exons and exon-intron boundaries of the *GBA* gene were sequenced in 144 Japanese patients with FPD and 100 Japanese controls. **Results:** We found 27 FPD patients with heterozygous mutations, which were reported in Gaucher's disease. The frequency of *GBA* mutations among FPD was significantly higher than in the controls (27/144=18.8% vs. 1/100=1.0%, $P<0.0001$).**Conclusions:** Our study suggests that heterozygous *GBA* mutation is a risk factor for FPD as well as sporadic PD, in the Japanese population.

Manganese-related T1 hyperintensities of the basal ganglia in hereditary hemorrhagic telangiectasia (HHT) with iron-deficiency anemia. *M. McKinnon[1], S. Appel-Cresswell[2], B. Jung[3], S. Langlois[1].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Pacific Parkinson's Research Centre, University Hospital, University of British Columbia, Vancouver, BC, Canada; 3) Department of Pathology and Laboratory Medicine, Children's and Women's Health Centre of British Columbia, Vancouver, BC, Canada.

Hyperintense T1-weighted MRI lesions secondary to deposition of paramagnetic Manganese (Mn) within the basal ganglia are reported in the setting of chronic hepatic dysfunction and environmental exposure to Mn, and may lead to neurotoxicity and parkinsonism. We present a 58-year old man with hereditary hemorrhagic telangiectasia (HHT) and findings of T1-hyperintensities of the globus pallidus with marked elevation of serum and whole blood Mn levels. Our patient presented with a history of recurrent nosebleeds resistant to therapy, severe transfusion-dependent iron-deficiency anemia, telangiectasias, pulmonary and duodenal arteriovenous malformations (AVM's) and a confirmed mutation in ACVRL1. On MRI screening for cerebral AVM's, incidental findings of T1-hyperintensities were observed within the globus pallidus bilaterally. He complained of mild memory disturbance without motor symptoms. On exam, he had mild retrieval issues on cognitive testing (Montreal Cognitive Assessment 23/30) and subtle bradykinesia and mild rigidity of the upper limbs. Mn levels were 55 nmol/L in serum (ref. range: 2–28 nmol/L)) and 835 nmol/L in whole blood (ref. range: 144–327 nmol/L). He had no history of exposure to Mn and no hepatic dysfunction on liver function tests; however, multiple hepatic arterio-portal shunts were evident on CT exam. Mn-related lesions of the basal ganglia have been rarely described in HHT and our case represents only the 7th reported. It is proposed that abnormal intra-hepatic connections in HHT allow Mn in the diet to bypass normal detoxification in the liver. Those with HHT may be at increased risk as trafficking of Mn relies on transferrin and upregulation of transferrin in the setting of HHT-related iron-deficiency anemia may increase intestinal absorption and accumulation of Mn in the brain. We propose that targeting this patient's chronic anemia and iron-deficiency may be the best approach to management. He is currently being treated aggressively with IV iron-sucrose with further efforts to control epistaxis. Planned directions at our centre include reanalysis of MRI's and retrospective chart review in order to further characterize the frequency of these lesions in HHT. We highlight this case in order to draw attention to a rarely reported, potentially treatable complication of HHT, so that appropriate testing and therapeutic intervention might be initiated to prevent the development of parkinsonism in this patient population.

3136F

***CASK* aberrations in males with Ohtahara syndrome and cerebellar hypoplasia.** *H. Saitsu[1], M. Kato[2], H. Osaka[3], N. Moriyama[4], H. Horita[5], K. Nishiyama[1], T. Yoshinori[1], H. Doi[1], N. Miyake[1], K. Hayasaka[2], N. Matsumoto[1].* 1) Human Genetics, Yokohama City University, Yokohama, Kanagawa, Japan; 2) Pediatrics, Yamagata University Faculty of Medicine, Yamagata, Japan; 3) Neurology, Kanagawa Children's Medical Center, Yokohama, Japan; 4) Pediatrics, Hitachi, Ltd. Hitachinaka General Hospital, Japan; 5) Pediatrics, Ibaraki Disabled Children's Hospital, Mito, Japan.

Purpose: Ohtahara syndrome (OS) is one of the most severe and earliest forms of epilepsy. *STXBP1* and *ARX* mutations have been reported in patients with OS. In this study, we aimed to identify new genes involved in OS by copy number analysis and whole exome sequencing. Methods: Copy number analysis and whole exome sequencing was performed in 34 and 12 patients with OS, respectively. Fluorescence *in situ* hybridization, quantitative PCR, breakpoint-specific and reverse transcriptase PCR analyses were performed to characterize a deletion. Key findings: Genomic microarray analysis revealed a 111-kb deletion involving exon 2 of *CASK* at Xp11.4 in a male patient. The deletion was inherited from his mother, who was somatic mosaic for the deletion. Sequencing of the mutant transcript expressed in lymphoblastoid cell lines derived from the patient confirmed the deletion of exon 2 in the mutant transcript with a premature stop codon. Whole exome sequencing identified another male patient harboring a c.1A>G mutation in *CASK*, which occurred de novo. Both patients showed severe cerebellar hypoplasia along with other congenital anomalies such as micrognathia, a high arched palate and finger anomalies. Significance: The detected mutations are likely to cause the loss of function of the CASK protein in males. *CASK* mutations have been reported in patients with intellectual disability with microcephaly and pontocerebellar hypoplasia or congenital nystagmus, and those with FG syndrome. Our data expand the clinical spectrum of *CASK* mutations to include OS with cerebellar hypoplasia and congenital anomalies at the most severe end.

3137W

Unusual presentation of combined saggital-metopic synostosis is caused by mutations in the MSX2 gene: expanding the phenotype of the Boston-type craniosynostosis syndrome. *OM. Vanakker[1], A. Janssen[2], M.J. Hosen[1], Ph. Jeannin[2], PJ. Coucke[1], A. De Paepe[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Department of Paediatrics, Jan Palfijn Hospital, Ghent, Belgium.

Background. Craniosynostosis, caused by early fusion of one or more cranial sutures, can include premature fusion of the saggital (scaphocephaly) or metopic suture (trigonocephaly). Though often occurring as isolated findings, their co- existence in a craniosynostosis syndrome is infrequent and mostly sporadic. Case description. The male proband, born at term, presented at birth with premature fusion of the saggital and metopic suture. Antropometric measurements were normal. Besides the scaphocephaly, a prominent boney mass on the forehead was noted, next to proptosis. Imaging suggested the frontal mass to originate partially from the fused metopic suture. Multiple endocranial hypoplastic areas of the skull were noted. Radiographs revealed bilateral agenesis of the middle phalanges in the feet. Family history revealed the father, his sister and half-sister, to have an isolated scaphocephaly with variable cutaneous syndactyly. The paternal grandfather did not have craniofacial anomalies nor syndactyly, though the great grandfather was said to have isolated syndactyly of both hands. Molecular analysis in this family revealed a missense mutation (p.P148L) in the MSX2 gene, associated with the Boston-type of craniosynostosis in a single family. Segregation analysis of the variant, which affects the same highly conserved residue as in the original report, confirmed non-penetrance in the paternal grandfather. Conclusion. This four-generation family shows various expression of a craniosynostosis phenotype with scaphocephaly and a particularly severe and unusual form of trigonocephaly. A saggital-metopic synostosis together with agenesis of the middle phalanges has to our knowledge not been reported. Molecular analysis revealed a MSX2 mutation, previously described in the Boston craniosynostosis family. Besides several unique features such as incomplete penetrance, the limb abnormalities and the cranial sutures involved, our patients share with the original family the autosomal dominant inheritance with anticipation and the observation of multiple endocranial hypoplastic areas on 3D CT imaging of the skull. Though these consistent findings prove to be important diagnostic clues for MSX2-related craniosynostosis, it must be noted that the generation initially affected in this family presented merely with an isolated scaphocephaly and syndactyly. Molecular analysis of the MSX2 gene should therefore also be considered in patients with scaphocephaly and syndactyly.

3138F

Automated Preparation of Samples for Benchtop Sequencing Applications. *I. Meek.* Caliper Life Sciences, Inc., Hopkinton, MA.

Next generation sequencing technologies continue to result in decreases in the cost per basepair of DNA sequencing data. This has enabled sequencing to be a tractable readout for a number of applications, and has made feasible large scale projects, looking across hundreds of samples, that continue to provide information to help answer questions that are fundamental to our understanding of the factors that govern human health. In the past 12–18 months, scaled down versions of next generation sequencing technologies have become commercially available. Dubbed “benchtop sequencers”, these instruments are finding a wide variety of applications that are specific for the throughput and decreased sample-to-answer time that they offer. The Janus NGS Express is an automated sample preparation instrument that was developed specifically as an upfront to benchtop sequencers. The platform comes with a variety of pre-installed, validated applications including several commercially available amplicon panels and kits, small RNA sequencing, and preparation of libraries for de novo assembly of bacterial genomes. Key advantages of the system include reduction in manual processing, increased reproducibility and sample traceability, and an increase in the number of sample a single technician can prepare.

Neurofibromatosis Type 1 (NF1) and Infantile Myofibromatosis: A shared genetic basis or independently co-existent entities? *S. Krishnamurthi[1], V. Cox[1], H. Guo[2], K. Rauen[1].* 1) Department of Pediatrics - Division of Medical Genetics, UCSF, San Francisco, CA; 2) Department of Pathology, Children's Hospital of Oakland, CA.

Neurofibromatosis Type 1 is a common RASopathy with variable expressivity that affects virtually every organ system of the body. It has been extensively studied and is caused by heterozygous mutations of the NF1 gene on chromosome 17q11.2. Infantile Myofibromatosis (IM) is a mesenchymal disorder presenting in infancy or early childhood with soft-tissue tumors involving skin, muscle, bones and occasionally viscera. Although relatively rare, IM is the most common fibrous tumor of infancy. In contrast to NF1, the etiology is unknown with reported congenital cases having autosomal dominant or autosomal recessive inheritance. We present a 2 year old male who originally presented at birth with multiple tumors in his calf, scalp and back. These progressed over time to involve his face, trunk, retroperitoneum and extremities. Excisional biopsy of the lesion showed focal spindle shaped cells arranged in fascicles. Immunohistochemical staining revealed revealed reactivity for smooth muscle actin and muscle specific actin; negative staining for S100 protein and Desmin. Based on this, a diagnosis of infantile myofibromatosis was made. At 11 months of age, he was noted with multiple café au lait macules. A brain MRI was done at a year of age in follow-up for an interhemispheric lesion that was previously noted during a screen for IM; the MRI revealed bilateral optic gliomas. NF1 mutation analysis demonstrated a causative heterozygous splicing mutation, c.6579+31T>G, providing a confirmatory molecular diagnosis of NF1. On our exam, in addition, he was noted to be macrocephalic and had a tongue lesion consistent with a neurofibroma. A concomitant diagnosis of NF1 and IM has previously been described by De Schepper et al (Dermatology 2004; 209:223–227). To our knowledge, this is the second case reported of a child with a histopathological diagnosis of IM and a confirmation of NF1 by molecular testing. Given that these two unique entities with common embryonal tissue origins presents in our patient, we raise the question and discuss whether these disorders are coincidental or disorders with a common genetic basis.

3140F

Homozygosity Mapping and Candidate Gene cloning identified CLDN10 variation to be possibly responsible for Congenital ichthyosis - renal hypokalemia in an Algerian family. *S. Hadj-Rabia[1], Y. Al-Sarraj[2], M. Kambouris[2,3], C. Bodemer[1], H. El-Shanti[2,4].* 1) Department of Dermatology - MAGEC Reference Center, Hôpital Universitaire Necker - Enfants Malades, INSERM U781, Paris V-Descartes University, Paris, France; 2) Shafallah Medical Genetics Center, Doha, Qatar; 3) Yale University School of Medicine, Genetics, New Haven CT, USA; 4) University of Iowa, Pediatrics, Iowa City, IA, USA.

Ichthyosis is one of the most frequent single-gene disorders in humans, comprising a large group of scaling disorders with diverse etiology. To date, more than 25 genes have been identified that encode a wide spectrum of epidermal proteins, including enzymes of lipid metabolism and of peptide cross-linking, proteases and their inhibitors, epidermal structural proteins, and proteins involved in cellular communication, signaling and gene transcription. Claudins are epithelial cell tight junction protein with Claudin1 involved in neonatal ichthyosis - sclerosis cholangitis. Claudin16 and 19, are involved in renal hypomagnesemia. We identified an Algerian family with two siblings, a boy and a girl, affected with ichthyosis, keratosis pilaris and palmoplantar keratoderma. The two siblings had xerostomia, abnormal shape of the teeth but normal nails and hair. Hypokalemia is a consistent finding in both. A skin biopsy showed hyperkeratosis and thick stratum corneum. The parents are first cousins once removed and there were three unaffected girls in the same sibship. We performed genome-wide SNP genotyping using 200K chips from Illumina for all family members. Data filtration and allele calling were performed by GenomeStudio2011v1. Two regions of homozygosity were identified by the web-based program Homozygosity Mapper, both shared by the affected siblings and were heterozygous in obligate carriers and the unaffected siblings were either heterozygous or homozygous for the other allele. The first is a 13.5 MBregion on the long arm of chromosome 13 (13q13.3-13q33.2) and containing about 44 genes. The second is a 15.3 MB in the pericentromeric region of chromosome 20 (20p11.21-20q12), containing about 135 genes. The two regions did not contain any of genes known to be implicated in ichthyoses or any other skin disorder. We identified 7 candidate genes from the two homozygosity regions and prioritized them according to their function and their plausible involvement of in a skin and possibly renal disease. We identified a missense mutation, p.S129Lin CLDN10, that segregates with the phenotype in the family and is not found in the 1000 genome. The mutation is predicted to be probably damaging by Polyphen. We are examining the allele frequency of the mutation in an ethnically matched control cohort. We will perform in silico protein modeling to anticipate the effect of this variant on the structure of the protein, and possibly perform functional studies.

3141W

Homozygous mutation of SIX1 associated with a severe Branchio-Oto-Renal syndrome phenotype. *S.L. Sawyer[1], M.A. Thomas[1,2], R. Lamont[1], L. Dimnik[3], P. Gordon[2], X.C. Wei[4], F.P. Bernier[1,2], J.S. Parboosingh[1,2], A.M. Innes[1,2].* 1) Medical Genetics, Alberta Children's Hospital, Calgary, Alberta, Canada; 2) Alberta Children's Hospital Research Institute for Child and Maternal Health, Calgary, Alberta, Canada; 3) Molecular diagnostic Lab, Alberta Children's Hospital, Calgary, Alberta, Canada; 4) Department of Pediatric Radiology, Alberta Children's Hospital, Calgary, Alberta, Canada.

Branchio-Oto-Renal syndrome (BOR, OMIM 602588) is an autosomal dominant syndrome caused frequently by mutations in EYA1 and less often SIX5 and SIX1 (1–3% of cases). A clinical diagnosis can be made based on the presence of 3 major features (second branchial arch anomalies, deafness, preauricular pits, auricular deformity and renal anomalies) or two major and two minor criteria (external auditory canal anomalies, middle or inner ear anomalies, preauricular tags, facial asymmetry or palate abnormalities). We report a child born to consanguineous parents who clinically has many features in keeping with BOR as well as other congenital and developmental anomalies. She was delivered at 29 weeks secondary to premature rupture of membranes and presented with multiple dysmorphic features including: a dysplastic left ear with absent external auditory canal on the left She also has bilateral branchial cysts, bilateral preauricular pits and a bilateral cleft lip and palate. She has hearing loss. Pyelectasis was noted on prenatal ultrasound and a follow up cystourethrogram demonstrated grade 2 reflux. Additional features not previously reported to our knowledge in the BOR spectrum include growth parameters <3rd percentile, hypotonia and severe gastro-esophageal reflux disease requiring fundoplication. On brain MRI she has absent olfactory bulbs, an empty sella with compressed anterior pituitary, partial absence of the anterior falx and persistent Blake's pouch cyst. She is grossly delayed developmentally. At 20 months of age she brings objects to her mouth and is babbling. She is unable to sit or roll. Given her phenotypic complexity and parental consanguinity we did not originally suspect a diagnosis of typical BOR. Array CGH was normal. A SNP homozygosity mapping array identified multiple regions of homozygosity. Follow-up whole exome sequencing revealed a homozygous c.560 +1 G>C mutation in SIX1. A mutation presumably affecting this splice site has been previously reported in the heterozygote state in an atypical BOR patient with ear pits and branchial cysts (c.560 +3 A>T). In our kindred, the obligate carrier parents have minor findings. Her father has an ear pit and her mother has hearing loss. In summary we demonstrate that homozygous mutations in SIX1 confer a more severe BOR-like phenotype, with structural brain anomalies, facial clefting and developmental delay.

Cardiac Malformations Associated With Germline WT1 Mutations in Children Presenting With Wilms' Tumour. *S. Bowdin[1,2], C. Owens[3], D. Malkin[2,3], N. Parkinson[1], M. Friedburg[2,4], R. Grant[2,3].* 1) Clinical & Metabolic Gen, Hosp Sick Children, Toronto, ON, Canada; 2) Department of Pediatrics, University of Toronto, Toronto, ON, Canada; 3) Division of Haematology/Oncology, Hosp Sick Children, Toronto, ON, Canada; 4) Division of Cardiology, Hosp Sick Children, Toronto, ON, Canada.

Background The WT1 gene was identified as a result of the cytogenetic investigation of individuals with WAGR (Wilms' tumor, Aniridia, Genitourinary anomalies and Retardation). Point mutations in WT1 have been shown to cause Denys-Drash, Frasier and Meacham syndromes, isolated Wilms' tumor and nephrotic syndrome type 4. WT1 encodes a zinc-finger protein which acts as a transcriptional activator or repressor depending on the cellular or chromosomal context. It is required for the normal formation of the genitourinary system and mesothelial tissues, and in the mouse is required for cardiovascular progenitor cell formation. Cardiac malformations are rarely reported in each of the known WT1 phenotypes in humans, and in certain case reports are hypothesised to be coincidental findings. We previously found that 18% of patients with Wilms' tumor at our institution had cardiac findings unrelated to treatment. Method Utilizing oncology and genetic databases at The Hospital for Sick Children, we identified patients with known WT1 mutations or 11p13 deletions and reviewed their cardiac evaluations (including clinical examination, echocardiograms, ECG). Results We identified 14 patients with Wilms' tumor and mutations in WT1 or 11p13 genomic abnormalities. Of two patients with WAGR and genetic testing concordance, 1 had insufficient cardiac information, the other normal findings. 5 of the remaining 12 patients had cardiac findings of note, including complete transposition of the great arteries, VSD, ASD, atrial tachycardia and right-sided aortic arch with aberrant left subclavian artery. Discussion This retrospective review provides evidence of an increased incidence of congenital heart defects in children with WT1 mutations presenting with Wilms' tumour. In conjunction with reports of abnormal cardiac morphogenesis in WT1 conditional knockout mice, evidence suggests the phenotypic spectrum of WT1-associated disorders might include cardiac malformations as well as Wilms' tumour and urogenital malformations.

False positive diagnosis of Marfan syndrome in adult patient with Homocystinuria who fulfilled Ghent Criteria. *S. Dyack[1,2], H. MacDonald[2], K. Schindeler[2], A. Rideout[2].* 1) Div Med Gen, Dept Pediatrics and Medicine, Dalhousie University, Halifax, NS, Canada; 2) IWK Health Centre, Halifax, NS, Canada.

We present an adult patient with a longstanding clinical diagnosis of Marfan syndrome who was discovered to have Cystathionine Beta Synthase (CBS) deficiency at 48 years of age. He was diagnosed with Marfan syndrome after he developed ectopia lentis (EL) in childhood. He developed a thrombus in his leg in his mid 20's that required anticoagulation therapy. He fulfilled the revised Ghent criteria for Marfan syndrome by having EL, dilatation of his aortic root (AoD) of >4.5 cm, and involvement of the skeletal system, including a reduced upper to lower segment ratio of 0.81 and increased armspan to height ratio of 1.08. He fulfilled the 2010 Ghent criteria by having EL and AoD with Z score >2. He also exhibited joint hypermobility of hips, crowding of his teeth, striae of shoulder, mild scoliosis and arachnodactyly. He had normal intelligence, was married, and had full time employment. His total plasma homocyst(e)ine was markedly elevated at 265.5 µmoles/L with a reference range of 7.1 to 17.3 µmoles/L; consistent with classic homocystinuria. His methionine was elevated at 691 with a normal range of 10–50. Bone density was normal. Three mutations of the CBS gene were found: P78R, K102N and C109R. All have been previously reported in individuals affected with CBS deficiency. He was responsive to B6 therapy. Currently with B6 200mg BID, Betaine 3 grams BID, and attention to diet, his total plasma homocyst(e)ine is in the 20–30 µmoles/L range. Methionine is normal or near normal. After treatment, obsessive compulsive symptoms, that had been attributed to “his personality”, were significantly reduced, by report of his astonished wife. CBS deficiency can be associated with normal intelligence in up to 10 percent of untreated individuals. As illustrated by this case, patients with CBS deficiency may fulfill Ghent Diagnostic criteria and be misdiagnosed with Marfan syndrome. It is important to distinguish between the two conditions as the natural history and treatment differ significantly. It is not known if this patient's AoD is related to CBS deficiency. In any adult patient with ectopia lentis, strong consideration should be given to assessing total plasma homocyst(e)ine even if the patient fulfills Ghent criteria for Marfan syndrome and has normal intelligence. Testing for total plasma homocyst(e)ine should always be done in this context if there is a history of thrombus formation.

3144F

VCP Disease is Associated with Cytokine Imbalances in Patient Plasma. *E. Dec[1], F. Zaldivar[2], M. Wencel[1], M. Khare[1], J. Vesa[1,3], V.E. Kimonis[1].* 1) Division Genetics, Dept. of Pediatrics, UC Irvine, Irvine, CA; 2) ICTS, Dept. of Pediatrics, UC Irvine, Irvine, CA; 3) UC San Diego, San Diego, CA.

VCP disease is caused by mutations in the gene for Valosin Containing Protein. VCP disease classically affects muscle, bone and brain however, new data suggest a common shared pathogenesis with proteinopathies such as amyotrophic lateral sclerosis (ALS) and Parkinson's disease consistent with the fundamental role VCP plays in protein homeostasis. The muscle wasting seen in VCP disease is suggestive of cytokine protein imbalances and was investigated in an effort to determine if VCP mutations alter cytokine profiles. We hypothesized that cytokine protein imbalances are apart of the dysfunctional protein homeostasis caused by VCP disease and contributes to the muscle wasting phenotype. Cytokine analysis was carried out on patient plasma drawn from 16 patients with IBMPFD, 2 pre-symptomatic mutation carriers and 16 controls. Plasma was analyzed for cytokine protein content via ELISA. Four cytokines (TNF alpha, IL-6, EGF, IL-4) historically implicated in muscle wasting and myogenesis were analyzed. Statistical analyses (A 2-sample T-test adjusted for age and gender) revealed the TNFalpha and Epidermal Growth Factor (EGF) were significantly altered in VCP disease as compared to control. TNFalpha was elevated, consistent with a cachexia phenotype, and EGF was low which is consistent with poor myogenesis. IL-4 and IL-6 were not significantly altered when taking in to account age and gender. Cytokine imbalances may be associated with VCP disease and may play a contributory role in VCP myopathy. Further understanding of how VCP dysfunction leads to aberrant protein homeostasis and subsequent cytokine imbalances may also aid in the understanding of other proteinopathies.

3145W

Further expansion of the Chediak-Higashi phenotype: three adult siblings with neurodegenerative disease and homozygous for a novel *LYST* deletion. *L. Mehta[1], C. Cho[2], F.R. Dembitzer[3], A. Szporn[3], M.C. Chicka[4], J.D. Wesfeld-Adams[1].* 1) Department of Genetics & Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Department of Neurology, Mount Sinai School of Medicine, New York, NY; 3) Department of Pathology, Mount Sinai School of Medicine, New York, NY; 4) Prevention Genetics, Marshfield, WI.

Mutations in *LYST*, a ubiquitously expressed gene concerned with lysosomal trafficking, cause Chediak-Higashi syndrome (CHS), an autosomal recessive disorder typically characterized by immune dysfunction, pigmentary abnormalities, and neurologic dysfunction. Rare, atypical CHS patients present with absent or subclinical immunologic abnormalities, and develop neurodegenerative disease in early adulthood. We present a 42-year-old South Asian woman with progressive spastic paraparesis, cognitive impairment, and parkinsonism. As an infant she developed diffuse hyperpigmentation, then mottled hypopigmentation. She had mild learning disability (LD) and developed widespread periodontitis in early adulthood. Examination revealed the pigmentary abnormalities described, and age-appropriate hair graying. MRI of the brain showed cortical atrophy; EMG revealed subacute axonal neuropathy. Skin biopsy demonstrated amphophilic globules in the papillary dermis. A 38 year old brother had mild LD and hypopigmentation in childhood, and lower extremity weakness and parkinsonism from the fourth decade. A 32 year old brother presented age 30 with neuropathic bladder and paraparesis initially attributed to a lumbar arteriovenous malformation. He reported hair graying from adolescence, and adult-onset fine skin hypopigmentation; skin appearances were similar to those of the siblings. Neither brother reported any infections or dental disease. The parents denied consanguinity. Further testing revealed, in all three affected siblings, lymphocytic inclusions, and pigmentary clumping in hair shafts visualized with light microscopy. Patients had abnormally low NK cell activity. Sequencing of the entire coding region of *LYST* in the female proband identified homozygosity for a novel 6 bp deletion in exon 43 (c.9827_9832ATACAA), predicting the loss of two amino acids from the protein product (p.Asn3276_Thr3277del). Targeted sequencing of *LYST* confirmed homozygosity for the deletion in both affected brothers. This family expands the phenotype of CHS to include milder cases with subtle pigmentary abnormalities and neurodegenerative disease, without classic immunodeficiency. The natural history of such cases remains to be defined. Milder, late onset lysosomal storage diseases are well described, and are likely to be under-ascertained. Variant CHS is phenotypically heterogenous and should be considered when young adults develop neurodegenerative disease and have pigmentary abnormalities.

3146F

Familial acanthosis nigricans: Phenotypic features of aberrant area cutanea and hyperpigmented dots identified by dermoscopy. *N. Oiso[1], M. Miyake[1], K. Fukai[2], A. Kawada[1].* 1) Department of Dermatology, Kinki University Faculty of Medicine, Osaka-Sayama, Osaka, Japan; 2) Department of Dermatology, Osaka City University Graduate School of Medicine, Osaka, Japan.

Acanthosis nigricans can be present in the following forms: inherited, obesity-associated, autoimmune-related, drug-induced, and malignancy-associated. Inherited acanthosis nigricans is sub-classified into non-syndromic and syndromic forms. It is characterized by papillomatous brownish lesions mainly in intertriginous areas. We used dermoscopy to examine such lesions in a family with non-syndromic acanthosis nigricans. The dermoscopic images from a 12-year-old Japanese female proband and an 11-year-old younger brother showed the same aberrant skin structure of linear crista cutis and sulcus cutis, and hyperpigmented dots in crista cutis. The hyperpigmented dots, which could not be seen with the naked eye, may contribute to the color of the pigmented skin. Recent studies show that syndromic acanthosis nigricans is caused by a germline mutation in FGFR2 encoding a receptor for the fibroblast growth factors, and epidermal nevi are caused by a somatic mutation in FGFR2. Epidermal nevi are additionally caused by a somatic mutation in the RAS (HRAS, NRAS, and KRAS) genes which are associated with neuro-cardio-facial-cutaneous syndromes including Leopard syndrome, Costello syndrome, and neurofibromatosis type 1. We hypothesize that the tiny dots develop along a pathway similar to lentiginosis in Leopard syndrome or café-au-lait macules in neurofibromatosis type 1, and that the hyperpigmented dots may contribute to the pigmented skin color.

Clinical clues to differentiate among severe forms of osteogenesis imperfecta. *P. Prasun, A. Jay, D. Stockton.* PEDIATRICS, Children's Hospital of Michigan, Wayne State University, Detroit, MI., USA.

INTRODUCTION Osteogenesis imperfecta (OI) is a hereditary collagen disorder with autosomal dominant and recessive forms. Autosomal recessive OI is rare. Recently several genes responsible for autosomal recessive OI have been identified. Identification of a genetic defect is helpful for accurate genetic counseling. Autosomal recessive OI is usually severe and clinically resembles severe forms of autosomal dominant OI caused by COL1A1 or COL1A2 mutations. However, certain clinical and radiological features may suggest autosomal recessive inheritance. Awareness of these features is helpful in formulating a time and cost effective diagnostic strategy. We describe three patients with autosomal recessive OI. CASE REPORTS Patient 1: Patient 1 was found to have fractures from the antenatal period. He had wide open cranial sutures, large fontanels, white sclerae, narrow chest, bowed lower extremities, rhizomelia, and postaxial polydactyly of hands. His parents are African American and non consanguineous. The patient was found to have compound heterozygous mutations in the CRTAP gene and no detectable COLIA1 or COL1A2 mutations. Patient 2: Patient 2 was found to have fractures from the antenatal period. She had white sclerae, bowed lower extremities, and rhizomelia. Her parents have Lebanese ancestry and are first cousins through their mothers and second cousins through their fathers. A maternal first cousin of the patient's father was reportedly diagnosed with OI in the 1990s. Patient 2 was found to have homozygous mutations (c.1345 G>A) in the LEPRE1 gene. Testing for COL1A1 and COL1A2 was not done. Patient 3: Patient 3 was found to have fractures and shortening of long bones from the antenatal period. He had wide sutures, large fontanels, white sclerae, and short bowed extremities. His parents are African American and non consanguineous. The patient was found to have compound heterozygous mutations in the LEPRE1 gene and no detectable COLIA1 or COL1A2 mutations. DISCUSSION White sclerae and rhizomelia suggest autosomal recessive inheritance in severe forms of OI. Testing for LEPRE1 and CRTAP may be offered first in presence of these features with consanguinity or African American ethnicity. Autosomal recessive OI may be more common in African Americans than realized before. We have developed an evaluation process based upon clinical and radiological features which may be helpful when investigating OI patients.

3148F

Description of a fetal syndrome associated with HNF1B mutation and a wide intrafamilial disease variability. *M. Rasmussen[1], I. Vogel[1], OB. Petersen[2], M. Ramsing[3], L. Sunde[1].* 1) Department of Clinical Genetics, Aarhus University Hospital, Skejby, Aarhus, Denmark; 2) Department of Obstetrics and Gynecology, Aarhus University Hospital, Skejby, Aarhus, Denmark; 3) Institute of Pathology, Aarhus University Hospital, Noerrebrogade, Aarhus, Denmark.

Introduction We present two fetuses and their father with a HNF1B mutation in heterozygous form. Clinical and fetopathological reports Fetus 1. The pregnancy was terminated at week 21+3 due to bilateral enlarged hyperecogenic kidneys with normal amniotic fluid volume. Post mortem examination: Male fetus with mild dysmorphic features. Severe pancreatic hypoplasia was observed and the pancreatic tail could not be identified. Scrotum was hypoplastic and histological examinations showed that the epididymis contained more connective tissue than normal. The kidneys were symmetrically enlarged and contained 1–3 mm cysts, separated by thin strands of parenchyma. The total weight of the kidneys was 11,8 g (expected weight 3 g). Histology showed a segmentally disorganized corticomedular differentiation, glomerular dysplasia, cysts derived from all nephron segments, and primitive ducts. Between the ductal structures regions of interstitial fibrosis were seen. Fetus 2. The pregnancy was terminated at week 22+0 due to bilateral enlarged hyperecogenic kidneys with normal amniotic fluid volume. Post mortem examination: Male fetus with mild dysmorphic features. Abdomen prominated due to the large kidneys and scrotum was hypoplastic. Internal investigation revealed massively enlarged kidneys with a total weight of 20,4 g (expected weight 4 g). The pancreas was hypoplastic and annular. The histological picture of the kidneys and epididymis were identical to fetus 1. The father. He was diagnosed with bilateral hypoplastic kidneys and slowly progressive kidney failure. Genetics. The HNF1B mutation p.Arg165His (c. 494G>A) was identified in heterozygous form in both fetuses and in the father. Discussion The molecular mechanism that causes this wide disease spectrum within the family remains unknown. It can be speculated that the father is a mosaic or the fetuses had inherited one or more modifying variants from the mother. Alternatively, the father could harbor one or more protective variants, which was not passed on to the fetuses. The fact that these two fetuses are siblings suggests a common genetic modifying background. In the severely affected fetuses previously described in the literature several different HNF1B mutations seem to cause a common phenotypic pattern of multicystic dysplasia, pancreas hypoplasia and abnormal genital tract. The repetition of very specific histological findings in two siblings supports the conclusion that a fetal HNF1B syndrome exists.

3149W

Novel Molecular Changes and Their Associated Clinical Characteristics in Saudi Patients with Familial Hemophagocytic Lymphohistiocytosis. *A. Al-Ahmari[1], O. Alsmadi[2], L. Elbaik[2], T. Elamin[2], B. Al-Saud[3], S. Al-Shambri[1], M. Al-Awwami[4], I. Al-Fawaz[1], M. Ayas[1], K. Siddiqui[1], M. Viqaruddin[1], A. Hawwari[2].* 1) Pediatric Hematology/Oncology, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia; 2) Section of Immunogenetics, Genetics, Research Center, King Faisal Specialist Hospital and Research Centre, Riyadh Saudi Arabia; 3) Pediatric Allergy/Immunology, King Faisal Specialist Hospital and Research Centre, Riyadh Saudi Arabia; 4) Pathology and Laboratory Medicine, King Faisal Specialist Hospital and Research Centre, Riyadh Saudi Arabia.

Familial Hemophagocytic Lymphohistiocytosis (FHL) is a rare autosomal recessive disorder which is characterized by uncontrolled activation of lymphocytes leading to massive lymphohistiocytic infiltration of body organs including central nervous system (CNS).The hallmark of the disease is impaired or absent function of cytotoxic lymphocytes and natural killer cells as a result of several genetic defects. Up to date, four FHL-causing genes have been identified: PRF1, MUNC13-4, and STX11 and STXBP2. Higher incidence of inherited diseases has been reported in Saudi Arabia due to high consanguinity. Saudi patients with the clinical diagnosis of FHL in the period of 1995 through 2011 and available DNA samples were identified. As of now, analysis for PRF1, MUNC13-4, and STX11 and STXBP2 mutations by direct gene sequencing from 40 patients were completed. Twenty-eight patients with ten different novel mutations were identified and their clinical and biochemical profiles were retrospectively captured. One novel STX11 mutation was identified in 7 patients of the same tribe whereas another mutation was identified in 2 related patients with PRFI genetic defect. Additional two novel mutations were identified in 10 patients of 9 unrelated families with STXBP2 gene defect. The remaining 6 novel mutations were identified in 9 patients of 7 unrelated families with Munc13-4 molecular defect. In addition, three previously reported mutations were detected in patients with Munc13-4 (two patients) and PRF1 (one patient) genes. No molecular defects were identified in the remaining 9 (23%) patients. The presenting clinical and biochemical features were similar in the various genetic groups. The disease presented in the first year of life in all but 2 patients with STX11 mutations where they presented at 5 and 3 years of age. Parents Consanguinity was observed in 70% of our patient's cohort. Two thirds of the Unc13-4 and all PRF1 patients died of disease of progression prior to Stem Cell Transplantation. Four STXBP2 patients with P477L nonsense mutation died either of disease progression or transplantation-related complications whereas two patients continued to have multiple episodes of disease reactivation after Stem cell transplantation with 9 and 12 years survival.

3150F

Hip Pathology in Majewski Osteodysplastic Primordial Dwarfism Type II. *M.B. Bober[1], A.F. Karatas[2], A.L. Duker[1], K. Rogers[2], C. Ditro[2], W.G. Mackenzie[2].* 1) Gen Div, DuPont Hosp Children, Wilmington, DE; 2) Orthopedics Department, DuPont Hosp Children, Wilmington, DE.

Introduction Majewski osteodysplastic primordial dwarfism type II (MOPDII; OMIM #210720) is characterized by severe pre- and postnatal growth failure alongside microcephaly, characteristic skeletal dysplasia, abnormal dentition, an increased risk for cerebrovascular disease and insulin resistance. MOPD II is caused by mutations in the pericentrin (PCNT) gene and is inherited in an autosomal recessive manner. Hip pathology in MOPD II patients includes: hip dysplasia, coxa vara, coxa valga and hip subluxation. The purpose of this study was to determine the incidence of hip pathology in molecularly confirmed MOPD II patients and describe the functional outcomes of surgical treatment. **Methods** An IRB approved Primordial Dwarfism Registry has been established at the Alfred I. duPont Hospital for Children. 33 enrolled patients have a clinical diagnosis of MOPDII. Biallelic PCNT mutations or absent pericentrin protein was confirmed in 25 of these patients. 13 patients (7 female and 6 male) had appropriate clinical and radiographic records and were included in this study. The data collected included: age at presentation, age at surgery, sex, body weight and height, weight-bearing status at diagnosis, and the clinical examination. Clinical evaluation included pain and functional complaints, hip, spine, and lower extremity ranges of motion. **Results** Four patients (31%) had coxa vara: 3 unilateral and one bilateral. Three unilateral patients had in-situ pinning at mean age 4 years. The bilateral coxa vara patient was operated at 5 years of age by valgus osteotomy. Two children had bilateral hip dysplasia and subluxation with no surgery. Two patients had developmental hip dislocations. One was unilateral, treated by closed reduction. One was bilateral, treated open reduction, and two years after surgery, coxa valga was noted. Another patient was diagnosed with bilateral AVN at 12 years old. Four patients did not have hip pathology. **Conclusions** Coxa vara seems to be a common hip pathology among MOPD II patients. Routine clinical and radiographic evaluation of the hips is important. The capital femoral epiphysis appears to slip down along the shaft giving the appearance of a proximal femoral epiphysiolysis. This pathology of the hip, diagnosed as slipped capital femoral epiphysis in early years of life, may progress to severe coxa vara on the follow up visits, often requiring surgery. Strong consideration for pinning is recommended to avoid this progression.

Boyadjiev-Jabs syndrome: clinical and molecular characterization of three new patients. *S.A. Boyadjiev Boyd[1], S. Kim[1], L. Bivina[1], E. Zackai[2], P.L. Crotwell[3], K. Õunap[4], J. Kim[1].* 1) Department of Pediatrics, Section of Genetics, University of California Davis, Sacramento, CA; 2) Children's Hospital of Philadelphia, Philadelphia, PA; 3) Sanford Clinic and Genetics Laboratory, University of South Dakota, SD; 4) Department of Genetics, United Laboratories,Tartu University Hospital, Tartu, Estonia.

Boyadjiev-Jabs syndrome (Cranio-lenticulo-sutural dysplasia, OMIM 607812) is a dysmorphic syndrome manifesting with late-closing fontanels and calvarial defects, typical gestalt due to facial dysmorphisms, hypertelorism and eye anomalies, generalized osteopenia and developmental delays. We identified a homozygous mutation F382L in SEC23A, an integral member of the COPII-mediated early secretory pathway in the original family. Here we present the clinical features of three new unrelated probands and expand the phenotypic characterization of this syndrome. We report a heterozygous M702V mutation in SEC23A causing a defect of collagen export from the endoplasmic reticulum (ER) and a heterozygous deletion of SEC23A in another proband. No second mutant allele was identified in these two probands raising the possibility of more complex inheritance pattern. We will present the effect of the mutant alleles on the export of procollagen from the ER as analyzed by cell-based assays and electron microscopy. We propose that Boyadjiev-Jabs syndrome is more common than previously thought and should be considered in patients with skull ossification defects, hypertelorism, eye and skeletal anomalies.

3152F

Schinzel-Gideon syndrome in two Brazilian patients: report of a novel mutation in SETBP1. *E.D.F. Carvalho[1], M. Lazar[2], T.F. Almeida[1], C.R.D.C. Quaio[1], G.L. Yamamoto[1], K.M Rocha[2], C.A. Kim[1], M.R. Passos-Bueno[2], D.R. Bertola[1,2].* 1) Unidade de Genética, Instituto da Criança do Hospital das Clínicas, Universidade de São Paulo, São Paulo, SP., Brazil; 2) Instituto de Biociências, Universidade de São Paulo, São Paulo, SP, Brazil.

Schinzel-Giedion syndrome (SGS) is an autosomal-dominant disorder recognizable by the presence of typical facies, growth failure, skeletal malformations, hydronephrosis, cardiac and urogenital defects, developmental delay and a propensity to develop neuroectodermal tumors. Most affected individuals die before the age of ten. SGS was recently regarded as caused by de novo mutations in SETBP1. In 2008, when SGS pathogenesis had not yet been determined, Lehman et al. proposed clinical diagnostic criteria (LDC) that yielded 100% sensitivity for the previously reported cases. The LDC considers the obligatory presence of both developmental delay and facial phenotype (prominent forehead, midface reatraction and short, upturned nose) plus one of the following features: hydronephrosis or typical skeletal abnormalities to establish the diagnosis. Only 15 patients with molecularly proved SGS have been described. We report two unrelated Brazilian patients with SGS confirmed by molecular analysis. Case 1 is a 1-month-old male, who fulfilled the LDC for SGS; he had microcephaly with large anterior fontanelle, typical facies, transverse palmar creases, typical skeletal malformations, bilateral ventriculomegaly, hydronephrosis and hypospadias. He presented seizures within the first month of life, profound developmental delay and hypertonia. Molecular analysis detected the previously described heterozygous mutation c.2602G>A. Case 2 is a one-year-old female that did not fulfill the LDC. She had typical facial phenotype, developmental delay, alacrimia and seizures. She did not have hydronephrosis or the typical skeletal malformations. The molecular analysis revealed a novel mutation (c.2601C>A), assumed as pathogenic by prediction analysis by Polyphen and SIFT, as it affects the protein function and by the fact that it is a de novo event. This is the first report of molecularly-confirmed patients with SGS in Brazil, one among whom presenting a new mutation. We emphasize the importance of the presence of the facial gestalt and developmental delay for the clinical suspicion of SGS. Once the molecular background of this syndrome is now recognized, it is possible that atypical cases or cases with a milder presentation (not fulfilling the LDC, such as the case here described) will be reported, broadening the phenotypic spectrum within SETBP1 gene mutations.

3153W

HOXA10 and HOXA13 sequence variations in human female genital malformations including congenital absence of the Uterus and Vagina. *A. Ekici[1], C. Büttner[1], P. Strissel[2], P. Oppelt[2], S. Renner[2], S. Brucker[3], M. Beckmann[2], R. Strick[2].* 1) Institute of Human Genetics, University of Erlangen-Nürnberg, Erlangen, Germany; 2) Department of Gynecology and Obstetrics, Laboratory for Molecular Medicine, University-Clinic Erlangen, Germany; 3) University-Clinic, Department of Obstetrics and Gynecology, Tübingen, Germany.

Background: Congenital genital malformations occurring in the female population are estimated to be 5 per 1,000 and associate with infertility, abortion, stillbirth, preterm delivery and other organ abnormalities. Complete aplasia of the uterus, cervix and upper vagina [Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome] has an incidence of 1 per 4,000 female live births. The genes responsible for the etiology of congenital genital malformations including MRKH are unknown. The homeobox (HOX) genes HOXA10 and HOXA13 located on chromosome 7 are involved in the development of human genitalia. **Methods:** HOXA10 and HOXA13 genes of 27 patients with the MRKH syndrome, 10 non-MRKH patients with genital malformations and 53 control women were sequenced. A novel exonic nucleotide deletion discovered in HOXA10 was analysed by real time PCR in a total of 103 patients with MRKH and 109 non-MRKH patients with genital malformations. **Results:** A total of 15 DNA sequence variations (11 novel and 4 known) within exonic and untranslated regions (UTRs) were detected in HOXA10 and HOXA13 among our cohorts. Five HOXA10 and two HOXA13 DNA sequence variations were found solely in patients with genital malformations. In addition to mutations resulting in synonymous amino acid substitutions, missense mutations in the HOXA10 gene were found in one MRKH patient and one non-MRKH patient with a bicornate uterus, with the latter predicted by computer analysis as probably damaging to protein function. An exonic HOXA10 cytosine deletion was identified in a non-MRKH patient with a septate uterus and renal malformations resulting in a premature stop codon and loss of the homeodomain helix 3/4. This cytosine deletion in HOXA10 demonstrated an incidence of one in a total of 212 MRKH and non-MRKH patients with genital malformations. Lastly, in the 5'UTR of HOXA10 in a non-MRKH patient with genital malformations, a cytosine to an adenosine base change was found. **Conclusions:** Rare DNA sequence variations in the HOXA10 gene were detected in MRKH patients but especially in non-MRKH patients with genital malformations. Consequences of non-synonymous mutations, a cytosine deletion or a 5'UTR mutation, could result in altered protein function or abnormal gene expression of HOXA10.

3154F

Establishing a paternal age effect for Crouzon syndrome with acanthosis nigricans. *T. Greer[1], C. LaDana[2], P. Barros-Nunez[3], F. di Rocco[4], C. Collet[5], E.W. Jabs[6], R.L. Glaser[1].* 1) Department of Biology, Stevenson University, Stevenson, MD; 2) Department of Cell Biology and Molecular Genetics, University of Maryland, College Park, Maryland; 3) Centro de Investigación Biomédica de Occidente, IMSS, Guadalajara, Mexico; 4) Unité de Chirurgie Craniofaciale, Pediatric Neurosurgery, Assistance Publique-Hôpitaux de Paris, Hôpital Necker Enfants Malades, Paris, France; 5) Service de Biochimie et de Biologie Moléculaire Assistance Publique-Hôpitaux de Paris, Hôpital Lariboisière, Paris, France; 6) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, New York.

Crouzon syndrome with acanthosis nigricans, also known as Crouzonodermoskeletal syndrome (CDSS), is an extremely rare autosomal dominant disorder with an estimated incidence of 1/ 1,000,000. CDSS is characterized by craniosynostosis, acanthosis nigricans, vertebral anomalies, along with choanal atresia, and hydrocephalus. Molecular diagnosis of CDSS can be established by confirming the presence of the Ala391Glu mutation in the fibroblast growth factor receptor 3 (FGFR3) gene. This is the only mutation which has been found in cases of CDSS. Parental age data was obtained for ten families. Parental ages at the time of the affected child's birth were matched to parental age data in the general population for each birth year. The average paternal age for fathers of affected children with CDSS was 38.47 (+9.62) years compared with 30.23 (+1.34) years in the general population (p=0.013). The average maternal age for mothers of affected children with CDSS was 31.20 (+4.86) years compared with 27.15 (+1.25) years in the general population (p=0.04). Fathers of affected children were, on average, 7.27 years older than mothers of affected children. DNA from parent-child trios was obtained from five families with sporadic CDSS. The DNA samples were PCR amplified and subjected to restriction enzyme digests to determine the informativeness of the families. Two of the five families were shown to be informative. For these two informative families, allele specific PCR was performed on the parents and affected child in order to determine which parent contributed the allele with the mutation. In both cases, it was determined that the mutations were paternal in origin. Our findings of a paternal age effect for CDSS and two paternally derived mutations in CDSS are consistent with findings in other autosomal dominant disorders such as Crouzon syndrome without acanthosis nigricans with FGFR2 mutations and achondroplasia and Muenke syndrome with FGFR3 mutations. All of these disorders are strongly associated with advanced paternal age and have an exclusive paternal origin of mutation.

Characterization of Hyper-IgM Syndrome Due to CD40 Deficiency in 11 Patients. *A. Hawwari[1], H. Alassiri[1,2], Z. Al-Sum[3,5], A. Al-Ghonaium[3], S. Al-Muhsen[3,5], H. Al-Dhekri[3], R. Arnaout[3], O. Alsmadi[1], E. Borrero[1], A. Abu-staiteh[1], H. Al-Mousa[1,4], B.K. Al-Saud[3,4].* 1) Section of Immunogenetics, Department of Genetics, Research Center, MBC03, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia; 2) College of Science, King Saud University, Riyadh, Saudi Arabia; 3) Section of Allergy and Immunology, Department of Pediatrics, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia; 4) College of Medicine, Alfaisal University, Riyadh, Saudi Arabia; 5) College of Medicine, King Saud University, Riyadh, Saudi Arabia.

Hyper-IgM syndrome due to CD 40 deficiency (HIGM3) is a rare form of primary immunodeficiency, where only few reported cases in the literature, therefore we review in this report our experience in the management of 11 patients. In this study, we sought to identify the Clinical, Immunological, and Molecular Characterization of Hyper-IgM Syndrome due to CD40 Deficiency. For this purpose, a clinical review and a molecular genetic analysis of patients diagnosed with HIGM3 at a single center from 1994–2011 was performed. Eleven patients from seven families were studied. The median age was 8 years (1–21). All 11 patients had recurrent chest infection at presentation. Pneumocystis jiroveci pneumonia was confirmed in three patients. Four patients had Sclerosing cholangitis and four patients had cryptosporidium isolated from their stool. Six patients had nasal and sinus infection, two with destructive nasal fungal infections. Eight patients had neutropenia, all had low IgG and normal or high IgM. IgA was undetectable in all patients except for three patients. Two novel mutations were identified in seven patients; a splice site mutation was found in 5 patients at position +2 of the invariant donor splice site of interon 3 (c. 256+2T>C) and a missense mutation was found in two patients in the coding region of exon 3 (c.170C>T). Two patients underwent successful stem cell transplantation from a matched donor. Five patients doing well on prophylaxis, two are very sick one with protracted diarrhea and persistent cryptosporidium and the other patient had neurological complications. Three patients died early in life because of severe sepsis. To our knowledge this is the largest and longest fellow up case series reported in this disease so far. Our series showed theat CD40 deficiency is s heterogeneous disorder with a spectrum of disease severity. In summary: Hyper-IgM syndrome due to CD40 deficiency is a rare primary immunodeficiency disorder, only few cases published. Here in this report and for the first time a study present 11 patients long term clinical outcome, immunological and molecular Characterization.

New insights into the renal aspects of hypotrichosis-lymphedema-telangiectasia syndrome caused by a mutation in the *SOX18* gene. *S. Moalem[1], M. Vikkula[2], E. Harvey[3], D. Chitayat[1,4].* 1) Department of Pediatrics, Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, The University of Toronto, Toronto, Canada; 2) Laboratory of Human Molecular Genetics, de Duve Institute Université catholique de Louvain, Walloon Excellence in Life Sciences and Biotechnology (WELBIO), Belgium; 3) Division of Nephrology, The Hospital for Sick Children, University of Toronto, Toronto, Canada; 4) Department of Obstetrics and Gynecology, The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital; University of Toronto, Toronto, Canada.

SOX18 - The SRY related HMG box-containing gene 18 transcription factors belongs to the highly conserved SOXF group of genes which plays a pivotal role in the development and/or maintenance of the developing heart, blood and lymphatic vessels by activating a transactivation domain adjacent to the HMG domain. SOX18 mutations in humans are associated with both recessive and dominant HLTS. We report a family with two affected children with SOX18 mutations, with the living child developing renal failure. The couple, who was healthy and non-consanguinous, had their first pregnancy complicated with nonimmune hydrops fetalis that resulted in death in utero at 30 wks gestation. The autopsy showed chylous effusions in the pleural and peritoneal cavities, generalized vascular congestion of the lungs with dilation of the lymphatic vessels. The pregnancy with the proband was uncomplicated. After delivery he developed RDS and CXR showed bilateral pleural effusions, which resolved spontaneously. He had large bilateral hydroceles that required surgical repair at 3 months of age and scrotal telangiectasia. At 6 months of age he experienced progressive hair loss resulting in alopecia universalis by the age of two. As an infant and toddler he experienced multiple episodes of facial, peripheral and mild pulmonary oedema. His IgG level was persistently low but he did not experience unusual or particularly severe infections. He was diagnosed with HLTS and DNA analysis for the SOX18 gene showed a novel heterozygous C865A mutation. DNA analysis done on his late brother showed the same mutation and parental DNA analysis using DNA extracted from peripheral blood showed no detectable mutation. At 5 years of age he presented with renal failure with severe hypertension. Renal biopsy demonstrated a chronic microangiopathy involving glomerular and extraglomerular vasculature. He required almost a year of chronic peritoneal dialysis but recovered sufficient renal function to discontinue dialysis for 9 years, during which time he had a slow progressive deterioration in renal function culminating in the need for transplantation at age 14. The SOX18 gene has a role in the formation of blood and lymphatic vessels and a mutation in this gene, as seen in our patient, results in HLTS. This is the first report of renal failure associated with a heterozygous SOX18 gene mutation, most probably due to abnormal angiogenesis. This is also the first reported case of gonadal mosaicism in HLTS.

Missense and synonymous *TCF4* mutations are responsible for splicing defects in Pitt-Hopkins Syndrome. *M. Nasser[1,2], L. Drévillon[1,2], A. Briand-Suleau[1,2], J. Ghoumid[1,2], T. Gaillon[1], V. Bodereau[1], L. Pasquier[3], M. Goossens[1,2], J. Amiel[4], D. Héron[5], I. Giurgea[1,2].* 1) AP-HP, Groupe hospitalier Henri-Mondor, Service de Biochimie et Génétique, Créteil, France; 2) INSERM U955, Equipe 11, and Université Paris-Est, Créteil, France; 3) Service de Génétique Clinique, CHU Rennes, France; 4) AP-HP, Service de Génétique, Hôpital Necker-Enfants Malades, Paris, France; 5) AP-HP, Groupe Hospitalier Pitié Salpêtrière, Unité Fonctionnelle de Génétique Clinique, Paris, France.

Pitt-Hopkins syndrome (PTHS, MIM #610954) is a neurodevelopmental disorder associating severe intellectual disability, hyperventilation episodes, and characteristic facial gestalt. *TCF4*, encoding a basic helix-loop-helix (bHLH) transcription factor which belongs to the family of E-proteins, was identified as the disease causing gene. PTHS patients usually carry *de novo*deletions or truncating mutations. So far, without two exceptions (c.1073G>T, p.Gly358Val and c.1604A>G, p.Asp535Gly), missense mutations are always localized in the bHLH domain. Recent data demonstrate impairment in the protein function for the bHLH missense mutations, but not for those located outside this domain. In this study, we investigated the impact on splicing of both missense mutations situated outside of the bHLH domain, and of a synonymous mutation (c.1071A>G, p.Ala357Ala) identified *de novo* in an unreported patient with typical PTHS phenotype. No splicing defects were predicted for these mutations by use of bioinformatics tools. Using a functional splicing assay based on a minigene construct, we showed the exon 14 skipping for the c.1071A>G and the c.1073G>T mutations and the skipping of 46 bp of the exon 17 for the c.1604A>G mutation. This results were confirmed by reverse transcription-PCR analyses from peripheral blood lymphocytes mRNA in two patients (c.1071A>G and c.1604A>G). In all cases, the mutations were responsible for frameshift and premature stop codons (c.1071A>G, p.Gly358LysfsX4; c.1073G>T, p.Gly358LysfsX4 and c.1604A>G, p.Asp535AlafsX8). In conclusion, we first demonstrate that the deleterious effect of the missense mutations located outside the b-HLH domain was due to *TCF4* splicing anomalies. Second, we describe the first synonymous mutation in PTHS, and proved its splicing deleterious effect. Finally, for the molecular diagnosis of PTHS we suggest to test the segregation in parents DNA, for the missense mutations outside b-HLH, and for the synonymous, or intronic not reported sequence variants. *De novo* variants in *TCF4* gene have to be cautiously interpreted and splicing tests have to be performed even in absence of *in silico* prediction of a deleterious effect.

3158F

Clinical genetics in silico: Use of an electronic medical record in an integrated healthcare system to identify individuals with undiagnosed Noonan syndrome. *M. E. Nunes[1], R. E. Barber[2], S. K. Kwok[2], R. R. Wilson[2], D. J. Levy[3].* 1) Dept Genetics/Pediatrics, Kaiser Permanente, San Diego, CA; 2) Consulting Services, Kaiser Permanente, San Diego, CA; 3) Dept Pediatrics, Cardiology, Kaiser Permanente, San Diego, CA.

Noonan syndrome (NS) is an autosomal dominant syndrome characterized by short stature, dysmorphology, pulmonic stenosis (PS) and hypertrophic cardiomyopathy (HCM). These and several other NS features can be coded in an electronic medical record (EMR) under the International Classification of Diseases (ICD-9). Left axis deviation (LAD) on electrocardiogram (ECG), independent of the presence of structural heart disease, is found in 50% of those with NS. LAD is an unusual ECG finding, present in 1% of the healthy Pediatric population. We used the EMR and ECG database to see if previously undiagnosed patients with NS could be identified. Using the EMR of an integrated healthcare system serving 954,650 individuals ≤ 19 years old, we identified those over a 5 year period with a combination of common NS features (short stature, PS, etc.) coded in their problem list. We also identified 73 patients with the ICD-9 diagnosis NS (759.89) already in their EMR (Pediatric prevalence 7.6/100,000). Using the ECG electronic database, we identified those in the same age range over the same period with ECG LAD (-30° to -90°). Lists were cross referenced. 65 individuals with at least 2 NS features and LAD on ECG were identified (study group). The EMRs of the study group were reviewed by both a Pediatric Cardiologist and Clinical Geneticist to identify those with additional documented features of NS for further evaluation. 7 (9.6%) of the 73 individuals with known NS coded by ICD-9, would have been identified by the outlined *in silico* process. 60 (82%) of these 73 with existing NS had an ECG, 32 (53%) ECGs revealed LAD. Of the 65 study group individuals identified with the combination of short stature, PS or HCM and LAD on ECG, 4 carried a diagnosis of NS, 1 cardiofaciocutaneous syndrome (CFC), and 1 Kabuki syndrome. 18 of the remaining 59 were felt to have a combination of additional NS associated features (e.g. hearing loss, ptosis) to warrant further evaluation. 8 of these 18 thus far have sufficient documented features to establish a clinical diagnosis of NS. Using an EMR and ECG database, undiagnosed patients with NS can be identified. This is the first demonstration of an integrated healthcare system's EMR being used to identify previously undiagnosed rare genetic disorders. ECG may be of utility in evaluating individuals with short stature and other NS associated clinical features. This method can be reproduced using unique ICD-9 codable features in other syndromes.

3159W

Detailed clinical and orofacial phenotype of three families with compound heterozygous *WNT10A* mutations using three-dimensional imaging methods. *C.W. Ockeloen[1], C. Vink[2], S. ten Kate[1], C. van Heumen[3], T. Kleefstra[1], C. Carels[2].* 1) Department of Human Genetics, Radboud University Nijmegen Medical Center, Nijmegen, the Netherlands; 2) Department of Orthodontics and Craniofacial Biology, Radboud University Nijmegen Medical Center, Nijmegen, the Netherlands; 3) Centre for Special Dental Care, Radboud University Nijmegen Medical Center, Nijmegen, the Netherlands.

Introduction: Odonto-Onycho-Dermal Dysplasia (OODD) and Schöpf-Schulz-Passarge Syndrome (SSPS) are autosomal recessive ectodermal dysplasia syndromes caused by homozygous or compound heterozygous mutations in the *WNT10A* gene. Mutations in *WNT10A* are also responsible for anhydrotic or hypohydrotic ectodermal dysplasia (ED). Moreover, heterozygous mutations account for almost half of isolated hypodontia cases. We present clinical data of three Dutch families with *WNT10A* mutations and a detailed description of the orofacial and dental phenotype using three-dimensional imaging techniques. The first family was diagnosed with OODD, the second family with SSPS and the third family showed hypohydrotic ED. **Methods:** Detailed medical history and examination was performed within our multidisciplinary Craniofacial Genetics clinic. Sequence analysis of *WNT10A* was performed using Sanger sequencing. The orofacial phenotype was documented using an orthopantomogram, a lateral headplate and intraoral and facial pictures. Threedimensional imaging was performed with facial stereophotogrammetry and dental models. **Results:** In the OODD and SSPS family, a similar compound heterozygous mutation in *WNT10A* was identified in the probands: c.321C>A (p.Cys107X) and c.682T>A (p.Phe228Ile). In the SSPS family, these mutations segregated with the phenotype in two affected siblings. The ED patient harboured a homozygous p.Cys107X mutation. Some of the heterozygous carriers displayed a milder phenotype. In the SSPS patients large diastemata were observed intraorally, due to absence of permanent teeth after loss of deciduous teeth. Facial profile analysis points to a retrognathic mandible in the OODD patient and one patient with SSPS, and a midfacial dished-in aspect in the SSPS and ED patients. Common to all affected individuals are the hypoplastic tooth bearing alveolar processes in maxilla and mandible. **Discussion:** These three families clearly demonstrate the broad phenotypic spectrum caused by identical *WNT10A* mutations. Until now, seven different mutations have been reported in *WNT10A* patients. p.Cys107X and p.Phe228Ile are the two most frequently identified mutations. To our knowledge, this is the first report that shows an extensive descriptive overview of the orofacial and dental characteristics of *WNT10A* patients. Part of the heterozygous carriers show a mild phenotype. Taken together, our data on these three families contribute to the expanding phenotype of *WNT10A* patients.

3160F

Tegumentary manifestations in RASopathies are common and deserve special attention. *C.R.D.C. Quaio[1], A.S. Brasil[1,2], A.C. Pereira[2], C.A. Kim[1], D.R. Bertola[1].* 1) Instituto da Criança, Genetics Unit, Faculdade de Medicina da Universidade de São Paulo, São Paulo, SP, Brazil; 2) Incor, Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo, SP, Brazil.

RASopathy is a class of common autosomal dominant syndromes with neurocardiofaciocutaneous involvement that includes Noonan syndrome and Noonan related disorders. These syndromes are caused by germline mutations in genes that participate in the RAS/MAPK pathway. Proteins belonging to the RAS/MAPK pathway play important roles in cell proliferation, differentiation, survival, and death. Some components of this pathway, like Gab1 and SHP-2, are related to the promotion of epidermal proliferation and they may interfere in the epidermal cell state and the tegumentary function. The objective of this article is to describe novel tegumentary findings in a cohort of 44 patients with molecularly-proven RASopathy. We found a considerable prevalence of patients complaining of tegumentary problems: 66% (29/44), including xeroderma (20/29), photosensitivity (13/29), hair loss (10/29) and recurrent oral ulcers (12/29). These patients presented mutations in PTPN11 (69%), SOS1 (17%), BRAF (7%), KRAS (3%) and SHOC2 (3%). We were not able to establish a genotype-phenotype correlation or a statistically-relevant ($p<0.05$) difference between the groups of patients presenting tegumentary disorders because the number of patients, though considerable for a genetic disorder, was small to reach a statistical significance. Although the role of the RAS/MAPK pathway in the development and functioning of the skin are not completely understood, several skin manifestations in individuals with RASopathies have been described, like pigmented lesions (café-au-lait spots, lentigines, melanocytic lesions), ectodermal lesions (ichthyosiform manifestations, follicular hyperkeratosis and short, curly, thin hair) and hyperplasia (redundant skin and papillomatous growths). Additionally, somatic mutations in genes of this pathway are associated with skin tumors. Several of the tegumantary manifestations reported in this article have not been previously described in the RASopathic literature. The high prevalence of tegumentary involvement in RASopathy deserves special attention and must be managed properly. Therefore, dermatologists must be part of the multidisciplinary team in the follow-up of RASopathic patients.

Molecular analysis and expression studies in a novel candidate gene for syndromic coloboma. *N.K. Ragge[1, 2], A. Wyatt[3], D. Robinson[4], D. Bunyan[4], D. Wong[5], I. Ragoussis[5].* 1) Oxford Brookes University, Oxford, UK; 2) Wessex Clinical Genetics Service, Princess Anne Hospital, Southampton, UK; 3) Vancouver Prostate Centre and Department of Urologic Sciences, University of British Columbia, Vancouver, British Colombia, Canada; 4) Wessex Regional Genetics Laboratory, Salisbury, UK; 5) Wellcome Trust Centre for Human Genetics, Oxford, UK.

Developmental eye anomalies affect around 1 in 3,500–4,000 of the population, and are responsible for up to 25% of childhood visual impairment. They range from rare severe forms of bilateral anophthalmia or severe microphthalmia, to milder forms of microphthalmia and coloboma. They form a highly heterogeneous group of disorders, and currently it is possible to identify genetic causes in around 25% of individuals. The commonest causes are genetic mutations or deletions in SOX2, which is responsible for around 10–15% of cases, and OTX2 (around 3–4%), but also include BMP4, BMP7, STRA6, GDF6, GDF3, FOXE3, VSX2, TFAP2A, SHH, HCCS, RABGAP1, RABGAP2, BCOR, SMOC1, ABCB6, FRAS1, FREM1, GRIP1, RAX, PAX6, and LRP2. Clues to genetic identification are provided by the combination of eye and other anomalies. We screened a cohort of 279 individuals with anophthalmia, microphthalmia and coloboma for mutations and deletions in a known transcription factor, not previously associated with a human condition, but known to interact with a known human eye gene. We identified a *de novo*missense mutation in a critical domain of this transcription factor in a girl with bilateral chorioretinal coloboma. She also had a heart defect, abnormal left kidney shape, hearing deficit, mild learning difficulties, and partial toe syndactyly and her growth was on the 2nd centile for height, 9th centile for weight, and <3rd centile for head circumference. We detected 4 heterozygous neutral variants in the gene in the rest of the cohort. This particular base is highly conserved across the phyla and in other members of the group of proteins. The missense alteration causes a change from polar positively charged arginine to non-polar hydrophobic leucine, and is predicted to be “probably damaging" by Polyphen and to “affect protein function" (p=0.01) by SIFT. It was not present in a screen of 280 members of the ECACC control panel, and it is not a reported SNP. We performed *in vitro* studies that demonstrated that the mutant protein had reduced DNA binding ability compared to wild type. Furthermore, we performed *in situ* expression studies in developing mouse and human eye tissue, and detected expression in the lens and retina. Our data implicates this gene in early eye development, and we suggest that it should be included when developing panels of genes to investigate the causes of ocular malformations.

3162F

Variable expressivity of FREM1 related anomalies in a family with novel mutation. *A. Singer[1], A. Slavotnek[2], H. Leiba[3], S. Josefsberg[4], C. Vinkler[5].* 1) Dept Clinical Gen Unit, Barzilai Med Ctr, Tel Aviv, Israel; 2) Department of Pediatrics, Division of Genetics, University of California, San Francisco USA; 3) Department of Ophthalmology, Kaplan Medical Center, Rehovot, Israel; 4) Institute of Medical Genetics, Kaplan Medical Center, Rehovot, Israel; 5) Institute of Clinical Genetics Wolfson Medical Center Holon, Israel.

Manitoba-oculo-tricho-anal (MOTA) syndrome (MIM 248450) is a rare autosomal recessive disorder. It was first described in 1992 by Marels SL among the Oji-Cree community of the Island Lake region of northern Manitoba, Canada. Since the first publication, a few patients were described originating in other parts of the world. The syndrome is characterized by an aberrant hairline, several eyes anomalies (e.g. eye coloboma), a bifid or broad nasal tip, and gastrointestinal anomalies . In 2011 it was found that MOTA syndrome is caused by mutations in FREM1. We present two sibs born to a Jewish couple originating from Uzbekistan, diagnosed with MOTA syndrome and carrying a novel mutation in the FREM1 gene. This is the first case described in Israel. The proband is a 3 month old male born at term to healthy parents who are second degree cousin. At birth, ocular hypertelorism, corneopalpebral synechiae and upper eyelid colobomas were noticed. The anterior hairline extended from the temporale regions bilaterally and the lateral margins of the eyebrows were sparse on both sides. He has a wide nose with a bifid nasal tip and pilonidal dimple. His younger sister had a similar bifid nasal tip and a depressed and hypoplastic columella. Both children were otherwise healthy and had normal development. FREM1 sequence analysis found both the proband and his sister, homozygous for the deletion of a single G nucleotide from a pair of two G nucleotides situated at the last base pair of intron 35 and the first base pair of exon 36. The deletion was predicted to produce a frameshift and to abolish the splice acceptor site. Both parents were heterozygous for the same mutation. MOTA syndrome has some clinical overlap with Fraser syndrome (FS) (MIM 219000), a complex multiple malformation with more severe phenotype. Fraser syndrome is genetically heterogeneous, with mutations in FRAS1 and FREM2 accounting for approximately half of cases. The FRAS1 and FREM2 proteins form a macromolecular ternary complex with a third protein, FREM1. Mutations in the FREM1 gene cause bifid nose sometimes with anorectal and renal anomalies, BNAR syndrome (MIM 608980). Our family emphasize the variable expressivity of FREM1 related anomalies.

3163W

Identification of a *KRIT1* p.Gln201Glu mutation in a Persian family with multiple cerebral, spinal and skin cavernous malformations. *S.M. Sperber[1], D. Fathi[2], M. Shahbazi[3], M.M. Motahari[4], B. Friedman[5], A. Haghighi[6].* 1) DNA Diagnostic Laboratory, Department of Pediatrics, University of Colorado, Anschutz Medical Campus, Aurora, CO, USA; 2) Department of Neurology, Golestan University of Medical Sciences, Gorgan, Iran; 3) Medical Cellular & Molecular Research Center, Golestan University of Medical Sciences, Gorgan, Iran; 4) Department of Ophthalmology, Golestan University of Medical Sciences, Gorgan, Iran; 5) GeneDx, Gaithersburg, MD, USA; 6) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

Cerebral cavernous malformations (CCM) are congenital vascular anomalies predominantly of the central nervous system but may include lesions in other tissues such as the retina, skin, and liver. These hamartous dysplasias, generally occurring sporadically, consist of dynamic clustered tortuous capillary cavities without intervening brain parenchyma that may lead to headaches, seizures, paresis, cerebral hemorrhages and focal neurological deficits. Familial forms of CCM, inherited in an autosomal dominant manner with incomplete penetrance, are attributed to mutations in three genes, KRIT1, CCM2 and PDCD10. Here we report a pedigree of Persian descent clinically evaluated and exhibiting a range of clinical symptoms that include seizures, multiple lesions of the brain, spinal cord and severe hyperkeratotic cutaneous capillary-venous malformations. Clinical sequencing and deletion-duplication testing of the three genes in the proband revealed a KRIT1 p.Gln201Glu mutation. These findings illustrate the phenotypic heterogeneity observed in such pedigrees, and highlight the importance of clinical testing for early diagnosis in familial CCM.

3164F

Novel 3q26 EVI1/MECOM deletion syndrome in a newborn with multiple severe congenital abnormalities and bone marrow failure. *L.T. van der Veken[1], M.B. Bierings[2], M.C. Maiburg[1], F. Groenendaal[3], A.C. Bloem[4], N.V. Knoers[1], A. Buijs[1].* 1) Dept. of Medical Genetics, University Medical Center Utrecht, Utrecht, Netherlands; 2) Dept. of Pediatric Oncology, University Medical Center Utrecht, The Netherlands; 3) Dept. of Neonatology, University Medical Center Utrecht, The Netherlands; 4) Dept. of Immunology, University Medical Center Utrecht, The Netherlands.

We report on a patient born with severe congenital abnormalities including macrocephaly, brain MRI abnormalities, bilateral clubfeet, and bone marrow failure with pancytopenia presenting with none but T-lymphocytes in the peripheral blood. A 824 kb to 868 kb heterozygous deletion on chromosome 3q26.2 was identified by array-CGH on peripheral blood using an Agilent 180k oligo array (Amadid 023363). The deletion truncated the 3' part of *EVI1/MECOM* and extended into microRNA 551b (*MIR551B*). The 3' *MECOM* deletion was confirmed by FISH using a*MECOM* specific probe on uncultured peripheral blood cells in 10 investigated metaphases and 200 interphase nuclei. To assess whether the deletion was constitutional, FISH analysis was performed on buccal swaps and cultured skin fibroblasts. Loss of one *MECOM* signal was observed in 200 interphases, and 10 metaphases of cells derived from buccal mucosa and skin fibroblasts, respectively, demonstrating the constitutional nature of the 3' *MECOM* deletion. Karyotyping and FISH analysis of both parents did not reveal a structural or numerical abnormality of 3q26.2 *MECOM*, indicating the deletion to be *de novo*. EVI1/MECOM is a transcriptional regulator essential for maintaining embryonic and adult hematopoietic stem cells by directly regulating transcription of *GATA2*. In mouse models, homozygous disruption of *MECOM* results in embryonic lethality, with hypocellular bone marrow, reduced body size, small or absent limb buds, abnormal development of the nervous system and heart and massive hemorrhaging. Furthermore, *MECOM* heterozygosity leads to a marked impairment of the self-renewal capacity of hematopoietic stem cells. In our case the heterozygous deletion results in 3' terminal truncated *MECOM* lacking the C-terminal acidic amino acid cluster domain (AD) encoding sequences. The AD of MECOM is important for activation of *GATA2* transcription *in vitro*. This supports the notion that haploinsufficiency of MECOM causes bone marrow failure due to loss of critical*MECOM* transcriptional AD encoding sequences in this case, supposedly by deregulating GATA2 mediated control of hematopoietic stem cell homeostasis. We will discuss our data in relation to one seemingly similar case deposited recently in the DECIPHER database. In conclusion, we report on a novel 3q26 *EVI1/MECOM* deletion syndrome with multiple severe congenital abnormalities and bone marrow failure due to *EVI1/ MECOM* haploinsufficiency.

KIAA 2022-related X-linked intellectual deficiency: confirmation of a discrete entity in five patients. *L. Van Maldergem[1], V.M. Kalscheuer[2], M. Doco-Fenzy[3], A. Medeira[4], A. de Brouwer[5], E. Landais[3], L. Villard[6], J. Dupont[4].* 1) Centre de Génétique Humaine, Univ Franche-Comté, Besançon, France; 2) Dept Hum Mol Genet, Max-Planck Instit for Molec Genet, Berlin, Germany; 3) Dept Genetics, CHU, Reims, France; 4) Dept Med Genet, Hosp Santa Maria, Lisbon, Portugal; 5) Dept Mol Genet, NUMC, Nijmegen, The Netherlands; 6) INSERM UMRS910, Univ de la Méditerranée, %Marseilles, France.

We describe five boys aged 7 to 22 years, belonging to three families, with a distinctive X-linked intellectual deficiency syndrome. Three of them were diagnosed with infantile autism and two of them suffered from severe epileptic encephalopathy. All but one affected males have hand stereotypies, bruxism, drooling, pes equinovarus with mild spasticity and a distinctive facial appearance that includes round face, strabismus and coma-shaped eyebrows. In two of the families where this phenotype is observed, the molecular basis is a mutation leading to the absence of KIAA2022 expression while in the singleton from the third family, a small interstitial duplication reduces the expression of KIAA2022 and gives rise to a milder phenotype, lacking severe autism and facial dysmorphia, although language delay and repetitive behaviors are present.

3166F

Extending the phenotype spectrum of IQSEC2 mutations : report of a patient with IQSEC2 intragenic duplication and atypical variant of Rett syndrome. *M. Willems[1], F. Tran Mau-Them[1], J. Puechberty[1], G. Lefort[2], A. Schneider[2], I. Touitou[1], M. Girard[2], M. Tournaire[2], N. Ruiz-Pallares[2], F. Rivier[3], S. Drunat[4], P. Sarda[1], D. Genevieve[1].* 1) Genetics Dept, INSERM U844, Hopital Arnaud de Villeneuve, Montpellier, France; 2) Cytogenetics Dept, Hopital Arnaud de Villeneuve, Montpellier, France; 3) Neuropediatrics Dept, Hôpital Gui de Chauliac, Montpellier, France; 4) Cytogenetics Dept, Hôpital Robert Debré, Paris, France.

Missense mutations in the IQSEC2 gene have recently been shown to cause a non-syndromic X-linked intellectual disability (XLID), characterized by substantial limitations in intellectual functioning and adaptative behavior. We report a male patient born from healthy unrelated parents, with normal birth parameters, severe intellectual disability (ID), non inherited postnatal onset microcephaly, hypotonia, hyperkinesia, strabism, Rett-like movements, seizures, and self-injury. Brain MRI, EEG, metabolic screening, and molecular analysis of the MECP2, CDKL5, MEF2C, and FOXG1 genes were normal. Using array-CGH (Agilent 180 k), we identified a de novo Xp11.2 intragenic duplication, interrupting the sequence of the IQSEC2 gene, encompassing exon2. Atypical variants of Rett syndrome correspond to a clinically and genetically heterogeneous group of diseases, characterized by stereotypical hand movements, postnatal microcephaly and severe neurodevelopment disorder. Mutations in the MeCP2, CDKL5, and FOXG1 genes has been identified in these entities. IQSEC2 is a guanine nucleotide exchange factor (GEF) for the ADP-ribosylation factor (ARF) family of GTP-binding proteins. Previous functional studies of the reported missense mutations in the IQSEC2 gene showed that partial loss of the GEF activity of IQSEC2 is the likely underlying molecular mechanism of IQSEC2-XLID. Such missense mutations lead to a reduction of the ARF6 substrate activation that influences the regulation of the actin cytoskeleton organization. The intragenic duplication described here may lead to an interruption of the IQSEC2 gene and generate a more severe loss-of-function of IQSEC2. It has recently been showed that MecP2 stabilizes microtubule dynamics and that MecP2 deficiency could lead to impaired microtubule stability. It is tempting to speculate that the partial loss of actin cytoskeleton organization by either mutation of the MecP2 or IQSEC2 genes could explain phenotypic similarities between our patient and Rett syndrome patients. RNA studies are performed in an attempt to explain the severe phenotype observed in our patient. In addition, molecular analysis of the IQSEC2 gene is performed in patients presenting with atypical variant of Rett syndrome without MecP2, FOXG1 and MEF2C mutations in an attempt to investigate if IQSEC2 mutations could be responsible for atypical variants of Rett syndrome.

Mutations in TGF-beta binding domains in the *FBN1* gene result in diverse connective tissue dysplasia syndromes with short stature. *K.H.C. Wu[1,2,3], A. Baxter[2], J.R. Pinner[4], D. Mowat[5], T. Dudding[6], B. Bennetts[7,3], K. Holman[7], E. Ormshaw[7], T. Gayagay[7], L.C. Adès[2,8,9], C.L. Goff[10], V. Cormier-Daire[10], D.O. Sillence[1,2,3].* 1) Genetic Medicine, Westmead Hospital, Westmead, NSW, Australia; 2) Department of Clinical Genetics, Sydney Children's Hospital Westmead, NSW, Australia; 3) Discipline of Genetic Medicine, Sydney Medical School at Sydney Children's Hospital Westmead, NSW, Australia; 4) Department of Molecular and Clinical Genetics, Royal Prince Alfred Hospital, Camperdown, NSW, Australia; 5) Department of Clinical Genetics, Sydney Children's Hospital Randwick, NSW, Australia; 6) Department of Clinical Genetics, Hunter Genetics, Waratah, NSW, Australia; 7) Department of Molecular Genetics, Sydney Children's Hospital Westmead, NSW, Australia; 8) Marfan Research Group, The Children's Hospital at Westmead, NSW, Australia; 9) Discipline of Paediatrics and Child Health, University of Sydney, NSW, Australia; 10) Département de génétique médicale, INSERM U781, Université Paris Descartes-Sorbonne Paris Cité Institut Imagine, Hôpital Necker-Enfants Malades, Paris, France.

Purpose: Heterozygous mutations in the 4th (exons 37 & 38) and the 5th (exons 41 & 42) TGF-beta binding protein-like domains in *FBN1* have recently been shown to cause stiff skin syndrome (SSS) and acromelic dysplasias, respectively. We report the clinical, radiological and molecular genetic findings in five patients with heterozygous mutations in *FBN1* from New South Wales, Australia and compare these with previously published reports. **Methods:** Retrospective chart review and molecular genetic testing. **Results:** Three patients had geleophysic dysplasia (GD), one had acromicric dysplasia (AD), and one had SSS. All cases were sporadic. All four patients with acromelic dysplasias had severe short stature (-3 to -4 SD) with onset in infancy, short hands/feet, variable joint contractures, characteristic facial features, and a heterozygous mutation in exon 41/42. The three patients with GD all had hepatomegaly and cardiac valvular involvement; the latter was progressive in one patient, in whom surgical intervention was unsuccessful at age 4 years, and stable in the other two (one required oxygen therapy at age 20 years and the other was an athletic male without any intervention at age 33 years). One GD patient was on medical therapy for primary pulmonary hypertension. The AD patient had laryngeal stenosis and borderline megalocornea. Skeletal features included delayed carpal bone age, predominantly acral changes, short long tubular bones, and a J-shaped sella. Notching of the 2nd & 5th metacarpals and femoral heads was an additional feature in the AD patient. The patient with SSS had generalized stiff skin from infancy, diffuse joint contractures, relative short stature (adult height <10th percentile) with hand length measuring between 3rd-25th percentile, and multiple interphalangeal nodules, as reported recently. This SSS patient had a mutation in exon 37 and had ectopia lentis, representing the second hybrid case following a recently reported similar case with a mutation in exon 38. He also had restrictive lung disease in the absence of significant kyphoscoliosis, normal cardiac status and no peripheral neuropathy at age 36 years. None of the five patients had aortic root pathology or known aneurysmal vascular disease. **Conclusion:** Our findings support the fact that mutations in the 4th and 5th (of seven) TGF-beta binding domains in *FBN1* result in diverse connective tissue dysplasia syndromes with short stature.

Clinical and Genetic Analysis in Chinese Patients with Megalencephalic Leukoencephalotathy with Subcortical Cysts. *M. Guo[1], Y. Jiang[1], H. Xie[1], Y. Wu[1], J. Shang[2], Q. Gu[1], X. Wu[1], J. Wang[1].* 1) Department of Pediatrics, Peking University First Hospital, Beijing, Beijing, China; 2) Department of Neurology, Shanxi Big Hospital, Shanxi, Taiyuan, China.

Objective Megalencephalic leukoencephalotathy with subcortical cysts(MLC,OMIM 604004)is a rare leukodystrophy caused by mutations in MLC1 (NM_015166)or HEPACAM(NM_152722.4).Up to now no case with HEPACAM mutation is identified in Chinese MLC patients. In our study,the analysis of clinical features and MLC1 and HEPACAM mutations screening were performed in 20 Chinese patients. Methods Clinical data were collected carefully for our 20 Chinese patients. Genomic DNA from 20 Chinese patients and their parents were screened for mutations in the entire coding region, including the exon-intron boundaries and the surrounding intronic regions,first of the MLC1 gene. For patients without MLC1 mutation, we performed HEPACAM mutation screening. Results All 20 enrolled subjects were diagnosed MLC clinically. We detected MLC1 mutation in these 20 patients and a total of 15 MLC1 mutations were identified, including three novel missense mutations(c.803C>G (p.T268R); c.881C>T(p.P294L); c.858C>G(p.I286M)), one novel small deletion (c.596delCAgt(p.S199Cfs220X)), eight known missense mutations(c.65G>A(p.R22Q);c.95C>T(p.A32V);c.206C>T(p.S69L); c.218G>A(p.G73E); c.274C>T(p.R92W); c.353G>T(p.T118M); c.823G>A(p.A275T); c.832T>C(p.Y278H)),one known splicing mutation(c.772-1G>C in IVS9-1), one known small deletion(c.907_930del(p.V303_L310del)), one known nonsense mutation (c.594delCTCA(p.Y198X)). HEPACAM screening were performed in 6 patients without MLC1 mutations. In one patient, we found two HEPACAM mutations (c.203A>T(p.K68M); c.395C>A(p.T132N)) and one mutation is from her father, while the other one from her mother. A reported HEPACAM missense mutation c.274C>T(p.R92W) was found in two patients from two families, respectively. One was inherited from his mother, another was de novo. Conclusions 17 out of 20 Chinese MLC patients diagnosis clinically were identified by gene mutations related MLC1 or HEPACAM. 14 MLC1-related MLC patients were diagnosed clinically and genetically. Mutation c.772-1G>C in IVS9-1, accounting for 21.4%(3/14) of the total number of MLC1 patients in this study, may be a putative hot-spot mutation in this present study group. Three HEPACAM-related MLC patients were diagnosed as one presented phenotype MLC2A, while the other two were MLC2B. The missense mutation c.274C>T(p.R92W) found in Chinese MLC2B patients maybe common mutations in phenotype MLC2B patients. A systemic study to assess mutation spectrum in different population needs to be carried out.

3169W

Skeletal Clinical Characteristics of Osteogenesis Imperfecta Caused by Haploinsufficiency Mutations in COL1A1. *I.M. Ben Amor, P. Roughley, F.H. Glorieux, F. Rauch.* Medical Genetics, Shriners Hospital, Montreal, QC, Canada.

COL1A1 haploinsufficiency mutations lead to a decreased production of collagen type I by osteoblasts and other cell types and consistently result in the mildest form of osteogenesis imperfecta (OI), OI type I. The skeletal clinical characteristics resulting from such mutations have not been characterized in detail. In this study we assessed 86 patients (36 male, 50 female; mean age 13.3 years; range 0.6 to 54 years) with COL1A1 haploinsufficiency mutations. Birth history was positive for fracture or long-bone deformity in 12% of patients. The average rate of long-bone fracture (femur, tibia/fibula, humerus, radius/ulna) was 0.57 fractures per year, half of which affected the tibia/fibula. Long-bone fracture rate was negatively associated with age and lumbar spine areal bone mineral density. Vertebral compression fractures were observed in 71% of the 58 patients who had lateral spine radiographs. The median number of vertebral fractures was higher for females (median 4; range 0 to 14) than for males (median 1, range 0 to 8) (P = 0.03). Lumbar spine areal bone mineral density was negatively associated with the severity of vertebral compression fractures, as reflected in the spine deformity index. Scoliosis was present in about 30% of patients but the Cobb angle was <30 degrees in all cases. The average final height z-score was -1.1, representing a deficit of 8 to 10 cm compared to the general population. In summary, OI patients with COL1A1 haploinsufficiency mutations have high rates of significant skeletal involvement. Systematic follow up of such patients including radiographic screening for vertebral compression fractures and scoliosis is warranted.

A new dominant frontonasal dysplasia with major posterior cranial defect. *S. Odent[1], S. Mercier[1], M. de Tayrac[2], J. Mosser[2], P. Loget[3], C. Rozel[4], S. Jaillard[5], J. Milon[4], L. Riffaud[6], G. Le Bouar[7], P. Poulain[7], E. Martin[8], C. Dubourg[9], V. David[9].* 1) Genetique Clinique CLAD-Ouest, CHU de Rennes Hopital SUD, Rennes Cedex 2, France; 2) Plateforme Biogenouest, CHU, Hopital Pontchaillou, Rennes, France; 3) Service d'anatomopathologie, CHU, Hopital Pontchaillou, Rennes, France; 4) Service de radiologie, CHU, Hopital Sud, Rennes, France; 5) Service de cytogenetique, CHU, Hopital Pontchaillou, Rennes, France; 6) Service de neurochirurgie, CHU, Hopital Pontchaillou, Rennes, France; 7) Service de gynecologie-obstetrique, Centre de diagnostic prenatal, CHU, Hopital Sud, Rennes, France; 8) Integragen Society, Genopole Campus1, Evry,, France; 9) Laboratoire de genetique moleculaire, CHU, Hopital Pontchaillou, Rennes, France.

Frontonasal dysplasia (FND) is characterized by distinctive facial appearance including medial facial cleft affecting the nose and/or upper lip and palate. Additional features may be present as upper eyelid ptosis and anterior encephalocele. Inheritance is heterogeneous. The ALX3-linked FND is of autosomal recessive inheritance but most FND cases are sporadic. We report on a recurrence of an atypical form of frontonasal dysplasia in a mother and a more severe phenotype in her male foetus. The 30 year-old mother was born at term with a cranio-facial malformation described as an “occipital meningocele” associated with a posterior cranial defect of 8 cm in diameter. No familial history was reported and her parents were not consanguineous. She had hypertelorism, ptosis, bifid nasal tip, high-arched palate and dysplastic ears. Surgical interventions were performed to place prostheses in occipital and frontal regions. She also had cosmetic surgery on nasal tip, maxillary osteotomy and genioplasty. Moreover she had a bilateral mixed deafness, but no mental retardation. During her first pregnancy, a large parietal defect with a voluminous encephalocele was noticed in a male foetus at 15 GW+6 by US scan. Foetal brain MRI at 17 GW found a cranial defect of occipital and parietal regions associated with large brain hernia and ventricular dilatation. Medical termination of pregnancy was performed at 18 GW+3. In addition to the major encephalocele, anatomopathological examination showed a facial dysmorphy resembling to his mother's and a sacral vertebral anomaly. Karyotype, array CGH, Ephrin B and ALX3 gene analyses were normal in the mother and the foetus. Whole exome sequencing led to the identification of a significant heterozygous missense mutation in two new genes. Conclusion: this atypical frontonasal dysplasia is concordant with dominant inheritance and phenotypic variability with increased severity in the male foetus. The occurrence of a de novo variant was confirmed in the mother.

Cerebrovascular changes in a patient with Noonan syndrome and a RAF1 mutation. *Y. Zarate[1], A. Lichty[1], G. Matheus[2], K. Champion[3], K. Clarkson[1], K. Holden[4].* 1) Greenwood Genetics Ctr, Columbia, SC; 2) Department of Radiology and Radiological Science. Medical University of South Carolina, Charleston, SC; 3) Molecular diagnostics laboratory. Greenwood Genetics Ctr, Greenwood, SC; 4) Department of Neurosciences. Medical University of South Carolina, Charleston, SC.

Noonan syndrome (NS) is a common autosomal dominant developmental disorder characterized by facial dysmorphism, skeletal abnormalities, short stature, and heart defects. Gain-of-function germline mutations affecting components of the Ras-MAPK pathway are involved in the development of NS. We present the case of a 6-year-old male with NS, a RAF1 mutation and unique cerebrovascular changes. The proband was noted to have macrocephaly at 10 months of age (HC: 49 cm, >97th centile) and a head CT showed hydrocephalus, requiring ventriculoperitoneal (VP) shunt placement. By 1 year of age he was diagnosed with hypertrophic cardiomyopathy. At the time of his most recent evaluation at 6 years of age, his height was below the 3rd centile, he had typical NS dysmorphic features, mild pectus excavatum, and a short broad neck. RAF1 gene sequencing revealed a de novo c.770C>T heterozygous change (p.S257L). His most recent brain MRI at 5 years of age showed stable decompressed ventricles with a VP shunt, mild parenchymal volume loss, and Chiari I malformation. However, there were numerous diffusely distributed abnormal small-caliber tortuous vascular structures over the subarachnoid space along the cerebral hemispheres and midbrain suggesting underlying vasculopathic changes. CT angiogram confirmed these prominent abnormal vascular structures predominantly in the region of the sylvian fissures as well as the frontal lobes within the prominent subarachnoid spaces. There was no evidence of an AVM or acute major sinus thromboses. Few cases of Chiari malformation/hydrocephalus have been reported in NS. The association between NS and structural cerebrovascular abnormalities is equally unusual and can rarely include: cerebral AVM, intracerebral occlusive artery disease, aneurysms, hypoplasia of the posterior cerebral vessels, cavernous hemangiomas, and moyamoya disease. The cerebrovascular changes seen in this patient do not fit well into these previously noted categories and their origin and potential clinical implications are currently unknown. While there is clear evidence of the important role of RAF1 in cardiac hypertrophy, its role in vasculopathic changes is more obscure. The findings reported here indicate that it is prudent for patients with NS, particularly in the context of a RAF1 mutation and neurological symptoms, to undergo a complete cerebral neurovascular evaluation.

Esophageal atresia (EA) with or without tracheoesophageal fistula is the consequence of an abnormal septation of the foregut into esophagus and trachea. The incidence is estimated at about 1/3,500 live births. The molecular bases for isolated EA are currently unknown and probably multifactorial. Mandibulofacial dysostosis (MFD) is the consequence of an abnormal development of the first and second branchial arches. The core phenotype is represented by malar and mandibular hypoplasia and dysplastic ears. Conductive hearing loss, lower lid anomalies and/or cleft palate are frequent associated features. The molecular bases of syndromic EA or MFD are being identified at a rapid rate. In particular the *EFTUD2* gene (MIM603892) encoding a protein of the spliceosome complex has been found mutated in patients with MFD and microcephaly (MFDM, MIM610536). Until now, no syndrome featuring both MFD and EA has been clearly delineated although EA is reported in about 5% of patients diagnosed with oculoauriculovertebral spectrum (OAVS, MIM 164210). We report on 2 cases presenting MFD and EA and a de novo 17q21.31 deletion encompassing *EFTUD2*, *CCDC103*, *FAM187A* and *GFAP* not reported in the Database of Genomic Variants. Under a contiguous gene syndrome model, *GFAP* and *CCDC103* were considered unlikely to explain EA while FAM187A could not be excluded. Subsequently, we identified a de novo, heterozygous *EFTUD2* loss-of-function mutation in 4 unrelated patients with MFDM and EA. These data exclude a contiguous gene syndrome, broaden the spectrum of clinical features ascribed to *EFTUD2* haploinsufficiency, define a novel syndromic EA entity and emphasizes the necessity of mRNA maturation through the spliceosome complex not only for global growth but also within specific developmental fields.

3173W

Al-Awadi/Raas-Rothshild/Schinzel-Fuhrman spectrum phenotypes in patients with no mutations in WNT7A. *O. Caluseriu[1], E. Sherridan[2], K.M. Girisha[3], J. Parboosingh[1], A.M. Innes[1], F.P. Bernier[1].* 1) Department of Medical Genetics, Alberta Children's Hosp and University of Calgary, Calgary, AB, Canada; 2) Leeds Institute of Molecular Medicine, Leeds, UK; 3) Genetics clinic, Department of Pediatrics, Kasturba Medical College and Hospital, Manipal, India.

Al-Awadi/Raas-Rothshild/Schinzel Syndrome (AARRS;MIM 276820) and Fuhrman Syndrome (FS; MIM 228930) are autosomal recessive disorders characterized by severe symmetric limb anomalies . All three axes of limb growth are affected: proximodistal, anteroposterior and dorsoventral, and mutual interplay of signalling pathways govern this complex process including fibroblast growth factors (FGFs), wingless (Wnt), sonic hedgehog (Shh), and bone morphogenetic protein (BMP). Mutations in WNT7A have been previously associated with AARRS and FS (Woods et al, 2006). Despite intra-familial variability and a range of anomalies found in the initial affected individuals, genetic homogeneity for AARRS has been proposed (Garavelli et al, 2010). We present a cohort of 5 patients with limb anomalies in the AARRS-FS spectrum with no mutations in WNT7A gene. Three cases of FS-like have been identified. Cases 1 and 2, are sisters born to consanguineous parents of Libyan origin. Case 1 had a single bone forearm with 2-ray ectrodactyly on the right, and 5 rays on the left hand with dislocation of the radial head. Case 2 had bilateral congenital radial head dislocation, 5 rays on both hands and 4 rays on both feet. Both sisters shared generalized nail hypoplasia/aplasia with suggestion of an anterior-posterior gradient, and palmar/plantar creases on the dorsal aspect of both hands and feet. Lower limbs showed hypoplasia of distal femurs that were fused to tibias, and no patellae and fibulae. Spine and pelvis were unremarkable. Case 3 is a boy born to nonconsanguineous parents previously reported (Girisha et al, 2011). A further 2 cases have a proposed diagnosis of AARRS. We provide detailed clinical description and imaging of these patients and discuss their relationship to the AARRS-FS spectrum and implications regarding possible clinical and genetic heterogeneity for this group of conditions.

3174F

A Long polyphenilalanine repeats expansion in the RUNX2 gene in a patient with Cleidocranial dysplasia. *M. Michelson-Kerman[1,2], E. Leshinsky-Silver[1], D. Lev[1,2], A. Singer[2,3], C. Vinkler[1,2].* 1) Inst Med Genetics, Wolfson Medical Ctr, Holon, Israel; 2) Genetic Clinic, Maccabi Health Services, Israel; 3) Medical Genetic Unit, Barzilai Medical Center, Ashkelon. Israel.

Cleidocranial dysplasia (CCD) is a autosomal dominant disorder characterized by skeletal anomalies such as patent fontanels, late closure of cranial sutures with Wormian bones, late erupting secondary dentition, rudimentary clavicles, and short stature. The locus for this disease was mapped to chromosome 6p21. RUNX2 is a member of the runt family of transcription factors and its expression is restricted to developing osteoblasts and a subset of chondrocytes. Deletions, insertions, nonsense and splice-site mutations, as well as missense mutations mutations in the RUNX2 gene have been shown to cause CCD. CCD is one of nine developmental disorders associated with expansions of polyalanine (polyA) tracts. The gene harbors a polyalanine stretch of around 17 GAG repeats. We present a 33y old patient with a severe phenotype of CCD and an expansion of the polyalanine stretch in RUNX2 to 29 repeats. The proband is a 33y old man born to healthy unrelated parents. After birth he had persistently open skull sutures with delayed closure, and hypolastic clavicles. At the age of 10y he presented in an Orthopedic clinic with short stature and lordosis. He also suffered of persistent first dentition which required surgical procedures. Skull X ray revealed Wormian bones and chest X ray show shortening of the lateral parts of both clavicles . A clinical diagnosis was made of Cleidocranial dysplasia (CCD). Molecular genetic testing sequencing the RUNX2 gene with fragment length analysis of the poly(GAG) repeats showed that our patient has 29 (GAG) repeat in one allele and 11th (GAG) repats in the second allele. The encoded protein RUNX2 is a transcriptional factor involved in skeletal morphogenesis. RUNX2 is essential for the osteoblast differentiation and chondrocyte maturation during fetal development. It has been previously suggested that expansion of polyalanine repeats may inhibit protein function. However, the exact mechanism of cellular toxicity for polyA-expansions is not known. One previous report of an affected family has been described, with minor clinical findings of CCD segregating with a 27 repeats expansion of a polyalanine stretch. Our patient has an expansion of 29 GAG repeats of the polyalanine stretch in the RUNX2 gene and a severe phenotype of Cleinocranial dysplasia.

3175W

Novel Mutation in the ADAMTSL4 gene in a child with bilateral Ectopia Lentis and Aortic Root Dilatation: expanding the phenotype? *R.L. Sanchez[1], Z. Ammous[2], P. Jayakar[1,2].* 1) Miami Children's Hospital, Miami, FL; 2) University of Miami, Miami, FL.

Ectopia lentis is a highly heterogeneous entity presenting as subluxation of the lens due to disruption in the zonular fibers. It can be an isolated finding but it is frequently seen in association with disorders such as Marfan syndrome, Weill-Marchesani syndrome, or Homocysteinuria. Isolated autosomal dominant ectopia lentis is caused by mutations in the FBN1 gene while autosomal recessive cases are due to ADAMTSL4 mutations. ADAMTSL4, a member of the ADAMTS like gene family, codes for a disintegrin and metalloproteinase with thrombospondin motifs. Mutations in this gene are associated with several congenital ocular anomalies, usually unrelated to other systemic abnormalities suggestive of connective tissue disorders. However a mild evidence of connective tissue instability was previously proposed but no phenotype-genotype correlation has been evident. We report the case of a 10 year old female born to non-consanguineous parents who presented with bilateral lens dislocation, mild aortic root dilatation, scoliosis, and flat feet hinting towards a connective tissue disorder. FBN1, TGFBR1, and TGFBR2 full gene sequencing was negative as well as a basic work-up that included a chromosomal microarray analysis and metabolic tests. ADAMTSL4 mutation analysis revealed a compound heterozygous state for two discrete changes. The first is c.2021_2022delCT in exon 12 known as a disease causing mutation. The second is a c.2977C>T transition in exon 18 which has not been previously reported. ADAMTSL4 is expressed in many tissues but it has been presumed that its role is unique for the composition of zonular fibers of the lens due to absence of other systemic manifestations in previously reported cases. Little is known on the exact function of ADAMTSL4. Moreover, mutations in other members of the ADAMTSL superfamily give rise to other connective tissue disorders. Our patient not only had bilateral lens dislocation but also mild aortic root dilatation, flat feet and scoliosis suggestive of a systemic connective tissue involvement. In addition the mutations detected in our patient are rare and one of them is a novel mutation. Thus there may be an abnormal gene product that is affecting other systems in addition to the eye. Given the unknown consequences on posttranscriptional level we cannot predict the phenotype. What was previously known as ADAMTSL4-related isolated ectopia lentis could be rather a systemic connective tissue disorder yet to be named and defined.

3176F

Mutations in DMD gene identified during clinical evaluation of patients with autism and/or global developmental delay. *J. Moeschler[1, 2], S. Upton[1], J. Ozmore[1].* 1) Dept Pediatrics, Gen, Dartmouth-Hitchcock Med Ctr, Lebanon, NH; 2) Geisel School of Medicine at Dartmouth, Hanover, NH.

We describe a series of four patients referred for global developmental delay (GDD) or autism spectrum disorder (ASD) who were ultimately diagnosed with mutations in the DMD gene. In two cases, the DMD mutations were identified by chromosome microarray analysis (CMA). In one boy referred for GDD, DMD mutation was identified by Next Gen sequencing. In a third case, a boy with ASD, signs and symptoms for Duchenne muscular dystrophy were noted and supported by marked elevation of serum CK. Case 1. 2 year 3 month old boy referred for GDD and short stature. Developmental ages at 32 months ranged 10–15 months. No history of weakness. Diagnostic evaluation included normal microarray but on 92-gene panel for X-linked intellectual disability demonstrated a stop codon in DMD gene: c.9403C>T (pQ3135X). On this basis, serum CK was obtained with elevation of 18,780 U/L. This patient had no calf psuedohypertrophy, negative Gower sign nor signs of weakness. Case 2. 2 year 9 month old boy referred for ASD, GDD and hypospadias. Developmental delays first noted at 9 months of age. ASD diagnosed in second year of life. Walked late at 24 months. As part of the diagnostic evaluation, CMA demonstrated two pathogenic deletions: 1p36.21-1p36.13 of 1.42 Mb and containing 33 OMIM genes; and, Xp21.1 involving DMD gene. Sequencing of DMD gene demonstrated deletion of exons 49–51. Serum CK was mildly elevated at 351 U/L. Examination was negative. Case 3. 11-year healthy boy whose sister was evaluated for GDD at another center and noted on CMA to have Xp21.1 deletion involving the DMD locus. Asymptomatic mother also had this deletion. Her 11-year old son was evaluated after serum CK elevation of 1081 U/L. This boy had normal neuromuscular exam. Case 4. 4 year 6 month old boy with autism referred for diagnostic evaluation. Mother noted delays and differences in first year of life. The diagnosis of ASD was established in his 3rd year. There was a six-month history of weakness. When seen on the first visit, Gower sign and other signs of weakness were present. Serum CK was 11,456 U/L. Deletion of exon 46 of DMD gene noted on deletion/duplication analysis. These cases demonstrate that: mutations in DMD gene may participate in the pathogenesis of GDD and ASD; “Secondary findings” challenge us to make proper clinical interpretation of genotype-phenotype relationships; and, serum CK screening in all boys presenting with global developmental delays and/or autism be done.

3177W

Copy number variants in monozygotic twins with neurofibromatosis 1. *E. Schorry[1], E. Sites[2], D. Viskochil[3], D. Stevenson[3], N. Ullrich[4], T. Smolarek[1], L. Martin[1].* 1) Div Human Gen, Cincinnati Childrens Hosp, Cincinnati, OH; 2) Children's Memorial Hospital, Chicago, IL; 3) Univ. of Utah, Salt Lake City, UT; 4) Children's Hospital, Boston, MA.

The gene for neurofibromatosis type 1 (NF1) displays extremely variable expressivity. Causes for this variable expression, which occurs within members of the same family and even within monozygotic (MZ) twins, are not yet well understood. We have undertaken a study of copy number variants (CNV) in monozygotic twins with NF1 to investigate possible differences in CNVs underlying the variable expression of NF1 features within twin pairs. We obtained DNA from blood and/or saliva from 11 pairs of proven MZ twins with NF1, who have been well characterized phenotypically and genotyped for NF1. Twin pairs were concordant for many traits such as pectus deformity, learning disability, and overall numbers of café-au-lait spots, but were discordant for other features including optic nerve glioma, scoliosis, plexiform neurofibromas, and MPNST. We tested samples of twins and their parents on the Illlumina 610K SNP-based CGH microarray, which detects microdeletions or microduplications of >80 kb. CNVs were compared within twin pairs and their parents to investigate for de novo changes or association with specific complications. RESULTS: All twin pairs analyzed contained CNVs, with a mean of 8.6 conservative CNVs per twin pair. On average, 3.6 CNVs per twin contained genes. No differences in CNVs to date have been found between co-twins. Several CNVs were located close to genes of potential interest in the Ras pathway, including PTPN20A/B and MAP2K3, and can be investigated as possible modifiers of NF1. One twin pair with severe involvement had a large duplication in chromosome 17 in trans to NF1, located 4.1 Mb from the NF1 gene, which we postulate could make the second allele more susceptible to rearrangement and hence tumorigenesis. SUMMARY: Our study of MZ twins with NF1 has identified several genes and genomic regions which may be of interest for future investigation as modifiers of NF1 phenotype.

A Novel Synonymous Mutation Causing Aberrant Splicing on the SLC26A4 Gene in a Korean Patient with a Hearing loss. *Y. Kim[1], J. Kim[1], J.Y. Choi[2], K-A. lee[1].* 1) Department of Laboratory Medicine, Yonsei University College of Medicine, Seoul, South Korea; 2) Department of Otorhinolaryngology, Yonsei University College of Medicine, Seoul, South Korea.

Mutations in PDS (SLC26A4) cause both Pendred syndrome (PS) and DFNB4, two autosomal recessive disorders that share hearing loss as a common feature. PS/DFNB4 is a genetically homogeneous disorder caused by bi-allelic SLC26A4 mutations. Here, we report a novel mutation (c.1803G>A, p.Lys601Lys) causing an aberrant splicing in a Korean boy who is clinically considered as PS/DFNB4 with congenital hearing loss and dilated vestibular aqueduct (DVA) in temporal bone computed tomography. After extracting DNA from whole blood using standard procedures, 21exons and flanking introns of SLC26A4were PCR amplified. In sequence analysis, we detected a known splicing mutation (c.919-2A>G, heterozygote), but the detection of this single known mutant on SLC26A4 allele was not sufficient to explain PS/DFNB4 phenotype of our patient. Thus, we considered a novel variant (c.1803G>A, p.Lys601Lys) detected in our patient in exon 16 of the SLC26A4 to be a disease causing mutation in our case. According to in silico analysis using the Berkeley Drosophila Genome Project (BDGP)(http://www.fruitfly.org/), the novel variant (c.1803G>A) affected canonical splice donor nucleotide position. To define the effect at transcript level of this novel 1803G>A variant, we have performed exon trapping.

Overlapping anophthalmia syndromes: SOX2, the new kid on the block. *A. Schneider, T. Bardakjian.* Dept Gen, Albert Einstein Med Ctr, Philadelphia, PA.

Anophthalmia is a rare birth defect which is thought to be on the severe end of a continuum of ocular anomalies with microphthalmia and coloboma on the milder end (MAC). MAC can occur as an isolated finding or associated with other anomalies. Many syndromes are known to be associated with these ocular anomalies. Two well described syndromes where anophthalmia may be seen are Septo-Optic-Dysplasia (SOD) and Lenz microphthalmia syndrome. Initial descriptions of mutations in the SOX2 gene were noted to be associated with bilateral severe eye findings including anophthalmia in most cases. The phenotypes of these three syndromes overlap significantly and as more individuals have been tested it is clear that the ocular phenotype associated with SOX2 mutations is very variable. Molecular diagnostics for SOX2 is clinically available and mutations are identified in up to 20% of individuals with bilateral ocular involvement. Molecular testing for SOD and Lenz syndrome is not as successful. We propose that perhaps the diagnostic paradigm should switch to one which utilizes molecular testing for SOX2 immediately in cases clinically thought to be SOD or Lenz syndrome with significant eye findings. Using data from the Anophthalmia / Microphthalmia Clinical Registry and DNA screening project at Einstein Medical Center in Philadelphia, we will demonstrate a significant proportion of individuals who carried a diagnosis of Lenz syndrome or SOD who were identified as having mutations in, or deletions of the SOX2 gene.

Distinct clinical and neurological features in a Korean boy with Schinzel - Giedion syndrome caused by a de novo *SETBP1* mutation. *J. M. Ko, B. C. Lim, K. J. Kim, Y. S. Hwang, C. H. Chae.* Pediatrics, Seoul National University Children's Hospital, Seoul, South Korea.

Schinzel - Giedion syndrome (SGS) is a rare multiple congenital malformation syndrome defined by characteristic facial features, profound developmental delay, severe growth failure, and multiple congenital anomalies including skeletal, renal, genital and cardiac malformations. Most affected individuals die in early childhood mainly due to progressive neurodegeneration and respiratory failure. The causing gene of SGS, SETBP1, has been identified quite recently, and there has been no report of Korean SGS patients with molecular confirmation. In this study, we present a 6-month-old boy with SGS complicated by epilepsy and profound developmental delay. Typical facial features, multiple congenital anomalies, and associated neurological findings could lead to the clinical diagnosis of SGS. The SETBP1 gene analysis revealed a pathologic mutation, p.Gly870Ser, and our patient was molecularly confirmed as SGS first in Korea. Although this syndrome is extremely rare, it is important to consider SGS in the differential diagnosis of infantile-onset neurodegenerative conditions, especially in patients with intractable epilepsy.

3181W

Crisponi Syndrome in a Turkish newborn : a possible founder mutation in the CRLF1 gene? *V. Benoit[1], P. Hilbert[1], M. Deprez[2], A. Charon[3], I. Maystadt[1], S. Moortgat[1].* 1) Centre de Génétique Humaine, Institut de Pathologie et de Génétique, Charleroi, Belgium; 2) Département de Neuropédiatrie, Grand Hôpital de Charleroi, Charleroi, Belgium; 3) Département de Néonatologie, Grand Hôpital de Charleroi, Charleroi, Belgium.

Crisponi syndrome (CS) is a rare, severe, autosomal recessive disorder characterized by congenital contractures of the facial muscles in response to slight tactile stimuli or during crying. The phenotype is complicated by intermittent hyperthermia unrelated to infectious agents, and by respiratory and feeding difficulties. Febrile crises frequently lead to death within the first months of life. Mutations in the cytokine receptor-like factor 1 (CRLF1) gene have recently been described in association with CS. We report here a Turkish patient with clinical presentation and dysmorphic features consistent with CS. Sequencing analysis of the CRLF1 gene showed a non-sense homozygous mutation (c.829C>T, p.Arg277X). This mutation has already been reported in another patient from Eastern Turkey. Considering that our family comes from the central part of this country, we could hypothesize that c.829C>T is an ancient founder mutation. Interestingly, the patient previously described by Okur et al. presents with additional features of velopharyngeal insufficiency, incomplete cleft palate and thin corpus callosum, which were not present for our patient, highlighting the difficulty to establish a phenotype-genotype correlation.

Interference with IS-PCR assays for Inv22 Testing of Hemophilia A. *T. Lewis[1], G. Pont-Kingdon[1], Y. Louie[2], J. Swenson[2, 3].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, Utah; 2) ARUP Laboratories, Salt Lake City, Utah; 3) Department of Pathology, University of Utah Health Sciences Center, Salt Lake City, Utaha.

Introduction: Hemophilia A is a common bleeding disorder affecting 1/5000 male newborns caused by mutations in the F8 gene. In severe hemophilia A (<1% factor VIII), an F8 intron 22-1 inversion is the causative gene defect in approximately 48% of the cases. A 9.5 kb sequence (int22h-1) occurring in intron 22 of the F8 gene and again twice more at telomeric positions allow for intrachromosomal homologous recombination, disrupting the gene. The cascade strategy for individuals affected with severe hemophilia A, or a family history of such, is targeted inversion analysis, followed by full gene sequencing, and finally deletion/duplication analysis. For inversion analysis, many diagnostic laboratories utilize the inverse shifting-PCR (IS-PCR) based approach described by Rossetti et al. in 2005 or the more discriminatory IS-PCR assay detailed by Rossetti et al. in 2008. Description: An asymptomatic African-American female, with a family history of severe hemophilia A, was submitted for carrier testing. Utilizing the IS-PCR strategy, inversion testing revealed apparent homozygosity for the inversion 22 band. As this result conflicted with the clinical information, further investigation was undertaken. Additional testing indicated the presence of two X chromosomes, no observable deletion within the inversion primer regions, and no point mutations under the primers or restriction site. A database search for SNPs in the 21kb wild-type Bcl1 fragment was positive for 144 SNPs, 26 of which were common. One of the common SNPs, rs73563631, creates a novel BclI restriction site. Primers were designed to amplify the region containing this variant in our patient and the product sequenced; the results indicated that our patient was positive for the SNP variant. Implications: The creation of a novel BclI restriction site in intron 22 of F8 by the SNP rs73563631 results in two BclI fragments. Ligation of the fragments creates two products, neither of which contains both primer sites for the inverse shifting-PCR assays. The effect is such that the wild-type product will not be observed in an inversion carrier female or a non-inversion male. This was the case in an additional patient, an African-American male, who had no observable bands on the inversion 22 assay. In a non-inversion female, the wild-type band will be seen but will be mistakenly interpreted as two copies. The SNP rs73563631 has an overall population frequency of 1% but is observed in 4.5% of Africans.

Complex Ear Abnormalities, Choanal Atresia, Coloboma and Renal Hypoplasia in a Patient with Mutations in *CHD7* and *EYA1* and Microdeletion of 2q23.1. *R. Badilla-Porras[1], L. Dupuis[1], T. Stockley[2], D.J. Stavropoulos[2], R. Mendoza-Londono[1].* 1) Division of Clinical and Metabolic Genetics, Hospital for Sick Children and University of Toronto, Toronto, Canada; 2) Division of Molecular Genetics, Department of Paediatric Laboratory Medicine, The Hospital for Sick Children and University of Toronto, Toronto, Canada.

Abnormal ear morphology is a feature of many genetic syndromes. In combination with iris coloboma and renal hypoplasia, it raises concern for three common diagnoses: CHARGE syndrome, Branchio-Oto-Renal syndrome (BOR) and chromosomal aberrations. CHARGE syndrome is an autosomal dominant condition characterized by coloboma, heart defects, choanal atresia, retarded growth and development, genital hypoplasia and ear anomalies/deafness. *CHD7* is the only gene currently known to be associated with CHARGE syndrome. BOR syndrome is characterized by malformations of the outer, middle, and inner ear associated with conductive, sensorineural, or mixed hearing impairment. Patients have branchial fistulas and cysts, and renal malformations ranging from mild renal hypoplasia to bilateral renal agenesis. Molecular genetic testing of the *EYA1* gene detects mutations in 40%; of individuals with this clinical diagnosis. We present the case of a female that developed perinatal oligohydramnios. At birth she was found to have bilateral choanal atresia, cupped ears with middle and inner ear abnormalities (absent semicircular canals and hypoplastic oval window), bilateral chorioretinal colobomas, atrophic optic nerves, facial asymmetry, right preaxial polydactily and hypoplastic kidneys and external genitalia. Family history was positive for branchial cyst and duplication of renal collecting system in the patient's father. Sequencing of *CHD7* revealed a pathogenic *de novo* mutation in exon 11 of the *CHD7* gene c.2905_2906del (p.Arg969fs), confirming a diagnosis of CHARGE syndrome. Given the family history, we performed sequencing of *EYA1* in the father and identified a mutation in exon 15 c.1460C>T (p.Ser487Leu) confirming a diagnosis of BOR. This mutation was inherited by his daughter. Array comparative genomic hybridization revealed a paternally inherited 0.059 Mb microdeletion on chromosome 2q23.1 encompassing intronic sequences of the MBD5 gene. At this time the developmental implications of the microdeletion and the contribution to the overall phenotype in this patient is being investigated. To the best of our knowledge, our patient is the first example of mutations in *EYA1* and *CHD7*and a chromosomal microdeletion in the same individual. This case highlights the clinical variability and overlap in the phenotype of patients with CHARGE and BOR syndromes. Detailed analysis of the phenotype demonstrates the additive effect of these two mutations on normal development.

3184F

Severe CHST3 mutations in two Brazilian families with spondyloepiphyseal dysplasia with congenital joint dislocations. *W.A.R. Baratela[1], T.F. Almeida[1], G.L. Yamamoto[1], J.H. Marques[1], O. Letaif[2], A.C. Pereira[3], C.A. Kim[1], D.R. Bertola[1].* 1) Unidade de Genética, Instituto da Criança - Hospital das Clínicas - Universidade de Sao Paulo, Sao Paulo, SP, Brazil; 2) Orthopedics Department, Hospital das Clínicas, Universidade de Sao Paulo, Sao Paulo,SP, Brazil; 3) Laboratório de Genética e Cardiologia Molecular, InCor, Universidade de Sao Paulo, SP, Brazil.

Spondyloepiphyseal dysplasia with congenital joint dislocations (SED-CJD) has been previously named as recessive Larsen syndrome, humerospinal dysostosis, spondyloepiphyseal dysplasia - Omani type, and chondrodysplasia with multiple dislocations, and is characterized by dislocations of elbows, hips, and knees at birth, with typical lumbar vertebrae changes, normal carpal age, recessive inheritance, and absence of facial flattening. Carbohydrate sulfotransferase-3 deficiency caused by CHST3 mutations is responsible for SED-CJD. We describe 3 individuals from 2 distinct consanguineous families from Brazil, with SED-CJD, and positively tested for CHST3 mutations. Patient 1 is an 8y4mo boy, born from a first cousin couple, by cesarian section, 2kg of BW, 44cm of BL, with dislocated knees and clubfeet. At current age he is 108 cm tall (<5th%ile), camptodactyly, bilateral radioulnar subluxation, dextroscoliosis are seen, and his knees are still dislocated. Patient 2 is the youngest sister, with 4y4mo. Positive nuchal translucency along with oligohydramnios, were seen during prenatal ultrasound. She was born preterm, cesarian section, BW 1910g, BL 35cm. Bilateral hip and right knee dislocation, and right clubfoot. At her last follow up, she was 81cm tall (<5th%ile), OFC was 48cm, and she had phalangeal, elbows, and knee joints contractures. Patient 3 is a 3y11mo boy, born from a first cousin couple, at term, BW 2500g, BL unknown, and OFC 34cm. He had bilateral hip and knee dislocation, and left side clubfoot. At current physical exam he is 81cm (<5th%ile), 50cm OFC, brachycephaly, opalescent and brittle teeth, and small ears are seen. Skeletal surveys of the 3 patients were strikingly similar, with a mildly progressive epiphyseal involvement. There is an increase and posterior decrease, in the interpedicular distance and vertebral endplate irregularities. Molecular studies for the 3 patients were directed for CHST3 mutations analysis. The 2 siblings had a IVS2-1G>C and c.141G>C homozygous mutation, with R47S substitution and putative missplicing. Patient 3 showed a c.718A>T p. K240X, nonsense mutation at homozygosity. The two families present a typical skeletal involvement, with dislocations at different sites evident at birth and severe mutations, giving further support to the fact that profound effects on CHST3 protein are responsible for the full-blown phenotype.

Computer-aided facial recognition of individuals with FG (Opitz-Kaveggia) syndrome caused by p.Arg961Trp mutation in MED12. *L. Basel-Vanagaite[1,2,3], L. Karlinsky[2], L. Wolf[2,3], M. Shohat[1,2,3], C. Skinner[4], C. Rogers[4], R. Stevenson[4], C.M. Schwartz[4], J.M. Graham, Jr.[5].* 1) Schneider Children's Medical Center of Israel, Raphael Recanati Genetics Institute, Rabin Medical Ctr and and Felsenstein Medical Research Center, Petah Tikva, Israel; 2) FDNA Ltd., Herzlyia, Israel; 3) Tel Aviv University, Tel Aviv, Israel; 4) J.C. Self Research Institute, Greenwood Genetic Center, Greenwood, SC, USA; 5) Medical Genetics Institute at Cedars-Sinai Medical Center, Los Angeles, CA, USA.

FG (Opitz-Kaveggia) syndrome is an X-linked recessive syndrome characterized by relatively large head, frontal upsweep, hypertelorism, ptosis, small ears, broad and flat thumbs, imperforate anus, hypotonia, agenesis of the corpus callosum and moderate intellectual disability. The classical form of FG syndrome is caused by a recurrent p.Arg961Trp mutation in the MED12 gene. FG syndrome is misdiagnosed and recent literature confirmed that several patients with similar features had microdeletion/microduplication syndromes and syndromes caused by FLNA mutations. With the advent of novel automatic face analysis techniques, our ability to analyze facial morphology from photographs has improved significantly. In this study we examined whether a computer-based dysmorphological analysis can be used in order to discern between FG patients and non-FG patients that present superficially similar facial features. For this, we used a collection of 18 genetically verified FG cases and 18 non-FG cases that were clinically suspected to be FG but do not carry mutations in the MED12 gene. A modern face analysis system that was developed specifically for dysmorphological analysis was used. The system is fully automatic and starts by detecting the face in the image. Then, 130 facial fiducial points are localized and various measurements are taken. The final classification is based on these measurements as well as on a global “gestalt” detector that estimate the probability of the subject having FG based on the appearance of the entire facial image. A statistical technique called cross validation was used to estimate the recognition capability of the computer system. At each one of 20 rounds, the data was split randomly to training and testing data, each comprising of 50% of the samples. The system was trained to separate between the two classes using the train dataset, and evaluated on the test data. The statistical power of the test in correct recognition of FG patients with the p.Arg961Trp mutation was estimated using the conventional recognition metric of average area under the ROC curve and was 90%, which is considered very high. The gestalt of the face as captured by multiple local patterns of facial texture contributed significantly to the correct recognition of the individuals with FG syndrome. Overall, we have demonstrated that computer-based analysis can be successfully used in supporting experts for the correct recognition of patients with FG syndrome.

3186F

Hand abnormalities in Loeys-Dietz syndrome: Expanding the clinical spectrum. *B. Chung[1], A. Hinek[2], T. Bradley[3], L. Grossse-Wortmann[3], S. Blaser[4], D. Chitayat[5,6].* 1) Paediatrics & Adol Med, The University of Hong Kong, Hong Kong; 2) Division of Cardiovascular Research, The Hospital for Sick Children, Toronto; 3) Division of Cardiology, The Hospital for Sick Children, Toronto; 4) Division of Neuroradiology, The Hospital for Sick Children, Toronto; 5) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto; 6) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto.

Loeys-Dietz syndrome is an autosomal dominant connective tissue disorder characterized by clinical manifestations including hypertelorism, bifid uvula and cleft palate, and arterial tortuosity. We report a patient with LDS with a mutation in the TGFBR2 gene who presented prenatally with clenched fist and clubbed feet and postnatally was found to have digital abnormalities including brachydactyly, camptodactyly, partial syndactyly and absent phalanges. The proband was the first baby born to a healthy non-consanguineous couple. The pregnancy was initially uneventful and fetal ultrasound at 21 wks showed bilateral club feet, small penis, mild right pelviectasis and a clenched right hand with abducted thumb. Amniocentesis showed a normal male karyotype and normal aCGH. Delivery was at 39 weeks gestation and uncomplicated. His birth weight was 4.490kg (>+2SD), the length was 50cm (mean) and his OFC was 39cm (> +2SD). He had ridges over multiple sutures, hypertelorism, retro-micrognathia, umbilical hernia, a right inguinal hernia and clenched hands. His left hand had a proximally inserted thumb and 3rd-5th finger camptodactyly. His right hand had a small, proximally inserted thumb with a hypoplastic distal phalanx. The 2nd- 4th fingers were bi-phalangeal with symphalangism and the 5th finger had a short mid-phalanx. There was skin syndactyly connecting the 2nd-3rd and 3rd-4th fingers. There were bilateral club feet, abnormal cervical vertebrae and mild thoracic scoliosis. Echocardiography showed a quadricuspid pulmonary valve, aortic root and main pulmonary artery dilatation and a large ductal aneurysm. Mutation analysis of the TGFBR2 gene showed a known pathogenic mutation c.1583G>A/p.Arg528His which confirmed the diagnosis. Subsequent imaging demonstrated generalized arterial tortuosity. Immunohisto-chemical staining of his skin fibroblasts showed intracellular accumulation of collagen type I in the presence of otherwise normal elastic fiber production, compatible with LDS associated with TGFBR2 mutations. The most common clinically important skeletal abnormalities in LDS include cervical vertebrae anomalies and instability, spinal cord abnormalities and foot deformities [Erkula et al., 2010]. Syndactyly and brachydactyly have not been reported in LDS and expand the spectrum of this condition. Recognition of all of the skeletal changes in LDS is important as they can be the earliest manifestation in this multi-system connective tissue disorder.

Gorlin Syndrome: Three unrelated female Mexican cases. *NO. Davalos[1,4], SA. Alonso Barragan[2,5], IM. Salazar-Davalos[3], MA. Aceves-Aceves[3], SA. Ramirez-Garcia[1], LR. Topete -Gonzalez[1,4], DA. Fierro-Rodriguez[1,4], DM. Prado[1,4], AR. Rincon-Sanchez[1], IP. Davalos[1,5], D. Garcia-Cruz[1].* 1) Institut of Human Genetics, Centro Universitario de Ciencias de la Salud,, Universidad Guadalajara, Guadalajara, Mexico,; 2) Doctorado en Genetica Humana, CUCS UdeG; 3) Facultad de Medicina, CUCS, U de G; 4) Genetica, Hospital Regional VGF, ISSSTE; 5) Genetica, Centro de Investigacion Biomedica, CIBO IMSS, Guadalajara Jalisco Mexico.

Introduction: Gorlin syndrome (GS) or Nevoid basal cell carcinoma syndrome (NBCCS), is charaterized by basal cell nevi, facial dysmorphology, odontogenic keratocysts and skeletal anomalies, is an autosomal dominant inheritance disease, with 97% penetrance and variable expressivity; about 40% of cases represents de novo mutations. The prevalence reported,1/57,000, with a sex ratio M:1:F:1. Report: We present three unrelated female cases, with other clinical findings not previously reported. Case I: 10 years-old, with family history of GS. At 11 months-old umbilical hernia is diagnosed. At 2 years-old, was diagnosed adduct foot and genu valgus. Oral findings shown dental malocclusion, within evidence of jaw cysts. Skin with nevi in face neck and multiple plantar pits detected. Dyslexia and intellectual disability presents. The CT scan revealed frontal-cortical atrophy and dilated lateral ventricles due to atrophy. Case II: 19 years-old. At 15 years-old detected nevi on scalp, removed and histolgically shown basal cell carcinoma. At 16 years-old detected maxilar and mandibular cysts. Radiologically shown calcification of the falx cerebri, broad ribs; calcification of vertebral bodies and rotation at T1-T3 and bifid spine. Case III: 40 years-old. At 10 years old maxilar and mandibular cysts diagnosed. Ophthalmologically presents right eye chalazion with sebaceous secretion. The proposita became pregnant three times, which ended in abortion, detected by US bicournate uterus. CT scan shown posterior fossa calcification, on straight sinus and cerebellar vermis that resemble a “Y” image; cortical atrophy detected and subcortical vascular lesions of the small vessels; mild hydrocephalus. Neuropsychological assessments reported, pause speech alterations. Discussion. We diagnosed three unrelated female cases with Gorlin Syndrome. Shown the clinical and radiological findings of the syndrome. In our cases we presented clinical and radiological findigs not described in Mexican cases, such as, cortical atrophy, presents in case II and III, multiple cortical calcifications. Neuropsychological abnormalities, dyslexia and neuropsychomotor deficit are an uncomun findings; as well as rotation of the lumbar vertebral bodies, that could be diagnosed in childhood. The bicornuate uterus could be the response of the repetitive abortions. This cases shown the wide spectrum of the GS, and suggests a detailed multidisciplinary study for search new findings in patients with GS.

3188F

Diamond-Blackfan Anemia: A Case Report and Seven-Year Follow Up. *M.G. González-Mercado[1,2], L. Bobadilla-Morales[1], N.O. Dávalos[1], D. García-Cruz[1], A. Corona-Rivera[1], C.E. Monterrubio-Ledezma[1], I.M. Salazar-Dávalos[3], A. González-Mercado[1,2], M.A. Aceves-Aceves[3], I.P. Dávalos[1,2].* 1) Doctorado en Genética Humana, Instituto de Genética Humana, CUCS, Universidad de Guadalajara; 2) División de Genética, Centro de Investigación Biomédica de Occidente, IMSS; 3) Facultad de Medicina, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México.

Diamond-Blackfan Anemia (DBA) (OMIM #105650) is an autosomal dominant entity characterized by congenital erythroid aplasia and in 30–40% of patients have other congenital anomalies. Approximately 10–25% of DBA cases are familial. Genetic heterogeneity has been reported in DBA and it is related to *RPS19* gene located on 19q13.3. Blood test could show high adenosine deaminase activity (ADA). **Case report:** The proposita aged 7 years old, was born from non-consanguineous parents, mother apparently healthy, the father was referred as affected with anemia. At birth was detected with acrocyanosis and the echocardiogram reported left ventricular dilatation with mild dysfunction and myopericarditis, also she presented hepatomegaly and decompensated anemia, treated with blood transfusion in two occasions. At 3 months she had recurrence of severe anemia without a primary cause (Hb 3.4, Hto 9.9) treated with blood transfusion. A bone marrow analysis was reported with decrease of the dysplastic erythroid normoblasts with some asynchrony in maturation. White blood cells reported all stages of maturation of normal appearance and an appropriate platelet production. At 7 months, a haematological study reported no alteration of Hb or red cell membranes and the diagnosis of pure red cell aplasia was confirmed and was started treatment with prednisone. Physical examination at 4 years 11 months she presented weight of 12kg (<p3), height of 99cm (p10) and OFC of 46.5cm (<p3), generalized pallor, microcephaly, small forehead, sparse eyebrows, almond shaped eyes, large philtrum, thin lips, micrognathia, thenar hypoplasia and digitized thumbs. The psychomotor development was normal. At 7 years presented weight of 16kg (<p3), height of 110cm (p10) and OFC of 47.7cm (<p3). The karyotype and chromosomal instability study were normal. The ADA quantification was 17.8 U/L (0-15U/L). She has been treated with prednisone, folic acid and B complex until now. **Conclusions:** The clinical and laboratorial studies lead us to diagnose DBA in the present case. Differential diagnosis includes ribosomopathies, Shwachman-Diamond syndrome and Fanconi anemia. The treatment in DBA is based on corticosteroids, blood transfusion therapies and stem cell transplantation, although it is known that only bone marrow transplant is a cure for DBA. This patient has been treated with steroids and blood transfusions with a favorable outcome.

Familial Beare-Stevenson cutis gyrata syndrome in the absence of craniosynostosis. *E. Leon[1], J. Jung[2], M. Ririe[2], D. Stevenson[1].* 1) Genetics, University of Utah, Salt Lake City, UT; 2) Dermatology, University of Utah, Salt Lake City, UT.

Beare-Stevenson cutis gyrata syndrome consists of skin furrows of corrugated appearance, acanthosis nigricans, craniofacial anomalies (particularly craniosynostosis and ear anomalies), anogenital anomalies, skin tags, and prominent umbilical stump. Cutis gyrata variably affects the scalp, forehead, face, preauricular area, neck, trunk, hands, and feet. Craniosynostosis is present in most of the cases and only rare cases have been reported with normal skull development. This syndrome has been reported to be caused by mutations in the *FGFR2* gene. We report a 1-month-old baby girl (proposita) and her 29-year-old mother with variable degree of cutis gyrata and normal cranium. The proposita was born full term to a 29-year-old primagravida mother and a nonconsanguineous 31-year-old father. Prenatal history was remarkable for preeclampsia. Delivery was uncomplicated. Apgar scores were 7/8. Growth parameters: birth length (50th centile), weight (10th centile) and head circumference (75th centile). At her first evaluation a skin tag on the scalp was noticed along with skin furrows of corrugated appearance with vertical orientation on the forehead, and circular skin furrows on posterior aspect of her scalp. Her ears had multiple preauricular creases, large lobules, and prominent antitragus. A nevus flammeus on forehead and deep creases on palms and soles were also present. Her mother, who is cognitively normal, had the same skin finding on the forehead when newborn which are now attenuated as well as the preauricular creases. *FGFR2* gene testing is pending. The above family represents a likely autosomal dominant cutis gyrata condition. The skin tags and location and appearance of the cutis gyrata are strikingly similar to the cases of Beare-Stevenson syndrome reported in the literature. We propose that these two individuals are part of a broader phenotypic spectrum of this rare disorder. Few patients with Beare-Stevenson syndrome have been tested for *FGFR2* gene analysis and to our knowledge none of the patients with normal craniums had genetic testing. In addition, this family would be the first reported familial case of Beare-Stevenson syndrome. Documentation of a pathogenic mutation in *FGFR2* in our patients will provide evidence of phenotypic variability. However, at this time genetic heterogeneity cannot be excluded.

Report of a novel mutation in the SLC26A2 gene found in a Colombian adult patient with Diastrophic Dysplasia. *T. Pineda[1], A. Rossi[2], L. Bonafé[3], A. Superti-Furga[3], H. Velasco[4].* 1) Genetics Institute, National University of Colombia, MD; 2) Department of Biochemistry "Alessandro Castellani", University of Pavia, Pavia, Italy; 3) Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 4) Morphology Department, Genetics Institute, National University of Colombia, MD, MSc,E.

Diastrophic Dysplasia is an osteochondrodysplasia belonging to the group of dysplasias caused by mutations in the diastrophic dysplasia sulfate transporter. This syndrome is a micromelic dysplasia with multiple bone deformities of the hands, feet, knees and spine. In this paper we report the case of a Colombian adult patient with diastrophic dysplasia whose clinical diagnosis was confirmed at the molecular level. In this first report of diastrophic dysplasia in Colombia we found that the patient was compound heterozygote for the already reported Arg279Trp substitution and an unpublished mutation, a Ser157Thr substitution in the SLC26A2 gene. Bioinformatic analysis on the latter mutation suggested that it could correspond to a deleterious mutation because it is found in a highly conserved domain of the sulfate transporter.

3191W

Intragenic NSD1 duplication of exons 14–17 in a patient with Sotos syndrome. *S. Ramanathan, R.D. Clark.* Pediatric Genetics, Loma Linda University, San Bernardino, CA.

We describe the second report of Sotos syndrome caused by an intragenic duplication in the NSD1 gene. In Sotos syndrome, characteristic facial features, overgrowth, and developmental/cognitive disabilities are caused by haploinsufficiency of the NSD1 gene. Gene sequencing detects mutations in 83–90% of clinically diagnosed individuals. Microdeletions of chromosome 5q35, encompassing the NSD1 gene, are found in 10% of non-Japanese patients. Partial NSD1 gene deletions of one or more exons are reported in about 5% of patients. Intragenic duplications, however, are rare. Our patient, now a 2-year old Hispanic male, was the product of a pregnancy notable for a 6 lb weight gain. He was born at 40 4/7 weeks by vacuum-assisted vaginal delivery with a birth weight of 4.77 kg, birth length 61 cm and head circumference 38 cm, all of which were over the 98th percentile. He was in the NICU for 3 weeks for respiratory distress and tremors. He had a tall forehead with dolicocephaly, downslanting palpebral fissures with puffy periorbital tissue and hypertonia. Increased extra-axial space, seen on brain MRI, later resolved. An abdominal ultrasound was normal, with no organomegaly. Bilateral strabismus has resolved. The diagnosis of Sotos syndrome was suggested by his clinical features. Sequencing of the NSD1 gene was negative. Chromosome analysis and oligo-SNP microarray were normal. MLPA analysis of the NSD1 gene detected an intragenic duplication of exons 14–17. Parents declined testing, but have no suggestive features of Sotos syndrome. The patient continues to be over the 98th percentile on all growth parameters with global developmental delays. We found only one published report of Sotos syndrome in a patient with an intragenic duplication of exon 4 (Saugier-Veber P et al. 2007). There is also one report of a 4-year-old girl with clinical features of Sotos syndrome with a 264 kb duplication on chromosome 5q35, downstream of, but not including, the NSD1 gene (Kasnauskiene J et al., 2011). On the contrary, patients with microduplications that include the entire NSD1 gene, spanning 650 kb to 6.5Mb, have microcephaly and growth retardation (Zhang H et al., 2011). In our patient, a duplication of exons 14–17 produced the classic findings of Sotos syndrome. This case illustrates the importance of including analysis for NSD1 deletions or duplications when gene sequencing and microarray studies are negative.

3192F

Craniosynstosis as a bone anomaly of Kabuki syndrome. *A. Shimada[1], I. Tamada[2], H. Yoshihashi[3].* 1) Div of General Practice, Tokyo Metropolitan Children's Hos, Fuchu-shi, Japan; 2) Div of Plastic and Reconstructive Surgery, Tokyo Metropolitan Children's Hos, Fuchu-shi, Japan; 3) Div Med Gen, Tokyo Metropolitan Children's Hos, Fuchu-shi, Japan.

Introduction: Kabuki syndrome(KS) is acongenital syndrome characterized by distinctive facial features, skeletal anomalies, persisting of fetal fingertip pads, postnatal growth deficiency, and intellectual disability. MLL2 (12q12-q14) was identified as causative gene of KS in 2010. As noted above, skeletal anomalies are one of the characteristic features of KS. Although various skeletal anomalies, such as vertebral defects and rib anomalies, were widely recognized in KS, craniosynostosisis had not been highlighted as comorbid skeletal anomaly of KS. There had been five cases of KS with craniosynostosis reported so far, but none of these cases were genetically diagnosed. We present two cases of KS with craniosynostosisand compare with the clinical features of previously reported cases. Material and methods:Case1. 5mth-male. 37w0d, 2630g. He had distinctive face, clinodactyly of fifth digits, developmental delay, postnatal growth deficiency, ASD, and hearing difficulties. A mutation analysis of MLL2 revealed a mutation in exon 39(c.12368C>A,S 4 123X). His head X-ray had showed mild craniosynostosis requiring no surgical treatments. Case 2. 16y-female.38w0d, 2860g. She had typical facial features, craniosynostosis, scoliosis, persistence of fetal finger tips,intellectual disability, postnatal growth deficiency, ASD, and left hydronephrosis. She was followed as craniosynostosis syndrome with multiple anomalies until 16 year-old. A surgical intervention for craniosynostosis was made in other hospital in 4mth-old.Despite of surgical treatments, her head deformity remained. Her parents brought her to our plastic surgeon and the diagnosis of KS was firstly made when she was 16 year old. Surgical treatmentis planned in our institution for cosmetic reason.Discussion:Craniosynostosis has not been recognized as striking structural anomalies in KS but it could be relatively frequent comorbid structural anomaly than it is noted before. KS should be considered when evaluating children with intellectual disabilities and postnatal growth deficiency in addition to craniosynostosis. Craniosynostosis in KS varies in severity as we experienced. Long-term follow up will be recommend since a surgical intervention is necessary in severe case. Further accumulation of cases and genetic study may provide insight into the clinical characteristics of craniosynostosis in KS.

3193W

The variable spectrum of SMAD4 mutations. *J. van den Ende[1], N. Van der Aa[1], T. Boiy[2].* 1) Dept Med Gen, Univ Hospital, Antwerp, Edegem, Belgium; 2) Dept Pediatrics, Univ Hospital Antwerp, Edegem, Belgium.

The SMAD4 gene on chromosome 18q21.1, previously known as MADH4, encodes a protein involved in signal transduction of the TGF-beta superfamily and Bone Morphogenetic Proteins (BMP`s). SMAD 4 comprises 11 coding exons and pathologic allelic variants in the different domains can have various consequences. Several syndromes have been described as a result of mutations in SMAD4. The SMAD4 gene was first identified as a tumor suppressor gene involved in human pancreatic carcinoma (Hahn et al. 1996) and later as one of the causes of Juvenile Polyposis Syndrome (JPS) (Howe, 1998). This syndrome is characterized by predisposition to hamartomatous polyps in the gastrointestinal tract, sometimes with malignant transformation. It is caused by mutations in BMPR1A or in SMAD4. About 15–22% of patients with JPS due to SMAD4 mutations also show symptoms of Hereditary Hemorrhagic Telangiectasia (JPS/HHT). HHT is characterized by the presence of multiple arteriovenous malformations, in the skin (telangiectasia), nose (frequent nose bleedings), lungs, liver and brain. The majority of cases is caused by mutations in the ENG gene or in the ALK1 gene. 1–2% Of persons with clinically HHT show a SMAD4 mutation. Probably variable expressivity and/ or age related penetrance play a role and all patients with a SMAD4 mutation might be at risk for both conditions. The most recent syndrome attributed to SMAD4 mutations is the Myhre syndrome, a developmental disorder with short stature, facial dysmorphism, muscular hypertrophy, deafness and developmental delay. Patients with this syndrome show heterozygous mutations in the MH2 domain of the SMAD4 gene, necessary for SMAD oligomerizaton and TGFB/ BMP signal transduction. We present 3 patients with SMAD4 mutations, one with JPS/HHT and 2 patients with Myhre syndrome, and discuss the role of SMAD4 in the different disorders.

A new frontonasal dysplasia syndrome associated with SIX2 deletion.

S.L. Zimmerman, H.M. Saal, Z.M. Ahmed, R.B. Hufnagel. Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Craniosynostosis is premature closure of the cranial sutures. Several genes including FGFR1, FRFR2, FGFR3, TWIST and SIX3 have been implicated. However, mutations of these genes have only rarely been implicated in sagittal suture synostosis. We present a 22 month old female with sagittal synostosis and dysmorphic features including frontal bossing, hypertelorism, ptosis with epicanthus inversus, wide lateral palatine ridges, depressed nasal bridge and a broad nasal tip. Genetic analysis showed a normal female karyotype or 46,XX and normal molecular studies for the genes most commonly known to cause craniosynostosis. However, SNP microarray identified a 108.3 kb deletion on chromosome 2p21 that included the SIX2 gene. The SIX2 gene is a homeobox containing transcription factor shown to play an essential and evolutionary conserved role during early development in mice, Xenopus and Drosophila. Significantly, her mother had similar dysmorphic features including, ptosis, dental diastasis, broad nasal tip, frontal bossing and was identified with having the same SIX2 hemizygous deletion. Studies in Six2-/- mice document similar craniofacial features and in addition renal dysplasia However, Six2 heterozygote mice did not show the craniofacial or renal defects. Our data supports that loss of the SIX2 function affects craniofacial development and lead to a novel frontonasal dysplasia syndrome. The specific mechanism of how the SIX2 gene affects craniofacial development is yet to be determined and further studies will include looking at regulation of SIX2 and a neighboring SIX3 gene in this patient's derived cell lines.

Importance of Orofacial Features and The Role of Dentistry in The Early Diagnosis of Developmental Disorders. *Z. Öncel Torun[1], D. Torun[2], K. Karaer[2], RO. Rosti[2].* 1) Dept. of Restorative Dentistry and Endodontics, Gulhane Military Medical Academy, Ankara, Turkey; 2) Dept. of Medical Genetics, Gulhane Military Medical Faculty, Ankara, Turkey.

Dental development disorders are seen as quite often in patients with developmental disabilities. But in the field of dentistry, patients with prominent craniofacial features are occasionally defined. Aim of the present case series was to provide oral data from three unrelated patients affected with cleidocranial dysplasia, pycnodysostosis and hallermann-streiff syndromes. All patients underwent regular dental investigation in the first examination. Unusual facial appearance and dental abnormalities has given rise to thought developmental impairment. Consultation with specialist in medical genetics and further laboratory assessments allow to the right diagnosis and treatment planning of the patients. This study suggests that dentist's familiarity with dental features of genetic diseases may affect the process of diagnosis and treatment of patients. In this process, consultation with clinical geneticist allows a valuable estimate of prognosis and the anticipation of complications.

3196F

Renin receptor/ATP6AP2 gene mutation: An X-linked cause of mental retardation, postnatal microcephaly and intractable seizures. *D. Chitayat[1,2], K. Sirewanda[2], R. Mendoza[2], S. Blaser[3], J. Raiman[2], J. Jessen[1], E. Donner[4], C. Schwartz[5].* 1) Prenatal Diag & Med Gen, Mount Sinai Hosp, Toronto, ON, Canada; 2) Department of Pediatrics, Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) 1Department of Pediatrics, Division of Neuroradiology, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Pediatrics, Division of Neurology, The Hospital for Sick Children, Toronto, Ontario, Canada; 5) Greenwood Genetic Center, 106 Gregor Mendel Circle, Greenwood, SC, USA.

The (pro)renin receptor [(P)RR] is abundantly expressed in heart, brain, placenta and eye. A mutation in the(P)RR gene, resulting in frame deletion of exon 4[4-(P)RR] was reported in association with X-linked mental retardation (XLMR) and epilepsy pointing to a novel role of (P)RR in brain development and cognitive function. We report the second case of XLMR and seizures associated with a de novo mutation in the (P)RR gene. The patient was the first child born to a 31-year-old healthy couple of Ashkenazi Jewish descent. The couple was healthy and non-consanguineous and their family history was non-contributory. The pregnancy was uncomplicated and delivery was at 39 weeks via emergency C-section. He was noted to have mild facial dysmorphism including a short forehead, bitemporal narrowing, flat and broad nasal bridge, bilateral epicanthic folds, almond shaped eyes, long eye lashes, long philtrum, microretrognathia and high arched palate. His ears were prominent and he had multiple flat hemangiomatous lesions on the face and body. At two weeks of age he was noted to have episodes of eye blinking, head turning and upper and lower limb twitching lasting 5–15 seconds that occurred up to 10 times a day. At one month of age his head circumference (OFC) was at the mean, his weight at the 50th-75th centile and his length at the 50th centile. He was noted to be alert and active and moved all four limbs symmetrically. His muscle bulk and tone were normal and his DTRs were +2. During the next 6 months he developed intractable seizures and at 6 months he was hypotonic with complete head lag, was not interactive and was unable to roll over or grab objects. He did not fixate or track and his OFC was at -1.5SD. He developed limbs' spasticity, his intractable seizures continued and his OFC centiles decreased being <-2SD at 3 years. His initial MRI showed diffuse supratentorial cerebral volume loss and a repeat showed delay in myelination with significant cerebral atrophy. DNA analysis for the XLMR panel showed a de novo variant in the ATP6AP2 gene [c.301-11_301-10delTT]. Analysis of membrane associated-receptor molecular forms showed the presence of full-length and truncated proteins in the patient. Our findings confirm the importance of the renin-angiotensin system and the renin receptor in brain development and cognitive function.

SCN1B sequence variations in Iranian Patients with Epilepsy, causality or susceptibility? *A. Ebrahimi[1,2], M. Moghaddasi[3], M. Houshmand[4], S. Zeinali[5], S.H. Tonekaboni[6], M.S. Fallah[5], M. Mamarabadi[3], Moghaddasi, M.* 1) Hematology Research Center, Shiraz University of Medical science, Shiraz, Fars, Iran; 2) Parseh medical Genetics Center, Tehran, Iran; 3) Rasool Akram Hospital, Tehran University of Medical Sciences, Tehran, Iran; 4) National Institute of Genetic Engineering and Biotechnology (NIGEB), Tehran - Karaj Highway, Tehran, Iran; 5) Kawsar Human Genetics Research Center, KAWSAR Genomics & Biotech Center, Tehran, Iran; 6) Shahid Beheshti University of Medical Sciences, Tehran, Iran.

Epilepsy is a common chronic neurological disorder that is characterized by recurrent unprovoked seizures. Molecular studies of candidate genes can help us to define a correct differential diagnosis. So we studied SCN1B gene in Iranian patients with Idiopathic Epilepsy includes Febrile Seizure, Generalized Epilepsy with Febrile Seizures (GEFS+) or Dravet syndrome, diagnosed clinically, to explain genotype-phenotype correlation. Materials and Method: We screened 34 selected epileptic unrelated Iranian probands for all coding regions of SCN1B by PCR amplification and direct Sequencing. All families and probands were previously screened for SCN1A and mtDNA mutations. Results: PCR amplification of whole coding regions and splicing sites of SCN1B followed by direct sequencing revealed two novel sequence variations in patients (p.R248S, p.L210P) which did not detected in the healthy normal family members. Conclusions: According to final results it seems that these two novels SCN1B variations are not causative mutations in epileptic patients' but they can act as genetic predisposition factors in epileptic phenotypes which introduce a susceptibility especially in response to antiepileptic drugs.

3198F

A novel KCNQ2 mutation in a mexican-american family with benign familial neonatal convulsions. *A. Sznewajs[1], E. Rider[2], E. Sherr[1, 2].* 1) Pediatrics, University of California, San Francisco, San Francisco, CA; 2) Child Neurology, University of California, San Francisco, San Francisco, CA.

Background: Benign familial neonatal convulsions (BFNC) is a rare autosomal dominant epileptic disorder that results from mutations in two voltage-gated potassium channels, KCNQ2 (20q13.3) and KCNQ3 (8q24). The majority (92%) of reported mutations are found in KCNQ2. The purpose of this study was to perform mutation screening of KCNQ2 and KCNQ3 in order to identify a disease-causing mutation in a three-generation Mexican-American family with BFNC. Methods: A BFNC family was identified at the University of California, San Francisco Children's Hospital after admission of the proband, a 3-day old female infant with a 1 day history of unprovoked, nonfebrile neonatal seizures. The family history was significant for a mother, two maternal uncles and a maternal grandmother with a history of BFNC. After informed consent, mutation screening of KCNQ2 and KCNQ3 was performed in affected family members and the proband's father in order to identify the disease-causing mutations. Results: A novel heterozygous 65 base pair deletion was found in the 3 prime region of exon 3 in KCNQ2, encompassing the splice site region of all 5 affected family members. Restriction enzyme analysis was performed using the unaffected family member as a control, thereby confirming the deletion. No other mutations were found in KCNQ2 or KCNQ3. Conclusions: Here we report a three-generation Mexican-American family with a large novel KCNQ2 deletion. These findings are consistent with prior studies which show that large deletions in KCNQ2 (49-479 kbp) comprise a substantial amount (16%) of KCNQ2 mutations. At 1 year of age, the proband's seizures have resolved on phenobarbital. No seizures outside the neonatal period have been reported in the other 4 affected family members. This KCNQ2 mutation has implications for diagnosis and prognosis of BFNC. Its presence suggests a benign course with good prognosis and its identification can spare patients and physicians the need for extensive investigations or therapy.

3199W

Coronal craniosynostosis and radial ray hypoplasia: a third report of Twist mutation in a 33 weeks fetus with diaphragmatic hernia. *P. Juliette[1], C. Collet[2], F. Arbez-Gindre[3], L. Van Maldergem[1].* 1) Centre de Génétique Humaine, Université de Franche Comté, Besançon, France; 2) Service de Biochimie et Biologie Moléculaire, CHU Lariboisière, Paris, France; 3) Service d'Anatomie Pathologie, Université de Franche-Comté, Besançon, France.

We describe a multiple malformation syndrome comprising coronal craniosynostosis, unilateral radial ray hypoplasia and diaphragmatic hernia in a 33w female fetus born to a 46 y-old male with an alleged personal and family history of Crouzon syndrome. By identifying an already described c.445C>T TWIST missense mutation, we were able to reassign the diagnosis of the family condition to Saethre-Chötzen syndrome. The present report illustrates clinical variability of a dominantly inherited TWIST mutation, adds diaphragmatic hernia in the spectrum of TWIST-related malformations and provides a third example of Baller-Gerold/Saethre-Chötzen overlapping phenotype.

Identification of a novel gene causing fetal akinesia deformation sequence. *M.M. Weiss[1], G. Tan[1], M. Smit[1], J.I. de Vries[2], J.P. vd Voorn[3], I. Kluijt[4], E. Sistermans[1], H. Meijers-Heijboer[1,4], S. Groffen[1,5], Q. Waisfisz[1].* 1) Clinical Genetics, VU University Medical Center, Amsterdam, Netherlands; 2) Obstetrics and Gynaecology, Research Institute MOVE, VU University Medical Center, Amsterdam, Netherlands; 3) Pathology, VU University Medical Center, Amsterdam, Netherlands; 4) Clinical Genetics, Academic Medical Center, Amsterdam, Netherlands; 5) Functional Genomics, Center for Neurogenomics and Cognition Research, VU University, Amsterdam, the Netherlands.

Fetal akinesia deformation sequence (FADS) refers to a group of disorders characterized by congenital malformations related to decreased or absent fetal movements, such as multiple joint contractures and lung hypoplasia, which is often lethal. The etiology is heterogeneous, but underlying neuromuscular disorders represent an important cause of fetal akinesia. Embryonic skeletal muscle development involves a proper organization of acetylcholine receptors at neuromuscular junctions, a process that is triggered by agrin and involves several downstream genes, including DOK7 and RAPSN both of which are previously implicated in FADS. Here we describe a consanguineous family with two affected children with FADS. SNP array analyses of the affected children revealed overlapping regions of homozygosity. Sequencing analysis of candidate genes detected a homozygous missense variant in another known component of the DOK7 / RAPSN signaling pathway. Because the parents of the affected children originated from a genetic isolate, we suspected that the mutation could be a founder mutation. We tested four other families with an affected child, who originated from the same genetic isolate, and confirmed the homozygous mutation in each of the affected children. The five families had common ancestors traced back 6 to 7 generations. To our knowledge, this is the first report of a mutation in this gene causing a fetal akinesia lethal phenotype.

3201W

Identification of a new syndrome with severe type of cutaneous photosensitivity, mild mental retardation and short stature caused by KIAA1530 (UVSSA) gene. *R. Sharifi, A. Ahmadi, E. Ozkan, R. Maroofian.* Medical Genetics, St George's University of London, London, United Kingdom.

Here we are reporting for the first time a new syndrome characterized by severe type of cutaneous photosensitivity, mild mental retardation and short stature without developing skin carcinoma. Using linkage studies and exome sequencing of several extensive families with autosomal recessive inheritance, we revealed that mutations in KIAA1530 (UVSSA) gene causing this syndrome. The undergoing investigations are focusing on the possibility RNA profile in affected cases in comparison with carriers and non-affected individuals which may provide fundamental understanding of transcription-coupled nucleotide-excision repair (TC-NER) pathway and explain the different clinical features across these TC-NER-deficient disorders.

3202F

Infantile cerebral and cerebellar atrophy population screening using PCR-RFLP method. *V. Adir, E. Shahak, E. Golinker, N. Ekhilevitch, Z. U. Borochowitz.* Dept Molecular Genetics, Bnai Zion Medical Ctr, Haifa, Israel.

Introduction: Infantile Cerebral and Cerebellar Atrophy (ICCA) patients present microcephaly of postnatal onset, epilepsy, and psychomotor retardation. Head circumference percentiles decline with age, and brain MRI shows cereberal and cerebellar atrophy with severe myelination defect. Screening of patients with ICCA identified the same homozygous mutation L371P (c.1112T>C) in the MED17 gene, in all affected individuals who were of Caucasus Jewish origin, indicating a founder effect. The c.1112T>C mutation was found in the heterozygous state in 4 of 76 unaffected individuals in this population, Kaufmann et al. (2010). Research Goal: Developing simple method for population screening for the c.1112T>C mutation in the MED17 gene, and screening the Caucasus Jewish origin population to validate the high frequency carriers in this population. Method: We developed a PCR mediated site directed mutagenesis (PSDM) followed by restriction enzyme digestion test that would enable easy analysis of the c.1112T>C mutation in the MED17 gene. We designed PCR primers in which the 5'-to-3' (forward) primer bordered the c.1112T>C mutation site and included one nucleotide change so that in the normal allele an Xba1 restriction site will be created (TCTAGA). MED17 F CCGGAGGACCACCTTTATGTtC MED17 R GCTATGTGAATAATCAAGACTCAGCA. Using this primer set for amplification from genomic DNA gave a 157bp fragment and generated Xba1differential cleavage products of the mutant allele (157bp) versus the wild-type allele (137bp +20bp). Results: Our screening results indicated lightly higher carriers frequency than what was found by Kaufmann et al, we suggest that the reason for that is the small sample size in both our and Kaufmann's screening. If we combine the results from Kaufmann's and ours screening the carries frequency is 6.25% (1:16). The severity of the ICCA disease and the combined results (which definitively show that there is a high frequency of carriers among Caucasus Jews), resulted in the recommendation by the Medical Geneticists Association of Israel that this genetic test be included in the recommended screening genetic tests for Caucasus Jewish couples who plan pregnancy .

3203W

Genotype-phenotype correlation of enlarged vestibular aqueduct syndrome. *R. Birkenhager[1], S. Arndt[1], W. Maier[1], A. Aschendorff[1], E. Löhle[1,2], R. Laszig[1].* 1) Department of Otorhinolaryngology, Head and Neck Surgery, University Medical Center Freiburg, Killianstrasse 5, D-79106 Freiburg, Germany; 2) Department of Otorhinolaryngology, Head and Neck Surgery, University Medical Center Freiburg, Section Phoniatry and Pedaudiology.

The enlarged vestibular aqueduct syndrome (EVA) is one of the most common inner ear malformations, a distinct clinical entity characterized by progressive sensorineural hearing impairment. It is often associated with Pendred- Syndrome (PDS), an autosomal-recessive disorder characterized additionally with goiter. PDS is associated with temporal bone abnormalities ranging from isolated enlargement of the vestibular aqueduct (EVA) to Mondini dysplasia, a more complex malformation that also includes cochlear hypoplasia. Hearing loss is prelingual in the majority of the cases; only subset of patients has a progressive hearing loss later in life. EVA and PDS are caused by mutations in the SLC26A4 gene. The SLC26A4 gene is expressed in the non-sensory epithelia of the inner ear. Additionally the genes FOXI1 and KCNJ10 are described which may also be responsible for Pendred-Syndrome and inner ear malformations. The FOXI1 gene is involved in the transcriptional control of the SLC26A4 gene. The KCNJ10 gene encodes for a K+-channel located in the stria vascularis. In this study we analysed 152 patients with EVA and hearing loss to accomplish a phenotype genotype correlations for enlarged vestibular aqueduct related deafness. Individual exon and intron transitions of the SLC26A4, FOXI1 and KCNJ10 genes of patients were sequenced. Audiometric thresholds were performed, and radiologically, the vestibular aqueduct midpoint and opercular width were measured. In the analysed patients with EVA, a total of 32 different SCL26A4 mutations were detected, mutations could not be detected in 68 % of the cases. FOXI1 and KCNJ10 analyses reveal only known polymorphisms but no mutation. The present results obtained in patients with EVA indicate that this phenotype is likely to be complex. Moreover, analysis of FOXI1 and KCNJ10 genes in our cohort of enlarged vestibular aqueduct hearing loss suggests a minor implication of these two genes in the phenotype of non-syndromic EVA and PDS.

Molecular diagnosis of congenital muscular dystrophies with defective glycosylation of alpha dystroglycan using next generation sequencing technology. *J. CHAE, B. Lim, J. Ko, J. Choi, M. Wo, W. Park, B. Min.* Seoul National University Hosp, Seoul, South Korea.

Background Targeted resequencing using next generation sequencing technology is being rapidly applied to the molecular diagnosis of human genetic diseases. Muscular dystrophies as a group may be the appropriate candidate, because this group showed genotype-phenotype heterogeneity. As a proof of concept study, we selected the four congenital muscular dystrophies with defective glycosylation of alpha-dystroglcyan patients. **Methods** A custom solution-based target enrichment kit was designed to capture whole genomic regions of the 26 muscular dystrophies related genes including 6 genes implicated with alpha dystroglycanopathies. A multiplexing strategy, wherein four differently bar-coded samples were captured and sequenced together in a single lane of the Illumina Genome Analyser, was applied. **Results** Although the approximate 95% of both coding and non-coding regions were covered with more than 15 read depths, parts of the coding regions of FKRP and POMT2 were insufficiently covered. The homozygote and compound heterozygote POMGnT1 mutations were found in two patients. Three novel non-coding variants of FKTN were identified in one patient who had retrotransposon insertion mutation of FKTN in only one allele. Family study revealed two of the three non-coding variants segregated in the other allele with unknown mutation. The possible causes of sub-optimal coverage in a small portion of coding regions were estimated to be high GC ratio and insufficient capture probe design **Conclusion** The current targeted resequencing strategy showed the promising results for the extension of this method to other muscular dystrophies. Since sub-optimal coverage in a small subset of coding regions may affect the diagnostic sensitivity, complementary Sanger sequencing may be required.

3205W

Various clinical manifestations in 40 cases with type 1 neurofibromatosis. *CK. CHEON.* Department of Pediatrics, Pusan National University, Children's Hospital, South Korea.

Background: Neurofibromatosis type 1 (NF1) is one of the most common autosomal dominant disorder caused by mutations in the NF1 gene. The classic features of the clinical phenotype include the presence of café-au-lait spots, neurofibromas, axillary and inguinal freckling, Lisch-nodules and deformities of the skeletal system. However, it is known from the literature that the phenotypic variability can pose a huge diagnostic difficulty. Objective: We present a clinical and molecular study of Korean patients with NF1. Molecular genetic testing of the NF1 gene has been performed since 2009; during this period several unusual phenotypic variants were found. Methods: A total of 40 patients, 14 females and 26 males, were enrolled in this study at a single center. All the NF1 patients met the diagnostic criteria proposed by NIH Consensus Conference in 1987. Clinical manifestations, clinical courses and results of genetic study were reviewed. Results: Approximately 72% of all NF1 patients lack a family history of the disease. Subcutaneous and cutaneous neurofibroma was seen in 15 patients (37.5%). Lisch nodule was found in 7 patients (17.5%). Kyposcoliosis was detected in 12 patients (30%). Developmental delay or mental retardation was shown in 4 patients (10%). Brain involvement of neurofibromatosis was detected in 13 patients (32.5%). Among them, 5 patients (12.5%) showed harmatoma on cerebellum and basal ganglia. Two patients revealed hydronephrosis.. One patient showed malignant neural sheath tumor at the age of 41. One patient presented with detected severe hypertension at the age of 54. She was found to have elevated serum and urinary catecholamines levels. This patient underwent right adrenalectomy. Histology was diagnostic for pheochromocytoma. A 27-year-old adult having NF-1 was diagnosed with polycythemia vera. The mutational analysis of the NF1 gene revealed three novel mutations (Leu1944PhefsX6, Leu1773Pro,Cys2371X). Conclusions: Clinical manifestations of NF1 are variable, but “café au lait” spots and neurofibromas are the frequently symptoms. On some cases studied by us, the NF1 is associated with pheochromocytoma, polycythemia vera, kyphoscoliosis, and developmental delay or mental retardation. Even if there is currently no effective drug treatment for NF1, genetic counseling is very important and some of the symptoms of NF1 can be treated individually.

3206F

Mutation Analysis Results of 5α Reductase Type 2 Enzyme Deficiency Patients. *H. Onay[1], D. Goksen[2], A. Aykut[1], F. Hazan[3], S. Darcan[2], F. Ozkinay[1,2].* 1) Medical Genetics Dept, Ege University School of Medicine, Izmir, Türkiye; 2) Pediatrics Dept, Ege University School of Medicine, Izmir, Türkiye; 3) Dr. Behcet Uz Children's Hospital, Izmir, Türkiye.

The 5α reductase type 2 enzyme deficiency is an autosomal recessive disorders and is one of the major cause of 46,XY disorders of sex differentiation. This enzyme is encoded by the SRD5A2 gene on chromosome 2 and catalysis the conversion of testosterone (T) to dihydrotestosterone (DHT) and the gene is expressed mostly in external genital tissues and prostate. DHT is the essential androgen for normal development of external genitalia in the male fetus. Males affected with this deficiency usually present perineoscrotal hypospadias, microphallus and cryptorchid testes. In this study the mutation analyses results of the 151 patients with 5α reductase type 2 enzyme deficiency who referred to Medical Genetic Department of Ege University Hospital between 2008–2012 were evaluated. SRD5A2 gene mutation analysis was performed by sequencing of the coding exons of the gene. No mutation was found in 136 patients (90,1%). Ten of 15 patients (6,6%) carried homozygous mutations and remaining (3,3%) carried mutations in heterozygous state. The most common mutation (in 4 patients) detected in homozygous patients was L55Q as expected and second one was G196S. As a result mutation detection rate was very low in our patient group. Careful examination of the clinical signs and the laboratory findings before SRD5A2 gene mutation analysis would higher the detection rate.

Griscelli Syndrome with RAB 27A mutation and prenatal diagnosis. *I. Panigrahi, R. Suther, B. Behera, A. Rawat, R. Marwaha.* Pediatrics, PGIMER, Chandigarh, Chandigarh (UT), India.

One year old female, the first child of parents, presented with febrile episode 1 month earlier, followed by seizures and developmental regression for 15 days. Examination revealed dolichocephalic head with silvery white hair, round face, silvery eyelashes, brown-black irides and tented upper lip. She had hepatosplenomegaly, liver was 5cm below right costal margin and spleen was 6cm below left costal margin. CNS examination revealed normal tone with elicitable deep tendon reflexes. Since she had acute seizures s he was treated as a case of meningitis. MRI brain done revealed multiple extensive hyperintense lesions in periventricular/subcortical /cerebellar white matter along with hydrocephalus. Leptomeningeal enhancement was seen along cerebellar folia and convexities. Her WBC counts were low (lowest of 1800/mm3 with 57% polymorphs). She was put on phenytoin, midazolam, leviracetam for seizures and ultimately on thiopentone infusion at 4mg/kg/hour with increase upto 5mg/kg/hour. Ketamine infusion was also given. IV methylprednisolone was also given. RAB 27A gene mutation analysis revealed splice mutation 239+1 G-T in intron 3. Thus, the child was confirmed to have Griscelli syndrome type2 (GS2), in which neurological and immunological abnormalities co-exist, leading to early mortality. She developed intractable seizures during hospital stay and expired around D14 of hospitalization. Mother is pregnant and prenatal diagnosis is planned by amniocentesis and DNA analysis.

Molecular diagnosis of rare Mendelian diseases using whole exome sequencing. *B. Rodríguez-Santiago[1,2], S. Boronat[3,4], J. Argente[5,6,7], I. Valenzuela[4], M. del Campo[2,4,8], L.A. Perez-Jurado[2,8], L. Armengol[1,2].* 1) qGenomics, Barcelona, Spain; 2) Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Instituto de Salud Carlos III, U-735, Barcelona, Spain; 3) Servicio de Neuropediatria, Hospital Universitari Vall d'Hebron, Barcelona, Spain; 4) Programa de Medicina Molecular i Genètica, Hospital Universitari Vall d'Hebron, Barcelona, Spain; 5) Departamento de Pediatría, Universidad Autónoma de Madrid, Madrid, Spain; 6) Servicios de Pediatría y Endocrinología, Instituto de Investigación La Princesa, Hospital Infantil Universitario Niño Jesús, Madrid, Spain; 7) Centro de Investigación Biomédica en Red de la Fisiopatología de la Obesidad y Nutrición (CIBEROBN), Instituto de Salud Carlos III, Madrid, Spain; 8) Unitat de Genètica, DCEX, Universitat Pompeu Fabra, Barcelona, Spain.

The development in the recent years of the so-called next generation sequencing technologies based on massive parallel methods currently allows the production of millions of DNA sequences at an unprecedented speed with an increasingly reduced cost per nucleotide. These technologies are producing very significant scientific achievements, with the identification of new genes and the resolution of the genetic basis of Mendelian diseases at the forefront. The potential of this technology is being used to create new applications and biological tests that are soon going to revolutionise the pre- and postnatal diagnosis of genetic disorders. In order to assess the utility of this technology in molecular diagnostics we have applied whole-exome sequencing to two groups of patients with normal aCGH results. Group 1 included patients diagnosed with rare Mendelian disorders with genetic heterogeneity and well defined phenotype whereas group 2 was formed by patients with severe phenotypes but no specific diagnosis. Among group 1, patients with primary autosomal recessive microcephaly (7 causative genes known), Bardet-Biedl syndrome (15 genes), Joubert syndrome (10 genes), microcephalic dwarfism (4 genes) and Walker-Warburg syndrome (6 genes) were analysed. Potential causative biallelic mutations were identified and validated in parental samples in 4 out of 6 cases (66%) from group 1. Candidate mutations putatively related to the phenotype were also detected in all group 2 patients, but follow-up studies are required to define their pathogenic role. Our data indicates that exome sequencing in a single patient is highly effective (and likely cost-effective) as the initial diagnostics tool to identify causative pathogenic mutations in rare Mendelian disorders while in phenotypes without specific diagnosis the technology is a research tool that provides new candidate pathogenic variants.

Next-generation sequencing for low and high-bone density disorders. *G. Sule[1], P. Campeau[1], S. Nagamani[1], B. Dawson[1], M. Grover[1], C. Bacino[1], J. Lu[2,3], E. Lemire[4], R. Gibbs[2], D. Cohn[5], V. Zhang[1], L. Wong[1], B. Lee[1,6].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 3) Department of Structural and Computational Biology & Molecular Biophysics, Baylor College of Medicine, Houston, TX, USA; 4) Department of Pediatrics, University of Saskatchewan, Saskatoon, Canada; 5) Department of Molecular, Cell, and Developmental Biology, University of California, Los Angeles, CA; 6) Howard Hughes Medical Institute, Houston, TX.

Osteogenesis imperfecta (OI), Ehlers-Danlos syndrome (EDS) and osteopetrosis (OPT) are collectively relatively common inherited skeletal diseases. Evaluation of subjects with the aforementioned conditions often includes molecular testing which has important counseling, therapeutic and even legal implications. Since multiple genes have been implicated in these conditions, Sanger sequencing of individual genes results in significant increases in cost and time to reach a molecular diagnosis. For example, a comprehensive evaluation for genetic causes for OI would entail sequencing of at least 9 genes totaling more than 150 exons. In order to circumvent these problems, we have designed a next-generation sequencing (NGS) platform that would allow sequencing of multiple genes implicated in OI, OPT, EDS, and other conditions leading to low or high bone mass on a single diagnostic platform. Our assay uses a liquid-phase library that captures 602 exons (~100 kb) of 33 genes. NGS of the captured exons by Illumina HiSeq2000 resulted in an average coverage over 900X. The platform was successfully validated by identifying mutations in 6 patients with known mutations. Moreover, in 4 patients with OI or OPT without a prior molecular diagnosis, the assay was able to detect the causative mutations. In conclusion, our NGS panel provides a fast and accurate method to arrive at a molecular diagnosis in patients with high or low bone mass diseases.

3210F

Molecular diagnosis of autosomal dominant polycystic kidney disease using massively parallel sequencing. *Y. Tan[1], A. Michaeel[1], G. liu[1], J. Blumenfield[2, 3], S. Donahue[3], T. Parker[3], D. levine[3], H. Rennert[1].* 1) Dept Pathology/Laboratory Med, Weill Cornell Medical College, New York, NY; 2) Dept of Medicine, Weill Cornell Medical College, New York, NY; 3) The Rogosin Institute, New York, NY.

Genetic testing of PKD1 and PKD2 is useful for diagnosis and prognosis of autosomal dominant polycystic kidney disease (ADPKD), particularly in those without a family history. However, PKD gene mutation analysis is complicated by the duplication of PKD1 exons 1–33 as six pseudogenes on chromosome 16, a high level of allelic heterogeneity (genetic variations), and the high cost of Sanger sequencing. We have developed and validated a clinical assay to analyze both PKD genes, using next-generation sequencing (NGS), by multiplexing barcoded libraries from long-range PCR (LR-PCR). We used this approach to characterize a cohort of patients with PKD gene mutations previously defined by Sanger sequencing. PKD1 and PKD2 genes were amplified in a total of ten LR-PCR reactions (1.4–10.9 kb), using locus-specific primers for PKD1 duplicated regions. LR-PCR amplicons from the same patient were combined and indexed with a unique DNA barcode. Indexed libraries from 25 patients were pooled together and analyzed using either a flow-cell of MiSeq or a single flow-cell lane of HiSeq system (Illumina Inc., San Diego, CA). Sequencing results were then sorted according to the barcodes with FASTX toolkit and aligned against the reference sequence with BWA program. Sequence variants were called and filtered with GATK software (The Genome Analysis Toolkit, The Broad Institute) following Best Practice Guidelines recommended by GATK. The raw variant calls were then annotated with ANNOVAR software. The data analysis pipelines were automated with Unix shell scripts. A total of 241 genetic variants were identified within exonic and adjacent intronic regions of PKD1 and PKD2 in 25 patients with the ADPKD phenotype. When compared with conventional Sanger sequencing, this NGS based approach achieved a sensitivity of 99.2%, and a specificity of 99.9%. Of these genetic variants, 16 variants were classified as definite pathogenic mutations, including two small deletions (a 4-bp and a 10-bp), and a 24-bp insertion. This NGS based testing detected all pathogenic mutations, achieving a sensitivity and specificity of 100%. By using the MiSeq platform, 25 patients were genotyped within one week for less than $100 per patient (including all reagents and sequencing costs). NGS-based ADPKD genetic analysis is a highly accurate and reliable approach for mutation analysis, achieving high sensitivity and improved intronic coverage with faster turnaround time and lower cost.

Genotype-phenotype correlation in Bardet-Biedl Syndrome. *E. Forsythe[1], K. Sparks[2], M.S.B. Huda[3], J. Hazlehurst[4], S. Mujahid[3], P. Carroll[3], B. McGowan[3], J.W. Tomlinson[4], S. Mohammed[5], P.L. Beales[1].* 1) Molecular Medicine Unit, UCL Institute of Child Health, London, United Kingdom; 2) Clinical Genetics, Great Ormond Street Hospital, London, United Kingdom; 3) Department of Endocrinology, Guy's and St Thomas' NHS foundation Trust, London, United Kingdom; 4) Centre for Endocrinology, Diabetes and Metabolism, Institute of Biomedical Research, University of Birmingham, Birmingham, United Kingdom; 5) Clinical Genetics, Guy's and St Thomas' NHS foundation trust, London, United Kingdom.

Background: Bardet-Biedl Syndrome (BBS) is a rare autosomal recessive ciliopathy. It is a clinically heterogeneous condition characterized by retinal dystrophy, obesity, post-axial polydactyly, renal dysfunction, learning difficulties and hypogonadism. The diagnosis can be confirmed in 80% of patients by sequencing the 16 known disease-causing genes. In northern European populations the majority of pathogenic mutations are found in *BBS1* and *BBS10* accounting for 23.2% and 20% respectively.

Purpose: To explore genotype-phenotype correlations in individuals with pathogenic mutations in *BBS1* and *BBS10* based on a questionnaire addressing key patient concerns about BBS and data from the national BBS clinic services.

Methods: 115 patients responded to the questionnaire. 35 patients had confirmed pathogenic mutations in *BBS1* and 15 in *BBS10*. The questionnaire was devised in collaboration with the UK patient support group and includes questions about visual deterioration, endocrine, renal and mental health problems. Fasted blood samples, height, weight and blood pressure were taken from 239 patients attending BBS clinics. Blood samples included full blood count, glucose, renal, liver, lipid and endocrine profiling. 96 patients seen in clinic had confirmed mutations in *BBS1* or *BBS10* (72 and 24 respectively). Results were assessed using standard statistical methods and the significance level was set at 0.05.

Summary of results: The age of onset of night blindness was significantly higher in patients with *BBS1* mutations (P=0.008, n=45). Individuals with *BBS1* mutations also reported being registered blind later (p=0.0008, n= 40). The *BBS10* cohort were more likely to report renal impairment (p= 0.042, n=40). Results from the BBS clinics revealed that patients with *BBS1* mutations have better albumin-creatinine ratios (p=0.038, n=45) and higher levels of HDL cholesterol (p=0.004, n=70) despite this group being significantly older (p=0.03, n=96). No other markers reached statistical significance even when corrected for age.

Conclusion: This study examines key issues prioritized by individuals affected by BBS and data from national BBS clinics. A milder ocular, renal and lipid phenotype is observed in patients with *BBS1* mutations. This should help guide genetic counseling and testing of patients with BBS.

Photoreceptor loss in LCR-deletion associated Blue Cone Monochromacy: implications for gene therapy. *R.B. Hufnagel[1,2], A. Dubra[3,4], R.A. Sisk[5], J.C. Gardner[6], S. Riazuddin[1,7], A.J. Hardcastle[6], A.T. Moore[6,8], J. Neitz[9], M. Michaelides[6,8], M. Neitz[9], J. Carroll[3,4,10], Z.M. Ahmed[1,2].* 1) Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Pediatric Ophthalmology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 3) Ophthalmology, Medical College of Wisconsin, Milwaukee, WI; 4) Biophysics, Medical College of Wisconsin, Milwaukee, WI; 5) Cincinnati Eye Institute, Cincinnati, OH; 6) Ophthalmology, University College London, London, United Kingdom; 7) Pediatric Otolaryngology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 8) Moorfields Eye Hospital, London, United Kingdom; 9) Ophthalmology, University of Washington, Seattle, WA; 10) Cell Biology, Neurobiology, & Anatomy, Medical College of Wisconsin, Milwaukee, WI.

Blue cone monochromacy (BCM) is an X-linked retinal disorder of cone photoreceptors caused by mutation that either prevents expression of both *OPN1LW* (encoding red opsin) and *OPN1MW* (encoding green opsin) or interferes with function of the encoded opsins. Patients with BCM have reduced visual acuity, markedly reduced color discrimination, photophobia, and nystagmus. While BCM does not usually demonstrate progressive visual deterioration, little is known about the effects of opsin loss on photoreceptor structure and function, both critical for predicting efficacy of gene replacement therapies. Here, we describe genetic, clinical, and in vivo cellular analyses of four families with BCM.

Clinical diagnosis was based upon clinical assessment, color vision testing, family history, and full-field and S-cone electroretinography (ERG). DNA was purified from blood samples obtained from affected individuals, parents, and unaffected siblings. Genomic segments harboring the *OPN1LW* and *OPN1MW* exons and promoter sequences were analyzed by PCR amplification followed by direct Sanger sequencing. Gene arrangement and copy number were evaluated by RT-PCR. Macular and photoreceptor structure was evaluated by Ocular Coherence Tomography (OCT) and Adaptive Optics (AO) imaging.

Probands ranged in age from 8 to 35 years old. All four families have mutations deleting the enhancer Locus Control Region (LCR), obviating expression of any of the *OPN1LW* or *OPN1MW* genes in the array. Affected individuals had moderate impairment in best corrected visual acuity, impaired cone ERGs, and reduced central macular thickness with changes in the retinal pigmented epithelium (RPE). AO imaging of foveal photoreceptors indicated diminished outer segment structure.

In conclusion, these families with LCR deletions had similar phenotypic manifestations, including foveal thinning with a granular RPE. Disease severity did not correlate with age or visual acuity. Macular photoreceptors exhibited diminished outer segment structure, critical for visual transduction. These previously uncharacterized architectural features of BCM suggest structural defects that may have implications for cellular viability and efficacy of future gene therapy approaches.

VCP-associated Inclusion Body Myopathy with Paget Disease of Bone and/or Frontotemporal Dementia: Expanding Natural History and Genotype-Phenotype characterization. *M. Khare[1], S.G. Mehta[2], R. Ramani[1], G.J. Watts[3], B. Martin[4], M. Simon[5], K.E. Osann[6], S. Donkervoort[1], E. Dec[1], A. Nalbandian[1], A. Wang[7], T. Mozaffar[7], C.D. Smith[4], V.E. Kimonis[1].* 1) Pediatrics, University of California, Irvine, Irvine, CA; 2) East Anglian Regional Genetics Service, Addenbrookes Hospital, Cambridge, UK; 3) Biomedical Research Center, University of East Anglia, Norfolk;; 4) Department of Neurology and Sanders-Brown Center on Aging, University of Kentucky, Lexington, KY; 5) Mitomed Laboratory, MAMMAG, University of California, Irvine, CA; 6) Division of Hematology/Oncology, University of California, Irvine, CA; 7) ALS and Neuromuscular Center, University of California, Irvine, CA.

VCP disease associated with Inclusion body myopathy, Paget disease of the bone and frontotemporal dementia is a progressive autosomal dominant disorder caused by mutations in the VCP gene, a member of the AAA-ATPase superfamily. To establish the natural history and genotype-phenotype correlations we analyzed the clinical and biochemical markers from a database of 190 members in 27 families harboring ten missense mutations. Individuals were grouped into three categories: symptomatic, presymptomatic carriers and non-carriers. The symptomatic families were further divided into ten groups based on their specific VCP mutations. We identified a higher prevalence of FTD in females with a ratio of 2:1. Survival analysis by Kaplan Meier survival method revealed an average life span after diagnosis of myopathy and Paget of 18 and 19 years respectively, and after dementia only 6 years. There were marked intra and interfamilial variations; and significant genotype phenotype correlations were only apparent between two of the most common mutation groups. The R155C mutation was more severe than R155H mutation with a significant earlier onset of myopathy and PDB along with a significant decrease in mean survival (p=0.03). We identified amyotrophic lateral sclerosis (ALS) in thirteen affected individuals in our study database (8.9%). Electromyography studies revealed neurogenic features such as fasciculations in 24% of individuals. Five individuals were also identified with Parkinson's disease (3%). We analyzed the tumor incidence because previous studies have implicated VCP's role in predicting the metastatic potential and, thus, the prognosis of patients with wide variety of tumors. We identified several patients with rare tumors including malignant thymoma, frontotemporal pleomorphic xanthoastrocytoma (a primitive neuroectodermal tumor), and peripheral nerve sheath spindle cell tumor of the thigh along with typical breast and colon cancers. This study represents the largest dataset of patients with VCP disease and has a potential to yield better understanding of the natural history, and possible genotype-phenotype correlations with atypical features such as ALS, Parkinson's disease, cancers and other features.

3214F

A novel short stature syndrome caused by defects in glycosaminoglycan synthesis due to altered xylosyltransferase 1 activity. *J. Schreml[1], B. Durmaz[2], O. Ço{{gab}}ulu[2], K. Keupp[1], F. Beleggia[1], E. Pohl[1], E. Milz[1], G. Nürnberg[3], P. Nürnberg[3], J. Kuhn[4], M. Coker[5], S. Kalkan Ucar[5], F. Özkinay[2], B. Wollnik[1].* 1) Institute of Human Genetics, University of Cologne, Cologne, Germany; 2) Department of Medical Genetics, Ege University, Bornova, Izmir, Turkey; 3) Cologne Center for Genomics, University of Cologne, Cologne, Germany; 4) Institute for Laboratory and Transfusion Medicine, Heart and Diabetes Center North Rhine-Westphalia, Ruhr University Bochum, Bad Oeynhausen, Germany; 5) Ege University, Department of Pediatric Metabolism, Bornova, Izmir, Turkey.

Glycosaminoglycans (GAGs) are essential components of various physiological processes that are indispensable for embryonic development. GAG synthesis is initiated by the sequential addition of a “linker chain“, comprising of four sugar residues, to a specific region of a core protein. During this complex process, xylosyltransferases 1 and 2 (XT1 and XT2), which are expressed in a tissue and time dependent manner and are mainly located in the cis-golgi network, initiate the important linker chain formation. Here we present a novel syndrome characterized by severe short stature, facial dysmorphism, alterations of fat distribution, and moderate intellectual disability. X-rays in affected individuals of a consanguineous Turkish family showed mild skeletal dysplasia in the form of metaphyseal widening, short femoral neck and thickened ribs. Using an innovative whole-exome sequencing strategy combined with exome variant analysis for homozygous stretches and independent homozygosity mapping, we identified the homozygous p.R481W missense mutation in *XYLT1* encoding xylosyltransferase 1 in both affected individuals of the family. The parents were heterozygous carriers and the healthy brother did not carry the mutation. *XYLT1* is located within the largest linked region on chromosome 16 and the missense mutation affects a highly conserved residue in close proximity to a functional domain of the enzyme. Therefore, the mutation is predicted to lead to a functional impairment of enzyme activity. Indeed, immunostaining of primary patient fibroblasts pointed towards a mislocalization of XT1 with a diffuse staining pattern compared to the distinct staining in the golgi region of wild-type control fibroblasts obtained from a healthy sibling. Moreover, Western blot analysis of the core protein decorin in cell culture supernatant showed evidence of glycosylation differences between patient and control cells. These data provide the first evidence that functional alterations of xylosyltransferase 1 cause a syndrome associated with short stature and intellectual disability in the investigated family.

Case studies for the clinical diagnosis of rare, congenital, pediatric disorders by whole genome sequencing. *S. Szelinger[1,2], V. Narayanan[2,3], H. Boman[4], A.F. Hahn[5], J.J. Corneveaux[1,2], A.L. Siniard[1,2], A.A. Kurdoglu[1,2], M.J. Huentelman[1,2], D.W. Craig[1,2].* 1) Neurogenomics Division, Translational Genomics Research Institute, Phoenix AZ., USA; 2) Childhood Rare Disorder Center, Translational Genomics Research Institute, Phoenix Arizona, USA; 3) Pediatric Neurogenetics Center, Barrow Neurological Institute, Phoenix Arizona, USA; 4) Center for Medical Genetics and Molecular Medicine Haukland University Hospital Bergen, Norway; 5) Department of Clinical Neurological Sciences London Health Sciences Centre University of Western Ontario London, Ontario, Canada.

Improved next-generation sequencing technology and reduced costs make whole genome analysis an attractive clinical diagnostic tool in hard-to-diagnose genetic disorders. We report two independent cases of neurogenetic disorder, where whole genome sequencing and candidate variant analysis was integrated with clinical information to identify one case as Crisponi Syndrome/CISS1 (Cold-Induced Sweating Syndrome1) and Mitochondrial encephalomyopathy (MtE) in the other case. The Crisponi Syndrome case was paired-end sequenced by Illumina Genome Sequencing Service on a Genome Analyzer IIX (GAIIX) to a mean genomic coverage of 39X. The MtE case was paired-end sequenced by Illumina's FastTrack Sequencing Service on a HiSeq2500 to a mean genomic coverage of 33X. Quality assessment, sequence alignment, short nucleotide polymorphism (SNP), insertion, deletion discovery were performed by Illumina. Variant annotation and candidate coding variant prioritization followed a tiered approach, integrating data from the 1000 Genomes Project, Ensembl, NCBI RefSeq, OMIM, Consensus CDS, ClinVar, and the Human Gene Mutation Database. Evaluation of candidate gene list in both cases resulted in the identification of novel heterozygous coding SNPs that were deleterious. However neither candidate variant lists contained a second hit in the selected candidate genes that would be expected under autosomal recessive inheritance. In the Crisponi case, the second hit, a frameshift deletion in exon1, was discovered after Sanger sequencing CRLF1 candidate gene, which is known to contain a hard-to-sequence first exon with high GC content. In the MtE case, the second hit, a frameshift deletion, in POLG gene was discovered after application of alternative bioinformatic approach. In both cases, availability of detailed clinical information for the interpretation and prioritization of genomic data was critical to discover the causative genes and make the diagnosis. However, the inability of the GAIIX to obtain reads in high GC content regions, and the false negative call of the POLG deletion highlight some of the challenges faced by next-generation sequencing in its routine application for clinical diagnostics. Although these problems are significant, the fact that quality and speed of next-generation sequencing is constantly improving with sequencing and analysis turnaround time of about two weeks, the main question is not if whole genome analysis will be routinely used in the clinic, but when.

3216F

Variable phenotypic spectrum in a cohort of patients with ARID1B mutations. *S. Boulanger, L. Mariage, D. Lederer, S. Moortgat, A. Destree, P. Hilbert, I. Maystadt.* Human Gen Ctr, Inst Pathology & Gen, Charleroi, Belgium.

In 1970, Coffin and Siris reported 3 girls with severe mental retardation, growth retardation, lax joints and absent or hypoplastic fifth distal phalanges and nails. Later, the Coffin-Siris syndrome (CSS) has been characterized by developmental delay, severe speech impairment, coarse facial features, hypertrichosis, hypoplastic or absent fifth fingernails or toenails and agenesis of the corpus callosum. Very recently, dominant mutations in ARID1B gene have been found by whole-exome sequencing in CSS patients (Santen et al, 2012). In that study, it was proposed that CSS could be consider in all individuals with intellectual disability, speech impairment and agenesis of the corpus callosum. In parallel, loss-of-function mutations in the ARID1B gene were found in a cohort of patients with non specific cognitive impairment, suggesting that haploinsufficiency of ARID1B is a common cause of intellectual disability (Hoyer et al, 2012). We screened a cohort of patients with developmental delay, moderate to severe intellectual disability, severe speech impairment, and some clinical features reported in Coffin-Siris syndrome (short stature, coarse face, flat nasal bridge, bulbous nasal tip, large mouth, sparse scalp hair contrasting with body hirsutism, nail dysplasia, hypotonia and joint laxity). The patients carrying an ARID1B mutation present with an atypical phenotype, not specific enough to allow for an unambiguous diagnosis of Coffin-Siris syndrome.

3217W

Whole Exome Sequencing in patients with Intellectual Disabilities. *I. Madrigal[1,2], U. Liljedahl[3], MI. Alvarez[1,2], O. Karlberg[3], L. Rodriguez-Revenga[1,2], A. Mur[4,5], AC. Syvänen[3], M. Mila[1,2].* 1) Biochemistry and Molecular Genetics, Hospital Clinic, Barcelona, Barcelona, Spain; 2) Centre for Biomedical Research on Rare Diseases (CIBERER), ISCIII, Barcelona, Spain; 3) Department of Medical Sciences, Molecular Medicine, Uppsala University, Uppsala, Sweden; 4) Servicio de Pediatría, Hospital del Mar, Barcelona, Spain; 5) Departamento de Pediatría y Obstectricia de la UAB, Barcelona, Spain.

Intellectual disabilities refers to a generalized disorder, characterized by substantial limitations in intellectual, functioning and adaptive behavior, diagnosed before 18 years of age and affecting about 1–3% of the general population. Genetically, the high heterogeneity and the unexpected great complexity of the genetic basis should be highlighted. From 50–60% of patients with intellectual disability remain undiagnosed. The use of Whole Exome Sequencing in families with some affected members increases the rate of diagnosis and facilitates the identification of new genes. The aims of this study were: to identify mutations in known intellectual disability genes, to identify new genes responsible for intellectual disability, to establish the phenotype-genotype correlation and to provide genetic counseling. We sequenced 32 individuals from eight families of self-reported European ancestry with unexplained moderate to severe intellectual disability using the Illumina HiSeq 2000 Sequencing System. We identified two new mutations in known genes responsible for intellectual disability: the c.2013 mutation delGfs*3 in the UBE3A gene and the c.1405C>T p. R469C mutation in the SMC1A gene; and one previously described mutation in the OCRL gene (c.1567 G>A p.D523N). In the remaining 5 families, several candidate mutations have been identified and more studies are being performed. In conclusion, this study confirms the high heterogeneity and difficulty in the clinical diagnosis of intellectual disability and demonstrates that Whole Exome Sequencing is a very efficient, reliable and cost-effective method which should be incorporated to routine diagnosis in the near future. Acknowledgements: FP7/2007–2011, grant agreement n°262055 (ESGI project).

Identification of the p.A140V mutation in MECP2 gene in a family with non specific X-linked mental retardation. *I. Maystadt[1,2], S. Boulanger[1], P. Vrielynck[3], S. Moortgat[1], A. Destree[1], D. Lederer[1].* 1) Ctr Human Genetics, Inst Pathology & Genetics, Gosselies, Belgium; 2) FUNDP, Namur, Belgium; 3) Service de Neurologie, Hôpital de Jolimont, Haine-Saint-Paul, Belgium.

Mutations in MECP2 gene, a gene located on the X chromosome and encoding a methyl CpG binding protein, have been identified in patients with Rett syndrome. This neurodevelopmental disorder, classically associated with normal early development followed by loss of acquired skills and deceleration of head growth, affects almost exclusively females because of the lethal effect of the mutations in hemizygous affected males. Here we report on the identification of the p.A140V mutation in the MECP2 gene in 4 males and 3 females of a family affected with X-linked mental retardation, and we provide a phenotypical description of the patients. Females present with mild cognitive impairment and speech difficulties. Males have severe intellectual disability, impaired language development, sociable affect, slowly progressive spastic paraparesis/pyramidal signs and dystonic movements of the hands. Two of them have microcephaly. None of them developed epilepsy. The p.A140V has been reported to preserve the methyl-CpG binding function of the MeCP2 protein while compromising its ability to bind to the mental retardation associated protein ATRX; and the p.A140V mouse model showed increased cell packing density and decreased neuronal dendritic arbors. This mutation was already described in 4 families with X-linked mental retardation and in two sporadic male patients with intellectual disability, indicating that MECP2 mutations are not necessarily lethal in males, and that this specific mutation seems to be recurrent and may be under-diagnosed in families with X-linked intellectual disability.

Whole exome sequencing identifies titin (*TTN*) mutations as a cause of centronuclear myopathy. *O. Ceyhan, P.B. Agrawal, K. Schmitz, E. DeChene, K. Markianos, A.H. Beggs.* Genetics, Children's Hospital, Harvard Medical School, Boston, MA.

Centronuclear myopathies (CNMs) are a group of rare and genetically heterogenous congenital myopathies, characterized by an abnormally high number of muscle fibres with internalized nuclei. To date, mutations in four genes involved in membrane trafficking and T-tubule assembly have been linked to CNMs; however, the genetic defects in 20% of the patients still remain unknown. We performed whole exome sequencing (WES) in a cohort of 28 CNM patients with no known genetic defects, and identified pathogenic mutations in the gene encoding the giant sarcomeric protein, titin, in 4 patients. All 4 patients are compound heterozygotes for unique frameshift, nonsense, or splicing mutations in the I- or A-band regions of the titin protein. Muscle biopsies show an increase in the number of cells with multiple internal nuclei, type I fiber hypotrophy/predominance, and disorganized sarcomeres. Clinical presentations range from birth-onset severe hypotonia with respiratory difficulties to milder childhood-onset muscle weakness, and do not involve cardiac abnormalities. Our results expand the wide phenotypic spectrum associated with *TTN* mutations, while suggesting novel mechanisms in the pathophysiology of CNMs. In addition, we demonstrate the value of WES for discovering mutations in genes that were previously insufficiently analyzed due to their large size.

3220F

Unexpected *EGFR3* variants confounding Achondroplasia mutation detection. *A. Millson[1], A.F. Rope[1,2], E. Lyon[1,3].* 1) ARUP Inst Clin & Exp Path, ARUP Labs, Salt Lake City, UT; 2) Department of Pediatrics, University of Utah, Salt Lake City, UT; 3) Department of Pathology, University of Utah, Salt Lake City, UT.

Achondroplasia is caused by a mutation in the fibroblast growth factor receptor 3 (*FGFR3*) gene located on chromosome 4p16.3 and is phenotypically expressed as short-limb dwarfism. Achondroplasia occurs in about 1/25,000 births worldwide. It is an autosomal dominant disorder with the majority of cases resulting from de novo sporadic mutations in the fibroblast gene. Homozygosity for the mutation results in a severe skeletal dysplasia that is lethal. The c.1138G>A mutation accounts for ~98% of sporadic cases with the c.1138G>C mutation causing ~1%. Both mutations result in G380R (Glycine to Arginine) amino acid substitution, giving rise to Achondroplasia. ARUP Laboratories offers testing for Achondroplasia utilizing PCR followed by Fluorescent Resonance Energy Transfer (FRET) probe analysis. Our protocol uses two reactions per sample, each reaction containing a FRET probe pair, with the reporter probe a perfect match to the wild type c.1138G or to the most common mutation c.1138A. Recently our clinical laboratory received a sample which after routine analysis was reported as wild type. The requesting clinician was suspect of the wild type result and sent the sample to another facility for sequencing, which found the less common mutation c.1138C. Subsequent sequencing at our facility confirmed the c.1138 mutation as well as identifying a variant under our clinical laboratory assay's forward primer, c.1097C>G, residing four bases from the 3' end. Presence of this variant inhibited amplification of the c.1138C mutation allele, therefore the 2 reside *in cis*. A search of various variant databases found no mention of c.1097C>G. This event led to an assay improvement incorporating a second set of unique primers to be used with the c.1138A matched FRET probe pair while keeping the original primer pair to be used with the c.1138G matched probe pair. During the assay improvement validation, which re-analyzed all prior samples sent in for testing (n=131), an aberrant melting pattern was seen with one heterozygous c.1138A sample. Sequencing of this sample found an intronic variant, c.1266+25C>T, located in the center of the newly designed reverse primer. A thorough search of variant databases failed to find mention of c.1266+25C>T. Here we describe two previously unreported *FGFR3* variants located near the c.1138G>A/C Achondroplasia causative mutation which have the potential to interfere with assay performance.

Analysis of C9orf72 repeat expansion in Japanese patients with ALS. *K. Ogaki[1], Y. Li[2], N. Atsuta[4], H. Tomiyama[1,3], M. Funayama[1,2], H. Watanabe[4], R. Nakamura[4], H. Yoshino[5], S. Yato[6], A. Tamura[7], Y. Naito[7,8], A. Taniguchi[7], K. Fujita[9], Y. Izumi[9], R. Kaji[9], N. Hattori[1,2,3], G. Sobue[4], the Japanese Consortium for Amyotrophic Lateral Sclerosis research (JaCALS).* 1) Dept of Neurology, Juntendo University School of Medicine, Tokyo, Japan; 2) Research Institute for Diseases of Old Age, Juntendo University School of Medicine, Tokyo, Japan; 3) Dept of Neuroscience for Neurodegenerative Disorders, Juntendo University School of Medicine, Tokyo, Japan; 4) Dept of Neurology, Nagoya University Graduate School of Medicine, Nagoya, Japan; 5) Setagaya Neurological Hospital, Tokyo, Japan; 6) Sayama Neurological Hospital, Sayama, Japan; 7) Dept of Neurology, Mie University Graduate School of Medicine, Tsu, Japan; 8) Dept of Neurology, Ise Red Cross Hospital, Ise, Japan; 9) Dept of Clinical Neuroscience, Institute of Health Biosciences, The University of Tokushima Graduate School, Tokushima, Japan.

Background and Purpose: Recently, a hexanucleotide repeat expansion in C9orf72 was identified as the most common cause of both sporadic and familial amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) in Western populations. The aim of this study was to investigate genetic and clinical characteristics of C9orf72 repeat expansion in a large cohort of Japanese patients with ALS. Methods: We analyzed 563 Japanese patients with ALS (552 sporadic and 11 familial) and 197 normal controls using fluorescent fragment-length analysis of C9orf72 and repeat-primed PCR analysis. Haplotype analysis was performed for 42 SNPs in patients with C9orf72 repeat expansion. Results: C9orf72 repeat expansion was found in two patients with sporadic ALS (2/552=0.4%) and no patients with familial ALS (0/11=0%). In the probands' families, one primary progressive aphasia (PPA) patient and one asymptomatic 76-year-old individual exhibited C9orf72 repeat expansion. The genotypes of all individuals with the C9orf72 mutation were detected for 24 or 25 consecutive SNPs in the 42 SNPs of original Finish risk haplotype. Conclusions: The frequency of the C9orf72 repeat expansion among Japanese patients is much lower than in Western populations. The existence of a 76-year-old asymptomatic carrier supported the notion of incomplete penetrance. The C9orf72 repeat expansion should be analyzed in sporadic ALS patients after determining their family histories not only of FTD but also of PPA. The haplotype bearing the C9orf72 repeat expansion was only shared in a narrow region between Western and Asian populations, suggesting that the C9orf72 repeat expansion may be an old mutation in human migration history from Western to East Asia.

3222F

Three pycnodysostosis cases with a novel mutation in cathepsin K gene. *T. Ozdemir[1], T. Atik[2], E. Karaca[1], H. Onay[1], F. Ozkinay[2], O. Cogulu[2].* 1) Ege University Faculty of Medicine, Department of Medical Genetics, Izmir, Turkey; 2) Ege University Faculty of Medicine, Department of Pediatrics, Division of Genetics, Izmir, Turkey.

Pycnodysostosis is a rare, autosomal recessive osteochondrodysplasia which is characterized mainly by short stature, abnormally high bone density, acroosteolysis, seperated cranial sutures with open fontanelles and bone fragility. It is caused by mutations in the cathepsin K gene (CTSK) which consists of 8 exons and results with impaired tissue specific expression of the lysosomal cysteine protease. Thirty-three mutations, associated with CTSK gene, have been reported in Human Gene Mutation Database. These mutations include particularly missense mutations, followed by frameshift, nonsense and splicing mutations. They mostly localize in exons 5 and 8, however only one case with frameshift mutation in exon 4 have been reported to date. Here we report 3 children (one female and 2 male) from 2 different families with c.354_355insT (p.V119Cfsx25) homozygous novel mutation in exon 4 of CTSK gene. The common clinical features of 3 cases were short stature, osteosclerosis, open fontanelles and sutures, beaked nose, hypoplasia of the jaws, obtuse mandibular angle, dental abnormalities, stubby hands and feet with acroosteolysis, dysplastic nails. Only one female case had a history of three fractures. In conclusion these cases make two contributions to the literature, firstly they are the first cases reported from Turkey in which a novel mutation in CTSK gene has been identified, secondly this novel mutation in three cases suggest a relatively mild clinical picture of pycnodysostosis.

Application of Next-Generation Sequencing for Mutation Detection in Autosomal Dominant Polycystic Kidney Disease. *H.C. Park[1,2], A. Kang[3], J.Y. Jang[3], Y. Hwang[2,4,5], H. Kim[1], M. Han[1], D.K. Kim[1], K. Oh[1], W. Park[2,6], H.I. Cheong[2,7], C. Ahn[1,2,3].* 1) Department of Internal Medicine, Seoul National University Hospital, Seoul, South Korea; 2) Research Center for Rare Diseases, Seoul National University Hospital, Seoul, South Korea; 3) Transplantation Center, Seoul National University Hospital, Seoul, South Korea; 4) Department of Internal Medicine, Eulji General Hospital, Seoul, South Korea; 5) Division of Genomic Medicine, Toronto General Hospital, Toronto, Canada; 6) Department of Biomedical Sciences, Seoul National University College of Medicine, Seoul, South Korea; 7) Department of Pediatrics, Seoul National University Children's Hospital, Seoul, South Korea.

Autosomal dominant polycystic kidney disease (ADPKD) is the most common hereditary renal disease characterized by multiple renal cysts and other extrarenal manifestations such as intracranial aneurysm and hepatic cysts. Although the genotype (PKD1 vs. PKD2) is the most important prognostic factor, it has not been so easy to detect mutation using conventional Sanger sequencing because of multiple duplicated regions (pseudogenes) along the chromosome 16 and a large mRNA transcript size of PKD1 with relatively high GC ratio. This study was performed to evaluate the efficacy of targeted exome sequencing in mutation detection of ADPKD compared to Sanger sequencing. We extracted DNA from whole blood of 24 ADPKD patients. ADPKD was typically diagnosed by family history and imaging such as ultrasonography or computed tomography with age-related criteria. We performed targeted exome sequencing using Agilent SureSelect in-solution enrichment system and verified the detected variants by Sanger sequencing methods. We designed the 120-mer RNA baits to cover the target exon three time (X3) and used hybridization target sequence capture strategy. The captured DNA was sequenced by ligation with the Illumina/GAIIx system. From the sequencing data, we aligned the sequences to the known reference sequence (GRCh37). In case of missense variants, we used PolyPhen-2, SIFT, and Mutation Taster to predict the functional effects. The process detected definitely and likely pathogenic variants in 21 (87.5%) out of 24 ADPKD patients. PKD1 mutations accounted for 81% (17/21) and PKD2 mutations for 19% (4/21). In addition, all of the mutations detected by novel next-generation sequencing method were confirmed by Sanger sequencing. Most of the PKD1 mutations were located at the exon 15 (12/25 mutations, 48.0%). Missense mutations accounted for 60% of PKD1 mutation; however, nonsense mutations and frameshift mutations were dominant in PKD2 mutations (80%). Conclusion: The targeted exome sequencing may be the promising tool to find out causative mutation in ADPKD in a high-throughput and an accurate way. We are currently working on the mutation data analysis from a larger ADPKD cohort and expect more comprehensive data to validate the efficacy of the targeted exome sequencing.

3224F

Whole exome sequencing identifies a missense mutation in *SEPT2* as a probable cause of a new autosomal dominant syndrome with distinctive face, ear anomalies, and learning disability. *A. Rump[1], K. Hackmann[1], A. Dahl[2], A. Fischer[3], M. Schweiger[3], M. Schilhabel[4], A. ElSharawy[4], A. Franke[4], E. Schrock[1], N. Di Donato[1].* 1) University of Technology Dresden, Institute of Clinical Genetics, Dresden, Germany; 2) University of Technology Dresden, Biotechnology Center, Dresden, Germany; 3) Max-Planck Institute for Molecular Genetics, Department of Vertebrate Genomics, Berlin, Germany; 4) Christian-Albrechts-University, Institute of Clinical Molecular Biology, Kiel, Germany.

Background: Recently, we have presented clinical data of three patients from two unrelated families with a unique combination of clinical features, including prominent eyes and bilateral ptosis. Other features include cleft palate, hearing loss, heart defects, and mild developmental delay. Since the condition is transmitted directly from mother to daughter (family 1) and observed in a male patient (family 2), autosomal dominant inheritance is suggested (Tyshchenko, N. et al. (2011) Am J Med Genet 155A (9):2060–2065). Method: Four members of family 1 (the affected mother, her affected daughter and her healthy parents) were analyzed by whole exome sequencing on a SOLiD4 system. Results: We identified a heterozygous missense mutation in the *SEPT2* gene. The mutation is present in the two affected individuals and absent in the healthy family members as well as in a large cohort of healthy, unrelated control individuals. According to both polyphen-2 and mutation taster, the mutation is damaging with a probability score of >0.999. The *SEPT2* gene encodes a filament-forming cytoskeletal GTPase. Unlike Ras-type GTP-binding proteins, septins form core oligomeric complexes and the human septin core structure is composed of a linear, nonpolar hexamer SEPT7-SEPT6-SEPT2-SEPT2-SEPT6-SEPT7. Sequencing of *SEPT2*, *SEPT6* and *SEPT7*, however, did not yield a plausible mutation in our second family. Conclusion: Septins have very recently been shown to regulate the collateral branching of axons (Hu et al., Curr Biol. 2012 May 16. [Epub ahead of print]). Since SEPT2 is also known to act as a scaffold of myosin II, the *SEPT2* gene is a plausible candidate for causing the clinical features of our patients upon mutation. Currently, we are investigating the effect of our *SEPT2* mutation on axon formation in retinoic acid induced SH-SY5Y cells. Since the affected boy of the second family did not show mutations in the septin genes mentioned above, family 2 is currently being sequenced on exome level.

Oculocutaneous Albinism (OCA1A/B) - founder mutations in the tyrosinase gene in Colombia. *O. Urtatiz, D. Sanabria, M.C. Lattig.* Universidad de los Andes, Bogota, Colombia.

Oculocutaneous albinism (OCA) is a group of inherited disorders of melanin biosynthesis characterized by a complete lack or generalized reduction in pigmentation of hair, skin and eyes. Mutations in the tyrosinase gene TYR on chromosome 11q14.3, are responsible of OCA1 (MIM203100) with OCA1A and OCA1B subtypes. The gene consists of 5 exons spanning about 65 kb of genomic DNA and encoding a protein of 529 amino acids. Mutations completely abolishing tyrosinase activity result in OCA1A, while mutations rendering some enzyme activity result in OCA1B allowing some accumulation of melanin pigment over time. In Colombia, the first study reported by Sanabria, et al. identified a missense G47D mutation in two unrelated individuals in heterozygous state. This mutation has already been reported in Puerto Rico and Sephardic/Moroccan Jews populations despite being two ethnically distinct populations. In this study we found the G47D mutation in 3 other unrelated Colombian individuals with OCA1A, and was not present in one individual with OCA1B. Two of the three OCA1A individuals were homozygous for the G47D mutation and the remaining individual was a compound heterozygote: G47D mutation and a novel nonsense mutation (S184X). This novel mutation is a c.551C-G nucleotide substitution in exon 1 resulting in an aminoacid change of serine to stop codon (S184X). The OCA1B individual also presented the novel mutation (S184X) in a heterozygous state, however the remaining mutation in the homologous allele was undetermined in TYR gene. According to this, we suggest that the G47D mutation in Colombian individuals is due to a founder mutation. This is reasonable if we take into account that haplotype analyses have shown that G47D mutation in individuals from Puerto Rico as well as Moroccan Jews share a common origin. Probably the G47D mutation found in Colombian individuals may have the same ancestral origin as the Sephardic Jews and Puerto Ricans, taking into consideration that Sephardic and Moroccan Jews had several waves of emigration arriving to America in the fifteenth century, fleeing persecution. The Canary Islands and Puerto Rico were part of the places they visited in their exploration trips thus probably brought the G47D mutation to the Caribbean and north of South America.

Ophthalmologic findings in Mexican patients with Myotonic Dystrophy Type I. *P. Barojas[1], JJ. Magaña[2], G. Ortega[1], N. Leyva[2], B. Cisneros[3], O. Hernández-Hernández[2], E. Barojas[1].* 1) Ophthalmology, National Rehabilitation Institute, Mexico City, Mexico City, México; 2) Department of Genetics, INR, Mexico City, México; 3) Genetics and Molecular Biology, CINVESTAV-IPN, Mexico City, México.

Myotonic dystrophy type 1 (DM1) is a dominantly neuromuscular inherited disorder caused by the expansion of an unstable CTG tract in the 3'UTR of the DMPK gene. Clinical manifestations of DM1 involve a great number of tissues including the ocular system. Several visual system alterations in DM1 have been described including cataracts, decreased intraocular pressure and ocular muscles alterations that result in ophthalmoplegia, bilateral motility disturbance, obicularis oculi, levator muscle weakness, and ptosis. To investigate visual system alterations in Mexican DM1 patients, an extensive ophthalmologic evaluation was performed. A sample of 44 individuals clinically diagnosed as DM1 were subjected to molecular test, applying a fluorescent PCR method in combination with capillary electrophoresis analysis. Patients were divided according with the CTG expansion on three groups: premutation, small mutation and greater than 100 CTG repeats. Opthalmologic applied tests included visual capacity, autokeratorefractometry, gaze positions and diplopia, examinations of lids, cornea, anterior chamber, iris and light response. Macula, retinal periphery, pachimetry, keratometries, lens density, endothelial cell count and macular optical coherence tomography (OCT) were also documented. Severe alterations were found in the group of higher CTG expansions: 50% of patients presented cortical punctate opacities in lens (previously undescribed), 30.7% showed impairment of epiretinal membrane (MER), meanwhile 11.5% showed neovascular membrane (MNV) damage. 80% of the patients presented cataract with a mean age of 35 years old, however we did not observe a christmas tree cataract in any subject. Interestingly, OCT examination showed hyperreflective dots on the inner layers of the retina in all of our patients including the premutation group. These results open a new avenue into the study of the cellular and molecular mechanisms to understand how hyperreflective dots in the retina are produced even in presence of small expansions. In addition, this sign on the retina could be used in the future as an early ophthalmologic marker of the disease.

3227W

Molecular diagnosis of Myotonic dystrophy type I by PCR Southern method. *GH. Kim[1], JJ. Lee[1], SH. Choi[1], JY. Lee[1], JM. Kim[1], YM. Kim[2], BH. Lee[1,2], HW. Yoo[1,2].* 1) Med Gen Clinic & Lab, Asan Med Ctr, Seoul, South Korea; 2) Asan Medical Center Children's Hospital, University of Ulsan College of Medicine, Seoul, Korea.

Myotonic dystrophy type 1 (DM1; MIM 176270) is a progressively degenerative skeletal muscular disease. Based on clinical severity, this condition is divided into three phenotypes, mild, classic, and congenital. It is inherited in an autosomal-dominant manner and caused by abnormal expansion of trinucleotide repeat, (CTG)n, in the 3'-UTR of Dystrophia myotonica-protein kinase (DMPK) gene located on 19p13.3. The aim of this study was to verify whether PCR Southern method is a useful molecular diagnostic tool for DM1. During the period of 2000 to 2011, 1,243 unrelated patients were requested for the genetic diagnosis of DM1. To assess the accuracy of our PCR Southern method, 54 DNA samples, obtained from Collage of American Pathology (CAP) molecular genetics survey program, were used as positive (18 samples) or negative (36 samples) controls. Genomic DNA was isolated from each patient's peripheral leukocytes. After PCR amplification, each product was separated by agarose gel electrophoresis, transferred to nylon membrane, and hybridized by biotin labeled (CTG)10 probe. Each band was exposed on X-ray film using streptoavidin conjugated alkarine phosphatase. The copy number of each band was measured according to DNA size marker. A total of 658 patients (52.9%) had abnormal (CTG)n in the DMPK. Twenty eight patients had congenital type (4.3%), 611 patients classic type (92.9%), and the remaining 15 patients had mild or premutation type (2.3%). The (CTG)n was inversely correlated with the request age of patients (R=-0.418, P<0.01). Maternally originated anticipation was observed in 15 families. The median fold change of (CTG)n in the offsprings to those in their mothers was 5.1. The sensitivity and specificity of PCR Southern method were all 100%, when this method was applied to positive and negative controls from CAP. The calculated copy numbers, however, were approximately 100 copies lower in our results than in CAP results, although these differences didn't influence the classifications of phenotypic subtypes according to our PCR Southern method. The limitation of PCR-based method is that large (CTG)n is difficult to detect by PCR method, even by triplet repeat primed PCR method, recently introduced to improve the detection efficiency of (CTG)n. In addition, the exact number of (CTG)n is difficult to measure due to cellular mosaicism. However, having very high sensitivity and specificity, PCR-Southern method is a proper molecular diagnostic tool for DM1.

3228F

Mutations in FOXP2 cause childhood apraxia of speech: report of a novel intragenic deletion in an Australian patient. *M.S. Hildebrand[1], S. Turner[2], J. Damiano[1], R.J.H. Smith[3], M. Bahlo[4], I.E. Scheffer[1,5], A.T. Morgan[2].* 1) Epilepsy Research Centre, Department of Medicine, University of Melbourne, Austin Health, Heidelberg, Victoria 3084, Australia; 2) Population Health, Genes and Environment Theme, Murdoch Childrens Research Institute & Department of Paediatrics, University of Melbourne, Parkville, Victoria 3052, Australia; 3) Department of Otolaryngology - Head and Neck Surgery, University of Iowa City, IA, 55242, USA; 4) Bioinformatics Division, The Walter and Eliza Hall Institute of Medical Research & Department of Mathematics and Statistics, The University of Melbourne, Parkville,Victoria 3052, Australia; 5) Florey Neuroscience Institutes and Department of Paediatrics, University of Melbourne, Royal Children's Hospital, Parkville, Victoria 3052, Australia.

Developmental speech and language problems are a heterogeneous group of disorders that can prove difficult to manage clinically. In most cases the etiology is unknown, although in a minority genetic variants have been implicated or shown to confer susceptibility. The first specific subtype to be directly linked to a molecular genetic defect was childhood apraxia of speech (CAS) due to mutation in the FOXP2 gene at the SPCH1 locus. We completed recruitment of eight Australian families where the proband had a primary diagnosis of motor speech disorder. Affected family members were phenotyped using a comprehensive assessment battery that comprised measures of speech, oromotor function, language, literacy skills and cognition. We screened the coding regions of the FOXP2 gene in all eight probands and identified novel variants in two. We then determined the inheritance pattern and segregation of the variant in the probands' families. Here we describe these variants including the first reported small, intragenic deletion of the FOXP2 gene. Our results support the current evidence that FOXP2 mutation is a well-defined cause of CAS, and extend the genotype-phenotype spectrum of FOXP2-related speech and language disorders.

3229W

Exome sequencing identifies a novel *MRE11* mutation in a patient with generalized myoclonic tremor. *R. Miyamoto[1,2], H. Morino[1], H. Maruyama[1], Y. Izumi[2], R. Kaji[2], H. Kawakami[1].* 1) Department of Epidemiology, Research Institute for Radiation Biology and Medicine, Hiroshima University, Hiroshima, Japan; 2) Department of Clinical Neuroscience, Institute of Health Biosciences, Graduate School of Medicine, University of Tokushima, Tokushima, Japan.

[Background] Ataxia-telangiectasia-like disorder (ATLD) is a rare autosomal recessive disorder caused by mutations in the *MRE11* gene. ATLD is characterized by slowly progressive ataxia, oculomotor apraxia, and cerebellar atrophy. To date, little is known about other clinical features associated with *MRE11* mutations. [Patient] The patient is a 52-year-old female from consanguineous parents. She developed a jerky neck movement at age 9. Three years later, she showed a hand tremor, which gradually expanded to the entire body. On physical examination at age 47, she presented short stature and bilateral ptosis with a masked face. She showed generalized myoclonic tremor that was exacerbated by emotional stress. Brain MRI demonstrated no signs of cerebellar atrophy. EEG was within normal limits. SEP and jerk-locked back averaging failed to show the evidence of cortical myoclonus. Surface electromyogram demonstrated 4Hz unsynchronized bursts in her limbs. [Methods] The genetic study was approved by the ethics committee, and the patient provided written informed consent. Genomic DNA libraries were prepared using the SeqCap EZ Human Exome Library v2.0. Sequencing was performed with 100bp paired-end reads on a HiSeq2000. The reads were aligned to the human reference genome with BWA. Variants were called with GATK, and were annotated with Annovar using dbSNP build 135. Pathogenicity predictions for variants were obtained from the algorithms, including SIFT and Polyphen-2. Sequencing depth was calculated using GATK. All reported genomic locations are from GRCh37/hg19. Validation of the sequence variant was assessed with Sanger sequencing. [Results] Exome sequencing produced 129 million sequencing reads for the sample, comprising 12 billion bases. Approximately 88% of the sequencing reads were aligned to hg19. The average depth was 116. We identified 80,852 variants located in exonic or splicing regions. After filtering these variants in a reasonable manner, a homozygous missense sequence variant in the *MRE11* gene (NM_005590:c.140C>T:p.A47V) was left as a candidate. This amino acid change was predicted to be damaging by all the prediction algorithms. [Conclusions] This case, with the novel *MRE11* mutation, predominantly showed myoclonic tremor. Clinical symptoms associated with *MRE11* mutations could be more numerous than previously thought. Exome sequencing could be a powerful method of diagnosing very rare diseases from a single sample.

Pathophysiological features of dermatan 4-O-sulfotransferase 1 (D4ST1)-deficient Ehlers-Danlos syndrome (DD-EDS). *T. Kosho[1], S. Mizumoto[2], M. Kobayashi[3], Y. Fujita[4], J. Nakayama[5], N. Miyake[6], Y. Nomura[7], A. Hatamochi[8], Y. Fukushima[1], K. Sugahara[2], N. Matsumoto[6].* 1) Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 2) Laboratory of Proteoglycan Signaling and Therapeutics, Hokkaido University Graduate School of Life Science, Sapporo, Japan; 3) Department of Food and Nutritional Environment, College of Human Life and Environment, Kinjo Gakuin University, Nagoya, Japan; 4) Division of Medical Research Engineering, Nagoya University Graduate School of Medicine, Nagoya, Japan; 5) Department of Molecular Pathology, Shinshu University Graduate School of Medicine, Matsumoto, Japan; 6) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 7) Scleroprotein and Leather Research Institute, Tokyo University of Agriculture and Technology, Fuchu, Japan; 8) Department of Dermatology, Dokkyo Medical University, School of Medicine, Mibu, Japan.

Dermatan 4-O-sulfotransferase 1 (D4ST1)-deficient Ehlers-Danlos syndrome (DD-EDS), caused by recessive loss-of-function mutations in CHST14, is a recently delineated form of EDS [Kosho et al., 2011], independently identified as “adducted thumb-clubfoot syndrome” [Dündar et al., 2009], “EDS, Kosho Type” [Kosho et al., 2010; Miyake et al., 2010], and “Musculocontractural EDS” [Malfait et al., 2010]. DD-EDS is characterized by a unique set of clinical features consisting of progressive multisystem fragility-related manifestations (skin hyperextensibilty/fragility, progressive spinal/foot deformities, large subcutaneous hematoma) and various malformations (facial features, congenital eye/heart/gastrointestinal defects, congenital multiple contractures). The cause of multisystem connective tissue fragility is postulated to be impaired assembly of collagen fibrils based on glycobiological analysis on patients' skin fibroblasts showing loss of dermatan sulfate replaced by chondroitin sulfate in the decorin glycosaminoglycan (GAG) side chain. However, most of the pathophysiology is still uncovered including skin pathology related to decorin and glycobiological effects on cells except skin fibroblasts. In this study, we report novel pathological and glycobiological findings. Light microscopy on three patients' skin specimens by Azan staining showed waving of the epidermis and fineness of collagen bundles in the dermis, compared with a normal control. Electron microscopy on a patient's skin specimen using cupromeronic blue, directly staining GAG side chains of proteoglycan, demonstrated shorter GAG side chains than those in a patient with another type of EDS. Decorin staining on four patients' skin specimens using human decorin antibody, specifically binding to decorin core protein, demonstrated filamentous staining along collagen bundles, markedly different from a normal control showing uniformly stained collagen bundles. Array-based expression study demonstrated increased or decreased expression of several genes, though the changes were not significant. Glycobiological study on five patients' urine specimens, using anion-exchange HPLC after digestion with chondroitinases ABC/AC/B, demonstrated complete loss of dermatan sulfate. These data present direct evidence on conformational abnormalities between decorin core protein and GAG side chains on collagen fibrils and demonstrate that generalized complete loss of dermatan sulfate is the essence of this disorder.

3231W

Rupture of chordae tendineae as an initial presentation of an haploinsufficiency mutation in COL3A1. *Z. Xu[1], B.F. Griswold[1], L.J. Sloper[1], A.S. Shah[2], N.B. McDonnell[1].* 1) National Institute on Aging, Baltimore, MD; 2) Johns Hopkins University, Baltimore, MD.

COL3A1 haploinsufficiency mutations usually result in milder phenotypes of Vascular form of Ehlers Danlos syndrome as compared to missense or splicing mutations. We describe the case of a 31 year old male who developed acute mitral insufficiency due to rupture of chordae tendineae during jogging. During the repair the mitral valve, tissue fragility was noted by the surgeon and the patient was referred for testing for pathogenic mutations in COL3A1. Sanger sequencing was performed for the COL3A1 gene. A novel nonsense mutation c.2569C>T, p.Q857X was identified in one allele of COL3A1 gene, leading to haploinsufficiency of procollagen III. Subsequent work showed that this mutation was inherited from the patient's father who had a history of aortic aneurysm. The mutation was also present in the patient's two young daughters and his brother. This case illustrates an unusual initial presentation for the Vascular form of Ehlers Danlos syndrome. The observation of tissue fragility by the cardiothoracic surgeon was the key to the correct diagnosis and genetic counseling of this family. Rupture of chordae tendineae in an otherwise healthy and young individual may be the first key to the identification of a hereditary connective tissue disorder in a family.

Prenatal diagnosis and identification of heterozygous frameshift mutation in *PRRX1* in an infant with agnathia-otocephaly. *M. Donnelly[1], E. Todd[1], M. Wheeler[1], V. D. Winn[1], D. Kamnasaran[2,3].* 1) Department of Obstetrics and Gynecology, University of Colorado, Aurora, CO; 2) Pediatrics Research Unit, Centre de recherché du CHUL, Quebec, Canada; 3) Department of Pediatrics, Laval University Quebec, Canada.

Recently, several infants diagnosed with agnathia-otocephaly, a severe disorder of first pharyngeal arch development, have been discovered to have loss of function mutations in the Prrx1 gene, which encodes a protein in the paired homeobox family important for facial development. We report the 3-D ultrasound prenatal diagnosis of an infant with agnathia-otocephaly, as well as a novel heterozygous frameshift loss-of-function mutation of PRRX1 in this infant. With sequencing of genomic DNA of this infant, a heterozygous deletion of an adenosine (c. 267 del A) was discovered in a poly A tract in the PRRX1 gene. This deletion is absent in both parents, and in normal individuals (n=100 tested). Subsequent functional assays with the wildtype PRRX1 protein (245 amino acid isoform) demonstrated a significant repression of the human tenascin-c (TNC) promoter fragment (-516 to +195) in COS7 cells. Such repression is also seen in COS7 cells transfected with the pcDNA3.1 vector only, since basal levels of wildtype PRRX1 are expressed endogenously. However, the PRRX1 protein with the p.Lys90Argfs*131 frameshift mutation demonstrated a significant inability to repress the human tenascin-c promoter fragment, and is therefore a loss-of-function mutation. This case provides additional evidence that the Prrx1 gene is important in the development of agnathia-otocephaly, and further work may lead to development of testing for use in prenatal diagnosis beyond ultrasound imaging.

3233W

Identification of the disease causing gene in a familial autosomal recessive form of congenital nystagmus by exome sequencing. *B. Isidor, J. Albuisson, S. Bezieau.* Service de génétique médicale, CHU Nantes, Nantes, France.

Congenital or infantile nystagmus (CN) is a rare disabling genetic condition, presenting as conjugate, horizontal oscillations of the eyes. It may be associated with torticollis, decreased visual acuity, strabismus, astigmatism, and occasionally head nodding. This heterogenous disorder can be transmitted in an X-Linked fashion, as a consequence of the FRMD7 gene mutations, leading to a pure, neurologic CN. To date, several loci have also been identified in autosomal dominant forms of CN, but no other causative gene could be identified. Recessive CN was exceptionally described and has never been investigated by genetic analyses. We present here our strategy to identifiy the gene responsible for autosomal recessive CN in a French family. The CN kindred is represented by three girls from healthy, apparently unrelated parents. Two of the girls had CN. No mutation could be identify by Direct sequencing of the FRMD7 gene in one of the affected girl. We also believe that a new gene could be responsible fro this very rare form of CN. Exome sequencing in 2 affected patients of this family and one healthy sister will probably lead to the identification the disease causing gene.

3234F

Identification of X-Linked RPGR ORF15 Mutations in Females Diagnosed with Autosomal Dominant Retinitis Pigmentosa. *J.D. Churchill[1], S.J. Bowne[1], L.S. Sullivan[1], R.A. Lewis[2], D.K. Wheaton[3], D.G. Birch[3], K.E. Branham[4], J.R. Heckenlively[4], S.P. Daiger[1].* 1) Human Genetics Center, UTHSC Houston, Houston, TX; 2) Department of Ophthalmology, Baylor College of Medicine, Houston, TX; 3) The Retina Foundation of the Southwest, Dallas, TX; 4) Kellogg Eye Center, University of Michigan, Ann Arbor, MI.

The purpose of this study is to identify the fraction of families with a provisional diagnosis of autosomal dominant retinitis pigmentosa that have disease-causing mutations in the X-linked retinitis pigmentosa GTPase regulator (*RPGR*) gene. Retinitis pigmentosa (RP) is an inherited retinal degeneration that affects approximately 1.5 million people world-wide. RP can be inherited in an autosomal dominant, autosomal recessive, or X-linked manner. However, X-linked RP (XlRP) may be mistaken for autosomal dominant RP (adRP) since some X-linked mutations cause disease in female carriers. Mutations in the *RPGR* gene are the most common causes of XlRP, accounting for over 70% of XlRP, and approximately 60% of disease-causing mutations in *RPGR* are found in ORF15. However, screening ORF15 of *RPGR* in females is technically difficult due to the presence of polymorphic insertions and deletions that often make sequence alignment impossible. To facilitate testing of *RPGR* in “adRP” families, the repetitive and purine-rich ORF15 of *RPGR* was subcloned and sequenced in females from 16 unrelated families that had a diagnosis of adRP, no male-to-male transmission, and no males available for testing. Analysis identified a disease-causing mutation (a single-nucleotide duplication) in one of the families examined in this study. In previous studies, we selected families with a provisional diagnosis of adRP and no male-to-male transmission from a cohort of 237 families and screened these families for mutations in *RPGR*. Eighteen of these “adRP” families were found to have *RPGR* mutations. Combining these data with data from our recent study shows that approximately 8% (19 in 237) of families thought to have adRP truly have XlRP. These results have significant implications for calculation of recurrence risk, counseling, and treatment and illustrate the importance in screening families with a provisional diagnosis of autosomal inheritance and no male-to-male transmission for mutations in X-linked genes. Additionally, these results show that for families in which males are not available for testing, subcloning and sequencing of ORF15 is a reasonable option for molecular diagnosis.

3235W

A recurrent 143 kb duplication in TSPAN7 as a possible cause of intellectual disability. *J. Hoyer, M. Krumbiegel, C. Kraus, A. Reis.* Institute of Human Genetics, University Erlangen-Nuremberg, Erlangen, Germany.

We identified with molecular karyotyping on a high density microarray a microduplication of 143 kb on chromosome Xp11.4 comprising only Tetraspanin 7 (TSPAN7) in a seven 7 years old boy of German origin with mild intellectual disability (ID) and body measurements within the normal range. We detected the same duplication in another male with body measurements below the 3rd centile, mild ID, particularly difficulties in expressive and perceptive speech, strabismus and suspected Attention Deficit Hyperactivity Disorder (ADHD). Both boys had normal male karyotypes and Fragile-X syndrome was excluded. The duplications were shown to be inherited from normal mothers coming from Germany and Kyrgyzstan respectively. X inactivation studies indicated a random pattern in both women. Abidi and colleagues reported in 2002 the implication of TSPAN7 in nonsyndromic X-linked MR (MRX58). The affected males had mild to moderate mental retardation and no consistent dysmorphic features, while obligatory carrier females were normal and showed a random pattern of X inactivation. TSPAN7 is highly expressed in the central nervous system and encodes a member of the transmembrane 4 family of proteins, which are known to contribute in molecular complexes that include beta-1 integrins. Zemni and colleagues speculated that through this interaction, TSPAN7 may play a role in the control of neurite outgrowth. The duplication identified in our two patients was not found among a cohort of 820 controls and is not listed in the database of genomic variants suggesting the copy number variation to be a recurrent alteration playing a pathogenic role in male ID. To support this hypothesis systematic analyses of members of family 1 are ongoing.

3236F

Alpha thalassemia /mental retardation X linked (ATRX) - an uncommon presentation. *U.H. Kotecha[1], R. Puri[1], C. Badens[2], I.C. Verma[1].* 1) Center of Medical Genetics, Sir Gangaram Hospital, New Delhi, India; 2) Laboratoire de Génétique Moléculaire, Département de Génétique Médical, Hôpital d'Enfants de la Timone, Marseille, France.

X-linked alpha thalassemia /mental retardation syndrome (ATRX) occurs due to mutations in the ATRX gene. Cardinal features are mental retardation, characteristic facies, hematological and genital abnormalities. Sporadic cases without the above are difficult to diagnose, especially in infancy as the facial features are still evolving. We describe a child with an uncommon phenotypic presentation of ATRX. A one year old boy was brought for evaluation of global developmental delay. Developmental milestones were limited to social smile and some vocalization. He was born at term to a non-consanguineous Asian Indian couple and had no history of birth asphyxia. There were no seizures. The family history was non contributory. Examination revealed microcephaly, and subtle dysmorphism (telecanthus, bilateral epicanthal folds and depressed nasal bridge). Contractures of distal interphalangeal joints of the third and fourth fingers of the right hand and all the fingers of the left as well as bilateral cryptorchidism were present. An MRI of the brain and ophthalmological examination showed cortical atrophy and myopia respectively. Karyotype was normal. A possibility of distal arthrogryposes atypical facies syndrome was considered. Since no gene for the same is known, patient was advised supportive management and annual follow up. He came for review after three years. On examination a frontal upsweep, small forehead, low set ears, hypertelorism, epicanthal folds, tented upper lip with thick lower lip were present. There was no progression of joint involvement. ATRX syndrome was suspected clinically. Haematological investigations revealed hypochromic microcytic anemia but HbH inclusions were absent. Molecular analysis of ATRX gene confirmed a novel missense mutation in exon9 c.A224E. This mutation is located in the zinc finger domain and is expected to affect splicing. The zinc finger region is located in the ADD domain which is a highly conserved segment and represents a major mutation site. Mutations in this region are known to be associated with severe mental retardation. Though microcephaly and some coarsening of facies was noted at the first visit, distal joint contractures were a predominant feature and hence delayed the diagnosis of ATRX. Though fixed flexion deformities of distal joints have been noted in ATRX, the above case highlights the difficulty in diagnosis in infants with this presenting feature in sporadic cases.

3237W

Proteolipid protein 1 (PLP1) gene mutation in 44 Chinese patients with Pelizaeus-Merzbacher disease and prenatal diagnosis of five fetuses in three Chinese families with PMD probands. *J. Wang[1], D. Li[1], Y. Wu[1], H. Zhao[1,2], J. Shang[1,2], J. Qin[1], F. Fang[3], X. Wu[1], Y. Jiang[1].* 1) Dept Pediatrics, Peking Uni First Hosp, Beijing, China; 2) Department of Neurology, First Hospital Affiliated to Shanxi Medical University, Taiyuan; 3) Beijing Childrenès Hospital, Beijing, China.

Purpose The object of this study was to identify Proteolipid protein 1(PLP1) mutations in 44 unrelated Chinese patients (P1-44) with Pelizaeus-Merzbacher disease (PMD) and prenatal diagnosis of five fetuses in three Chinese families with PMD probands. Methods Genomic DNA was extracted from peripheral bloods samples. At 19 or 20 weeks gestation, amniotic fluid sampling (AFS) was performed. Gene dosage was determined by Multiplex Ligation-dependent Probe Amplification (MLPA). All 7 exons and exon-intron boundaries of PLP1 gene were amplified and analyzed by direct DNA sequencing. Results Of these 44 patients, there were 24 classical, 15 transitional, and 5 congenital PMD according to the clinical and radiological presentation. PLP1 duplications were identified in patients 1–30 with PMD, account for 75% (30/44). 8 hemizygous missense mutations including c.517C to T (p. P173S), c.709T to G(p.F237V), c.623G to T(p.G208V), c.467C to T(p.T156I), c.353C to T(p.T117R) and c.646C to T(p.P214S), c.96C to G(p.F32L), IVS5-1G to A were found in Patients31–38 with PMD(18.2%). 6 (13.6) were not found any changes with PLP1. For the results of prenatal diagnosis, the three fetuses in family 1 showed normal PLP1 dosage and chromosome analysis demonstrated a 46,XX and two 46,XY chromosome pattern, respectively. The fetus in family 2 revealed three cope of PLP1 which suggested a PLP1 duplication carrier after chromosome pattern was a 46, XX. In family 3, duplication of PLP1 was detected in the fetus imply as a PMD patient with 46, XY chromosome pattern. Conclusions We identified 30 genomic duplications and six missense mutation of PLP1 gene in 38 Chinese patients with PMD, account for 86.4% (38/44). Prenatal diagnoses for five fetuses in three PMD families were performed, which is useful and helpful for those families. This is the first report about PLP1 mutations and prenatal diagnosis in PMD patients in mainland of China.

3238F

Four Years of Data from the California Cystic Fibrosis Newborn Screening Program and Experiences of the Sutter CF Center. *M. Tsang[1], B. Chipps, MD, FAAP, FAAAI, FCCP[2], M. Kharrazi, PhD[3], K. Pearson, NPN, MS[1], S. O'Bra, BSHS[1].* 1) Sutter Medical Center 1625 Stockton Blvd. #112 Sacramento, CA 95816; 2) Capital Allergy and Respiratory Disease Center 5609 J. St. Suite C Sacramento, CA 95819; 3) Genetic Diseases Screening Program California Department of Public Health 850 Marina Bay Parkway Rm F175 Richmond, CA 94804.

The purpose of population-wide newborn screening for CF is to improve health and survival through early preventative care and therapeutic interventions. Every state in the US now screens for CF but the screening protocol differs for each state and as a result, the detection rates, false positives, and false negatives vary widely. California started screening newborns for cystic fibrosis in July 2007. The program is unique and includes comprehensive genotyping of the cystic fibrosis transmembrane conductance regulator gene (CFTR) and long term follow up of hypertrypsinogenemic infants with two or more CFTR mutations regardless of sweat chloride results. When indicated, parent testing is provided to determine if the mutations are in cis or trans phase. Sutter Medical Center is an approved specialty care center for CF located in Sacramento, CA. Staff have seen 56 newborns with a positive screen to date. Of these, 24 have a diagnosis of CF (including 2 Hispanic patients with novel mutations), 17 have CFTR-Related Metabolic Syndrome (CRMS), 13 are carriers, 2 are pending and 1 has transferred to another center. A designation of CRMS is made based on the patient's mild clinical manifestations, results from sweat chloride, fecal elastase and other tests, and may take several months to a year to determine. Every new patient at the Center receives a phone call by the genetic counselor (GC) to review results within days of a positive screen and to discuss preparation for the sweat chloride test. At the first visit, the family is seen by the GC, nurse practitioner, and dietician. At subsequent visits, the MD, social worker and respiratory therapist are also involved with the family. The novel mutations/variants have provided the most challenges for us in that there is very little information regarding symptoms, organ involvement, and degree of severity. Most of these patients have CRMS and are doing well. We have learned that keeping the families informed and being optimistic while stressing the importance of consistent follow-up with our CF Center and pulmonologist, so early treatment can be implemented, is the best approach. In conclusion, the CA CF Screening Program has a screened more than 2 million babies in 4 years with a 93% detection rate and 22 missed cases. The ratio of screen positives to cases detected is 2.9 to 1. The Sutter CF Center is a family oriented clinic dedicated to providing comprehensive care and treatment to our patients with CF and CRMS.

3239W

Polymicrogyria awareness is a critical first step in facilitating early diagnosis and intervention for those affected by this rare congenital brain anomaly. *C. Byrge[1], A. Perszyk[2], PMG Awareness Organization, Inc.* 1) PMG Awareness Organization, Inc., Jacksonville, FL; 2) Univ. of Florida - Jacksonville, Medical Genetics, Jacksonville, FL, USA.

The lack of polymicrogyria awareness is a major factor in the late diagnosis of those affected. Both patient and doctor education are needed to improve medical care and patient outcomes. Polymicrogyria is an under recognized medical condition that can be present as a congenital, developmental brain disorder. Both environmental and genetic etiologies have been described in the literature. Many forms have been identified as genetic and therefore have an increased risk of recurrence. Recently, we surveyed patients or families of those diagnosed with polymicrogyria. Ages at the time of diagnosis ranged from pre-term infants to adults. We report here the data on over 100 individuals. The majority of patients had more than a 6 month delay in diagnosis of their brain malformation. Feeding and aspiration risks, gastroesophageal reflux and the use of tube feedings were common. Hypotonia and non-specific developmental delays were seen in half. Seizures, often refractory, also present in approximately 35 percent; of those affected. Seizures that resulted in a referral to a pediatric neurologist typically expedited diagnosis. Family support and education is important. Among those diagnosed, few families recalled any specific education about the diagnosis, genetic testing, or seizure precautions. Of critical note, the survey identified that 85 percent of their pediatricians were not familiar with polymicrogyria; therefore, over 44 percent of families stated that their pediatricians were not able to assist them in managing the care of their children. The majority of them also report that there is no single physician who manages the overall care of their children. Polymicrogyria is associated with perinatally acquired cytomegalovirus infections as one of the known environmental causes. This information was lacking in 90 percent of those surveyed. This situation suggests a need for more education regarding CMV modes of transmission and prevention on early prenatal visits. Based on this survey earlier diagnosis could be achieved and this can help to prevent some of the potential effects of polymicrogyria. Of special concern are the long term sequelae of uncontrolled seizure activity and of aspiration-related events. Much more research needs to be done regarding the unique treatment difficulties that are present for those affected by polymicrogyria. Further investigations are needed to explore survival data and long term outcomes.

3240F

Novel KIF7 mutations extend the phenotypic spectrum of acrocallosal syndrome. *A. PUTOUX[1,2], S. NAMPOOTHIRI[3], V. CORMIER-DAIRE[1,2,4], N. LAURENT[5], P. BEALES[6], A. SCHINZEL[7], D. BARTHOLDI[7], C. ALBY[2,8], S. THOMAS[1,2], N. ELKHARTOUFI[4], J. LITZLER[4], F. ENCHA-RAZAVI[1,2,4], R. KANNAN[9], A. MUNNICH[1,2,4], L. FAIVRE[10,11], N. BODDAERT[12], A. RAUCH[7], M. ATTIE-BITACH[1,2,4].* 1) INSERM U781 et fondation IMAGINE, Hopital Necker Enfants Malades, Paris, France; 2) Université Paris Descartes, Paris Sorbonne Cité, Paris, France; 3) Department of Pediatric Genetics, Amrita Institute of Medical Sciences, Kerala, India; 4) Département de Génétique, Hôpital Necker-Enfants Malades, Assistance Publique Hôpitaux de Paris (AP-HP), Paris, France; 5) Service d'Anatomie et de Cytologie Pathologique, Hôpital du Bocage, Dijon, France; 6) Molecular Medicine Unit, University College London (UCL) Institute of Child Health, London, UK; 7) Institute of Medical Genetics, University of Zurich, Schwerzenbach, Switzerland; 8) Service de Gynécologie - Obstétrique, Hôpital Necker Enfants Malades, AP-HP, Paris, France; 9) Department of Radiology, Amrita institute of Medical Sciences, Kerala, India; 10) Service de Génétique Médicale, Hôpital du Bocage, Dijon, France; 11) EA GAD, IFR Santé - STIC, Université de Bourgogne, France; 12) Service d'Imagerie Médicale, Hôpital Necker-Enfants Malades, AP-HP, Paris, France.

Acrocallosal syndrome (ACLS) is a rare recessive disorder characterised by corpus callosum agenesis or hypoplasia, cranio-facial dysmorphism, duplication of the hallux, postaxial polydactyly and severe mental retardation. Recently, we identified mutations in KIF7, a key component of Sonic hedgehog pathway, as responsible for this syndrome. We sequenced KIF7 in five suspected ACLS cases, one fetus and four patients, based on facial dysmorphism and brain anomalies. Seven mutations were identified at the KIF7 locus in these five cases, six of which are novel. We describe the first four compound heterozygous cases. In all patients, the diagnosis was suspected based on the craniofacial features, despite the absence of a corpus callosum anomaly in one and of polydactyly in another. Hallux duplication was absent in 4/5 cases. These results show that ACLS has a variable expressivity and can be diagnosed even in the absence of the two major features namely polydactyly or agenesis or hypoplasia of the corpus callosum. Facial dysmorphism with hypertelorism, prominent forehead in all, as well as vermis agenesis with brainstem anomalies (molar tooth sign) strongly indicated the diagnosis. KIF7 should be tested in less typical cases in whom craniofacial features are suggestive of ACLS.

Goldberg-Shprintzen Syndrome: KBP, the *KIAA1279* encoding protein, is located to cytoskeleton, but not to mitochondria. *L. Drévillon[1,2], A. Megarbane[3], B. Demeer[4], C. Matar[1,6], P. Benit[5], A. Briand-Suleau[1,2], J. Ghoumid[1,2], M. Nasser[1,2], V. Bodereau[1], M. Doco-Fenzy[7], P. Rustin[5], D. Gaillard[7], M. Goossens[1,2], I. Giurgea[1,2].* 1) AP-HP, Groupe hospitalier Henri-Mondor, Service de Biochimie et Génétique, Créteil, France; 2) INSERM U955, Equipe 11, and Université Paris-Est Créteil, Créteil, France; 3) Laboratory of Molecular Biology and Cytogenetics, Faculty of Medicine, University Saint-Joseph, Lebanon; 4) Pôle pédiatrie, Hôpital Nord, CHU Amiens, Amiens, France; 5) INSERM U676, Hôpital Robert Debré, Paris, France; 6) INSERM U955, Equipe 07, and Université Paris-Est, Créteil, France; 7) Service de Génétique, CHU, UFR de médecine, IFR53, Reims, France.

Goldberg-Shprintzen syndrome (GOSHS, MIM #609460) is a rare an autosomal recessive disorder associating severe intellectual disability, facial gestalt particularities, and Hirschsprung disease. In 2005, *KIAA1279* was identified as the disease causing gene with homozygous nonsense mutations in two consanguineous families. The encoded protein, named KBP (KIF-binding protein) due to its related interaction with kinesin-like protein, was initially claimed to be located at the mitochondria, a subcellular localization not confirmed by a recent study. KBP was implicated in axonal structure, outgrowth and maintenance in zebrafish. Since 2005, no supplementary patients with GOSHS have been reported, and data concerning the underling mechanism are poor. In this report, in parallel with the detailed phenotype of five novel patients from three different families, we studied, at the mRNA and at the protein level, the functional consequences of the *KIAA1279* mutations (c.303C>T p.Arg90X, c.599C>A p.Ser200X, and c.604–605delAG p.Arg202IlefsX2) carried by these patients. We proved that a NMD (nonsense mediated decay) mechanism occurred for all three truncating mutations. Indeed, in fibroblasts of patients with homozygous mutations, *KIAA1279* mRNA was barely detectable, and in those with heterozygous mutations, it was two-fold decreased. The addition of a NMD inhibitor in cell culture medium restored partially the mRNA level in fibroblasts with homozygous mutations. We showed that the activities of respiratory chain complexes and the oxydative stress, measured by spectrophotometry, were normal in fibroblasts from all the patients. We studied the subcellular localization of KBP by confocal microscopy, and revealed KBP co-localization with microtubules and filamentary-actin, but not with mitochondria, in human fibroblasts. Microtubule - KBP and filamentary-actin - KBP interactions were confirmed by biochemical binding assays. Finally, by extinction (si-RNA) or over-expression of KBP in a neuroblastoma cells line, we confirmed KBP implication in neurite outgrowth. In conclusion, this study permitted advances in the understanding of GOSHS molecular mechanism: i) by demonstrating NMD mechanism in *KIAA1279* truncating mutations, ii) by showing that KBP absence did not influence mitochondrial respiratory chain complex activity in human fibroblasts, iii) by proving KBP interactions with cytoskeleton, and iv) by confirming *in vitro* the implication of KBP in axonal outgrowth.

Craniofacial and Dental Development in Cardio-facio-cutaneous Syndrome: The Importance of Ras Signaling Homeostasis. *A. Goodwin[1], S. Oberoi[1], M. Landan[2], C. Charles[2], J. Groth[1], A. Martinez[3], C. Fairley[2], W.E. Tidyman[1], L.A. Weiss[4], O.D. Klein[1,2,3], K.A. Rauen[3].* 1) Center for Craniofacial Anomalies, Department of Orofacial Sciences, UCSF, San Francisco, CA; 2) Program in Craniofacial and Mesenchymal Biology, UCSF, San Francisco, CA; 3) Department of Pediatrics, UCSF, San Francisco, CA; 4) Department of Psychiatry and Institute for Human Genetics, UCSF, San Francisco, CA.

Cardio-facio-cutaneous syndrome (CFC) is a RASopathy that is characterized by craniofacial, dermatologic, gastrointestinal, ocular, cardiac and neurologic anomalies. CFC is caused by activating mutations in BRAF, MEK1, MEK2 or KRAS, all of which are components of the Ras/mitogen-activated protein kinase (MAPK) signaling pathway, which, in turn, is part of receptor tyrosine kinase (RTK) signaling. RTK signaling is known to play a central role in craniofacial and dental development. However, to date, no studies have systematically examined a large cohort of CFC individuals to define key craniofacial features, and lacking are reports of the dental phenotype in CFC. In this study, we examined a large cohort (n=32) of individuals with a clinical and molecular diagnosis of CFC who attended the 2009 and 2011 CFC International Family Conference. The goal was to systematically evaluate the craniofacial and dental phenotype of CFC. We determined that there was a unique phenotype of CFC including malocclusion with open bite, posterior crossbite, teeth crowding and a high-arched palate. Individuals with CFC also presented with oral habits including tongue thrusting and open mouth posture. For the vast majority of CFC individuals, tooth number, size and morphology were normal. This thorough evaluation of the craniofacial and dental phenotype in CFC individuals provides a beginning to understand the role of RTK/MAPK signaling in human craniofacial and dental development and will aid clinicians who care for patients with CFC.

3243W

Sotos Syndrome Diagnosis Confirmed by aCGH. *F.I. Sahin[1], Y.K. Terzi[1], M. Derbent[2].* 1) Department of Medical Genetics, Baskent University Faculty of Medicine, Ankara, Turkey; 2) Department of Pediatrics, Baskent University Faculty of Medicine, Ankara, Turkey.

Sotos syndrome is an overgrowth syndrome caused by mutations or deletions of the NSD1 gene located at chromosome region 5q35.2-q35.3. The condition is characterized by a wide spectrum of clinical abnormalities. Overgrowth is a finding from the prenatal development through childhood as well as long, thin face, broad forehead, sparse frontotemporal hair, downslanting palpebral fissures and malar flushing. Cardiac and renal anomalies are associated features of the syndrome as well as hypotonia, scoliosis, seizures and advanced bone age. Here we report a 2 year 2 months-old girl with mental and motor retardation. The patient was the second child of healthy non-consanguineous parents. At the time of presentation, she was 8 months old and had mildly prominent and high forehead, depressed and broad nasal bridge, anteverted nares, low-set ears, micrognathia, and high-arched palate. Neurological findings were normal except for developmental delay and pronounced hypotonia. Chromosome analysis performed on peripheral blood sample resulted in a normal karyotype (46,XX). In order to explain dysmorphic features, array comperative genomic hybridization (aCGH) method was performed by Roche NimbleGen Human CGH 3×720K Whole-Genome Tiling v3.0 Array. For the analysis of raw data, web based Genoglyphix programme (Signature Genomics) was used. As a result of aCGH analysis, 4 chromosomal regions were marked as important regions. Three of them were copy losses and one was copy gain. However, only one region was found to be clinically significant. One hundred and twelve kb long region was located at 5q35.2-q35.3, and 11 probes marked this region as a copy loss. This region comprises NSD1 gene which has been reported to be related to Sotos syndrome. Molecular genetics methods are useful as additional tools to conventional cytogenetics in cases similar to our patient. Although the clinical findings were insufficient for diagnosis of Sotos syndrome, aCGH results supported and confirmed the diagnosis.

3244F

Expanding (or narrowing) the phenotype of Beckwith-Wiedemann syndrome. *E. Todd, G. Bellus.* Clinical Genetics and Metabolism, Children's Hospital Colorado, Aurora, CO.

This is a case report of a child with a molecular diagnosis of Beckwith-Wiedemann syndrome and an atypical phenotype. Perinatal course: This male patient was appropriate for gestational age, born at term. Upon prenatal ultrasound at 20 weeks gestation, the fetus was found to have a cystic retroperitoneal mass. No other anatomic abnormalities were identified. There were no complications in the perinatal period. Pertinent negatives include no hypoglycemia and no problems with feeding due to macroglossia. Studies: Abdominal computed tomography after birth revealed a low density inhomogeneous mass in the left upper abdomen measuring 4.2 × 4.1 × 4.5 cm with mass effect upon neighboring organs. Pathology following left adrenalectomy demonstrated a hemorrhagic macrocyst and adrenal cytomegaly, concerning for a known association with Beckwith-Wiedemann syndrome (BWS). LIT1/H19 molecular studies identified abnormal allele-specific hypermethylation of H19 in the 11p15.5 chromosomal region, consistent with a diagnosis of BWS. The methylation index detected was above a threshold for abnormal methylation of > 0.65 (2SD greater than the normal mean). No loss of normal imprinting-specific methylation for maternal or paternal alleles of the LIT1 gene was identified. Genetics encounters: At 3 months of age, the patient presented to Genetics clinic. Developmentally he was on track. The patient continued to have normal growth parameters. On examination, there were no physical features consistent with BWS. There was no evidence of neoplasia. Serial screening for tumors was recommended. At 15 months of age, the patient continues to have normal growth parameters and a normal physical examination. Developmentally, he has some mild delays. He is continuing to follow the standard tumor surveillance protocol for children with BWS. Discussion: BWS is a disorder of growth characterized by macrosomia, macroglossia, hemihyperplasia, embryonal tumors, anterior abdominal wall defects, neonatal hypoglycemia, and adrenocortical cytomegaly. It is interesting that while the adrenal cyst which our patient presented with is considered almost diagnostic for BWS, he does not demonstrate any of the other phenotypic manifestations of this disorder. This is, to our knowledge, the first report of a child with isolated adrenal cytomegaly with molecular BWS. His findings probably indicate that the phenotypic spectrum of abnormal imprinting of H19 at 11p15.5 is broader than initially believed.

Genetic Studies in VACTERL Association. *J. Winberg[1], P. Gustavsson[1], E. Sahlin[1,2], G. Annerén[3], E. Iwarsson[1], P-J. Svensson[4], F. Bradley[1], E. Nordenskjöld[1], N. Papadogiannakis[5], A. Nordgren[1], A. Nordenskjöld[4, 6].* 1) Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden; 2) Department of Clinical Genetics, Karolinska University Hospital, Stockholm, Sweden; 3) Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden; 4) Department of Pediatric Surgery, Karolinska University Hospital, Stockholm, Sweden; 5) Department of Laboratory Medicine, Division of Pathology, Karolinska Institutet, Stockholm, Sweden; 6) Department of Woman and Child Health and Center for Molecular Medicine, Karolinska Institutet, Stockholm, Sweden.

In order to identify genetic causes of VACTERL association (V vertebral defects, A anorectal malformations, C cardiac defects, T tracheoesofageal fistula E esophageal atresia, R renal anomalies and L limb deformities), we have collected DNA samples from 20 patients diagnosed with VACTERL or a VACTERL-like phenotype. In addition, we have collected samples from 20 aborted fetuses with VACTERL. To screen for gene dose alterations, array-CGH (comparative genomic hybridization) was performed on genomic DNA from all patients and fetal cases using a 180K oligonucleotide array with whole genome coverage. Patient and fetal DNA samples were also screened for mutations in three candidate genes using DNA sequencing. We present clinical findings in both patients and fetal cases. Results from array-CGH revealed two clinically significant gene dose alterations indicating that pathogenic copy number variants (CNVs) are not a frequent cause of VACTERL. DNA sequencing of candidate genes showed that three fetal cases and one patient carried mutations possibly associated with VACTERL.

A homozygous AHI1 mutation in a Moroccan consanguineous Joubert Syndrome family. *L. Baala[1, 2], S. Chafai Elalaoui[3], M. Chalon[1], N. Elkhartoufi[4], M. Mansouri[3], Y. Kriouele[5], O. Perche[1, 2], S. Briault[1, 2], T. Attie[4], A. Sefiani[3, 6].* 1) INEM- UMR7355 CNRS-Université Orleans, France; 2) Pole Biopathologie, Centre Hospitalier Régional d'Orléans (CHRO), Orléans, France; 3) Département de génétique médicale, Institut National d'Hygiène, Rabat, Morocco; 4) Département de Génétique et INSERM U781, Hôpital Necker-Enfants Malades, Paris France; 5) Service de pédiatrie IIA, Hopital d'Enfants, Rabat Morocco; 6) Centre de Génomique Humaine, Faculté de Médecine et de Pharmacie, Université Mohamed V Rabat, Morocco.

Joubert syndrome (JBTS, MIM 213300) is a highly genetically heterogeneous disorder, characterized by a developmental delay with hypotonia, ocular-motor apraxia, and breathing abnormalities. The diagnosis is based on brain imaging feature showing “molar tooth sign” (MTS) with vermis agenesis and brainstem accompanying components. Fifteen genes have been identified thus far, 14 of which are autosomal recessive and one X linked-recessive. All encode proteins involved in primary ciliary function including JBTS in the group of so-called ciliopathies. We described a consanguineous Moroccan family (parents are german cousins) with 3 affected sibs (2 boys of 18 and 8 years and one girl of 13 years) showing typical signs of JBTS: hypotonia, developmental delay, mental retardation, bilateral nystagmus, ataxia, retinitis pigmentosa and a cerebelar vermis hypoplosia and molar tooth sign on brain MRI. To identify the underlying genetic defect in this family, we performed a genome-wide homozygosity mapping using the high resolution Affymetrix SNP 6.0 array containing 906,600 polymorphic SNPs and more that 946,000 unique probes for CNV detection. We found that only three homozygous regions were shared between affected siblings, with a size of 1.7-Mb (at 5q33.3), 30.1 Mb (at 14q22-24) and 28.9 Mb (at 6q22.1-24) respectively. Overall, the three intervals contained 100 to 300 genes. We compared the detected homozygous regions with known JS loci and found that the homozygous region on chromosome 6q contains AHI1 considered as the gene at JBST3 locus. Direct sequencing of the 26 coding exons revealed a novel homozygous mutation (c.910dup, p.Thr304AsnfsX6) located in exon 6 (NM_017651.4) in all patients. This mutation was heterozygous in their parents and not found in controls in the same ethnic background. Otherwise, no pathological CNV (deletion or duplication) was detected. Interestingly, the c.910dup mutation was previously reported in a JS family originating from Spain suggesting a possible founder effect. Our study highlights that homozygosity mapping is a powerful method to rapidly detect the disease causing gene especially in genetically heterogeneous disorders such as JBTS. This result allows an accurate genetic counseling and molecular prenatal diagnosis in this family.

Twin Discordance and Congenital Hydrocephalus. *C. Lee[1], J.T.C. Shieh[1,2].* 1) Division of Medical Genetics, Department of Pediatrics, University of California San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California San Francisco, San Francisco, CA.

Abnormalities that arise during human development such as congenital hydrocephalus may have an unclear etiology, however twin studies may help identify factors that lead to disease. Hydrocephalus is defined by dilated cerebral ventricles, and these may arise due to abnormal cerebral spinal fluid flow, obstruction or impaired fluid balance. The association of congenital hydrocephalus with VACTERL, genomic microarray abnormalities, and single gene alterations suggest that hydrocephalus may arise in the context of genetic alterations. Whether genetic factors underlie apparently isolated hydrocephalus is unclear. Here we present data on identical twin phenotypic discordance with hydrocephalus. We present clinical course, MRI findings and candidate gene sequencing as these may help us understand factors that contribute to disease. We examined a case of hydrocephalus in one twin of a discordant twin pair who was found to have ventriculomegaly with dilatation of bilateral lateral ventricles and third ventricle by fetal MRI at 23 weeks gestation. The co-twin was normal. The male twins were born prematurely at 33 weeks. Head size was large in the affected twin, and neurological examination at birth was unremarkable but mild tone abnormalities were noted in subsequent exams. Postnatal MRI revealed non-communicating hydrocephalus and aqueduct of Sylvius obstruction in the affected twin, and a shunt procedure was performed. The twins appeared non-syndromic, and although a family history of hydrocephalus was absent, L1CAM testing was discussed and test results are pending given its potential impact on prognosis. We also compare this case to other twin studies of hydrocephalus. We propose that further twin studies may help us understand heritability and the factors that lead to this disease.

Hallermann-Streiff Syndrome: Case report from Mongolia. *P. Erkhembulgan[1], M. Purevdorj[2], T. Altansukh[2], I. Purevdorj[2].* 1) National Center for Maternal and Child Health, Ulaanbaatar, Mongolia; 2) Health Sciences University, Ulaanbaatar, Mongolia.

Hallermann-Streiff Syndrome is a rare genetic disorder that is characterized primarily by head and face abnormalities. Hallermann-Streiff Syndrome was first described completely in 1948 by Hallermann, in 1950 by Streiff, and in 1958 by Francois. We report a Hallermann-Streiff Syndrome case from Mongolia. Proband B, 17-years-old female was admitted to the Center of Genetic counseling, Health Sciences University of Mongolia in November 2011. Physical examination revealed alopecia, beak-shaped nose, bilateral microphthalmia, hypognatia, brachycephaly, bird-like face, lack of hair in frontal and parietal parts of the head, congenital cataract, microstomia, high arched palate, abnormal dentition and natal teeth, severe caries, absence of teeth in lower jaw. Despite retarded growth, the mental development of the patient was normal. Examination of eyes revealed that the child had impaired vision (VOD=0.04, VOS=0.03), sparse eyebrows and eyelashes. The patient underwent lensectomy at 8 and 14 months. Seven essential signs (bird like face, abnormal dentition, hypotrichosis, atrophy of skin especially on the nose, congenital cataract, microphtalimia, proportional dwarfism) were described by Francois as diagnostic criteria for Hallermann-Streiff Syndrome. Our patient had six of these seven signs. Based on our findings the patient was diagnosed to have Hallermann-Streiff Syndrome. Sleep apnea, one of the life threatening complications among patient with Hallermann-Streiff syndrome was detected in our patient. Recently, she underwent nasal cavity surgery due to respiratory embarrassment. An interdisciplinary approach including early preventive-care programs, detailed oral hygiene instructions, dietary recommendations, counseling of the parents and regular dental visits are the essential procedures for the Hallermann-Streiff Syndrome.

Global Gene Profiling Identifies A Novel Cytoskeleton Pathway Involved in VCP-Associated Myopathy. *A. Nalbandian[1], S. Ghimbovschi[2], S. Radom-Aizik[1], E. Hoffman[2], V. Kimonis[1].* 1) University of California, 2501 Hewitt Hall, Irvine, CA; 2) Children's National Medical Center, 111 Michigan Avenue, NW, Washington, DC.

Inclusion body myopathy associated with Paget's disease of bone and frontotemporal dementia (IBMPFD) is an increasingly recognized disorder caused by Valosin containing protein (VCP) mutations and is now identified in 2% of familial amyotrophic lateral sclerosis (fALS). VCP disease is characterized clinically by adult onset of progressive proximal muscle weakness, Paget's disease of bone, frontotemporal dementia, and clinical evidence of motor neuron disease in approximately 10% of individuals. Patients may express only one or two phenotypic components and need not demonstrate all three phenotypic features. Pathology includes ubiquitin and TDP-43-positive inclusions also seen in ALS and other proteinopathies. VCP is a key regulatory protein and is involved in a plethora of cellular functions and signaling transduction pathways. Current theories suggest VCP disease mutations may cause disturbances in common signaling pathways, including autophagy, lysosomal, and ubiquitin-proteasomal pathways. We have conducted a microarray profiling study examining the muscles from patients with VCP mutations versus their first degree unaffected and non-mutation carrying relatives to identify the key disrupted pathways in VCP disease. With this global analysis, we have elucidated several dysregulated transduction cascades. Interestingly, the microarray results showed most significant changes in the regulation of actin cytoskeleton pathway including genes critically involved in cell communication, multiple structural and dynamic processes including maintenance of cell shape, cell movement, cell signaling, cell differentiation, and apoptosis. Downregulated genes in this pathway included alpha actinin 1, actin related protein 2/3 complex, myosin light chain 10, and fibroblast growth factor receptor 2, directly linked to cytoskeletal integrity. Upregulated genes in the actin cytoskeleton included protein tyrosine kinase 2, integin beta 1, protein-activated kinase 1, and protein phosphatase 1. These proteins are expressed in muscle and may be involved in attaching muscle tissue to the extracellular matrices. Thus, a dysregulation of these proteins may lead to aberrations in the cytoskeleton, thereby leading to myopathy. Dissecting the signaling intermediates of the actin cytoskeleton cascade will help in understanding the pathogenesis of VCP-associated disease and for the development of potential therapeutic targets in related neurodegenerative diseases.

External validation of the Bartholdi clinical scoring system for Silver-Russell syndrome: a report of a Brazilian cohort. *G.L. Yamamoto[1], A. Bonaldi[2], A.M. Vianna-Morgante[2], I. Gomy[1], C.A. Kim[1], D.R. Bertola[1].* 1) Genetica Medica ICR-FMUSP, Universidade de Sao Paulo, Sao Paulo, Sao Paulo, Brazil; 2) Instituto de Biologia, Universidade de Sao Paulo, Sao Paulo, Sao Paulo, Brazil.

Silver-Russell syndrome (SRS) is a genetic heterogeneous disorder with a variable phenotype characterized by pre and post-natal growth deficiency, typical facial features, body asymmetry and other malformations. SRS is caused by imprinting disorders in at least two different regions: chromosome 7 and the 11p15.5 locus. The clinical criteria for diagnosis and recommendations for molecular testing have been widely discussed in the literature without reaching a consensus. In this study, we report on 27 suspected SRS patients using molecular testing, and 18 of these patients (67%) were positive, with 14 patients (78%) possessing hypomethylation of Imprinting Center Region 1 (ICR1), one patient (6%) with a duplication of ICR2 and 3 patients (17%) with maternal uniparental disomy of chromosome 7. The clinical features and genotype-phenotype correlations were in accordance with the literature for the asymmetry and clinodactyly of fifth finger associated with ICR1 hypomethylation. Four different clinical criteria were applied, specifically, Bartholdi, Netchine, Price and Saal, to compare their efficacy in this population. The Bartholdi criteria performed better than the other tests, with 100% specificity and sensibility being observed for all positive and negative molecular SRS patients.

Gene expression differences are shaped by selective pressures and contribute to phenotypic differences between species. We identified 964 copy number differences (CNDs) of DNA segments that are highly conserved at the sequence level across human, chimpanzee, and rhesus macaque and examined their potential effects on gene expression profiles. Samples with copy number different genes had significantly different expression levels than samples with neutral copy number for those genes. In particular, genes encoding regulatory molecules, such as transcription factors, were enriched both for overlap with copy number differences and for significant expression level differences. We also identified 127 CNDs which were actually processed pseudogenes and some of which were found to be expressed. Furthermore, copy number different noncoding regulatory regions, such as ultraconserved elements and long intergenic noncoding RNAs with the potential to affect expression, were also identified. We postulate that CNDs of these conserved sequences fine-tune developmental pathways by altering the levels of RNA. Many of these conserved, copy number different, and differentially expressed regions are implicated in human disease.

3252T

Linkage disequilibrium, population structuring and genome-wide association studies reveal metabolism and craniofacial dysmorphology mutations in the domestic cat. *L.A. Lyons, H. Alhaddad, B. Gandolfi, R.A. Grahn.* Population Hlth Reprod/Vet Med, Univ California, Davis, Davis, CA.

Domestic cats are increasingly attracting the scientific community as a model organism for human hereditary and infectious diseases as well as attracting the general public as a legitimate household pet. There are more cats in the USA than people and approximately 30% of households own a cat. Our research efforts have focused on the genetic structuring of cat populations, indicating that SNPs and STRs can define eight worldwide “races” of cats and that the most common 29 breeds form only ~ 21 cat breed populations. The feline scientific community used this population data and additional information to support the sequencing efforts for the appropriate selection of cats for efficient SNP discovery and the development of an Illumina Infinium 63K Feline iSelect DNA array. The DNA array also contains SNPs that define phenotypic and known disease traits in the cat. Linkage disequilibrium (LD) studies of 1536 SNPs across ten 1 Mb regions have shown that some breeds such as Burmese have fairly extended LD, comparable to horses and some dog breeds, but the LD of random bred cats is more comparable to human populations. The initial testing of the DNA array considered 288 cats, including 10–20 cats per breed population, five trios and two random bred populations. The cats were selected to test the array's efficiency by remapping several known traits - with and without the causative mutations present. Several additional case-control projects, investigating hypokalemia in Burmese and coat traits in other breeds have been been successful, regionally localizing the traits with subsequent causative mutation identification with as few as 11 cases. Presented will be the highlights of the cat population and LD studies, initial studies of the array development, showing the power of trait mapping, and the subsequent successful case-control studies for feline hypokalemia and a craniofacial defect that also causes brachycephaly.

3253F

Genome-wide scan for identifying selection footprints in immune related pathways. *J. Molineros, S. Nath.* OMRF, 825 NE 13th, Oklahoma City, OK. 73104.

Immune-related genes have been previously identified in scans for positive selection. Genome-wide scans of selection are important to autoimmunity because they might be able to identify loci carrying deleterious mutations linked to positively selected loci. The effects of selection would be expected to be detected on the pathways as well. Our objective was to identify autoimmune genes that are under natural selection and their associated pathways. We used 1000 genomes project genotype data for the Illumina Omni2.5 SNP platform for European (CEPH, Finnish, British, Tuscan, Iberian) and African (Yoruba, Luhya and Massai) populations to estimate the newly reported spatial statistic (SPA), as well as Fst and iHS. Loci with evidence of selection were analyzed using gene set enrichment analysis to determine overrepresented pathways as well as overrepresented protein domains through their gene ontology. Adjusted p-values were obtained using the false discovery rate statistic. We identified selection signals on 2888 loci. Only 38 KEGG categories pathways passed the multiple testing correction threshold value FDR (P<0.05). Whereas 535 categories of gene ontology were significantly overrepresented, among those, metal-ion binding domains and extracellular structure organization domains were particularly enriched (P = 0.04, for both), as well as Zinc ion binding domains (P = 0.02). Of particular interest were loci *KCNH7*, *XKR6*, *CANCB4*, *STAT1* and *STAT4* that have been implicated in autoimmunity. Our results suggest that single genes rather than immune pathways were under selection.

3254W

Signatures of selection surrounding large insertions and deletions in coding regions identified between modern and Denisovan humans, as well as four other species of primates genome-wide. *W. Guiblet[1], K. Zhao[3], D. Ferrer-Torres[1], C.T. Ruiz-Rodriguez[1], A. Roca[3], S. Massey[2], J.C. Martinez-Cruzado[1], T. Oleksyk[1].* 1) Department of Biology, University of Puerto Rico at Mayaguez, Mayaguez, PR. 00680; 2) Department of Biology, University of Puerto Rico at Rio Piedras, San Juan, PR 00931; 3) Department of Animal Sciences, University of Illinois at Urbana-Champaign, Urbana, IL 61801.

Genes have highly conserved sequences and usually show very few differences between closely related species, such as humans and nonhuman primates. In this study, we focused on >10 bp insertions and deletions (indels) found when comparing modern humans, Denisovans, chimpanzee, gorilla, orangutan, and rhesus macaque reference genome sequences, with the purpose of testing indel flanking regions for the signatures of selection. From 36,422 indels identified by comparing reference genomes pairwise, we chose 186 indels within coding regions because of the potentially high impact on protein sequence. These fragments had been earlier validated in the laboratory by PCR and electrophoresis to distinguish real features from the computational artifacts, and further tested for the presence of polymorphisms in multiple human populations. We used five different algorithms (PAML package) to produce over 7,000 pairwise Ka/Ks ratios from 98 filtered genes. Among the 98 genes containing indels, ten showed significant Ka/Ks ratios between human and at least one primate sequence. We also search for and identify indels within candidate chromosomal regions for positive selection displaying unusually low multilocus heterozygosity and high divergence (FST) in pairwise comparisons between populations or continental groups from the the Human Genome Data Panel (HGDP). The comparisons include all the possible pairwise combination for the continental groups as well as populations within groups for all chromosomes. Our findings are evaluated against the random expectation by a resampling method, where exactly the same procedures and tests are performed with a dataset of randomly positioned indels matched by size distributed across the human reference genome. Those indels still polymorphic in humans for the alleles discovered in cross-species comparisons (ex: USP7), are further interrogated for recent selection signatures by evaluating extended haplotype homozygosity around ancestral and derived alleles. The genes examined in our study may have been shaped by selection in the human or other primate lineages, thus adding to the understanding of our recent evolution. Some of these may harbour adaptation to disease, and benefit discoveries in the future biomedical studies.

An optimized panel for Ancestry Informative Markers derived from the Mexican Genome Diversity Projec. *JC. Fernandez-Lopez[1], A.V. Contreras[1], MJ. Gomez-Vazquez[2], C. Rangel-Escareño[1], I. Silva-Zolleżzi[1,3].* 1) Computational Genomics Department, Instituto Nacional de Medicina Genómica, Ciudad de Mexico, Distrito Federal, México; 2) Universidad Autónoma de Nuevo León; Monterrey N.L. México; 3) BioAnalytical Science Department Nestle Ltd, Nestlé Research Center Lausanne, Switzerland.

Genome wide association studies (GWAS) were not common in Mexican and Latino populations until recently. These studies have contributed to the search for genetic variants underlying the inheritance and development of complex traits and diseases within Mexican mestizos. The process of identifying functional variants can be long and difficult, one of these difficulties is the huge number of false positive results observed in these studies due to population stratification between cases and controls groups. In recent years, a variety of methods that aim to minimize the effect of population stratification in Mexican and Latinos have been developed. One of these tools is the development of Ancestry Informative Marker (AIM) panels. Nevertheless, it remains extremely important to generate new additional panels to address the admixed populations using different feature-discriminators and approaches. With this work we decided to release the top 260 AIMs panel based on a list of 1,814 unpublished AIMs selection used in Silva-Zolezzi et al. (2009). That list of AIMs was created using unlinked SNPs based on allele frequency differences with (δ) $\geq$ 0.4. This AIMs selection captures East Asian structure in addition to European, African and Native-American structure not included in another Latino panels. The top 260 AIMs, was selected by taking all pairwise comparisons to discriminate between populations. Caucasian vs East-Asian (40), Caucasian vs African (40), East-Asian vs African (40), African vs Native-American (40), Caucasian vs Native-American (50) and East Asian vs Native-American (50). To validate this top 260 AIMs panel we genotyped 400 Mexican-mestizos from Age-related macular degeneration GWAS. The performance of this subset of markers captured the ancestry proportions as accurate as that using all genomewide data. Next, we tested using candidate gene approach 200 Chronic Obstructive Pulmonary Disease study in Mexican mestizos, the preliminary results were consistent with the ancestry expected in this selection group.

A fish-specific transposable element shapes the repertoire of p53 target genes in zebrafish. *M.N. Loviglio[1,2], L. Micale[2], M. Manzoni[3], C. Fusco[2], B. Augello[2], E. Migliavacca[1], G. Cotugno[2], E. Monti[3], G. Borsani[3], A. Reymond[1], G. Merla[2].* 1) Center for Integrative Genomics (CIG), University of Lausanne, Lausanne, Canton Vaud, Switzerland; 2) Medical Genetics Unit, IRCCS “Casa Sollievo della Sofferenza”, San Giovanni Rotondo, Foggia, Italy; 3) Department of Biomedical Science and Biotechnology, University of Brescia, Brescia, Italy.

Transposable elements (TEs) represent the largest genomic component of most eukaryotic organisms. Often erroneously referred as “junk DNA”, they actually play a central role in the structural organization and plasticity of genomes and are known to mediate the establishment of new cellular functions during evolution. Recent discoveries support the hypothesis that gene regulation can be influenced by TEs, which can directly mediate novelties at the network level by contributing to transcriptional and post-transcriptional modulation due to their proximity to nearby genes. For instance, TEs partecipate to the origin of new functional elements, as promoter sequences, transcription factors binding sites and enhancer, silencer and insulator elements. For example, binding sites of the pleiotropic master transcription factor p53 reside in LINE1, Alu and LTR repeats in the human genome. Similarly, here we demonstrate that regulatory information controlling expression of a repertoire of p53 target genes in zebrafish (Danio rerio) is coming from a mobile element, the non-autonomous DNA transposon EnSpm-N6_DR. Through their embedded p53 responsive elements, the multiple copies of the EnSpmN6_DR transposon drive in several instances p53-dependent transcriptional modulation of the adjacent genes, whose human orthologs were often previously annotated as p53 targets. The domestication of EnSpm-N6_DR repeats and their embedded p53REs is likely associated to the involvement of the targeted genes in shared pathways; in fact, these transposons define a set of target genes that contribute to axonogenesis, synaptic transmission and the regulation of programmed cell death. Consistent with these biological functions, the expression data of EnSpmN6_DR-colonized loci notably show an enrichment for genes expressed in both adult and fetal brain, as well as specific brain structures, such as amygdala, hippocampus, and brain cortex. Accumulating evidences demonstrate that p53, besides its well studied features as master regulator in cell-cycle and apoptosis, plays a leading role in the regulation of neural stem cell proliferation and differentiation, as well as axon outgrowth and regeneration. In this scenario, our data corroborate these recent findings and pinpoint a remarkable example of convergent evolution: the exaptation of lineage-specific transposons to establish networks of p53-regulated genes crucially involved in neuronal morphogenesis in both a hominid and a teleost fish.

3257W

Meiotic recombination hotspots in humans - dynamics and controlling factors. *L. Odenthal-Hesse, A.J. Jeffreys.* Genetics, University of Leicester, Leicester, Leicestershire, United Kingdom.

Meiotic gene conversion has a major impact on genome diversity. Both crossovers and non-exchange conversions cluster into distinct recombination-active regions that we call hotspots. Hotspot analysis in humans has focused on the description of crossover profiles and only few hotspots had been tested for crossover and non-exchange gene conversion. Therefore, very little was known about the frequency and distribution of non-exchange conversions and how well they correlate with crossing over. Six extremely active recombination hotspots were analysed by using small pool PCR approaches on sperm DNA to detect both types of recombinant molecules. Non-exchange conversions were detectable and arose at high frequencies (0.01–0.47%) per sperm, in addition to crossovers (0.2–0.70%). Conversion tracts were short and their distribution defined a steep conversion gradient, centred at the peak of crossover activity and probably marking the zone of recombination initiation. It was also observed that non-exchange gene conversion and crossover frequencies were positively correlated, not just between men at the same hotspot but equally when compared across several hotspots. On average, non-exchange gene conversions spanning a marker close to the centre of the hotspot occurred at 50% of the crossover frequency. Hotspot regulation in cis had been described previously to results in different initiation efficiencies between interacting haplotypes. Preferential initiation on a more active haplotype, in turn leads to the overtransmission of alleles from the less active haplotype. Additional hotspots that showed a phenomenon of biased gene conversion were described in this study, with crossovers and non-exchange gene conversions influenced to the same degree. More unusually, biased gene conversion specifically affecting non-exchange events was also observed at two hotspots. Here single SNP heterozygosities appear responsible for triggering the bias in cis. Crossovers were not affected, which may provide evidence for distinct crossover and non-crossover pathways operating at human hotspots.

3258T

The MHC linkage haplotype in the Finnish Population. *A. Wennerström, ML. Lokki, MHC Disease Research Group.* HLA Laboratory, Transplantation Laboratory, Haartman Institute, Helsinki, University of Helsinki, Finland.

Previously, the Major Histocompatibility Complex (MHC) has been associated with a variety of infections (e.g. HSV, Pogosta, otitis) and immunologically mediated diseases (e.g. sarcoidosis). The genes in the MHC region (6p21) encoding HLA molecules fall into two major classes, Class I (HLA-A, -B, and -C) and Class II (HLA-DP, -DQ, and -DR). The MHC Class III genes containing, e.g., complement C4, TNF-α, LTA and BTNL2 reside between the HLA Class I and Class II genes. Our aim was to explore the MHC linkage haplotypes in the Finnish population and utilize the information in disease association studies. The HLA class I (HLA-A and -B) and Class II (HLA-DRB1, -DQB1 and -DPB1) allele and haplotype frequencies of a Finnish population (n=150) were calculated. In addition, C4 gene copy numbers (CNV) and 89 MHC Class III tag-SNPs were genotyped. Linkage disequilibrium (LD) and Hardy-Weinberg distributions were analyzed and haplotypes were constructed with ARLEQUIN 3.11, GenePop 4.0.10 and PHASE v.2.1.1, respectively. The most common Finnish A-B-DR -haplotype (7 %) was not-so-usual-Caucasoid A*03-B*35-DRB1*01:01, which possibly reflects the isolated nature of the Finnish population. The haplotype has been previously suggested to be protective for diabetes but predispose to coronary artery disease. The most frequent Caucasoid haplotype AH8.1 including A*01-B*08-DRB1*03:01, was present at frequency 4%. As expected, AH8.1 haplotype had strong pairwise LD (D'> 0.8) covering Class I, Class II and Class III genes. However, when studying other haplotypes including Class III markers and HLA-DPB1, we noticed that the pairwise LD between alleles and loci varied suggesting conserved regions and potential recombination hotspots. Further, this data clearly shows the importance to study several MHC markers covering a long chromosomal region to distinguish different predisposing alleles and haplotypes. This data provides useful information for disease association studies and here, preliminary results from our Sarcoidosis project will be presented.

Fine-scale mapping of meiotic recombination in Mongolians and Koreans. *T. Bleazard[1,2], Y.S. Ju[1], J. Sung[1,3], J.S. Seo[1,4].* 1) Genomic Medicine Institute (GMI), Medical Research Center, Seoul National University, Seoul, Korea; 2) College of Natural Sciences, Seoul National University, Seoul, Korea; 3) Department of Epidemiology, School of Public Health and Institute of Environment and Health, Seoul National University, Seoul, Korea; 4) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul, Korea.

Meiotic recombination causes a shuffling of homologous chromosomes as they are passed from parents to children. Finding the genomic locations where these crossovers occur is important for genetic association studies, understanding population genetic variation, and predicting disease-causing structural rearrangements. There have been several reports that recombination hotspot usage differs between human populations. But while fine-scale genetic maps exist for European and African populations, none have been constructed for Asians. We present the first Asian genetic map with resolution high enough to reveal hotspot usage. We constructed this map by applying a hidden Markov model to genotype data for over 500,000 single nucleotide polymorphism markers from Korean and Mongolian pedigrees which include 980 meioses. For direct comparison of genetic maps between ethnic groups, we also constructed a map for CEPH families using identical methods. We used these data to investigate hotspot usage and the hypothesized contribution of recombination problems to age-related aneuploidy. We found high levels of concordance with known hotspots, with approximately 72% of recombination occurring in these regions. Importantly, this shows that the proportion of human recombination which occurs in hotspots is considerably greater than previously though. Our large sample size allowed us to detect a weak but significant negative effect of maternal age on recombination rate. Our map fills an important gap in the understanding of recombination pattern variation and will be a valuable resource for future research in population genetics. This will improve the accuracy of linkage studies and inform the design of genome-wide association studies in the Asian population.

Heterogeneity in recombination among African populations. *M. Capredon[1], J. Hussin[1, 2], J. Quinlan[1, 3], Y. Idaghdour[1], L. Barreiro[1], T. de Malliard[1], JC. Grenier[1], E. Gbeha[1], P. Awadalla[1].* 1) Pediatrics, CHU Sainte Justine, Faculty of medicine, University of Montreal, Montreal, Quebec, Canada; 2) Biochemistry, Faculty of medicine, University of Montreal, Montreal, Quebec, Canada; 3) School of public health, Faculty of medicine, University of Montreal, Montreal, Quebec, Canada.

Heterogeneity in recombination can have substantial impacts on the shape of genetic variation within and among populations and the signature for selection in human genomes. For genome-wide association approaches to be effective and replicated among different ethnic groups or populations, heterogeneity in recombination rates needs to be factored. Here we present both a method and results for recombination rate variation across the genome for different African populations. Analyses were performed on genome-wide data for three populations from Benin (n=300), two cohorts from Central Africa (n=80, including a Pygmies sub-cohort) and also African Hapmap phase 3 population data and data from the HGDP. An analysis of the SNPs generated a set of common SNPs that were analyzed across populations. Recombination rates were inferred using both phased and unphased data. An IBD index using Plink was computed in each population in order to exclude most of the related individuals. Finally, recombination events were calculated with Recmin, and rates were inferred for data with a subset of common positions in all populations. Recombination rates and hotspots were inferred using the interval option of LDhat 2.1 and LDhot softwares. A CEU population from the Hapmap project was also used as control outgroup for our comparison of hotspots. Population structure analyses allowed us to make comparisons for recombination rates among populations that are more distantly related as well as among very closely related populations, both geographically and genetically. For example, with PCA we visualized a western Africa cluster. The first axis separated central and southern African populations and the second axis the eastern African populations and highlight a Bantu sub-cluster. In order to compare results, the recombination rates were normalized and hotspots predicted with LDhot were then compared between all the populations by their presence or absence. Naturally, we observed that mean map lengths were generally consistent across all populations. However, we were able to capture rapid evolution in hotspots even among populations that are geographically close. Although most events are shared, subtle changes can be detected, even after correcting for differences in sample size.

3261T

Linkage disequilibrium patterns in a Brazilian population: a comparison of X chromosome STR markers with autosomal and Y chromosome STR markers. *S. Oliveira[1], C. Mendes-Júnior[2], A. Trindade-Filho[3].* 1) Genetica e Morfologia, Universidade de Brasilia, Brasilia, Distrito Federal, Brazil; 2) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, São Paulo, Brazil; 3) Laboratório de Antropologia Forense, Instituto de Medicina Legal, Polícia Civil do Distrito Federal, Brasília, Distrito Federal, Brazil.

The X chromosome has a peculiar mode of inheritance: it is transmitted to males exclusively from their mothers, whereas it is transmitted to females by both parents. Such eccentricity makes the genetic markers located in this chromosome particularly useful in population genetics studies, especially to access the extension and distribution of Linkage Disequilibrium (LD). LD may be reduced in comparison to the estimates from the Y chromosome as X chromosomes recombine in females, but higher in comparison to autosomal chromosome. LD arises from genetic linkage, population stratification and natural selection. Here, we compare LD patterns estimated using autosomal, X-linked and Y-linked STR data in a Brazilian population sample. Ten STRs located on the human X chromosome (DXS8378, DXS9898, DXS7133, GATA31E08, GATA172D05, DXS7423, DXS6809, DXS7132, DXS9902, and DXS6789); 10 autosomal STRs (CSF1PO, D3S1358, D7S820, D8S1179, D13S317, D16S539, D21S11, TH01, TPOX, and vWA); and 10 Y-linked STRs (DYS456, DYS390, DYS389II, DYS458, DYS19, DYS439, DYS635, DYS392, DYS438, and DYS448) were analyzed in a sample of unrelated people from Brasilia (Brazilian Federal District), comprising 204 chromosomes (204 men for X and Y chromosomes; and 102 men for autosomal chromosomes). For each of these three aforementioned sample sets, there are 45 possible pairs of loci for which the LD Likelihood Ratio Test was calculated using the Arlequin 3.11 software. LD analysis revealed three pairs of autosomal loci, five pairs of X-chromosome loci and 35 pairs of Y chromosome loci with significant LD ($p \leq 0.05$). The 45 LD probability values revealed mean p-values of 0.5504, 0.4614 and 0.0420 for autosomal, X-linked and Y-linked STR pairs, respectively. The observed LD pattern for the autosomal loci reflects both random segregation and small population stratification, while the p-values among the Y-chromosome loci reflect physical attachment and lack of recombination among the loci. On the other hand, the X-chromosome STRs behave in an almost independent manner (such as the autosomal STRs), with slightly smaller LD probabilities. In conclusion, the X-chromosome STRs show an LD pattern that resembles the behavior of autosomal STRs and completely differs from that observed for Y chromosomes, whereby STRs are inherited as a cluster. Our results could assist current debates regarding the estimation of X-chromosome STR profile frequency in forensic casework. Acknowledgments: CAPES, CNPq, FAPDF.

Association of (ccttt)n polymorphism in the nos2a gene with tuberculosis in two population groups of india. *M. Jena[1,2], P. Das[2], R. Bamezai[1].* 1) National center applied human genetics,school of life sciences,JNU,New Delhi,; 2) Anthropology, Utkal University, Bhubaneswar,Odisha,India, India,.

NOS2 is a molecule that plays a key role in the immunological control of a broad spectrum of infectious agents.Investigation is hampered by difficulty in estimating in vivo production of nitric oxide(NO),but genetic studies provide a potential means of examining the relation between NO production and disease outcome.In this study we assess the influence of CCTTT pentanucleotide microsatellite repeat polymorphism in the NOS2A gene on the risk of developing pulmonary TB in two population(Odisha in eastern india and Chhattisgarh tribe in central india) groups of India .This study included a total of 658 individuals(186 TB patients and 254 controls from odisha and 78 TB patients and 140 controls from Chhattisgarh) .The polymorphism was analyzed by PCR-Electrophoretic method and by direct sequencing. Statistical analysis was done by using Graph pad instat v3.00 for windows (Graphpad software,San Diego CA,USA). Analysis revealed significant difference between patients and controls with NOS2A CCTTT polymorphism in both groups. The overall CCTTTn distribution showed statistically significant differences between TB patients and healthy controls in odisha(p=0.006) and chhatisgarh(p=0.007).We analyzed the possible contribution of the 10-repeat allele (186 base pairs) to TB predisposition in both the population .Decreased allele frequency of (CCTTT)10 in cases as compared to controls resulted in a significant association indicating protection against tuberculosis in odisha (p=0.0002, OR=0.47, 95%CI=0.31-0.70) and chhatisgarh(p= 0.0005, OR=0.37, 95%CI=0.20–0.66). This was confirmed when NOS2A alleles were stratified into short (CCTTT)7–11 and long (CCTTT)12–17 repeats, and a significant difference observed again with short repeats between patients and controls of odisha (p=0.04, OR=0.7, 95%CI=0.5–0.9) and chhatisgarh(p=0.01,OR=0.59, 95%CI=0.39–0.88). Individuals carrying long repeats (CCTTT)12–16 provided a very low risk towards TB in odisha population (p=0.04, OR=1.33,95%CI=1.01–1.74),but shows a significant difference in chhatisgarh population(p=0.01,OR=1.68,95%CI=1.13–2.50).Again combined analysis of short and long repeats in both the groups shows long repeat carriers provided risk(p=0.002, OR=1.43, 95%CI=1.14–1.79)towards TB. In conclusion, further replication studies in different populations are necessary to fully establish the role of this iNOS CCTTT'npolymorphism in TB and its relationship with other genes implicated in tuberculosis susceptibility.

Purifying selection in mitochondrial protein-coding genes is highly effective in mammals and congruent with evolution of nuclear genes. *S.I. Nikolaev[1], K. Popadin[1], T. Junier[1], M. Baranova[2], S.E. Antonarakis[1].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School; 1 Rue Michel Servet, 1211 Geneva, Switzerland; 2) Faculty of Bioengineering and Bioinformatics, M.V. Lomonosov Moscow State University, Leninskiye Gory, GSP-2, building 73, Moscow, 119992, Russia.

The mammalian mitochondrial genomes differ from the nuclear genomes by maternal inheritance, absence of recombination and higher mutation rate. All of these differences decrease the effective population size of mitochondrial genome and make it more susceptible to accumulation of slightly-deleterious mutations. It was hypothesized that mitochondrial genes, especially in species with low effective population size, irreversibly degrade leading to decrease of organismal fitness and even to extinction of species through the mutational meltdown. To interrogate this hypothesis we compared the purifying selections acting on the representative set of mitochondrial (potentially degrading) and nuclear (potentially not degrading) protein-coding genes in species with high and low effective population size. For 21 mammalian species we calculated the ratios of accumulation of slightly-deleterious mutations approximated by Kn/Ks separately for mitochondrial and nuclear genomes. 75% of variation in Kn/Ks is explained by two independent variables: type of a genome (mitochondrial or nuclear) and effective population size of species approximated by generation time. Firstly, we observed that purifying selection is more effective in mitochondria than in the nucleus that implies strong evolutionary constraints of mitochondrial genome. Mitochondrial de novo nonsynonymous mutations have at least 5 fold more harmful effect as compared to nuclear. Secondly, Kn/Ks of mitochondrial and nuclear genomes are positively correlated with generation time of species, indicating relaxation of purifying selection with decrease of species-specific effective population size. Most importantly the linear regression lines of mitochondrial and nuclear Kn/Ks's from generation times of species are parallel, indicating congruent relaxation of purifying selection in both - mitochondrial and nuclear genomes. Thus our results provide evidence against any mitochondria-specific detrimental genetic processes in the mammalian species.

3264T

Molecular phylogeny of an autosomal region under natural selection. *V.A. Canfield[1], A. Berg[1], S. Peckins[1], S. Oppenheimer[2], K.C. Cheng[1].* 1) Penn State College of Medicine, Hershey, PA; 2) Oxford University, Oxford, UK.

The derived (A111T) variant of SLC24A5 is associated with lighter skin pigmentation compared to the ancestral allele. A111T is fixed or nearly fixed in most European, North African and Middle Eastern populations, extending east to Pakistan. In Europeans, a large genomic region of diminished variation on chromosome 15, nearly 150 kb in extent, includes SLC24A5. We analyzed the haplotypes in this region using existing genomic data. Eleven haplotypes, defined on the basis of 16 SNPs that span a 76 kb genomic region in which recombination was rare, account for 95% of the total. A single haplotype (here called C11) carries A111T, suggesting that its origin did not long predate the onset of selection. Haplotype C11 was the product of recombination between haplotypes C3 and C10, followed by the A111T mutation. C3 and C10 are both present in East Asia and the New World but virtually absent in Africa, suggesting that C11 originated outside of Africa, most likely in the Middle East. The current distribution of A111T is consistent with the view that it originated after the divergence between populations that settled Europe and those that settled East Asia.

MtDNA analysis of global populations supports that major population expansions began before Neolithic time. *H. Zheng[1], S. Yan[1,2], Z. Qin[1], L. Jin[1,2].* 1) School of Life Sciences, Fudan University, Shanghai, China; 2) Partner Institute for Computational Biology, Chinese Academy of Sciences.

Agriculture, as one of the most important innovations in human history, resulted in extensive population growths and human activities. However, whether major human expansions started after Neolithic Time still remained controversial. With the benefit of 1000 Genome Project, we were able to analyze a total of 1,277 samples without ascertainment bias from 15 populations in East Asia, Africa, Europe and Americas. From complete mtDNA of these random samples, we identified the expansion lineages and reconstructed the historical demographical variations in the four continents. In all the continents analyzed above, we found that most lineages underwent expansions coalesced before the first appearance of agriculture, but after the Last Glacial Maximum. Consistent to this observation, further analysis showed that the time of major population expansions was concordant to that of major lineage expansions, also between the Last Glacial Maximum and the Neolithic Time. Considering results in current and previous study, global mtDNA evidence showed that rising temperature after Last Glacial Maximum offered amiable environments and might be the most important factor for prehistorical human expansions. The initial population growth constituted a need for the introduction of agriculture, and might be one of the driving forces that led to the further development of agriculture.

Different DNA methylation of FOXP2 target genes in adult cortices of humans and chimpanzees. *U. Zechner[1], D. Seifert[1], E. Schneider[2], N. El Hajj[2], B. Navarro[3], I. Kondova[4], R.E. Bontrop[4], O. Bartsch[1], T. Haaf[2].* 1) Institute of Human Genetics, Mainz University Medical Center, Mainz, Germany; 2) Institute of Human Genetics, University of Würzburg, Germany; 3) Institute of Legal Medicine, University Medical Center of the Johannes Gutenberg University, Mainz, Germany; 4) Department of Comparative Genetics and Refinement, Biomedical Primate Research Center, Rijswijk, The Netherlands.

The molecular mechanisms governing language acquisition in the human brain are largely unknown. Up to now, mutations in the gene encoding the transcription factor FOXP2 (forkhead box P2) are the only reported monogenic cause of language and speech disorders in humans (Lai et al., 2001). A recent study analyzing differential gene expression in human neuronal cells overexpressing human or chimpanzee FOXP2 as well as in human and chimpanzee brain provided evidence for human-specific transcriptional regulation of FOXP2 target genes to be implicated in the development and evolution of language circuitry in humans (Konopka et al., 2009). We set out to investigate if the observed differential expression of FOXP2 target genes may be due to differential methylation of their promoter regions in human and chimpanzee brains. Overall, we quantified the methylation levels of 15 differentially expressed target genes in adult frontal cortices of 13 humans and 6 chimpanzees using bisulphite pyrosequencing. Two genes, NPTX2 and GJA12 (GJC2), displayed mean methylation levels that were significantly different in human and chimpanzee samples ($p < 0.05$). For both genes, the mean methylation levels were higher in the human (7.6% for NPTX2 and 37.3% for GJA12) compared to the chimpanzee (4.7% for NPTX2 and 27.5% for GJA12) brains. For the promoter region of the GJA12 gene whose mutations are associated with delayed speech development in Pelizaeus-Merzbacher-like disease (PMLD), we confirmed these results using a more in-depth methylation analysis of multiple CpG sites by classical bisulphite sequencing. The observed higher methylation levels in human brains correlate very well with the data of Konopka et al. (2009) that showed a downregulation of GJA12 expression in both neuronal cells overexpressing human FOXP2 and human brain samples. Thus, our findings suggest that differential methylation of regulatory regions is involved in regulating differential expression of at least a subset of FOXP2 target genes in human and chimpanzee brains. In addition, our study provides additional support for the use of comparative methylation analyses as an important methodology to detect evolutionary changes in gene regulation that have operated in human-specific brain development and function. Lai et al., 2001, Nature 413: 519–523 Konopka et al., 2009, Nature 462:213–217.

Skin Color Variation in the Orang Asli Tribes of Peninsular Malaysia. *K.C. Ang[1], M.S. Ngu[2], K.P. Reid[1], M.S. Teh[2], A.S. Zamzuraida[2], D.X.R. Koh[2], A. Berg[1], S. Oppenheimer[3], S. Hood[2], M.M. Clyde[2], B.M. Md-Zain[2], V.A. Canfield[1], K.C. Cheng[1].* 1) Penn State College of Medicine, 500 University Drive, Hershey, PA. 17033; 2) Universiti Kebangsaan Malaysia, Bangi. 43600. Selangor. Malaysia; 3) Inst. of Cognitive and Evolutionary Anthropology, University of Oxford, Oxford, United Kingdom.

Pigmentation is a readily scorable and quantitative human phenotype, making it an excellent model for studying multifactorial traits and diseases. Convergent human evolution from the ancestral state, darker skin, towards lighter skin colors involved divergent genetic mechanisms in people of European vs. East Asian ancestry. It is striking that the European mechanisms result in a 10–20-fold increase in skin cancer susceptibility while the East Asian mechanisms do not. Towards the mapping of genes that contribute to East Asian pigmentation there is need for one or more populations that are admixed for ancestral and East Asian ancestry, but with minimal European contribution. This requirement is fulfilled by the Senoi, one of three indigenous tribes of Peninsular Malaysia collectively known as the Orang Asli. The Senoi are thought to be an admixture of the Negrito, an ancestral dark-skinned population representing the second of three Orang Asli tribes, and regional Mongoloid populations of Indo-China such as the Proto-Malay, the third Orang Asli tribe. We have calculated skin reflectance-based melanin indices in 492 Orang Asli, which ranged from 28 (lightest) to 75 (darkest); both extremes were represented in the Senoi. Population averages were 56 for Negrito, 42 for Proto-Malay, and 46 for Senoi. The derived allele frequencies for SLC24A5 and SLC45A2 in the Senoi were 0.04 and 0.02, respectively, consistent with greater South Asian than European admixture. Females and individuals with the A111T mutation had significantly lighter skin ($p=0.001$ and 0.0039, respectively). Individuals with these derived alleles were found across the spectrum of skin color, indicating an overriding effect of strong skin lightening alleles of East Asian origin. These results suggest that the Senoi are suitable for mapping East Asian skin color genes. We will also report the results of ongoing skin color analysis of the Iban tribe from West Malaysia who are subjectively lighter than the Proto-Malay.

Exome and RNA Sequencing of French-Canadians reveals an excess of rare variants that are enriched at functionally important sites. *A. Hodgkinson, F. Casals, Y. Idaghdour, J. Hussin, V. Bruat, T. de Malliard, J-C. Grenier, J-P. Goulet, E. Gbeha, E. Hip-Ki, S. Girard, J-F. Spinella, V. Saillour, D. Sinnett, G. Rouleau, P. Awadalla.* Sainte Justine Research Centre, University of Montreal, Montreal, QC, Canada.

The French-Canadian population of Quebec are descendants of around 8,500 French settlers who colonised the province around 400 years ago. Since this migration event, the French-Canadian population has undergone massive population growth and has become genetically isolated from France with limited exchange with other non-French communities in the same geographical area. Subsequent colonisation events into new territories have also added to the rich demographic history of Quebec and it has been hypothesised that the high incidence of several genetic diseases are a consequence of regional founder effects. Here we analyse over 100 whole exome and over 1000 RNA sequencing datasets from French-Canadians and attempt to describe how this complex demographic scenario has shaped genetic variation in the region. Interestingly, we observe an excess of rare variants in the French Canadian population when compared to European populations and subsequent analysis points to an enrichment of alleles at functionally important sites in French-Canadians. Furthermore, we find intriguing differences in fundamental population genetic parameters between French Canadians and Europeans, highlighting potential variation in fitness and selection across the two groups.

3269W

Evidence for selection at the BDNF Val66Met polymorphism in 1000 Genomes Project populations. *C.V. Van Hout, A.G. Clark.* Dept of Molecular Biology and Genetics, Cornell University, Ithaca, NY.

The Val66Met SNP (rs6265) in the Brain Derived Neurotrophic Factor (BDNF) gene is of particular interest due to its pleiotropic effects in humans and model organisms, encompassing molecular, cellular, organ, and behavioral aspects (1). Previous studies of populations, including the Human Genome Diversity Panel, have reported that 1. population differentiation at this polymorphism is in the top 1% genome-wide, 2. extended linkage disequilibrium (LD) at this locus is consistent with recent positive selection of the Val allele, and 3. the Met allele likely arose after early humans migrated out of Africa (2). We evaluated the evidence for selection at the Val66Met locus in publicly available 1000 Genomes Project resources which, in comparison to previous studies, offers a larger number of individuals in subpopulations, and whole genome sequence, thus, increased resolution for signatures of selection. To elucidate gene flow at this locus, we applied the pairwise sequentially Markovian coalescent model (PSMC) (3) to genome sequence flanking the Val66Met variant, and estimated mean TMRCA for each subpopulation conditioning on the presence of the Met allele. Consistent with previous studies, population differentiation is high at the Val66Met SNP among continental groups as measured by Fst. Additionally, SNP specific and haplotype homozygosity based tests of selection (4) are consistent with recent positive selection of the Met allele. In contrast to previous reports, we did not observe evidence for positive selection favoring haplotypes harboring the ancestral Val allele. Furthermore, the haplotype carrying the Met allele is present (~2% MAF) in 1000 Genomes Project participants of native African ancestry, i.e., YRI and LWK, which is consistent with the arrival of the Met allele prior to migration out of Africa (or, with very low probability, back migration). We also find that the TMRCA for the Met haplotypes is far younger than expected given its frequency, a finding that is also consistent with positive selection for this haplotype. Understanding the evolutionary history of the Val66Met variant and its haplotype background in worldwide populations, is critical for the interpretation of the many studies of pleiotropic effects of this variant. 1. Bath and Lee, Cognitive, Affective, & Behavioral Neuroscience, 2006 2. Petryshen, et. al., Molecular Psychiatry, 2010 3. Li and Durbin, Nature, 2011 4. Voight, et. al., PLOS Biology, 2006.

Mobile element evolution of the *Callithrix jacchus* (common marmoset). *M.K. Konkel[1], J.A. Walker[1], B. Ullmer[2], R. Hubley[3], A.F.A. Smit[3], M.A. Batzer[1] for the Marmoset Genome Sequencing and Analysis Consortium.* 1) Department of Biological Sciences, Louisiana State University, Baton Rouge, LA; 2) Department of Computer Science, Center for Computation and Technology (CCT), Louisiana State University, Baton Rouge, LA; 3) Computational Biology, Institute for Systems Biology, Seattle, WA.

The common marmoset (*Callithrix jacchus*) is the first New World monkey (NWM) species for which a draft genome sequence is available. The purpose of this study was to investigate mobile element propagation and evolution in the NWM lineage through the lens of the common marmoset. Moreover, our aim was to examine NWM phylogeny and the population genetic composition of common marmosets raised in captivity in one of three U.S. Primate Centers (New England, Southwest, Wisconsin) using selected retrotransposon markers. Our analysis of the *C. jacchus* draft genome assembly [CalJac 3.2] revealed that the common marmoset has an overall repeat composition similar to other sequenced and analyzed primate genomes. For example, in the lineage leading to the common marmoset, two primary non-LTR (long terminal repeat) retrotransposon families, long interspersed elements (LINE1, L1) and short interspersed elements (SINEs) contribute the bulk of lineage-specific insertions. However, these retrotransposon families evolved uniquely in the lineage leading to *C. jacchus*. The NWM-specific L1 lineage intersects with the human-derived L1 tree between L1PA6f and L1PA7, and evolved in a mostly linear manner. In contrast, the reconstruction of the *Alu* subfamily evolution shows a `star-like' pattern with several subfamilies being active in parallel. The youngest *Alu* subfamilies are derivatives of *Alu*Ta15, a previously identified NWM-specific subfamily. Moreover, about half of the NWM-specific *Alu* elements appear to be derived from *Alu*Ta15 or its derivatives, indicating that a small burst of *Alu* retrotransposition coincided with the rise of *Alu*Ta15 and its derived subfamilies. Intriguingly, *Alu*Ta15 resulted from a gene conversion event of two *Alu* subfamilies, indicating that the new *Alu* subfamily may have initially escaped repression. In recent history, *Alu* activity appears to be slower than in humans and rhesus macaques. Our population genetic analysis with polymorphic *Alu* markers using the Structure software indicates the presence of population structure with at least two different clusters, indicating diversity among common marmosets. In addition, we investigated the evolution of *Alu* subfamilies with respect to the radiation of NWMs through the lens of the common marmoset. This study provides insights into the evolution of mobile elements in the lineage leading to the common marmoset and represents the first comprehensive analysis of the mobilome of an NWM species.

Association of GSTT1,MI & M3 gene polymorphism with age and quantity of smoke in Northern Indian COPD patients. *R.K Shukla[1], S. Kant[1], S. Bhattacharya[2], B. Mittal[3].* 1) Dept of Pulmonary Medicine, CSMMEDICAL UNIVERSITY, (ERSTWHILE KGMC), LUCKNOW, INDIA, India; 2) Dept of Physiology, CSMMEDICAL UNIVERSITY, (ERSTWHILE KGMC), LUCKNOW, INDIA, India; 3) Dept of Medical Genetics, Sanjay Gandhi Post Gratute Insitute of Medical Sciences, Lucknow, India.

Background: There is increasing evidence for a close relationship between aging and chronic inflammatory diseases. COPD is a chronic inflammatory disease of the lungs, which progresses very slowly and the majority of patients are therefore elderly. Smoking is the major risk factor in development of COPD. In the present study, we assess whether age and quantity of smoke affect in metabolism of phase 2 enzyme gene polymorphisms (GSTT1, GSTM1 & GSTM3) in northern Indian Population. Material & Methods: In this case Control study, we have enrolled 412 study subjects (208 Controls and 204 COPD patients). All the subjects were enrolled after the spirometry evaluation. Smoking quantity were taken in predefine questionnaire and genotyping were done by PCR-RFLP method. Results: The frequency of homozygous GSTM1 null was found to be significantly higher in COPD patients as compared with healthy controls (OR=2.08; 95%;CI=1.40–3.09; P=0.0001), but there were no significant differences in the distribution of genotypes of polymorphisms of GSTT1 and GSTM3 between COPD patients and healthy controls. In subgroup analysis in age we found GSTM1 Null/Present polymorphism significantly associated with the age group (50–60 years) for COPD development (43.5%/21.2%, p=0.015).In case of Smoking, quantity of smoke was not associated with the COPD patients. Conclusion: we conclude that GSTM1 null polymorphism was associated with COPD patients, and we also observe that GSTM1 null polymorphism was associated between age group 50–60 years COPD patients.

Polymorphic miRNA genomic sequences embedded in CNV sites: a prospective screening in Brazilian admixed population sample. *T.C.L. Lins[1], D.E. Jimenez[2], A.P.M. Barbosa[2], R.W. Pereira[1,2].* 1) Universidade de Brasília, Brasília, DF, Brazil; 2) Universidade Católica de Brasília, Brasília, DF, Brazil.

Copy number variation (CNV) has a major impact on gene expression in the human genome. Furthermore, the mechanism of post-transcriptional regulation by microRNAs is one of the key components in regulation of gene expression. Bioinformatics studies have identified several pre-miRNA genomic sequences embedded in CNV sites that may vary in a polymorphic manner within a population. In this work we aimed to screen five putative polymorphic miR-CNV loci by real-time quantitative PCR in an admixed sample of the Brazilian population (n=90), with genetic ancestry previously estimated. The miR-499b region was determined to be the most polymorphic, ranging from zero to 6 copies, with 47% of individuals showing 2 copies. The region with the lowest variation was that of miR-650, where 2 copies were observed in 98% of subjects, and 3 copies in 2%. An interesting phenomenon was observed in the region of miR-126, where the most frequent copy number was 3 (66.7%), whereas in a diploid organism, the most frequent expected number would be 2. No correlation with genetic ancestry was observed. In summary, we have validated these miR-CNV sites as polymorphic in the Brazilian population and will further quantify the expression of these microRNAs, a factor which may be impacted by the number of genomic copies found.

Ascertainment Bias in Microsatellites: Impact on Estimates of Mutation Rates. *B. Li, M. Kimmel.* Depts. of Statistics and Bioengineering, Rice University, Houston, TX.

Microsatellite loci play an important role as markers for identification, disease gene mapping and evolutionary studies. Mutation rate, which is of fundamental importance, can be obtained from interspecies comparisons, which however are subject to ascertainment bias. This bias arises when a locus is selected based on its large allele size in one species (cognate species 1), in which it is first discovered. This bias is reflected in average allele length in any non-cognate species 2 being smaller than that in species 1. This phenomenon was observed in various pairs of species, including comparisons of allele sizes in human and chimpanzee. Various mechanisms were proposed to explain ascertainment bias. Here, we examine the framework of a single-step asymmetric and unrestricted stepwise mutation model with genetic drift. The mechanism of ascertainment bias in this model is a tighter correlation of allele sizes within a cognate species 1 than of allele sizes in two different species 1 and 2. This is a follow-up presentation based on the work presented at the previous meeting. The current study includes more realistic demography to consider the bottleneck of recent human population and discusses a wider range of reasonable settings of model parameters with sensitivity analysis of each parameter. We will show computations of the expected bias, given the mutation rates, effective population sizes of species 1 and 2 and their ancestral population, time of separation of species 1 and 2, the age of the allele and the ascertaining scheme. In particular, we show that when the past demographic history of the cognate and non-cognate taxa are different, the rate and directionality of mutations will impact the allele sizes in the two taxa differently than the simple effect of ascertainment bias. This effect may exaggerate or reverse the effect of difference in mutation rates. This effect may exaggerate or reverse the effect of difference in mutation rates. The theoretical results are cross-validated by simulations using simuPOP, a general purpose forward-time population genetics simulation framework. We re-analyze literature examples, and conclude that despite the bias, the microsatellite mutation rate in human exceeds that in chimpanzee.

Characterizing recent evolutionary changes on the human lineage using the high-coverage Denisovan genome. *F. Racimo, M. Kircher, J. Kelso, S. Pääbo, The Archaic Genome Analysis Consortium.* Max Planck Institute for Evolutionary Anthropology, D04103 Leipzig, Germany.

We have increased the sequence coverage of the previously published genome of an archaic human from Denisova cave in southern Siberia to approximately 30-fold coverage. This high-coverage genome provides the opportunity to identify the complete set of sequence changes that have risen to high frequency or fixation in modern humans since the split from the common ancestor with Denisovans. These recent changes may set anatomically modern humans apart from other extinct hominin forms. Here we present an updated catalog of all single nucleotide changes (SNCs) and insertion/deletion events (InDels) now identified using the high-coverage genome data. Using variation data for modern humans we are able to identify sites where the Denisova genome sequence is ancestral while the derived allele is either fixed or at high frequency (>90%) in modern human populations. We can confidently identify 260 fixed and 393 high-frequency amino acid substitutions in protein-coding genes. A further set of nucleotide changes and InDels in 3' and 5' UTRs, splice sites, miRNAs and motif patterns in regulatory regions were also identified. An analysis of the functional impact of specific amino acid changes, as well as Gene Ontology and Human Phenotype enrichment analyses, allow us to prioritize substitutions that might have important phenotypic effects.

3275W

Recurrent tissue-specific mtDNA mutations are common in humans. *S.M. Williams[1,2], D.C. Samuels[1], B. Li[1], Z. Song[1], E. Torsteson[1], A. Rokas[3], T.A. Thornton-Wells[1], J.H. Moore[2], T.M. Hughes[1], R.D. Hoffman[4], J.L. Haines[1], D.P. Mortlock[1], C. Li[1].* 1) Ctr Human Gen Res, Vanderbilt Univ Med Ctr, Nashville, TN; 2) Genetics, Dartmouth College, Hanover, NH; 3) Biological Sciences, Vadnerbilt University, Nashville, TN; 4) Pathology, Vanderbilt University, Nashville, TN.

Mitochondrial DNA (mtDNA) variation can affect cell function and phenotypes; therefore, knowing its distribution is of importance to understanding many human diseases. Tissue-specific differences are also an important source of variation in disease presentation. Inter-tissue mtDNA variation (heteroplasmy) within an individual has been generally assumed to be random. However, we discovered that certain tissues, notably kidney, liver and skeletal muscle, display identical recurrent tissue-specific mutations in different individuals that are absent from other tissues in the same individuals. This was done using massively parallel sequencing to assess heteroplasmy across 23 samples from two subjects taken at autopsy. Eight tissue-specific, recurrent mutations were identified in both our subjects, and they all are tightly clustered between nucleotide positions 60 and 408. All of these recurrent mutations are within or in very close proximity to sites known to regulate mtDNA replication, strongly implying that these variations alter the replication dynamics of the mutated mtDNA genome. No other tissue-specific mutations were found elsewhere in the mtDNA. The most parsimonious explanation of the data is that these frequently repeated mutations experience tissue-specific positive selection, probably through replication advantage.

3276T

Associations of Human Leukocyte Antigen G with Resistance and Susceptibility to HIV-1 Infection in the Pumwani Sexworker Cohort. *M. Luo[1,2], W. Turk[1,2], J. Kimani[2,3], C. Wachihi[3], T. Bielawny[1], T. Ball[1,2], F. Plummer[1,2].* 1) HIV and Human Genetics, Public Health Agency of Canada, Winnipeg, Manitoba, Canada; 2) Department of Medical Microbiology, University of Manitoba; 3) University of Nairobi, Kenya.

Objective: To determine the association between HLA-G genotypes and resistance or susceptibility to HIV-1. **Design:** A group of sex trade workers in Pumwani, Kenya can be epidemiologically defined as resistant to HIV-1 infection despite frequent exposure and provide an example of natural protective immunity. Human leukocyte antigens (HLA) class I and II molecules have been shown to be associated with resistance/susceptibility to infection in this cohort. HLA-G is a non-classical class I allele that is primarily involved in mucosal and inflammatory response which is of interest in HIV-1 resistance. **Methods:** In this study, we used a sequence-based typing method to genotype HLA-G in this cohort and examined the influence of HLA-G genotypes on resistance to HIV-1 infection. **Results:** The G*01:01:01 genotype was significantly enriched in the HIV-1 resistant women (p=0.002, OR:2.11, 95%CI:0.259–0.976), whereas the G*01:04:04 genotype was significantly associated with susceptibility to HIV-1 infection (p=0.039, OR:0.502, 95%CI:0.259–0.976). Kaplan-Meier survival analysis correlated with these results. G*01:01:01 genotype was associated with significantly lower rate of seroconversion (p=0.001). Whereas, G*01:04:04 genotype was significantly associated with an increased rate of seroconversion (p= 0.013). The associations of these HLA-G alleles are independent of other HLA class I and II alleles identified in this population. **Conclusions:** Our study showed that specific HLA-G alleles might play an important role in resistance/susceptibility to HIV-1 acquisition in this high-risk population. Since HLA-G is important in mucosal and inflammatory responses further studies are needed to better understand it's functional significance in HIV-1 transmission.

3277F

Alleles at the rs3212368 SNP at the 3'UTR of the MC1R gene are associated with human pigmentation by possible microRNA influence. *L.A. Marano[1], A.L. Simoes[1], E.A. Donadi[2], C.T. Mendes-Junior[3].* 1) Departamento de Genetica, Faculdade de Medicina de Ribeirao Preto, Universidade de Sao Paulo,14049-900, Ribeirao Preto-SP, Brazil; 2) Divisao de Imunologia Clínica, Departamento de Clinica Medica, Faculdade de Medicina de RibeiraoPreto, Universidade de Sao Paulo, 14048-900, Ribeirao Preto-SP, Brazil; 3) Departamento de Quimica, Faculdade de Filosofia, Ciencias e Letras de Ribeirao Preto, Universidade deSao Paulo, 14040-901, Ribeirao Preto-SP, Brazil.

Some human genetic markers have been associated to prediction of externally visible traits such as skin, hair and eye color. Prediction of such traits is potentially useful for forensic genetics casework in several situations. Among the known genes influencing these traits, melanocortin-1 receptor (MC1R) encodes a protein in melanocytes responsible for melanin synthesis regulation. Many MC1R alleles have already been associated to red hair, freckles and fair skin in Europeans but none of the studies done so far considered the MC1R regulatory regions or expression levels. Considering that some 3' untranslated region (UTR) mutations may create potential microRNA targets on the mRNA and alter its stability, the present study aims to genotype the 3'UTR SNP (rs3212368; +2346 A/G) of MC1R gene on a Brazilian population sample and to analyze its functional influence on human pigmentation by in silico methods. When the sample was stratified according to pigmentation features, the A allele was associated with hyperpigmentation (black hair, dark skin and dark brown eyes), while the G allele was associated with a lighter pigmentation (brown hair, fair skin and green eyes) of the evaluated traits. No association concerning the presence or absence of freckles was identified. The in silico analysis revealed the existence of several miRNAs with stronger affinity for the G allele, which may result in a diminished stability of MC1R mRNA carrying the +2346 G allele and lower MC1R expression levels and eumelanin production, thus resulting in lighter phenotypes such as green eyes and fair skin. Experimental studies must be carried out in order to corroborate the presented hypothesis.

Targeted Re-Sequencing of 328 Inherited Disease-Associated Genes in a Family Trio and HapMap Populations using the Ion Ampliseq™ Inherited Disease Panel and Ion PGMTM Semiconductor Sequencing. *I. Casuga, B. Kong, D. Joun, S-M. Chen, C-Y. Li, D. Ruff, R. Bennet, M. Shannon.* Ion Torrent part of Life Technologies 7000 Sierra Point Way South San Francisco, CA.

The Ion Ampliseq™ Inherited Disease Panel (IDP) provides ready-access to hundreds of genes involved in some of the most common inherited diseases in humans, making it ideal for broad targeted re-sequencing studies of individuals and populations. The panel employs more than 10,000 primer pairs to amplify the coding exons of 328 genes that are associated with neuromuscular, cardiovascular, developmental, metabolic and other types of disorders. This panel is part of the transformative Ion AmpliSeq™ technology suite that enables the selective amplification of 10s to 1000s of target sequences in a single multiplexed PCR. The IDP is comprised of only 3 pools of primer pairs, requires just 30ng of sample DNA, and can generate comprehensive data from a sample on a single 316TM chip using Ion PGMTM semi-conductor sequencing. In this study, the panel was used to examine the set of genes in a family trio from the CEPH population as well as in 24 unrelated HapMap samples from 4 ethnic populations (CEPH, YRI, CHB and JPN). We demonstrated Mendelian inheritance within the trio by analyzing known variants passed from parent to child. We also demonstrated highly similar performance of IDP with samples from all 4 ethnic populations tested as well as the ability to identify genetic variants between populations, which highlight the benefits of using the panel for studies of genetically diverse populations. Taken together, the results of this study demonstrated that the IDP can be used to detect multiple variants in more than 300 genes in families and across populations and is ideally suited for a broad range of investigations, including genetic risk and susceptibility studies in families and disease-association studies in ethnic populations.

3279T

Sequencing of an extended pedigree in Western chimpanzees. *O. Venn[1], I. Turner[2], Z. Iqbal[1], I. Mathieson[1], N. de Groot[3], G. McVean[1,2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Department of Statistics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 3) Department of Comparative Genetics and Refinement, Biomedical Primate Research Centre, Rijswijk, The Netherlands.

A wide spectrum of processes including crossover, gene conversion, mutation and DNA repair impact genomes from the level of single nucleotide changes to multiple megabases. Although many of these processes have been studied biochemically, their relative genome-wide distributions are not fully characterized. The analysis of genetic variation estimated from high-throughput population sequencing is a potentially powerful approach to study such processes. However, a major challenge in interpreting this information is the detection of erroneous, mis-assembled, or incorrectly genotyped genetic variants. Currently these errors are identified using ad hoc filters, which have limited application for the analysis of *de novo* mutation events.

We present an approach to study rare events in large genomes through the whole genome sequencing of a Western chimpanzee, *Pan troglodytes verus*, pedigree. We sequenced three founder, three F1, and three F2 individuals to a combined mapped coverage of 315x. This combined coverage is utilized effectively because 7/8 of the founder genomes are transmitted at least once, thereby improving precision to identify and validate genomic changes of different types. To detect events we called variants and Indels across the samples using both alignment-based and *de novo* assembly algorithms. The data enabled 99.2% of sites that are polymorphic across all individuals to be phased unambiguously. By resolving transmission vectors we were able to accurately observe a wide spectrum of genomic changes enabling insight into biological processes. For instance, we describe the impact of meiotic recombination on the chimpanzee genome at crossover, non-crossover, and gene conversion events across the two generations.

3280F

Allelic and genotypic associations of SNPs of the OCA2 and HERC2 genes with eye, hair and skin pigmentation and the presence of freckles in Brazil. *E.S. Andrade[1], N.C.A. Fracasso[1], P.S. Strazza Júnior[2], A.L. Simões[1], C.T. Mendes-Junior[3].* 1) Department of Genetics, School of Medicine of Ribeirao Preto, University of Sao Paulo, 14049-900, Ribeirao Preto, Sao Paulo, Brazil; 2) Department of Biology, School of Philosophy, Sciences and Letters of Ribeirao Preto, University of Sao Paulo, 14040-901, Ribeirao Preto, Sao Paulo, Brazil; 3) Department of Chemistry, School of Philosophy, Sciences and Letters of Ribeirao Preto, University of Sao Paulo, 14040-901, Ribeirao Preto, Sao Paulo, Brazil.

Panels composed of Single Nucleotide Polymorphisms (SNPs) in genes related to pigmentation, when associated with different phenotypes such as skin, eyes and hair color can be very useful in criminal cases assisting in predicting the physical appearance of an individual from an unknown biological sample found in crime scenes. The OCA2 (oculocutaneous albinism II) gene (15q11.2-12) encodes the protein P, a transmembrana protein involved in small molecule transport, specifically tyrosine, a precursor of melanin (Branicki et al. 2008). Mutations in this gene result in type 2 oculocutaneous albinism. Its neighboring gene, HERC2 (HECT and RLD domain containing E3 ubiquitin protein ligase) (15q13), encodes for functional protein domains involved in intracellular transport (Yonggang et al. 2000) and has been reported to influence OCA2 expression (Eiberg et al., 2008; Kayser et al., 2008; Sturm et al., 2008). Both genes have been associated with skin/hair/eye pigmentation variability (Eiberg et al., 2008; Branicki et al. 2009). The present study aimed at evaluating the influence of OCA2 and HERC2 alleles and genotypes in the determination of pigmentation traits in a highly admixed Brazilian population sample. Seven SNPs (four from OCA2 gene and three from the HERC2 gene) were evaluated in 286 unrelated individuals from the Ribeirao Preto area, located at the Northwestern region of the Sao Paulo State, Southeastern Brazil. SNPs were genotyped by PCR-RFLP, followed by Polyacrylamide Gel Electrophoresis. The associations' tests (Fisher's Exact Test and Odds Ratio) were performed using the GraphPad InStat 3.06 software. All the seven SNPs presented one allele associated with phenotypes from at least two pigmentation features and the alternative allele associated with the opposite phenotypes from the same trait. The A allele of the rs1800404 SNP (OCA2), for instance, was associated with the presence of blond/red hair, pale skin and freckles and blue/green eyes, whereas the G allele was associated with dark eyes, hair and skin and the absence of freckles. The genotypic associations followed the same pattern for all seven SNPs. The SNPs panel showed to have predictive value for phenotypic characteristics. However, further studies, including haplotype analysis, are needed to determine the effects of SNPs in the OCA2 and HERC2 genes in human pigmentation and their forensic application. FINANCIAL SUPPORT: CNPq/Brazil (Grants 478843/2009-7 and 305493/2011-6) and CAPES.

AKT3, ANGPTL4, eNOS3, and VEGFA associations with high altitude sickness in Han and Tibetan Chinese at the Qinghai-Tibetan Plateau. *N. Buroker[1], X.-H. Ning[2], Z.-N. Zhou[3], K. Li[4], W.-J. Cen[4], X.-F. Wu[3], W.-Z. Zhu[3], C. R. Scott[1], S.-H. Chen[1].* 1) Pediatrics, 356320, University of Washington, Seattle, WA; 2) Division of Cardiology, Seattle Children's Hospital. Institute. Foundation, Seattle, WA; 3) Laboratory of Hypoxia Physiology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Beijing, China; 4) Lhasa People Hospital, Lhasa, Tibet, China.

Mountain sickness (MS) occurs among humans visiting or inhabiting high altitude environments. Genetic analyses of the AKT3, ANGPTL4, eNOS3 and VEGFA genes was made between lowland (Han) and highland (Tibetan) Chinese. Ten SNPs within these genes were evaluated in Han and Tibetan patients with Acute (A) and Chronic (C) MS. We compared 74 patients with AMS to 79 Han unaffected with MS as well as 48 CMS patients to 31 Tibetan unaffected. The ten SNPs studied are AKT3 (rs4590656, rs2291409), ANGPTL4 (rs1044250), eNOS3 (rs1007311, rs1799983) and VEGFA (rs79469752, rs13207351, rs28357093, rs1570360, rs3025039). Direct sequencing was used to identify individual genotypes for these SNPs. Hb, Hct and RBC were found to be significantly associated with the AKT3 SNP (rs4590656), Hb was found to be associated with the eNOS3 SNP (rs1007311) and RBC was found to be significantly associated with the VEGFA SNP (rs1570360) in Tibetan patients with CMS. CMS patients were found to diverge significantly for both eNOS3 SNPs as measured by genetic distance (0.042, 0.047) and for the VEGFA SNP (rs28357093) with a genetic distance of 0.078 compared to their Tibetan control group. HR was found to be significantly associated with the eNOS3 SNP (rs1799983) and SaO2 was found to be significantly associated with the VEGFA SNPs (rs13207351, rs1570360) in Han patients with AMS. The Han and Tibetan control groups were found to diverge significantly for the ANGPTL4 SNP and VEGFA SNP (rs28357093) as measured by genetic distance (0.049 & 0.073), respectively. Seven of the SNPs from non-coding regions are found in the transcriptional factor response elements and their possible role in gene regulation was evaluated with regard to HAS. AMS and CMS were found to be significantly associated with the four genes compared to their Han and Tibetan control groups, respectively, indicating these nucleotide alterations have a physiological effect for the development of high altitude sickness.

3282T

A population genetic measure of the de novo mutation rate using identity-by-descent estimates. *C.W.K. Chiang[1], J. Li[2], M.G. Ehm[3], M.R. Nelson[3], J. Novembre[1].* 1) Department of Ecology and Evolutionary Biology, UCLA, Los Angeles, CA; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Quantitative Sciences, GlaxoSmithKline, RTP, NC, USA; Upper Merion, PA, USA; and Stevenage, UK.

The *de novo* mutation rate is an important parameter that underlies much of population genetics theory and is critical for understanding the genetic architecture of human traits and disease. Estimates of mutation rate have been derived using family-based approaches based on direct sequencing in pedigrees, or using evolution-based approaches by modeling the demographic history of a population and analyzing its impact on the site frequency spectrum. However, family-based approaches provide a mutation rate estimate based on only a few families and evolution-based approaches are sensitive to the assumed demographic model. Therefore, a parallel method for estimating mutation rates would be useful to complement the current approaches. Here we present a novel method to estimate an average mutation rate using identity-by-descent (IBD) tracts coupled with sequence data. Using genome-wide genotyping data at over 716,000 SNPs for 7,401 individuals of European descent, we inferred pair-wise IBD tracts by Beagle. In total we detected 4.96 million tracts of IBD over 1 cM in length, averaging 1.79 cM of IBD per 10,000 pairs of individuals, consistent with the observed average in Europeans. By cross-referencing with deep sequencing data in the exons of 202 genes distributed genome-wide for these individuals, we identify putatively novel mutations since the IBD event, and use these to infer a preliminary estimate of $\sim 8\times10^{-8}$ mutations per generation. While this estimate is higher than previous estimates, we anticipate that by developing a more sophisticated framework to take into account the uncertainty of imputation errors, haplotype phasing errors, and IBD tract lengths we will produce a more refined estimate of the average *de novo* mutation rate. These measures provide context to aid in the interpretation of how variants are related to phenotypes.

3283F

Determination of PON1 and P2RY12 polymorphisms distribution in Hungary living population samples. *B. Melegh, I. Janicsek, Cs. Sipeky, B. Duga, B.I. Melegh, L. Jaromi, L. Magyari, J. Bene.* Department of Medical Genetics, University of Pecs, Pecs, Hungary.

Objectives: Clinical efficacy of clopidogrel in the antiplatelet therapy has recently been in the focus of clinical investigations. Recent studies suggest that, among others, genetic factors like SNPs in genes of specific receptors and enzymes have a large contribution to the high interindividual variability observed in clopidogrel response. The pharmacogenomic investigation of these factors might also have clinical benefit. The purpose of our study was to determine the distribution of variants of paraoxonase 1 (PON1) and purinergic receptor P2Y, G-protein coupled, 12 (P2RY12) genes in 477 average Hungarian and 491 Roma (gipsy) samples. For the PON1 gene rs662 (Q192R) and rs854560 (L55M), for the P2RY12 gene 3 SNPs, rs2046934, rs6798347 and rs6801273 were analyzed as the most frequently investigated naturally occurring variants. Methods: The different genotypes were determined by PCR-RFLP. Results: For the Q192R variant the frequency of the GG genotype was found more than 2.5 times higher in the Hungarian group compared to the Romas (11.3% vs 4.3%, $p<0.001$). In the G allele frequencies similar, significant difference could be observed (24.8% vs 31.7%, $p<0.001$). For the L55M variant the frequency of the TT genotype was more than 2.5 times higher in the Roma group than in the Hungarian one (10.0% vs 3.8%, $p<0.001$). For the 3 P2RY12 variants significant differences were found only in rs2046934: the frequency of the CC genotype is 7 times higher in Hungarians than in Romas (1.4% vs 0.2%, $p<0.05$). Conclusion: The data presented here confirm major differences between the distribution of PON1 and P2RY12 variants in Hungarian and Roma patients that might have clinical implications.

3284W

Mapping the genetic diversity of HLA haplotype in Asia populations. *W.Y Saw[1], R.T.H Ong[2], C.C Khor[3], N. Kato[4], Y.Y Teo[1,2,3,5].* 1) Life Science Institute, National University of Singapore, Singapore; 2) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 3) Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore, Singapore; 4) Department of Gene Diagnostics and Therapeutics, Research Institute, International Medical Center of Japan, Japan; 5) Department of Statistics and Applied Probability, National University of Singapore, Singapore.

Numerous studies have identified disease associations with genetic variants located in the HLA regions, and recent population genetics studies have also discovered genetic evidence of population differences at HLA loci between seemingly homogeneous populations in North and South China. Here we report a systematic survey of the entire major histocompatibility complex (MHC) across 3,499 individuals from eighteen populations from seven countries in Asia, including China, Japan, India, Sri Lanka, Thailand, Vietnam and Singapore. In the study, we are looking at the MHC region which locates on chromosome 6, 25Mb to 35Mb in humans, consisting of approximately 1600 common SNPs across the eighteen populations. In this study, we have investigated different strategies to perform haplotype phasing of the genotype data from these samples in order to minimize artifactual diversity introduced as a result of the phasing. By comparing the haplotype diversity across the samples from these populations, we observed a geographical cline in terms of haplotype variation across populations in East and Southeast Asia, and even between seemingly homogeneous populations within Japan and China separately, we observe differences in the genetic architecture of the MHC region.

3285T

Long runs of homozygosity contain a higher fraction of all genome-wide deleterious homozygotes relative to the fraction of all genome-wide non-damaging homozygotes. *Z.A. Szpiech[1,2], J. Xu[3], T.J. Pemberton[1], W. Peng[3], S. Zöllner[4], N.A. Rosenberg[1], J.Z. Li[3].* 1) Department of Biology, Stanford University, Stanford, CA; 2) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 4) Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Exome sequencing offers the potential to study the genomic variables that underlie patterns of deleterious variants. Here we consider how runs of homozygosity (ROH) correlate with these variants. In general, short ROH represent homozygosity for ancient haplotypes; ROH of intermediate length represent homozygosity arising from background relatedness in a population; and long ROH result from recent parental relatedness. Because many deleterious variants act recessively, they can be more effectively purged by selection in ROH-rich regions than in non-ROH regions. Thus, ROH could contain a lower fraction of all genome-wide damaging homozygotes relative to the fraction of all genome-wide non-damaging homozygotes. However, inbreeding can present low-frequency variants in homozygous form, and many of these are more likely to be deleterious than common variants. When the homozygous deleterious variants are not lethal, one might expect ROH to contain a higher fraction of genome-wide deleterious homozygotes compared to the fraction of all genome-wide neutral homozygotes, and longer (newer) ROH might have a higher fraction than shorter (older) ROH. We sequenced the exomes of 27 individuals from 6 HGDP populations, representing a wide range of genomic ROH coverage (4%–46%, Pemberton et al. 2012). We classified non-reference variants as damaging or non-damaging using PolyPhen2. Consistent with the work of Lohmueller et al. (2008), the proportion of variants private to a given population that are damaging increases with the distance of the population from Africa. For the individual genomes, the fraction of all genome-wide homozygotes lying in ROH is positively correlated with the total length of ROH in the genome. Damaging homozygotes show a significantly higher fraction falling into any size ROH than non-damaging homozygotes ($p < 0.001$). This trend is also significant for long ROH only ($p < 0.05$) but not for intermediate or short ROH only. These results can be explained by ROH containing more rare and damaging variants in homozygous form as a result of inbreeding. Our study provides a demonstration that long ROH harbor disproportionately more deleterious homozygotes than would be predicted solely by the ROH coverage of the genome.

The genetic structure of Western Balkan populations based on autosomal and haploid markers. *K. Tambets[1], L. Kovacevic[1,2,3], D. Primorac[4], G. Lauc[5], A. Leskovac[6], Z. Jakovski[7], K. Drobnic[8], S. Kovacevic[9], T. Bego[10], E. Metspalu[11], D. Marjanovic[2,5], R. Villems[1,11].* 1) Estonian Biocentre, Tartu, Estonia; 2) Institute for Genetic Engineering and Biotechnology, Sarajevo, Bosnia and Herzegovina; 3) Faculty of Pharmacy, University of Sarajevo, Sarajevo, Bosnia and Herzegovina; 4) University Center of Forensic Science, Split, Croatia; 5) Genos doo, Zagreb, Croatia; 6) Vinca Institute of Nuclear Sciences, Belgrade, Serbia; 7) Institute of forensic medicine, criminology and medical deontology and Medical Faculty, University of "St. Cyril and Methodious", Skopje, Republic of Macedonia; 8) Faculty for Justice and Security, Ljubljana, Slovenia; 9) Forensic Center, Bozova glavica, Danilovgrad, Montenegro; 10) Faculty of Farmacy, University of Sarajevo, Sarajevo, Bosnia and Herzegovina; 11) University of Tartu, Tartu, Estonia.

Contemporary inhabitants of the Balkan Peninsula belong to several ethnic groups of diverse cultural backgrounds. In this study, three ethnic groups from Bosnia and Herzegovina - Bosniacs, Bosnian Croats and Bosnian Serbs - and four other Slavic-speaking Western Balkan populations: Serbians, Croatians, Macedonians from Republic of Macedonia, Montenegrins, and Albanian-speaking Kosovars have been characterized for the genetic variation of 660 000 autosomal single nucleotide polymorphisms. Genetic structuring of Western Balkan populations has been analyzed in a global context. Comparison of the variation within autosomal and haploid data sets of studied Western Balkan populations revealed their genetic closeness regardless of a genetic system inspected, in particular among the Slavic speakers. Hence, culturally diverse Western Balkan populations are genetically very similar to each other. Only the Kosovars show slight differences both in the variance of autosomal and uniparentally inherited markers from the other populations of the region, possibly also due to their historically strict patrilineality. In a more general perspective, our results reveal clear genetic continuity between the Near Eastern and European populations, lending further credence to extensive, likely multiple and possibly bidirectional ancient gene flows between the Near East and Europe, cutting through the Balkans.

3287W

Analysis of TLR4 SNPs 299 and 399 in a population of full term Wisconsin infants. *D. Pillers[1], J. DeValk[1], M. Baker[1], S. Schrodi[2], S. Tokarz[1].* 1) University of Wisconsin-Department of Pediatrics, Madison, WI; 2) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI.

Background: Toll-like receptors (TLRs) are present in many cell types and serve as the first point of defense in the innate immune system by initiating the inflammatory cascade in response to infectious microorganisms. Single nucleotide polymorphisms (SNPs) are present in many TLR genes and have been associated with many disorders of infection and inflamation. TLR4 229 and 399 SNPs are associated with increased susceptibility to infection from various pathogens. As infection can play a role in the development of preterm labor, TLR SNPs that alter the response to infection may have a different frequency in the pre-term population as compared to individuals of full-term birth status. Most current population data on SNP frequency does not exclude individuals who were born preterm. To this end, we screened a cohort of full-term infants, selected at random, for a subset of TLR4 SNPs to determine their population frequencies. **Objective**: Determine the allele and genotype frequencies of TLR4 299 and 399 in a population of full-term infants **Design/Methods:** We have analyzed the genotypes of these SNPs in a population of 487 full-term Wisconsin newborns between 2010 and February 2012. Anonymized DNA samples from 487 (≥37 weeks of gestational age) infants were obtained from the Wisconsin State Laboratory of Hygiene. SNP assays were purchased from Applied Biosystems Inc. (ABI) and performed on the ABI StepOnePlus system. Data were analyzed using ABI StepOne Software. **Results:** The allele frequencies for TLR4 299 found in this population are 0.94 (A) and 0.06 (G) and 0.95 (C) and 0.05 (T) for TLR4 399. For TLR4 299 the observed genotype frequency was 0.88 (AA), 0.13 (AG), and 0.0 (GG). In TLR4 399 we observed genotype frequencies of 0.90 (CC), 0.10(CT), and 0.0 (TT). **Conclusions:** As expected we found a higher allele frequency for the TLR4 major alleles (A and C). However, although TLR4 299 and 399 are tightly linked, TLR4 299 had a slightly lower frequency of homozygous major allele (AA) than TLR 399 homozygous major allele (CC). TLR4 SNP 299 and 399 have been linked to alteration in the innate immune response and correlated to preterm birth. Published population data that correct for the factor of prematurity are few, making our work a beginning in filling in this gap in population information.

Using Time to Most Recent Common Ancestor to detect selection in population samples of whole-genome sequences. *H. Hunter-Zinck[1], A.G. Clark[2].* 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY.

Previous studies have investigated the use of Identity-by-Descent (IBD) measures to detect the past action of positive selection (Albrechtsen, et al. 2010, PMID 20592267). However, these studies used IBD inference methods that define IBD as a binary statistic and apply only to genotype data. Inferring Time to Most Recent Common Ancestor (TMRCA) in whole-genome sequence provides a richer metric for the characterization of shared ancestry and, potentially, greater power for applications of IBD in population genetics. We used the pairwise sequentially Markovian coalescent (PSMC) model, developed by Li and Durbin (2012, PMID 21753753), to infer TMRCA for chromosomes pairs both within and between individuals in the 1000 genomes data (1000 Genomes Project Consortium, 2010). Using the distribution of TMRCA at each genomic locus, we then investigated the presence of natural selection genome-wide. A recent complete sweep would result in an unusually recent TMRCA, while a partial sweep may appear as a strongly skewed or even bimodal TMRCA distribution. Balancing selection may manifest as an exceptionally deep TMRCA. We also compared the distribution of pairwise TMRCA for chromosomes within individuals with the distribution of TMRCA for chromosomes between individuals at respective loci. Differences between these distributions may arise due to departures from random mating or due to selection, and these cases may be distinguished when nonrandom mating results in genome-wide effects. Several loci show significant differences in the TMRCA distributions for chromosome pairs within and between individuals. Inferring TMRCA in sequence data from population samples provides a powerful approach to infer forces that impact the ancestral history of the sample.

Estimating inbreeding coefficients from NGS data: impact on genotype calling and allele frequency estimation. *F.G. Vieira[1], M. Fumagalli[1], A. Albrechtsen[2], R. Nielsen[1,2].* 1) Integrative Biology, UC Berkeley, Berkeley, CA, USA; 2) Department of Biology, University of Copenhagen, Copenhagen, Denmark.

Next-generation sequencing (NGS) methods provide fast, cheap and reliable large-scale DNA sequencing data. They are used in de-novo sequencing, disease mapping, gene expression and in population genetic studies, providing rapid and complete sequencing of candidate genes, exomes, transcriptomes or even whole genomes. Current NGS technologies produce short read sequences that are later de-novo assembled or mapped to a reference genome and used for SNP and genotype calling. However, this data typically has high error rates due to multiple factors from random sampling of homologous base pairs in heterozygotes to sequencing or alignment errors. Furthermore, many NGS studies rely on low coverage sequence data (<5x), making SNP and genotype calling difficult, and often associated with considerable uncertainty. It is, therefore, crucial to quantify and account for this uncertainty, as it will influence downstream analyses. One way of reducing this uncertainty is to sequence target regions deeply (>20x)but,the ever-increasing demand for larger samples suggests that medium- (5–20x) or low-coverage sequencing will be the most common and cost-effective study design in many applications of NGS data for years to come. Recent genotype calling methods rely on probabilistic frameworks to accurately call SNPs and genotypes, even at lower depths.These methods integrate base quality scores with other error sources to calculate an overall genotype likelihood which, in conjunction with a genotype prior, can be used to calculate a posterior probability. This way it is possible to get higher accuracy levels, an associated measure of statistical uncertainty and a natural framework for incorporating prior information. Various prior sources can be used but one of the most common is based on genotype frequencies under Hardy-Weinberg Equilibrium (HWE). However, HWE assumes random mating and, while this assumption might hold for most species, it is clearly violated in others like self-polinating plants, domesticated species (inbreeding) as well as species with asexual life cycles. This violation can result in the under-calling of homozygotes, biasing downstream analysis. Here, we've developed an algorithm to estimate HWE deviations from NGS data. These estimates can then be incorporated into the prior to get an improved genotype posterior probability. We demonstrate the accuracy of our method using simulations and report the increased accuracy in genotype calling and SFS estimation.

Maternal genetic variation near *PRKAA1* and *EDNRA* is associated with birth weight among residents of high altitude. *A.W. Bigham[1], M.J. Wilson[2], V.A. Browne[3], C.G. Julian[2], E. Vargas[4], C. Rodriquez[5], M.D. Shriver[6], L.G. Moore[7].* 1) Department of Anthropology, University of Michigan, Ann Arbor, MI; 2) Altitude Research Center, University of Colorado Denver, Aurora, CO; 3) Department of Health and Behavioral Science, University of Colorado Denver, Denver, CO; 4) Instituto Boliviano de Biología de Altura, La Paz, Bolivia; 5) Clinica Siraní, Santa Cruz, Bolivia; 6) Department of Anthropology, Pennsylvania State University, State College, PA; 7) Graduate School of Arts and Sciences, Wake Forest University, Winston-Salem, NC.

The hypoxic environment of high altitude restricts fetal growth. However, long-term residents of high altitude are protected from altitude-associated intrauterine growth restriction (IUGR) compared to recent migrants. To identify the genes protecting against IUGR and therefore affecting infant birth weight, we performed a quantitative association study of birth weight in a sample of 178 self-identified Andean and European women living at low and high altitude in Bolivia who were longitudinally studied during pregnancy. We tested 63 SNPs from 16 candidate gene regions with previously identified evidence of natural selection in Andeans. Significant associations between birth weight and maternal SNPs near endothelin receptor type A (*EDNRA*) and protein kinase, AMP-activated, alpha 1 catalytic subunit (*PRKAA1* also known as [aka] *AMPKa1*) were identified. Our results suggest that maternal variation in these genes may influence maternal physiological responses to pregnancy that are instrumental in determining fetal growth and indicate that altitude-selected genes in the hypoxia inducible transcription factor (HIF) pathway play a role in the determination of birth weight at high altitude.

Selective turnover in human regulatory regions: out with the old, in with the new. *L.D. Ward[1,2], M. Kellis[1,2], The ENCODE Project Consortium.* 1) CSAIL, Massachusetts Institute of Technology, Cambridge, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA.

The ENCODE project is revealing active transcription and chromatin marks spanning ~80% of the human genome, while comparative genomics of multiple mammals suggests that only ~5% of the human genome is constrained across those species. Analyses of the pilot ENCODE data were statistically underpowered to quantify human constraint for active unconserved elements, leaving open the question of whether they are functional and associated with negative selection in the human lineage. Here, we revisit this question using three new resources: (1) a much higher-resolution map of mammalian constraint using 29 species which pinpoints specific constrained elements covering 4.5% of the human genome; (2) genome-wide experimental coverage from the scaled-up ENCODE project enabling a nearly comprehensive annotation of functional elements; and (3) variation data from the 1000 Genomes Project, enabling us to estimate constraint within the human lineage. We also developed a bootstrapping method to detect human constraint over genomic intervals which accounts for the regional patterns in diversity caused by variable mutation rate and LD. We find strong evidence of human-specific selective constraint in active elements that are not constrained across mammalian genomes. This spans a broad range of unconserved noncoding elements, including: TF binding sites, accessible chromatin regions detected by DNase and FAIRE, transcribed regions outside previously-annotated genes, and candidate promoter and enhancer regions showing specific combinations of histone marks. On aggregate, these show a 16% reduction in diversity in active regions compared to inactive regions, despite not showing constraint across mammals. We confirm that this signal of negative selection is due to recently-gained selection acting in the human lineage: it is also reflected in a depressed frequency of derived alleles, and is robust to controls for background selection, CpG content, biased gene conversion, and read mapping bias. Conversely, we find a recent loss of purifying selection in the human lineage for those elements that are conserved in mammals but lack evidence of activity in ENCODE datasets. Lastly, we study the likely functional implication of recent human-specific selection. We find that enhancers that lack mammalian constraint but show the strongest evidence of human-specific selection are associated with color vision and nervous system development genes, consistent with recent human evolution.

3292F

Signs of high populational differentiation on the MHC (Major Histocompatibility Complex) region on Native South American populations. *K. Nunes[1], E.J.M. Santos[2], J.F. Guerreiro[2], D. Meyer[1].* 1) Universidade de Sao Paulo, Sao Paulo, Brazil; 2) Universidade Federal do Para, Belem, Brazil.

The MHC (Major Histocompatibility Complex) is a 4Mb region of human chromosome 6 (6p21.31) in which is the highest concentration of immune genes. Many of these genes, especially HLA (Human Leukocyte Antigens), present a pattern of genetic variation in their coding regions and/or regulators consistent with that expected for regions that are (or have been) on balancing selection. The balancing selection is characterized by maintaining highest levels of population variability than expected under neutrality. In the case of HLA genes, this pattern is explained by the co-evolution between hosts and pathogens. Also, there is a positive correlation between the abundance of pathogens in a geographic region and the diversity of HLA genes. Based on this, the American continent is an interesting region of the world for studies of selection in the HLA genes. America was the last continent peopled by modern human and has a large variation on latitude, biomes, climates and pathogens, many of which are endemic and could have exercised selective pressure in the MHC genes. In the present study we are looking for signs of selection in the region of the MHC genes in Native populations of South America. We genotyped 16 STRs in the MHC region and compared the genetic profile with 61 STRs spread over genome (demographic control) in 11 Amazon Native populations (Arara do Laranjal, Arara do Iriri, Araweté, Assurini, Awa-Guajá, Kayapó Krokaimoro, Xikrin Kayapó, Parakanã, Urubu-Kapoor, Tiryó and Zoe). We found that the population differentiation (FST) of MHC STRs is greater than the STRs throughout the genome (FST MHC = 0.16 and FST Genomic = 0.11). Based on the finite islands model and exploring the relationship between population differentiation (FST) and the heterozygosity rate, implemented in the LOSITAN program, we found that the 7 of the 16 MHC STRs are outside the null distribution obtained by 61 genomic STRs (C.I. 95%). The highest differentiated MHC STRs are located near the HLA-B gene (D6S2926, D6S2927, D6S2928 e MICA) and DQB1 gene (D6S2876). This result suggest that there are signs of selection in the HLA genes of the Native American populations and indicates that selection favors different sets of alleles in different populations, resulting in a high genetic diversity and differentiation pattern among the populations.

High diversity of *ADH1B* gene among the Tibetans. *L. Kang[1,2], L. Yan[2], K. Hu[1], F. Chen[1], H. Li[1,2].* 1) School of Medicine, Tibet University for Nationalities, Xianyang, Shaanxi, China; 2) MOE Key Laboratory of Contemporary Anthropology, Fudan University, Shanghai, China.

ADH1B is one of the most studied human genes with many polymorphic sites. One of the single nucleotide polymorphisms (SNP), rs1229984, coding for a variant of Arg47His, has been proved to be associated to many serious diseases including alcoholism and cancers of digestive system. The derived allele, ADH1B*47His, reaches high frequency only in East Asia and Southwest Asia, and is highly associated to agriculture. Micro-evolutionary study defined seven haplogroups for ADH1B. Haplogroups H5, H6, and H7 contain the ADH1B*47His allele. H5 is in Southwest Asia and the other two are found in East Asia. H7 has an additional derived allele of rs3811801 than H6 and was proved to have undergone significant positive selection in Han Chinese, Hmong, Koreans, Japanese, Khazak, Mongols, etc. In this study, we typed 19 SNPs in region covering ADH1B gene among 1175 individuals of 12 Tibetan populations from all districts of the Tibet Autonomous Region. The major populations of the Tibetans (Qamdo, Lhasa, Nagqu, Nyingchi, Shannan, and Shigatse), most of whom are farmers, have around 12% of H7 and 2% of H6. The minor populations, living on hunting or switched to farming recently, have lower H7 frequencies (Tingri 9%, Gongbo 8%, Monba and Sherpa 6%). Luoba (2%) and Deng (0%) have even lower frequencies. Long range haplotype analyses revealed very weak positive selection signals for H7 among the Tibetans. Interestingly, the haplotype diversity of H7 is the highest in the Tibetans than any other populations studied, indicating a longest diversification history of the haplogroup in the Tibetans. Network analysis on the long range haplotypes revealed that H7 in the Han Chinese did not come from the Tibetans but from a common ancestor of the two populations. In conclusion, we argued that H7 of ADH1B originated in the ancestor of Sino-Tibetan populations and flowed to the Tibetans very early. However, as the Tibetans have only a relative short history of agriculture, selection has only laid weak effects, and the frequency of H7 has not risen to high, whereas the diversity of the gene has accumulated to very high level.

Natural selection increases mutational robustness in complex diseases: Mendelian evidence from early versus late onset common diseases. *B.E. Baysal.* Pathology, Roswell Park Cancer Institute, Buffalo, NY.

Complex diseases are common phenotypic variations that are influenced by genetic factors. Therefore complex diseases should be subject to the process of natural selection, the defining principle of evolutionary change. However, the empirical impact of natural selection on the genetic architecture of complex diseases is poorly understood. It is fundamentally important that we better understand whether and how natural selection affects the genetics of complex diseases. Here, I hypothesize that negative selection of diseased individuals leads to systemic genetic differences between common diseases that primarily occur before or during the reproductive years (early onset) and those that occur after the reproductive years (late onset).

To test this hypothesis, a comprehensive literature survey of nonpleiotropic, nonsyndromic susceptibility genes with a penetrance of at least 80% (Mendelian phenocopies) was completed for early (average age at onset less than 30 years) versus late onset (average age at onset 30 years or more) common diseases, organized using the World Health Organization (WHO) ICD-10 disease classification scheme. Mendelian phenocopies were identified for 16 primarily late onset common diseases from 9 distinct WHO categories including papillary renal carcinoma, obesity, Alzheimer disease, Parkinson disease, frontotemporal dementia, amyotrophic lateral sclerosis, primary open angle glaucoma, age-related hearing loss, coronary artery disease, small vessel stroke, pancreatitis, thrombotic thrombocytopenic purpura, systemic lupus erythematosus, Paget's disease of bone, inclusion body myositis and focal segmental glomerulosclerosis. In contrast, no Mendelian phenocopy was found for any primarily early onset common disease ($p<5.8\times10^{-4}$; Fisher's exact test; two-sided). Thus, rare coding variants are highly predictive for a subset of late onset common diseases, but not for early onset common diseases.

These results suggest that the genetic architecture of early onset common diseases is more robust against the phenotypic expression of highly penetrant predisposing mutations than is the case for late onset common diseases, implying that clinically significant rare variants are less likely to be discovered for early onset common diseases. The primary candidate for increased genetic robustness in early onset common diseases is proposed to be natural selection.

Evolutionary role of the human skull: comparing neutral and selective markers. *D.V. Bernardo[1], T.F. Almeida[2].* 1) Department of Genetic and Evolutionary Biology, University of São Paulo, São Paulo, São Paulo, Brazil; 2) Unity of Genetics. Children's Institute. HCFMUSP, São Paulo, Brazil.

The microevolutionary processes involved in the human skull evolution are researched in many different ways. Recent studies compared the biological distances obtained for human skulls and microsatellites, attempting to test the correlation between them. Most of them found a positive and significative correlation between morphology and neutral molecular markers and concluded that the evolution of human skull as a whole followed stochastic events such as genetic drift and gene flow. Some found a correlation with climatic events and explained the morphological patterns based on this. Following this line of thought we compared the biological distances of genes known to be under positive selection with microsatellites and with craniometrics to investigate if the morphology preferably obeys a neutral pattern, or if it is associated with selective genes. To accomplish the test we used ten populations representative of Africa, Europe, Asia and Oceania in which molecular and craniometric data were available for the same populations. We constructed distances matrices for all the variables and then calculated the correlation and significancy between them. The results obtained were significative and positive between morphology and microsatellite between morphology and two selective genes and also between three selective genes and microsatellites. They showed that it is possible to obtain positive correlations between features under selection and neutral molecular markers possibly because of the shared demographic history and that this correlation is not always synonymous of an exclusively neutral pattern of evolution. Besides, the EDAR, described previously related to the thickness of hair in Asians, had a significant correlation with morphology and not with microsatellite, suggesting a non-neutral configuration of the skull. Just as this gene, the human skull suffered a possible selective pressure in the asian populations (appearing as the mongoloid morphology), this can be due either by climate or by other environmental pressures that separated these groups in a recent human evolutionary history. This findings favors the interpretation that selective forces are more important for the evolution of human skulls, than previously assumed, because the genetic neutral markers are not exclusively related to the neutral features and a known selective gene is correlated only with morphology, excluding the background role that genetic drift might have in their evolution.

3296W

Characterization of human-specific duplicated neural genes suggests a model of functional antagonism. *M.Y. Dennis[1], F. Antonacci[1], C. Golzio[2], J. Huddleston[1], T.A. Graves[3], P.H. Sudmant[1], D.W. Raible[4], N. Katsanis[2], R.K. Wilson[3], E.E. Eichler[1,5].* 1) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA, USA; 2) The Center for Human Disease Modeling, Duke University, Durham, NC, USA; 3) The Genome Institute at Washington University School of Medicine, Washington University School of Medicine, Saint Louis, MO, USA; 4) Department of Biological Structure, University of Washington, Seattle, WA, USA; 5) Howard Hughes Medical Institute, Seattle, WA, USA.

Gene duplication and divergence is an important source for phenotypic change and adaptive evolution. We previously identified 23 genes that are duplicated exclusively in the human lineage, many of which have been implicated in neuronal function and brain development. Using a haploid clone resource to resolve the duplicate loci that are missing or misassembled within the human reference genome, we are systematically cloning and sequencing these recent duplicate genes in order to understand their evolution and potential role in human-specific neurocognitive traits. Our previous analysis of *SRGAP2* suggests that the duplicate genes may function to antagonize or modulate the function of an ancestral gene. Here, we assess this paradigm in two other gene families, *ARHGAP11A* and *CHRNA7*, implicated in cortex development and synaptogenesis as well as autism, schizophrenia, and epilepsy. We show that each gene duplicated once in the last six million years producing truncated paralogs found in nearly all humans today (1000 Genomes Project, N = 661). Specifically, a 41 kbp segment containing the putative promoter and first seven exons of *ARHGAP11A* duplicated to create *ARHGAP11B* ~5.5 million years ago (mya), shortly after the human-chimpanzee split. For *CHRNA7*, a larger region (~150 kbp), containing the terminal six exons of the gene, duplicated and created a novel fusion gene, *CHRFAM7A*, less than 1 mya. We show that all paralogs are expressed in both fetal and adult brain and are predicted to encode proteins. Interestingly, though these genes are fixed in most humans, their locations and potential cis-regulatory machinery are varied due to polymorphic inversions of the 15q13.3 locus. Preliminary functional experiments show that knockdown of *CHRNA7* and *ARHGAP11A* orthologs in zebrafish leads to distinct neuronal defects suggesting that dosage is important during development and a potential role of the duplicate genes as functional antagonists. We are simultaneously screening these recent gene innovations for disruptive mutations among patients with idiopathic intellectual disability and neuropsychiatric disease. Our preliminary data suggest that these and other duplicate genes have contributed to unique aspects of human brain evolution and function.

A genetic mechanism for Tibetan high-altitude adaptation. *C.D. Huff[1,2], F.R. Lorenzo[3], M. Myllymäki[4], S. Swierczek[3], M.E. Salama[5], G.L. Semenza[6], V. Gordeuk[6], J. Xing[2,7], T.S. Simonson[2,8], L.B. Jorde[2], P. Koivunen[4], J.T. Prchal[2,3].* 1) Department of Epidemiology, The University of Texas M.D. Anderson Cancer Center, Houston, TX; 2) Eccles Institute of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT; 3) Division of Hematology, University of Utah School of Medicine, Salt Lake City, UT; 4) Biocenter Oulu, Department of Medical Biochemistry and Molecular Biology, Oulu Center for Cell-Matrix Research, University of Oulu, Oulu, Finland; 5) Department of Pathology, University of Utah and ARUP Laboratories, Salt Lake City, UT; 6) Vascular Program, Institute for Cell Engineering, Johns Hopkins University School of Medicine, Baltimore, MD; 7) Department of Genetics, Rutgers, the State University of New Jersey, Piscataway, NJ; 8) Department of Genetics, University of California in San Diego, San Diego, CA.

Many physiological responses to hypoxia, including erythropoiesis, metabolism, respiration, angiogenesis, and development, are mediated by hypoxia-inducible factors (HIFs). The prolyl 4-hydroxylase PHD2 (encoded by *EGLN1*) is a negative regulator of HIFs. Several haplotypes have undergone positive selection in Tibetans, including a haplotype at the *EGLN1* locus. Chronic exposure to hypoxia leads to an elevation of hematocrit due to an increased number of erythrocytes (polycythemia). While increased hemoglobin concentration may be considered a beneficial adaptation to hypoxia, excessive erythrocytosis results in high blood viscosity, which impairs tissue blood flow and leads to impaired tissue oxygen delivery. In contrast to non-adapted populations, the majority of Tibetan highlanders maintain hematocrit levels comparable to populations living at sea level. In our previous work, we demonstrated that the advantageous *EGLN1* haplotype is associated with protection against polycythemia in Tibetan highlanders. We now describe two high-frequency Tibetan variants, $PHD2^{D4E}$ and $PHD2^{C127S}$. We observed complete linkage disequilibrium between the advantageous haplotype and the two mutations, each with an observed allele frequency of 0.92 among Tibetans. In closely related Asian populations (Korean, Han Chinese, Japanese, and Mongolian), we observed allele frequencies of 0.3 for $PHD2^{C127S}$ and 0.02 for $PHD2^{D4E}$ (*Fst*=0.76, empirical p-value=6.3×10^{-6}). We estimate that the $PHD2^{D4E}$ mutation originated ~6,000 years ago on a $PHD2^{C127S}$ haplotype. Individually, we observed no measurable phenotype for either variant. However, together, these variants demonstrated a lower K_m value for O_2 than wild-type PHD2, suggesting that they downregulate HIFs more efficiently under hypoxic conditions. This was experimentally verified in native erythroid progenitors homozygous for $PHD2^{D4E,C127S}$ that had decreased proliferation under hypoxic conditions, whereas wild-type progenitors have increased proliferation. Thus, $PHD2^{D4E,C127S}$ interferes with the hypoxic augmentation of erythropoiesis that is normally mediated through HIF activation. Our results suggest that the both the $PHD2^{D4E}$ and $PHD2^{C127S}$ mutations are required to produce a gain of function in PHD2 and that the two mutations were favored by selection as a coadaptation to high-altitude beginning approximately 6,000 years ago in Tibetan ancestors.

3298F

Selection and migration in spatially structured populations. *I. Mathieson[1], G. McVean[1,2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Statistics, University of Oxford, Oxford, United Kingdom.

Identifying which regions of a genome are, or have been, under selection is important in many settings. In humans, it can provide clues to human population history and the genetic origin of differential disease risk across populations. In ecology, selection can tell us about species' response to changing environmental pressures. In cancer, identifying selection within a tumor can help understand why different tumors respond differently to intervention, and thus guide treatment. However, in all these cases, the effects of selection can be confounded by structure, demography and spatially varying selection. We demonstrate that incorporating spatial structure is important for modeling selection in realistic settings, and that it is possible to make robust inference about relatively strong selection, with selection coefficients on the order of 0.01 or greater.

First we consider the situation where we have time series data of samples of allele frequencies. Working in a simple lattice model of spatial structure, we develop an estimator for selection coefficients and migration rates in a spatially structured population. By treating the true allele frequency as a hidden variable, we can pose the problem as a hidden Markov model, which we can then solve to obtain maximum likelihood estimates. We illustrate this approach by estimating selection coefficients from classical datasets of frequencies of different morph frequencies for the moth species Panaxia dominula and Biston betularia, collected across England over the 20th century. We estimate that the selection coefficient against the medionigra allele of P. dominula is 0.063, and that against the carbonaria allele of B. betularia varies from 0.06 to 0.12 across England.

Finally, we consider the case, relevant to humans and most cancer studies where, rather than time series information, we have only a single observation. We present a structured coalescent model incorporating recombination. In this framework, we simulate haplotypes with structure and selection. We demonstrate inference in this model using human samples from the POPRES dataset. We also use this model to make qualitative predictions about the effect of changing selection and migration on population variation.

3299W

Evidence of recent positive selection in Africans at known and novel BMI loci. *T. Edwards[1], G.J. Papanicolaou[4], K. North[3], D.R. Velez Edwards[2], The. African American BMI Consort.[3].* 1) Center for Human Genetics Research, Department of Medicine, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics Research, Department of Obstetrics and Gynecology, Vanderbilt University, Nashville, TN; 3) University of North Carolina, Department of Epidemiology, Chapel Hill, NC; 4) Division of Prevention and Population Sciences National Heart, Lung, & Blood Institute, Bethesda, MD.

The obesity epidemic in the US is a major public health concern with notable disparity between Europeans (EA) and persons of recent African ancestry (AA). AAs have higher rates of obesity, higher risk of sequelae, and more acute sequelae of obesity compared with EAs. The genetics of obesity have been studied extensively in EAs and many genes have been discovered, although similar work has not been done for AAs. The interplay of environmental influences and genetics has not been as carefully studied as the direct effects of genetic variation. We participated in a meta-analysis of 39,144 AA adults with GWAS data and imputation from 19 studies, and subsequent analysis in 10,000 additional participants to discover the genetic determinants of body mass index (BMI) in AAs. We evaluated the novel and previously discovered gene regions for evidence of recent positive selection using Treeselect, iHS, XP-EHH, Tajima's D, and Fst in the Human Genome Diversity Panel, HapMap, Perlegen, and the BioVU GWAS data. The region near the novel BMI gene region containing KLHL32 had corroborating evidence of recent selection in Africans from all statistics (iHS = 4.05 [p-value = 0.04], XP-EHH = 1.3, Tajima's D = 2.7, Treeselect p = 4×10-4, Max Fst = 0.30), and has been previously associated with cardiac traits and mitochondrial complex 1 deficiency. The gene ADCY3 also lies in a region of recent selection in Africans (iHS = 5.2 [p-value = 9×10-4], XP-EHH = 1.8, Tajima's D = 2.8, Treeselect p = 2.6×10-3, Max Fst = 0.27), and is associated with obesity in humans and mice. ADCY3 -/- mice also lack olfaction, research has shown that ADCY3 functions in olfaction in higher mammals, and previous olfaction research in humans has described statistically significant differences in olfaction between AAs and EAs. These results suggest that selective pressure at BMI loci may determine in part the phenotypic disparity in BMI between AAs and EAs.

Characterizing the adaptation to high altitude in Tibetans. *E. Huerta-Sanchez[1], X. Jin[2], B. Peter[1], Y. Liang[2], M. He[2], X. Yi[2], A. Asan[2], Y. Shan[2], P. Ni[2], J. Wang[2], R. Nielsen[1], J. Wang[2].* 1) Statistics and Integrative Biology, UC Berkeley, Berkeley, CA; 2) BGI, Beijing genomics institute, BGI-Shenzhen, China.

High altitude environments have exerted a strong selective pressure on some human populations leading to one of the most convincing examples of human adaptation. One gene (EPAS1) in particular has been identified in multiple genome scans of high-altitude residents and harbors some of the largest frequency differences observed between two closely related populations (the Han and the Tibetans). Re-sequencing the gene, however, reveals a very distinctive pattern of genetic variation. Both haplotype and frequency based summary statistics do not support the case of selection on a de novo mutation. Preliminary results using the within-patterns of genetic variation in the Tibetan population suggest that another model, selection on standing variation is a more likely model, but the probability of selection on standing variation is not large enough (about 0.70) to be convincing. Therefore, we modify a Bayesian computation framework to include between population differences (between Han and Tibetans) to gauge whether both the strong signature of differentiation between populations and the level of within population variation are consistent with a model of selection on standing variation. In addition, we estimate both the timing and the strength of selection.

Recent positive selection of *HLA-DPB1*04:01* in Japanese population. *M. Kawashima[1], J. Ohashi[2], N. Nishida[3], K. Tokunaga[1].* 1) Human Genetics, Graduate School of Medicine, The Univ. of Tokyo, Bunkyo-ku, Japan; 2) Molecular and Genetic Epidemiology, Graduate School of Comprehensive Human Sciences, University of Tsukuba, Ibaraki, Japan; 3) Research Center for Hepatitis and Immunology, International Medical Center of Japan Konodai Hospital, Ichikawa, Chiba, Japan.

The human leukocyte antigen (HLA) genes exhibit the highest degree of polymorphism in the human genome. This high degree of variation at classical HLA class I and class II loci has been maintained by balancing selection for a long evolutionary time. However, little is known about recent positive selection acting on specific HLA alleles. To detect the signature of recent positive selection, we genotyped six HLA loci, *HLA-A*, *HLA-B*, *HLA-C*, *HLA-DRB1*, *HLA-DQB1*, and *HLA-DPB1* in 418 Japanese subjects, and then assessed the haplotype homozygosity (HH) of each HLA allele. There were 120 HLA alleles across the six loci. Among the 80 HLA alleles with frequencies of more than 1%, one allele, *DPB1*04:01*, which had a frequency of 6.1%, showed exceptionally high HH (0.53). The *DPB1*04:01* allele, which was present in the most common 6-locus HLA haplotype (4.4%), *A*33:03-C*14:03-B*44:03-DRB1*13:02-DQB1*06:04-DPB1*04:01*, seems to have flowed from the Korean peninsula to the Japanese archipelago in the Yayoi period. A theoretical calculation indicated that the strong linkage disequilibrium between *DQB1*06:04* and *DPB1*04:01* observed in Japanese cannot be explained without positive selection favoring *DPB1*04:01*. A computer simulation further revealed that the selection coefficient of *DPB1*04:01* was 0.0365 (95% credible interval 0.0254–0.0550). These results suggest that *DPB1*04:01* has recently undergone strong positive selection in Japanese population.

3302W

Haplotype signatures of negative selection. *D. Ortega Del Vecchyo[1], J. Novembre[1,2].* 1) Interdepartmental Program in Bioinformatics, University of California, Los Angeles, CA; 2) Department of Ecology and Evolutionary Biology, University of California, Los Angeles, CA.

In line with the nearly neutral theory, recent sequencing projects have identified a high proportion of functional variants at a low frequency in human populations. If negative selection is acting on those functional variants, the genetic variation surrounding them should be different than that of a neutral allele. That implies that the haplotype diversity patterns around a deleterious allele should be informative about the strength of negative selection. Here we propose a simulation framework to study the neutral genetic variation that surrounds a deleterious allele with a specific frequency and negative selection coefficient. We simulated a set of haplotypes using an importance sampling method and the coalescent model. The simulated haplotypes were used to study the haplotypic diversity patterns expected using a collection of different summary statistics such as iHS. The frequency and the selective coefficient of the deleterious allele impacted the neutral variation of the haplotypes, as assessed by the summary statistics. We explain how these findings will be used to analyze the strength of negative selection by estimating the distribution of selective coefficients in alleles at different frequencies.

Genome-wide signatures of natural selection in diverse African populations. *L.B. Scheinfeldt[1], S. Soi[1], C. Lambert[2], D. Hu[1], A. Coulibaly[1], H. Hutton[1], C. Elbers[1], W. Ko[1], W. Beggs[1], A. Ranciaro[1], S. Thompson[1], J. Hirbo[1], J. Bodo[3], O. Doumbo[3], M. Ibrahim[4], A. Froment[5], G. Lema[6], T. Nyambo[6], S. Omar[7], C. Wambebe[8], D. Meskel[9], G. Belay[9], S.A. Tishkoff[1,10].* 1) Department of Genetics, Univ Pennsylvania, Philadelphia, PA, USA; 2) Cold Spring Harbor Laboratories, Cold Spring Harbor, NY, USA; 3) Malaria Research and Training Center, University of Bamako, Bamako, Mali; 4) Department of Molecular Biology, Institute of Endemic Diseases, University of Khartoum, 15-13 Khartoum, Sudan; 5) UMR 208, IRD-MNHN, Musée de l'Homme, Paris, France; 6) Department of Biochemistry, Muhimbili University of Health and Allied Sciences, Dar es Salaam, Tanzania; 7) Kenya Medical Research Institute, Center for Biotechnology Research and Development, 54840-00200 Nairobi, Kenya; 8) International Biomedical Research in Africa, Abuja, Nigeria; 9) Department of Biology, Addis Ababa University, Addis Ababa, Ethiopia; 10) Department of Biology, University of Pennsylvania, Philadelphia, PA, USA.

Over the past decade, several genome-wide scans for selection have been developed and applied to worldwide human genetic data; however, these studies did not take into account the extensive continental variation within Africa. Here we interrogate genome-wide data from a geographically and ethno-linguistically diverse set of African population samples for signatures of recent positive selection. Our study includes 589 individuals from 22 populations living in distinct environmental conditions, encompassing regions with a range of disease exposures and regions at a range of altitudes. In addition, our study includes populations that practice a wide range of subsistence, such as agriculture, pastoralism, fishing, and hunting and gathering. We collected over 1 million SNP genotypes with the Illumina 1M Duo array and utilized genome-wide scans of positive selection, e.g. F_{ST}, iHS, and XP-CLR. Our results demonstrate several strong signals of recent, regionally restricted positive selection in genes involved in immune response, insulin resistance, and fertility, many of which, have not been highlighted in previous genome-wide scans of selection.

3304F

Contrasting selective forces shaping the type-II C-type lectin receptor family. *H. Quach, S. Fornarino, G. Laval, L. Quintana-Murci.* Human Evolutionary Genetics, Institut Pasteur, Paris, France.

The C-type lectin receptors (CLRs), which are crucial proteins in immunity, recognize carbohydrate structures of self and non-self origin. By binding to endogenous carbohydrate moieties, CLRs support specific functions that contribute to immune homeostasis, such as cell-cell or cell-matrix adhesion. By detecting pathogen associated molecular patterns, they are responsible of antigen recognition and internalization for presentation on MHC molecules. Evolutionary studies have already showed that some human CLRs have been subject to selective forces following host-pathogen co-adaptation. Here, we investigated how natural selection has targeted the type- II CLR family, by resequencing the 15 genes of this family in a panel of 186 individuals from various human populations worldwide. Our results revealed that natural selection has influenced the patterns of diversity of these receptors to different extents, going from strong selective constraints to high levels of amino-acid variation. As an instance, we found that the two genes encoding the Ashwell receptor (ASGR1 and ASGR2), which is functionally active in the liver as a hetero-oligomer, have been both subject to strong purifying selection, preventing the accumulation of amino-acid changes. This is consistent with an essential role of the Ashwell receptor in host survival. In mice, for example, it has been shown to be critic during Streptococcus pneumonia sepsis. By contrast, Langerin (CD207) presents an opposite evolutionary pattern. This receptor recognizes HIV-1 gp120 and structures specific to Candida albicans and Mycobacterium leprae, thus assuring a key protection against a broad range of pathogens.We detected an excess of non-synonymous polymorphisms at Langerin in humans, with respect to divergence, suggesting that some form of diversifying selection has been targeting the protein, making it prone to adapt to environmental changes. Our studies aim to deepen our understanding of the evolutionary relevance of the different type-II CLRs in host defense, to gain knowledge on how variation at these genes may be involved in differential susceptibility to human infectious diseases.

Balancing selection in the human genome. *M. DeGiorgio[1], K.E. Lohmueller[1], R. Nielsen[1,2,3,4].* 1) Department of Integrative Biology, University of California, Berkeley, CA; 2) Department of Statistics, University of California, Berkeley, CA; 3) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 4) Beijing Genomics Institute, Shenzhen, China.

Balancing selection is an evolutionary process that maintains variability within a population. Two major mechanisms of balancing selection are heterozygote advantage and frequency-dependent selection. A common characteristic of balancing selection is the maintenance of polymorphism for extended periods of time, which is reflected in deep coalescence histories at linked neutral sites. Previous scans for balancing selection have focused on the use of summary statistics, such as the Hudson-Kreitman-Aguade (HKA) test and Tajima's D. Here, we develop two coalescent-based composite likelihood ratio methods that utilize between-species substitution and within-species polymorphism data to detect balancing selection. Our methods take advantage of the effect of balancing selection on genealogies at linked neutral loci and use background patterns of substitution and polymorphism to adjust for demographic history. Through simulations, we show that both methods outperform the HKA test and Tajima's D and are robust to demographic history. Further, we apply our methods to whole-genome sequences from human individuals, using chimpanzee as an outgroup. We find strong support for balancing selection on a number of genes across the genome, including genes previously hypothesized to be under balancing selection, such as the HLA loci and PRIM2, validating our method. We also identified several novel candidate genes. In particular, through gene ontology analysis, we find enrichment for genes that are involved in immunity. Our two methods have been implemented in C and incorporated into the existing software package SweepFinder.

3306T

Reproduction and immunity driven natural selection in the hominid *WFDC* locus. *Z. Ferreira[1, 2, 3], S. Seixas[2], A. Andres[4], W. Kretzschmar[5], J. Mullikin[1, 6], W. Swanson[7], M.K. Gonder[8], S. Tishkoff[9], A. Stone[10], A.G. Clark[11], E. Green[1, 6], B. Hurle[1], NIH Intramural Sequencing Center, Bethesda, MD.* 1) NHGRI, NIH, Bethesda, MD; 2) IPATIMUP, Porto, Portugal; 3) Department of Zoology and Anthropology, Faculty of Sciences, University of Porto, Porto, Portugal; 4) Genetic Diversity and Selection, Department of Evolutionary Genetics - Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany; 5) Genomic Medicine and Statistics, Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 6) NIH Intramural Sequencing Center, Bethesda, MD; 7) University of Washington Seattle, WA; 8) Department of Biological Sciences University at Albany, State University of New York, Albany NY; 9) Departments of Genetics and Biology, University of Pennsylvania, Philadelphia, PA; 10) Department of Anthropology, Arizona State University, Tempe, AZ; 11) Department of Biology of Molecular Biology and Genetics, Cornell University, Ithaca, NY.

The *WFDC* and *SEMG* genes warrant a concerted evolutionary analysis because of their strikingly high K_A/K_S, indicative of response to adaptive pressures during vertebrate evolution. *WFDC* is the whey acidic protein (WAP) four-disulfide core domain locus located on human chr20q13. This locus spans 19 genes with WAP and/or Kunitz domains. These genes participate in antimicrobial, immune, fertility and tissue homoeostasis activities. WFDC-related genes include nearby genes encoding seminal proteins Semenogelin 1 and 2 (SEMG1 and SEMG2). To understand better the selection pressures acting on *WFDC* genes in human populations, we sequenced 17 genes and 54 non-coding tags in 71 European (CEU), African (YRI) and Asian (CHB+JPT) individuals. We identified 484 Single Nucleotide Polymorphisms (SNPs), including 65 coding mutations, of which 49 were non-synonymous substitutions. Using classic neutrality tests we confirmed a signature of short-term balancing selection on *WFDC8* in Europeans; and a signature of positive selection spanning genes *PI3*, *SLPI*, *SEMG1* and *SEMG2*. Associated with the latter signal, we identified an unusually homogeneous derived haplotype with a frequency of 88% in Asians. A putative candidate variant targeted by selection is Thr56Ser in SEMG1, which may alter the proteolytic profile of SEMGI and antimicrobial activities of semen. Ancestral Thr56 was traced to the last common ancestor of SEMG1 in Old World Monkeys and hominoids ~25 million years ago (MYA) - with derived allele Ser56 arising less than 0.25 MYA. These results are all consistent with patterns of variation seen in the 1000 genomes data as well. To examine if the adaptive pressures and patterns of genetic variation within the *WFDC* locus differ among hominoids, we sequenced 68 chimpanzees (*P. t. troglodytes*, *P. t. verus* and *P. t. ellioti*), the most closely related species with a different mating system and exposure to pathogens. For that, we generated ~13 Mb of high-quality sequence data, identifying 847 SNPs, and we calculated summary statistics for each gene. Both the chimpanzee data and the human-chimp joint analysis indicate selective signals in the *EPPIN* and *WFDC6* genes, which have been shown to have active roles in primate fertility and immune response. This study provides further evidence that the *WFDC*s and *SEMG*s have been under strong adaptive pressures within hominid evolution, improving our knowledge of biological dynamics of rapidly evolving genomic regions in primates.

3307F

Identification of Hypoxia-Tolerance Regions in High-Altitude Populations. *R. Ronen[1], N. Udpa[1], D. Zhou[2], T. Stobdan[2], O. Appenzeller[3], K. Frazer[1,2], J. Liang[4], Y. Li[4], V. Bafna[1,5], G. Haddad[2].* 1) Bioinformatics and Systems Biology, University of California at San Diego, La Jolla, CA; 2) Department of Pediatrics, University of California at San Diego, La Jolla, CA; 3) New Mexico Health Enhancement and Marathon Clinics Research Foundation, Albuquerque, New Mexico, United States of America; 4) BGI-Shenzhen, Shenzhen 518083, China; 5) Department of Computer Science and Engineering, University of California at San Diego, La Jolla, CA.

The body's response to hypoxic stress is known to play a crucial role in many cardiovascular, neonatal, and oncological conditions (Zhou et al., PLoS Genetics, 2007). However, the mechanisms underlying the basic pathobiology are not well understood. One way to determine the genetic elements of this response is to identify regions undergoing long-term selective sweeps in (healthy) individuals living at high-altitude, low-oxygen environments. There are three major high-altitude environments in which individuals are known to reside permanently - the Ethiopian highlands, the Himalayan plateau, and the Andes mountains (Beall, Integr. Comp. Biol., 2006). Previous genetic studies of these populations have focused on either sparse genotyping of a number of locations across the genome or sequencing of just the protein-coding exome (Yi et al., Science, 2010; Bigham et al., PLoS Genetics, 2010, Scheinfeldt et al., Genome Biology, 2012). Both of these designs only sample a subset of the genome, and thus, can potentially bias the data and result in a loss of statistical power. In this work, we performed high (15–43x) coverage, whole genome sequencing of 37 individuals from the Ethiopian (~3500m altitude) and Andean (~4300m altitude) highlands. To gauge the impact of time under selection, we sampled two different populations from Ethiopia - one has been in the highlands for thousands of years, whereas the other is a recent (~700 years) migrant to the area. In contrast to the Ethiopians, the Andean highlanders display a variety of physiological responses to hypoxia, ranging from perfect fitness to a condition known as chronic mountain sickness. We sequenced Andean individuals from the extremes of this distribution. In all these populations, we identify a number of regions based on changes in the SNP frequency spectrum expected under a model of classical positive selection. In this model, beneficial mutations not only increase in frequency, but also raise the frequencies of “hitchhiking” alleles on the same initial haplotype. We prioritize regions that have sharp SNP frequency differences in our adapted populations, compared to the individuals with chronic mountain sickness and multiple lowlander populations. We then select the strongest gene candidates and characterize differences and similarities in the response mechanisms between populations. Finally, using model organism systems, we show that these genes are important for survival in low oxygen environments.

Positive selection on Base Excision Repair Pathway in Yoruba and British Populations. *M. Wang[1], R. Li[1], Y. He[1], L. Jin[1,2].* 1) CAS-MPG Partner Institute for Computational Biology, Shanghai, Shanghai, China; 2) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, China.

Base Excision Repair (BER) pathway is the primary repair system involved in the removal of endogenous DNA base damage throughout the cell cycle that could otherwise cause mutations by mispairing or lead to breaks in DNA during replication. Therefore, it is crucial to understand evolutionary role of the BER system when genetics and biochemistry of this system have being clarified. Using the last full-genome sequencing data from the 1000 genome project, we examined 152 genes of the BER pathway to identify potential genetic signature of positive selection in Yoruba (YRI) and British (GBR) populations. For each gene, all genetic variants located in the gene and its' surrounding 200Kb genome region were examined by inspecting pattern of linkage disequilibrium (LD) between and within populations using XP-EHH and iHS methods. A proposed summary statistic was applied on initial results to combine p-values of each 50 neighboring SNPs. All summary statistics with corrected p-value less than 0.01 were declared to be significant after Bonferroni corrections. Nine genes that might experience positive selection were discovered in between-population comparison using XP-EHH. Meanwhile, eight and six genes were selected as candidates within YRI or GBR population using iHS, respectively. PTEN (correct p-value < 4.24E-22) and ATMIN (correct p-value < 4.26E-20) gene discovered by XP-EHH method were also identified by iHS method in YRI population. The sharing of selected genes indicated that the two genes might experience positive selection in the YRI population. No selected gene was shared by the between-population analysis and within-population investigation for GBR population. However, the results for seven out of the nine selected genes were still reliable because power of the XP-EHH method was believed to be superior to that of the iHS method in many genetic scenarios. XPC gene was highlighted by within-population investigations in both YRI and GBR populations with corrected p-value less than 1.28E-23 and 6.88E-17, respectively. The sharing results for XPC gene suggested positive selection might act on this gene both before and after the Out-of-Africa. Our discovery about positive selection on BER pathway suggested evolutionary activities of the critical pathway were still promptly going on in human populations. The discovery supported the hypothesis that biological mutation rate was largely determined by mutation-selection balance.

3309T

Expression quantitative trait loci (eQTLs) are adaptive to multiple environmental factors. *K. Ye, Z. Gu.* Division of Nutritional Sciences, Cornell University, Ithaca, NY, 14850.

The relative importance of regulatory SNPs and coding SNPs in adaptation to local environment has been controversial. eQTLs have been suggested to be targets of natural selection and to be enriched in trait-associated SNPs. However, whether eQTLs are adaptive to different types of environmental factors and its relative importance compared with non-synonymous SNPs have not been systemically explored. Recently a Bayesian linear model method was developed to identify local adaptation signals by detecting a correlation between the frequency of an allele and an environmental factor. This method has been applied in three genome-wide analyses involving 42 environmental variables, for each of which more than 500,000 SNPs were tested for evidence of correlation. Utilizing these data, we performed a systemic examination of the adaptive patterns of eQTLs to different environmental factors. Compared with intergenic neutral SNPs, eQTLs tend to be enriched in adaptive signals to the majority of 42 environmental factors. The significant enrichment is independent of recombination rate, although recombination rate is reversely correlated with the degree of enrichment. The enrichment of eQTLs in adaptive signals is due to their functional effect as supported by the discovery that groups of eQTLs with higher true positive rate tend to have higher degree of enrichment. Over all 42 environmental factors, the enrichment of eQTLs in adaptive signals is similar to that of non-synonymous SNPs, while both of them are higher than that of genic SNPs. At the individual level, some environmental factors, including climate, latitude, and virus diversity, have an enrichment of eQTLs in adaptive signals significantly higher than that of non-synonymous SNPs. Further pathway enrichment analysis identified a number of pathways enriched with adaptive signals from eQTLs but not from other genic SNPs. These pathways are mostly related with immune system, cellular signaling and metabolism, such as peroxisomal lipid metabolism with adaptive signals to short wave radiation flux (Summer), long-term depression to climate, and systemic lupus erythematosus to latitude. Our analyses demonstrate that eQTLs are in general adaptive to local environment while for some environmental factors and pathways, eQTLs have an adaptive effect stronger than non-synonymous SNPs.

3310F

Balancing selection on a non-coding region with regulatory function. *Q. Zhu[1,2], O. Gokcumen[1,2], L. Mulder[3], R. Iskow[1,2], C. Austermann[3], M. Steward[3], C. Scharer[4], T. Raj[2,5], J. Boss[4], S. Sunyaev[2,5], A. Price[6,7], B. Stranger[2,5], V. Simon[3,8,9], C. Lee[1,2].* 1) Department of Pathology, Brigham and Women's Hospital, Boston, MA; 2) Harvard medical school, Boston, MA; 3) Department of Microbiology, Mount Sinai School of Medicine, New York, NY; 4) Department of Microbiology, Emory University, GA; 5) Division of Genetics Department of Medicine, Brigham and Women's Hospital, Boston, MA; 6) Department of Epidemiology, Harvard School of Public Health, MA; 7) Department of Biostatistics, Harvard School of Public Health, MA; 8) Global Health and Emerging Pathogens Institute, New York, NY; 9) Division of Infectious Diseases, Department of Medicine, New York, NY.

Most functionally important loci in modern humans, including the majority of exons, are under negative (purifying) selection and consequently show little, if any, genetic variation. In contrast, other forms of selection, such as balancing or directional positive selection, occur less frequently and identifying genomic loci under such selection entails the detection of variants that show unexpectedly high population differentiation or deviation from the prevalent haplotype structure. In this study, we have identified a ~36 kb DNA segment at the upstream of Apobec3 locus that has an ancient substructure, predating Human-Neandertal sequence divergence, and examined SNP data around this locus from 629 individuals originating from 12 human populations. The variation at this DNA segment exists primarily as two highly divergent haplogroups. One of the haplogroups, which includes the Neandertal haplotype, contains a 4.6 kb deletion polymorphism in perfect linkage disequilibrium with 12 SNPs across diverse populations, while the other more ancestral haplogroup does not contain this 4.6 kb deletion. Population genetic analyses of these SNPs within each of these haplogroups revealed high population differentiation and signatures of balancing selection. This DNA segment harbors no protein-coding genes, but the presence of balancing selection, bioinformatic predictions of transcription factor binding, in vitro experiments and expression quantitative trait loci analyses indicate putative regulatory function.

3311W

Characterizing selection signatures associated with high-altitude adaptation in Tibetans. *A. Ferrer Admetlla[1], Y. Wang[1], B. Peter[1], N. Vinckenbosch[1], E. Sanchez-Huerta[1], X. Jin[2], A. Asan[2], J. Wang[2], J. Wang[2], R. Nielsen[1].* 1) Department of Integrative Biology, UC-Berkeley, Berkeley, CA, US; 2) Bejing Genomics Institute, Shenzhen, China.

The oxygen concentration (21% at sea level) decreases with altitude (~13% at 4000m). Some human populations live at very high elevations (>4000 meters), where the reduction of oxygen concentration represents a challenge for the body. Residents of the Tibetan Plateau have adapted to this extreme condition. To date, several studies have looked for the genetic basis of high-altitude adaptation in the Tibetan population and found signatures of selection in several genes, but the time and strength of selection in these regions have been not yet characterized. In this work we gather 23 candidate genes that have been associated with altitude adaptation in Tibetans to determine the selective regime that has acted on them as well as the time and the strength of selection. To this purpose, we have analyzed targeted next -generation sequencing data for these 23 regions in 148 Tibetan samples from 5 villages ranging from 3000 to 4800 meters. We have also correlated the genotypic information of these samples to phenotypic information related to oxygen transportation, such as hematocrit and hemoglobin. Our results indicate a subset of the genes were selected during the same time range and, that this time range overlaps with previous estimates of the colonization of the Tibetan Plateu.

Detecting population structure and genetic differentiation from high-throughput re-sequencing data. *M. Fumagalli[1], T. Korneliussen[2], T. Linderoth[1], F. Vieira[1], A. Albrechtsen[2], R. Nielsen[1,2].* 1) University of California, Berkeley, CA; 2) University of Copenhagen, Copenhagen.

New, high-throughput, DNA re-sequencing technologies provide a cost-effective means of obtaining large-scale genetic data, and are now a primary resource for population genetics studies. Some drawbacks for being able to fully benefit from this technology, however, is the computational challenge associated with large datasets and high sequencing error rate. Moreover, many re-sequencing studies employ medium to low sequencing coverage. Under such circumstances, SNP and genotype calling can be unreliable and lead to a biased allele frequency distribution. Accurate estimation of the site frequency spectrum is vital to population genetic inference of demography, natural selection, and population subdivision, as well as the statistics used to summarize these processes. Many previously used methods for estimating allele frequencies that are primarily based on direct counting of sequencing reads, lead to inaccurate estimates of local nucleotide diversity indices, and FST, a measure of genetic population differentiation. Recently, more sophisticated algorithms for SNP and genotype calling have been proposed. Most promising are those that use a Bayesian framework to incorporate base quality scores and statistical uncertainty in order to obtain posterior probabilities associated with each genotype. Accordingly, I propose several new strategies for computing estimates of FST from estimation of allele frequencies per site. I will demonstrate the high performance of these novel methods for detecting population subdivision, especially when facing high error rates and low sequencing coverage. I will also discuss how population structure can be investigated with principle component analysis within this probabilistic framework. In addition, I will perform sliding-window analyses on previously published low-coverage re-sequencing data from multiple populations to demonstrate an efficient and reliable strategy for genome-wide scans of natural selection. This analysis will highlight genomic regions displaying exceptionally high genetic differentiation along with reduced levels of nucleotide diversity among pairs of populations. Methods herein presented are powerful and reliable tools for investigating population genetic variation on a large scale directly from high-throughput re-sequencing data.

Different haplotypes in East Asia and Europe both show positive selection in 1q24. *C. Heffelfinger[1,2], A.J. Pakstis[2], W.C. Speed[2], M.P. Snyder[3], K.K. Kidd[2].* 1) Dept MCDB, Yale University, CT; 2) Genetics Dept, Yale University, CT; 3) Genetics Dept, Stanford Univerity, CA.

We have identified a region of chr1q24 under positive selection in East Asia and Europe, with smaller signatures of selection present in Southwest Asia, Central Asia, and South Central Asia. Tests for selection were conducted using normalized Haplosimilarity (nHS) and Relative Extended Haplotype Homozygosity (REHH) on a set of 140 SNPs from chr1:168653857 to chr1:169640109 (Hg19) in the 52 HGDP populations. Heterozygosity and linkage disequilibrium were assessed using the same panel for all populations using HAPLOT. Amino-acid changing SNPs and major structural variants were also tested in the HapMap and 1000Genomes panels to identify variants in linkage disequilibrium with the selected haplotype. The strongest signatures of selection occur for two different haplotypes. One shows evidence of selection in East Asia where it is present at approximately 65% frequency. The other shows evidence of selection in Europe where it is present at approximately 35% frequency. Most SNP alleles differ between these two haplotypes, but the highest REHH scores for both haplotypes occur near the 7th exon of the NME7 gene. In East Asia this core haplotype is GTA (rs2157597, rs12121994, rs12118611) whereas in Europe it is ATG. While the haplotypes with the highest REHH scores are in NME7, significant REHH and nHS scores extend across a region containing ATP1B1, NME7, BLZF1, C1orf114, and SCL19A2. Possible candidates for selection were also examined. A deletion from ~169229000-39000 was tested for linkage disequilibrium with the core selected haplotype in the HapMap dataset. The deletion was consistently present on the European selected haplotype but absent on the East Asian Haplotype. The derived allele of rs1028180, a missense mutation in BLZF1, has frequencies matching the East Asian haplotype under selection but is virtually absent in Europe. Finally the derived allele of rs3820059, a missense mutation in C1orf114, has frequencies matching the European selected haplotype but is at much lower frequency in East Asia. Funding for this research was provided by NIH grants 5T32GM007223 and 5P50HG00235711.

Early Origins of Southeast Asian Ovalocytosis during the Austronesian Expansion. *J.A. Wilder, A.M. Paquette, M.K. Thompson.* Biological Sciences, Northern Arizona University, Flagstaff, AZ.

Southeast Asian Ovalocytosis (SAO) is a recessive lethal trait that confers significant protection against malaria-related mortality in heterozygous carriers. SAO is caused by a 27-bp exonic deletion in *SLC4A1*, which encodes the Band 3 protein in red blood cells. Here we describe the first analysis of haplotypic variation among SAO chromosomes from across its range in Southeast Asia. Our survey of 60 SAO-bearing chromosomes reveals substantial short-range haplotype diversity, caused primarily by the action of a nearby recombination hotspot. Previous studies have found that SAO is uniformly associated with the rare nonsynonymous “Memphis” allele at a nearby SNP; the “Memphis” allele is known to cause altered Band 3-mediated anion transport across the erythrocyte membrane. We find that a fraction of SAO chromosomes do not share a haplotype with the “Memphis” allele, suggesting that there may be functional variation among SAO-carriers with respect to erythrocyte properties. We used variability among SAO chromosomes to estimate that the causal mutation occurred at least 3,500 years bp, making it the oldest malaria-resistance mutation found in Southeast Asia to date. Previous studies have noted an association between the SAO mutation and speakers of Austronesian languages. Our result suggests that the SAO mutation likely occurred during the early stages of the Austronesian expansion, and then accompanied this movement of people as they migrated throughout Island Southeast Asia. Despite being a recessive lethal, SAO occurs at elevated frequencies in many malarial populations, with an observed allele frequency as high as 0.176. This is congruent with the action of exceptionally strong balancing selection favoring heterozygotes (*i.e.*, wild-type homozygotes have a fitness as low as 79% that of heterozygotes). Our study suggests that the Austronesian expansion into malarial regions may have been facilitated by the early appearance of SAO and its associated fitness benefits relative to non-SAO carriers.

Local Genome Diversity Studies in Puerto Rico: uncovering distribution of ancestry proportions and disease allele frequencies across the island. *Y.M. Afanador[1], I. Rivera[2], E.P. Tascón-Peñaranda[2], J.L. Rodriguez-Florez[3], C.A. Winkler[4], A.V. Washington[2], E. Suárez[5], J.C. Martinez-Cruzado[2], T.K. Oleksyk[2], Local Genome Diversity Studies Consortium.* 1) RISE 2 BEST Program University of Puerto Rico, Mayaguez Campus, Mayaguez, PR; 2) Biology, University of Puerto Rico, Mayaguez Campus, Mayaguez, PR; 3) Department of Genetic Medicine, Weill Cornell Medical College, New York NY, USA; 4) Molecular Genetic Epidemiology Studies Section, Frederick National Lab, Frederick, MD; 5) Biology, University of Puerto Rico, Ponce Campus, Ponce, PR.

Describing local population diversity in the context of recent evolution can enhance large-scale studies emerging from the concerted effort of the international scientific community. With whole genomes of many Puerto Rican (PR) individuals publicly available from the 1,000 Genome Project, the ancestral contributions and evolutionary history of the PR population across the island can now be examined in detail to uncover patterns of migration, extent and character of admixture, resistance to the local infectious diseases, and recent adaptations to climate and food. We develop, evaluate and implement a new instructional strategy built into an educational curriculum. Local Genome Diversity Studies (LGDS) involved 42 undergraduate students that carried out sample collection, DNA extraction and genotyping in a series of individual projects within the LGDS cycle. A geographically representative DNA samples from more than 2,000 individuals across 40 out of 78 municipalities of PR have been collected. Using our sample set, we identify patterns of European, African and Amerindian admixture proportions across different parts of the island using a panel of 93 autosomal, 24 maternally inherited, and 11 paternally inherited Ancestry Informative markers (AIMs). This information is used to develop a map of local genome diversity and to uncover the complexity of the islands' rich genetic background. In the second phase of the cycle, called Adopt-a-Gene Project, students use 1,000 Genome data to identify evolutionarily relevant, locally polymorphic genetic variants, related to disease, local environment, or other adaptations. Candidate loci are analyzed in the LGDS samples to document their actual geographic distributions. Preliminary island-wide analysis revealed non-random distribution of some disease-relevant variants (CCR5 Δ32). Polymorphisms involved in kidney disease (e.g. APOL1, MYH9, NPHS2) and other chronic diseases (e.g. obesity, diabetes, and asthma), as well as physical phenotype determinants (EDAR, OCA2, MC1R, ABCC11) are genotyped, while a panel of cancer candidate genes is re-sequenced for the entire sample using next generation technology. Our project is an example of a successful local community outreach and integration of minority undergraduate education into the research process that shows a new way to deepen our knowledge about the local genome diversity of human populations worldwide following the effort led by the 1,000 Genomes Project.

Indian genome architecture reveals high diversity and suggests ancient African ancestry. *S. Kumar[1], R. Singh[1], N. Banerjee[2], H. Gowda[3], M. Kramer[4], S. Kamalakaran[2], V. Varadan[2], A. Janevski[2], B. Muthusamy[3], B. Chakrabarti[1], SM. Srikanth[3], S. Keerthikumar[3], TS. Keshava Prasad[3], S. Vivekandandan[1], V. Makkapati[1], A. Panigrahi[1], P. Kumar[3], P. van Hooft[5], E. Ghiban[4], L. Gelley[4], S. Muller[4], G. Atwal[4], WR. McCombie[4], A. Pandey[3,6,7], A. Chakravarti[6], N. Dimitrova[2].* 1) Philips Research, Philips Innovation Campus, Bangalore-560045, Karnataka, India; 2) Philips Research NA, 345 Scarborough Road, Briarcliff Manor, NY 10510, USA; 3) Institute of Bioinformatics, International Technology Park, Bangalore 560066, India; 4) Cold Spring Harbor Laboratory, 1 Bungtown Rd, Cold Spring Harbor, NY 11724, USA; 5) Philips Research, eScience Support, HTC36-03, High Tech Campus 36, 5656 AE Eindhoven, The Netherlands; 6) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore 21205, Maryland, US; 7) Departments of Biological Chemistry, Oncology and Pathology, Johns Hopkins University School of Medicine, Baltimore 21205, Maryland, US.

Present day Indians are thought to contain huge genetic diversity which is attributed to multiple waves of migration and gene flow that took place since the early human dispersal out of Africa. Recent studies on population genomics are starting to map the route of migration of modern humans into Indian subcontinent, however at a limited resolution. We report the diploid genome sequences of two South Indian individuals and co-analyze their genomes with samples from Africa, Europe and Asia. The two Indian individuals exhibit highest nucleotide diversity next only to individuals of African ancestry. At the protein level, diversity varies by 10-fold across proteins and 100-fold across domains at levels that are characteristic of all humans. We identified multiple pathways that were significantly enriched for non-synonymous variants in the Indian individuals suggesting local adaptation. Our analysis of population histories suggests that Indian genomes have had contributions from African ancestry in multiple waves: from 200,000–600,000 years ago and the more recent `Out of Africa' ancestry (100,000 years). These results, consistent with previous marker data, are the first genome-wide evidence of a Southern coastal migration and colonization of India by early humans. Consequently, Indian genome sequences not only contribute new features of human genome variation but suggest that additional sequencing of South Indian samples will be critical for human history, biology and medicine.

Genetic Evidence of Paleolithic Colonization and Neolithic Expansion of Modern Humans on the Tibetan Plateau. *B. Su[1], X. Qi[1], C. Cui[2], Y. Peng[1], X. Zhang[1,5], Z. Yang[1,5], H. Zhong[1], H. Zhang[1], K. Xiang[1,5], X. Cao[1], Y. Wang[1,5], O. Ouzhuluobu[2], B. Basang[4], C. Ciwangsangbu[4], B. Bianba[2], G. Gonggalanzi[2], T. Wu[3], H. Chen[6], H. Shi[1].* 1) State Key Laboratory of Genetic Resources and Evolution, Kunming Inst Zoology, Chinese Academy Sci, Kunming, China; 2) High Altitude Medical Research Center, School of Medicine, Tibetan University, Lhasa, China; 3) National Key Laboratory of High Altitude Medicine, High Altitude Medical Research Institute, Xining, China; 4) People's Hospital of Dangxiong County, Dangxiong, China; 5) Graduate University of Chinese Academy of Sciences, Beijing, China; 6) Department of Epidemiology and Biostatistics, Harvard School of Public Health, Boston MA, USA.

Sitting 4,000 m above sea level, at the foot of the northern Himalayas of western China, the Tibetan Plateau is a remarkable area for cultural and biological studies of human population histories. However, the chronological profile of the Tibetan Plateau's colonization remains an unsolved question of human prehistory. By studying genetic markers from both paternal (Y-chromosome) and maternal (mitochondrial DNA) lineages of 6,109 individuals from 41 Tibetan populations sampled across the Tibetan Plateau, we found there have been two distinct, major prehistoric migrations of modern humans into the Tibetan Plateau. Among these populations, we identified ancient Tibetan-specific genetic signatures dated to around 30,000 years ago, indicating that the initial peopling of the Tibetan Plateau by modern humans occurred during the Paleolithic rather than Neolithic. We also found evidences for relatively young (only 7–10 thousand years old) shared Y chromosome and mitochondrial DNA haplotypes between Tibetans and Han Chinese, suggesting a second wave of migration during the Neolithic. Collectively, the genetic data indicate that Tibetans have been adapted to high altitude environments since initial colonization of the Tibetan Plateau in the early Upper Paleolithic, before the Last Glacial Maximum, followed by a rapid population expansion triggered by the establishment of farming and yak pastoralism in the early Neolithic.

3318T

Genomic ancestry and structure of the African-European admixed population of the Cape Verde islands. *S. Beleza[1,2], N.A. Johnson[3], S.I. Candille[1], D.M. Absher[4], I.I. Araújo[5], A. Correia e Silva[5], M.D. Shriver[6], J. Rocha[2,7,8], G.S. Barsh[1,4], H. Tang[1].* 1) Dep of Genetics, Stanford University School of Medicine, Stanford, CA., USA; 2) Instituto de Patologia e Imunologia Molecular da Universidade do Porto (IPATIMUP), Porto, Portugal; 3) Department of Statistics, Stanford University, Stanford, California, USA; 4) HudsonAlpha Institute for Biotechnology, Huntsville, Alabama, USA; 5) Universidade de Cabo Verde (Uni-CV), Praia, Santiago, Cabo Verde; 6) Department of Anthropology, The Pennsylvania State University, University Park, Pennsylvania, USA; 7) Centro de Investigação em Biodiversidade e Recursos Genéticos (CIBIO),Vairão, Portugal; 8) Departamento de Biologia, Faculdade de Ciências da Universidade do Porto, Porto, Portugal.

Over the past few years, recognition of the unique utility of admixed populations in studies of complex traits and diseases that differ in risk between populations has increased. However, given the cultural and genetic heterogeneity of admixed groups, it is essential that multiple admixed populations are studied to fully appreciate the relationships among the genetic, historical, and environmental determinants of those traits. Cape Verde is an archipelago of ten islands located 300 miles off the coast of West Africa. The islands were uninhabited until discovery by the Portuguese in the 15th Century and were initially peopled by European immigrants and enslaved Africans. We performed an analysis of the genetic structure and admixture of Cape Verde based on high-density genotype data on 697 individuals living in the six most populated islands. Principal component analysis is reminiscent of the geographic map of Cape Verde. Clustering analysis reveals extensive genetic admixture between European and African ancestral populations (median African ancestry=0.58, sd=0.12), with individual African ancestry proportions varying considerably among the islands. The European ancestors of these individuals genetically resemble Portuguese. The African ancestry of Cape Verdeans is largely derived from West African populations, as opposed to African Americans who derive their ancestry from West-Central African groups. The parsing of the European and African components of the Cape Verdean genomes allows for a more detailed characterization of the genetic diversity and differentiation across the islands. Kinship coefficients corrected for the bias introduced by admixture and IBD analysis indicate that individuals are genetically more related within an island than between islands, as expected, and that the magnitude of relatedness varies across the archipelago, reflecting island-specific demographic histories. The observed genetic heterogeneity can be explained by historical events that have taken place during and since the colonization period. Cape Verde genetic structure is a dramatic example of the complex interplay between demographic events influencing the genetic diversity and structure of human populations: founder and drift effects along with admixture. This work provides a foundation for admixture-based genetic studies in Cape Verde and highlights the great potential for research on the genetic basis of complex traits of this population.

Mitochondrial DNA in Myanmar: Complete mitochondrial genome sequencing revealed several new lineages within macro-haplogroup M. *J. Horst[1], M. Summerer[2], G. Erhart[2], D. Horst[3], B. Horst[4], S. Sanguansermsri[5], A. Manhart[2], F. Kronenberg[2], A. Kloss-Brandstätter[2].* 1) Institut für Humangenetik, Universität Münster, Germany; 2) Division of Genetic Epidemiology, Innsbruck Medical University, Innsbruck, Austria; 3) Pathologisches Institut, Ludwig-Maximilians-Universität, Münster, Germany; 4) Department of Dermatology, Section of Dermatopathology, Columbia University, New York, NY; 5) Department of Pediatrics, Chiang Mai University, Chiang Mai, Thailand.

Background: Myanmar (Burma) is the largest country in Southeast Asia, with a population of 56 million people subdivided into more than 100 ethnic groups. The Bamar represent the largest group amongst them. Ruled by changing kingdoms and dynasties and lying on the trade route between India and China, Burma was influenced by a variety of cultures. Since Burma's independence after the British occupation, minorities suffer from government's repression and especially the Karen people struggle against the domination of the Bamar culture. We analyzed the mtDNA control region of 327 unrelated donors from Myanmar according to highest quality standards. To refine haplogroup (HG) information, especially in the complex haplogroup M, 44 selected individuals were subjected to complete mitochondrial genome sequencing. Results: The distribution of the macro-haplogroups M and N and the geographic assignment of the haplogroups were typical for Southeast Asia, however, the frequency of individual haplotypes was very specific in Myanmar. In general, the Myanmar sample exhibited pronounced mtDNA diversity, with the ethnic group of the Bamar being the most diverse. The 44 complete mitochondrial genome sequences revealed 10 new so far un-described mtDNA lineages, represented by 15 haplotypes, all lying within macro-haplogroup M. One lineage, comprising 3 haplotypes, clustered within HG G2, two lineages represented subgroups of HG M49 and two lineages with in total 4 haplotypes clustered within the M13'46'61 group. In addition, we found 5 yet undefined basal M lineages. Their exact phylogenetic position can only be defined with deeper knowledge of macro-haplogroup M. Conclusions: The multi-ethnic population and the complex history of Myanmar are well reflected in its distinct mtDNA heterogeneity. In this region with its long history of human settlement, plenty of mitochondrial haplogroups, especially in the complex haplogroup M, await to be newly described.

3320W

Asian Expansion of Modern Human out of Africa. *H. Li.* MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai 200433, China.

Global population of the modern human originated in Africa around 200 thousand years ago, which has been proved by various evidences, especially by genetic evidences. Recent studies revealed another important event during the natural history of modern human, i.e., the Asian Expansion. The Asian Expansion was supported by both linguistic and genetic evidences. In 2011, Atkinson reported a study on the phonemic diversity of world languages, and found an African Origin of the present languages. However, more detailed analyses on the phonemic diversity reflected an Asian Expansion rather than an African Origin. All the languages, except for the Khoisan languages, derived from the expansion from western Asia around Iran. The Asian Expansion was also supported by genetic evidence. Y chromosome haplogroup phylogenetic tree has an African root, but only haplogroups A and B were African aboriginal types, i.e., these two haplogroups have never leaven Africa. All the other haplogroups, all within CF and DE, derived from one ancient type with a marker M168 out of Africa around 50–70 thousand years ago. They expanded from western Asia around 3–4 thousand years ago, and gave birth to all the haplogroups from C to T. Therefore, the haplogroup with highest frequency in Africa, haplogroup E, was also from the Asian Expansion. In Africa, Haplogroup A is mostly in Khoisan and Saharan populations, and haplogroup B is mostly in Pygmies and other populations around Congo. The major populations of Africa, sometimes called Bantu or Niger-Congo people, were then most probably came back from Asia. The Asian Expansion was firstly hypothesized by German biologist Ernst Haeckel in his map of human origin and migration in 1863. Now, we are accumulating more evidences.

Using Y-Chromosome Haplotypes to Improve Inferred Ancestral Origins in European Populations. *N. Myres[1], P. Underhill[2], R. King[2], J. Byrnes[1], K. Noto[1], S. Woodward[1], N. Angerhofer[1], C. Ball[1], K. Chahine[1].* 1) AncestryDNA, Provo, UT; 2) Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA.

Studies analyzing datasets of autosomal single nucleotide polymorphisms (SNPs) have shown that significant amounts of information can be inferred about an individual's ancestral origins. Methods for assigning geographic origins according to continental boundaries can be achieved with high accuracy, but more localized geographic assignments have proven more challenging. Identifying ancestry informative markers (AIMs) has been shown to significantly improve geographic assignments for populations of close proximities, but for certain regions within Europe accuracy rates are highly variable, ranging from 20%–74%. Such variability likely arises from Europe's complex population history as well as limitations of current autosomal systems for assessing the temporal components of underlying SNP variants. In contrast, robust and well resolved haploid phylogenies have been developed which delineate the sequential branching order and coalescent times of genetic variants within global populations. In particular, Y-chromosome diversity within Europe is well characterized and has been used extensively for elucidating ancient and recent contributions to extant European genetic diversity, including both external (intrusive) and local (in situ) elements. Thus, although haploid systems capture only a narrow component of a population's or an individual's ancestry, Y-chromosome analysis offers a relatively uncomplicated framework for disentangling complex patterns of gene flow. Herein, we assess the extent to which augmenting autosomal population data with Y-chromosome information improves the accuracy of ancestral origin assignments in regions of Europe. Ancestral origins are inferred from autosomal SNPs for a dataset of >1000 individuals with well documented and long standing histories in Europe using principal component analysis (PCA) and clustering algorithms. Leave-one-out analysis is used to determine the accuracy of ancestry inferences. Male samples are additionally analyzed with Y-SNP markers to determine their membership in haplogroups known to be informative for differentiating European populations, thereby providing a phylogeographic framework for interpreting autosomal patterns of diversity that result in imprecise inferences of ancestral origins. Additionally we incorporate highly informative Y-SNP markers into the inference calculations and report changes to accuracy rates compared to those based on autosomal SNPs alone.

Humans and their ancestors have traversed the Ethiopian landscape for millions of years and present-day Ethiopians show great cultural, linguistic and historic diversity, which makes them essential for understanding African variability and human origins. Following the genotyping of 235 individuals from 10 Ethiopian and two neighboring (South Sudanese and Somali) populations we confirmed substantial genetic diversity both within and between populations, and revealed a match between genetic data and linguistic affiliation (Pagani et al. 2012, AJHG). Using comparisons with African and non-African reference samples in 40-SNP genomic windows, we identified “African” and “non-African” haplotypic components within each individual Ethiopian genome and found evidence for substantial gene flow into East Africa to ~3 KYA, as expected from historical records. To refine the genomic information and overcome the ascertainment bias of the genotyping procedure, we sequenced the whole genomes of 25 individuals from each of five representative Ethiopian populations on the Illumina HiSeq Platform (24 samples at ~10X and 1 sample at ~30X from each population). These data provide an unbiased description of Ethiopian genomic diversity and place the Ethiopian populations among the most diverse worldwide. Our ongoing analyses aim to further refine the “African” and “non-African” genetic partitioning to elucidate the admixture dynamics and identify regions with “African” or “non-African” ancestries. These regions will be independently analyzed in search of signatures of selection and for the information they can provide about the genetic source of the out-of-Africa migration.

Analysis of whole mitochondrial genomes from Iñupiat populations of the Alaskan North Slope. *J. Raff[1], M. Rzhetskaya[1], J. Tackney[3], M.G. Hayes[1, 2].* 1) Division of Endocrinology, Metabolism, and Molecular Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 2) Department of Anthropology, Northwestern University, Chicago, IL; 3) Department of Anthropology, University of Utah, Salt Lake City, UT.

Much has been inferred about the population history and colonization of the North American Arctic from the analysis of mitochondrial genomes of Siberian, Canadian, and Greenlandic peoples. However, inhabitants of the Alaskan North Slope—the presumed geographic origin of the Thule culture, and the hypothesized staging point for at least two trans-Arctic colonizations eastward (at 4000 YBP and 800 YBP)—have not been genetically characterized. While the ancestors of modern Iñupiat/Inuit peoples have been placed squarely within the more recent Thule cultural expansion, the extent to which earlier Holocene migrations of extinct Paleo-Eskimo contributed genetically to present day Arctic gene pools is unclear. Our analysis of mitochondrial HVSI and II from 139 North Slope individuals had previously revealed unexpected genetic diversity in this region. We therefore sequenced complete mitochondrial genomes from these individuals and have found new subtypes of the expected haplogroups A2a, A2b and D3, common among modern Inuit populations. We have also sequenced haplotypes of D2a, common in North America amongst the Aleutian Island chain, and C4, a recently established pan-American founding C lineage currently represented by only a handful of complete mtDNA genomes. Our findings of the expected subset of Beringian-specific mtDNA haplotypes, seen throughout the eastern Arctic, supports the hypothesis that the Alaskan North Slope was the source of the Paleo- and Neo- Eskimo expansions. However, the addition of haplotypes D2a and C4 in these northern-most populations raises interesting questions concerning Holocene gene flow in the North Slope. We present revised phylogenies for these haplogroups and the test various models for the origin and expansion of Arctic populations.

3324T

Genetic ancestrality estimative for Brasilia population using CODIS autosomal markers. *A.E. Svidzinski, G.C. Dalton, R.C. Toledo, A.C. Arcanjo, S.F. Oliveira.* Laboratório de Genética, Departamento de Genética e Morfologia, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, Distrito Federal, Brazil.

The Brazilian settlement process was carried out by three major population groups: the Amerindian land inhabitants, the European colonizers and the African slave workers. Considering its continental size, different regions of the country had unique populating and migration characteristics, resulting in many particular realities inside the same country. The Midwest region has a relatively recent occupation history, due to a large settlement process when the new capital of the country, Brasilia, was built far from the coastal region. Because of the intensive migration from all the parts of the country, the Brazilian Midwest region is considered to be a portrait of the whole Brazilian population. The objective of this study was to evaluate 12 STRs CODIS autosomal markers in a sample of Brasilia's population, compare with other Brazilian population groups and analyze its relation with the three parental population groups - Amerindian, European and African - aimed to extract genetic ancestrality information from these STR markers. The markers D8S1179, D21S11, D7S820, CSF1PO, D3S1358, TH01, D13S317, D16S539, vWA, TPOX, D5S818 and FGA were genotyped in a sample of 1715 individuals. The genetic profiles were analyzed using the STUCTURE software, OMNIPOP and MPGO/EHSTRAFD spreadsheets to seek for the genetic contribution of the parental groups and population structure in the sample. The results showed that, compared with other local groups in Brazil, the sample from Brasilia had no significant difference in genetic constitution. Regarding to ancestrality information, the estimated parental contributors were 69% Europeans, 20% Africans and 11% Amerindians. This result is very similar to the one obtained from AIMs specific ancestrality markers. Especially in five markers (TPOX, D5S818, TH01, D13S317 and FGA), there are significant allele frequency differences that allow an association between the individuals and the parental groups. Therefore, when analyzing an autosomal STRs genetic profile from an individual from Brasilia's population, even with markers that were not developed for this purpose, it is possible to retrieve ancestrality information regarding the Amerindian, European and African parental groups.

3325F

The population genetics of native Peruvian populations: evolutionary inferences and biomedical implications. *E. Tarazona-Santos[1], L. Pereira[1], M. Scliar[1], R. Zamudio[1], G.B. Soares-Souza[1], L.W. Zuccherato[1], M. Gouveia[1], F. Soares[1], F. Kehdy[1], W.C.S. Magalhaes[1], M.R. Rodrigues[1], E. Hollox[2], S.J. Chanock[3], R.H Gilman[4].* 1) Dept Biol Geral, CP 486, Univ Federal Minas Gerais, Belo Horizonte, Brazil; 2) Department of Genetics, University of Leicester, UK; 3) Laboratory of Translational Genomics, National Cancer Institute, NIH, US; 4) Johns Hopkins School of Public Health, MD US; Universidad Peruana Cayetano Heredia, Peru; Asociacion Benefica PRISMA, Peru.

Peru has the largest Native American (NA) population in South America. In the Andes, populations derive from a unique complex of societies that evolved during the last 10000 years along the Andes and its adjacent coast. During Pre-Columbian times, they reached a level of socioeconomic development unmatched elsewhere in South America. Smaller populations are settled in the Amazonian region, and in the hereafter called transition area between the Andes and the Amazonas. A mestizo population of millions is also settled in current Peruvian cities. We are studying the population genetics of Peruvians, addressing evolutionary inferences and biomedical implications of their diversity. We summarize three results: 1. Using 20kb resequenced from neutral inter-genic regions, we made inferences about the history of Andeans Quechua and a population from the transition area (Shimaa). These populations derived from an ancestral population with an effective size (Ne) of ~6000 individuals that split about 1025 years ago. At this time the Ne of Quechuas (Ne=5000) was five times larger than the Ne of the Shimaas, the former showing an evidence of a posterior demographic expansion, and the latter of a bottleneck. Thus, Andean and transition-area populations, even if they speak languages from different families and being culturally differentiated, share very recent ancestral populations. 2. Populations considered as mestizo have very high NA ancestry. A sample (n=297) from Lima, genotyped for 106 AIMs, has 78.4% of NA ancestry, suggesting that the Peruvian population is a potential target for large epidemiological studies in NA. 3. We identified genes with variants that are common in NA and rare elsewhere. The FCGR3B CNV locus has a high frequency of deletions in our native samples. This variant has been elsewhere associated with lupus erythematosus and rheumatoid arthritis, two diseases associated with NA ancestry. On the basis of the genotyping of 1442 SNPs on 411 genes, we determined that the following genes, that on the basis of recent GWAS are associated with complex diseases, show a differentiated haplotype structure in Native Americans: CASR, CAV1, CYP19A1, DRD2, FUT2, IL13, IL15, IL6R, IL7R, KRT23 and SCARB1 are highly differentiated from Africans/Europeans; ADH1C, APOB, CASR, CCND1, CDKN2A, CDK5, CYP19A1, ESR1, IGF2, IL1RN, LEPR and SCARB1 are highly differentiated from Asians. We are performing enrichment and functional analyses to validate these results.

Coalescent Inference of Evolutionary Parameters Using Serially Sampled Genomic Sequence Data: Theory and Applications in Human Population Genetics. *D.A. Vasco[1], M. Kato[2], Z. Ye[3], D. Lee[4], T. Carter[1], S.J. Hebbring[1], A. Rodrgio[5], S. Schrodi[1], S. Lin[3].* 1) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI.,; 2) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 3) Biomedical Informatics, Marshfield Clinic Research Foundation Marshfield, WI; 4) Department of Animal Life and Environment Sciences, Hankyong National University Republic of Korea; 5) Dept of Biology, Duke University, Durham, NC.

Estimating ancestral and current effective population sizes using genomic information in expanding populations is a fundamental problem in human population genetics. Also, patterns of genomic variation may be used to estimate divergence times between human populations that split apart in the recent past such as Africans and non-Africans. This is possible because current patterns of genomic information in a sample of sequences are a reflection of past evolutionary processes of demographic change, mutation, migration, genetic drift and selection. These historical processes can be efficiently studied using a random genetic process, the coalescent, which mimics the evolutionary biology of genealogies underlying these complex processes going backwards in time. It has been one of the main statistical tools to infer parameters using sequence data by population geneticists. Coalescent inference in molecular population genetics has often been based upon full-likelihood methods which potentially offer a powerful statistical framework for inferring population genetic parameters. Recently, next generation sequencing methods have allowed developing evolutionary parameter inference pipelines for very large data sets, with large numbers of whole genomes of individuals sampled through space and time. However, for large and complex data sets computationally intensive methods based upon full-likelihood estimates may encounter difficulties. First, the methods may be slow or difficult to implement. Second estimation bias may markedly affect the accuracy and reliability of parameters. This has led to methods that tackle some of these problems by reducing the dimensionality in the full data set by adequately summarizing the information in the data. For example, historical population growth rates for putative population bottlenecks and expansions have recently been inferred by summary statistic coalescent methods using genomic data. We build upon this recent work using sampled ancient human DNA sequences. Using simulations and empirical data analysis we show how to extend current coalescent summary statistic estimation methods for serially sampled genomic data. A second problem to be discussed involves the evolutionary analysis of within-patient somatic cell line data obtained from flow cytometry using a next generation sequencer, we present a method to infer population divergence times at which punctuated clonal expansions occur with evolved population changes in ploidy.

3327T

Ancestry Perception Bias in Latin American Admixed Populations. *K. Adhikari[1], A. Ruiz-Linares[1], G. Bedoya[2], C. Bortolini[3], S. Canizales[4], C. Gallo[5], S. Gibbon[1], R. Gonzalez[6], F. Rothhammer[7], The CANDELA consortium.* 1) University College London, London, United Kingdom; 2) Universidad de Antioquia, Colombia; 3) Universidad Federal do Rio Grande do Sul, Brazil; 4) Universidad Nacional Autonoma de Mexico, Mexico; 5) Universidad Peruana Cayetano Heredia, Peru; 6) Centro Nacional Patagónico-CONICET, Argentina; 7) Universidad de Chile, Chile.

CANDELA (Consortium for the Analysis of the Diversity and Evolution of Latin America) is an international collaboration involving researchers from the UK and several Latin American countries (Argentina, Brazil, Chile, Colombia, Mexico and Peru). With its history of extensive population mixture, Latin America in many ways represents a form of natural experiment providing an advantageous opportunity to explore genetic and social aspects related to human biological diversity. CANDELA aims to perform a multidisciplinary study of a wide range of phenotypic, social and genetic data for about 8,000 Latin American individuals. An initial analysis including 40 Ancestry Informative Markers enabled estimation of individual Amerindian, European and African ancestry proportions (using STRUCTURE software) and their contrast with self-reported ancestry as well as with a range of phenotypic and social variables. As expected, we find a significant positive correlation of the genetic and self-perceived ancestries. However, across the region, we observe strong biases in self-perceived relative to genetic ancestry. For example, individuals with low to moderate (0–40%) European genetic ancestry tend to self-perceive their European ancestry as even lower; while individuals with high (>60%) African or Native American genetic ancestries tend to estimate these ancestries as even higher. There is also significant variation across countries in these biases, as much as 20–30% difference in the genetic v. self-perceived ancestries - in the Mexican or Chilean samples, individuals underestimate their Native American ancestry by about 20%, while in the Brazilian or Colombian samples individuals overestimate their Native American ancestry by a similar amount. Several factors could underlie these biases in self-perception of ancestry. For instance, we find that individuals with darker skin color significantly overestimate their African ancestry. We also find a strong effect of gender - relative to men, women underestimating their European ancestry and overestimating their African ancestry. Overall, we find evidence of a complex interplay of social and phenotypic factors in self-perception of ancestry: while visible traits such as skin color have an important impact, perception of ancestry is also intricately linked with social factors, as evidenced by variation across the countries examined.

OriginMiner : show me your genes and I'll tell you where you come from. *M. de Tayrac[1,2], M.C. Babron[3,4], E. Génin[3,4].* 1) CNRS, UMR 6061, Institut Génétique et Développement de Rennes, F-35043 Rennes, France; 2) Université Rennes 1, UEB, IFR 140, Faculté de Médecine, F-35043 Rennes, France; 3) INSERM U946, Univ Paris-Diderot, Sorbonne Paris Cité, F-75010 Paris, France; 4) Institut Universitaire d'Hématologie, Univ Paris Diderot UMRS946, F-75010 Paris, France.

Many genetic markers show significant differences in allele frequencies between human populations. These differences can lead to false positives in genetic association studies if not taken into account. A solution to limit this problem is to match patients and controls according to their population of origin. However, the population of origin is not always known or reliable. Fortunately, dense genotype information makes possible to determine it beforehand. The objective of our work was to develop a user-friendly tool, OriginMineR, to infer the population ancestry of individuals based on their genotypes. We used worldwide reference panels for which both population and genotype information are available: the HAPMAP3 panel consisting of 1,301 individuals from 11 populations and the Human Genome Diversity Panel (HGDP-CEPH), which includes 940 individuals from 51 populations. The genotypic information of these panels was restricted to subsets of SNP markers shared by the most commonly used genotyping arrays (Affymetrix Array 5.0 and Illumina Human660W-Quad). From these data, we identified the genetic signatures of the reference populations by Principal Component Analysis (PCA). For a set of unknown individuals for which only genotypic data are available, OriginMineR determines their geographic origin, allows their visualization by projection on the reference PCA maps and provides their posterior probabilities of geographic membership. According to the reference panels used, it is possible to refine the determination of the geographical origin of an individual within the major world regions. Our tool was validated on several samples of individuals recruited as part of genome-wide association studies. OriginMineR is a valuable tool both in the fields of genome wide association studies (GWAS) and of population genetics. For GWAS, it includes the possibility for each patient to extract a list of closely related controls from the reference panels. It is also possible to match cases and controls when both are provided. OriginMineR allows locating unreferenced populations on the worldwide map, thus providing clues for population genetics studies. The OriginMineR tool has been implemented in an R package.

Genetic ancestry and admixture analysis in a Bermudian population reveals evidence of Native American origins consistent with oral histories and genealogies. *J.B. Gaieski[1], E. Elhaik[2, 3], A.C. Owings[1], M.G. Vilar[1], A.T. Walia[1], D.F. Gaieski[4], R.S. Wells[5], T.G. Schurr[1], The Genographic Consortium.* 1) Anthropology, University of Pennsylvania, Philadelphia, PA; 2) Department of Mental Health, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Department of Emergency Medicine, Hospital of the University of Pennsylvania, Philadelphia, PA; 5) Mission Programs, National Geographic Society, Washington, D.C.

Background: Shortly after its colonization in the early 17th century, Bermuda became the first English speaking dependency to forcibly import its labor by trafficking in enslaved Africans, European ethnic minorities, and indigenous Americans. Unlike the many ethnic groups that now call the island home, Bermuda's St. David's Islanders claim to be linked to Native American ancestors. In particular, their use of oral traditions and complex genealogies helps to reinforce their Native American identity. To elucidate the influence of historical events on genetic ancestry and native cultural identity among St. David's Islanders, we examined mtDNA and Y-chromosomal variation in over 100 individuals. We found that the majority of their mtDNA and Y-chromosome haplotypes (greater than 98%) were African and West Eurasian in origin. However, due to the limitations of this approach in reconstructing the genetic history of admixed populations, and because most participants were interested in learning more about their genetic genealogies, we expanded our analysis to include autosomal markers using a novel genotyping platform. Methods: To identify genetic contributions of putative indigenous American ancestors among the St. David's Islanders, we used the GenoChip to genotype Bermudians along with 200 samples from ~20 worldwide populations. Developed by Genographic Project scientists, the GenoChip is a SNP array ascertained from over 450 worldwide populations, and is dedicated to enhancing our knowledge of genetic anthropology. Results: Principal component analysis of the autosomal SNP data separated our participants into three discrete clusters. An admixture analysis identified up to 9% ancestry associated with Native Americans overall. The two largest clusters overlapped with African Americans and Puerto Ricans, and distributed evenly amongst the two main clusters (mean of 3% each). Samples from the third cluster averaged an unusually high Native American ancestry (mean of 6%). Conclusions: The GenoChip enabled us to detect otherwise elusory Native American ancestry among the Bermudians of St. David's Island. We speculate that the uneven distribution of this ancestry is due to admixture of Africans, Europeans, and Native Americans in varying degrees in the different source populations for modern-day St. David's Islanders. Application of this novel genotyping platform has provided new insights into the complex history of the Bermudian population.

3330T

The MHC and HLA alleleic diversity of the 1000 Genome samples. *P. GOURRAUD[1], N. Cereb[2], P. KhanKhanian[1], M. Maiers[5], S. Yang[2], R. Dunivin[3], M. Feolo[3], J. Rioux[4], S. Hauser[1], J. Oksenberg[1].* 1) UCSF, San Francisco, CA; 2) Histogenetics Ossining, NY; 3) National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, Bethesda, MD; 4) 4-University of Montreal Quebec Montreal Canada; 5) National Marrow Donor Programm, Minneapolis MN.

The 1000 Genomes (KG) Project aims to provide a deep characterization of human genome sequence variation. Specifically, the goal is to characterize over 95% of variants that are in genomic regions accessible to current high-throughput sequencing technologies in each of the five major population groups (about 100 individuals sampled in 14 populations from Europe, East Asia, South Asia, West Africa and the Americas). The KG project currently plans to sequence each sample to an average 4X coverage, which should allow the genome-wide detection of most variants with frequencies as low as 1% (the classical threshold for definition of polymorphisms). However, in the MHC, only the top 10 frequent haplotypes are in the 1% frequency range whereas thousands of haplotypes are present at lower frequencies. Because of the limitation of the sequencing techniques used by the KG project and due to the known genetic diversity of HLA genes in the MHC region, we have used sequence based techniques to type the HLA-A, HLA-B, HLA-C, HLA-DRB1 and HLA-DQB1 genes of 932 KG samples and combine the results with the 103,310 variants in the MHC region genotype by the KG project. Using pairwise Identical By Descent distances between individuals and Multiple Dimension Scaling, we establish the relationship between ancestry and the genetic diversity in MHC region and determine the correlation between the MHC based IBD distances (class I and/or Class II) to the genome-wide based corresponding estimations (r=0.53, p<1e-16). We use the data to reassess the existence and the robustness of MHC region variants tagging specific HLA alleles and assess the limitations of SNP-based HLA imputations. Further, we present plan to make this HLA information publically available on the DbMHC portal.

3331F

Identification of Sickle Cell Disease Alleles in the Eastern Caribbean Population. *C. Logronio, M. Graham, K. Wiitala, P. Gibbons, E. Bashover, C. Headland, I. McIntosh.* American University of the Caribbean School of Medicine, Cupecoy, St. Maarten.

Sickle Cell Disease (SCD) results from homozygosity or compound heterozygosity for mutations at codon 6 of β-globin and is commonly seen in populations of African origin. SCD has been studied extensively in N. America, Africa and Jamaica, however studies of Eastern Caribbean populations are limited. We developed a noninvasive method to detect the sickle cell mutations through extraction of DNA from buccal cells, PCR amplification and identification of the p.Glu6Val (Hb-S) and p.Glu6Lys (Hb-C) alleles through restriction endonuclease digestion and gel electrophoresis. We substantiated the efficacy of the method by testing 38 volunteers of African ancestry in St. Maarten and identified 5 Hb-S and 4 Hb-C heterozygotes. Amongst 26 subjects self-identified as Afro-Caribbean the frequencies of Hb-S and Hb-C were 0.074 and 0.056, respectively. The ratio of Hb-S:Hb-C alleles among Afro-Caribbeans is lower than previously reported for African-Americans suggesting diversity in founder populations. This non-invasive method could be used for future newborn screening and carrier detection on St. Maarten and broaden our understanding of SCD in the Caribbean population.

3332W

Khoesan genomic signatures in contemporary populations from southern Africa. *D.C. Petersen[1], O. Libiger[2], R. Hardie[3,4], L.I. Hannick[1], R. Wilkinson[5], R.H. Glashoff[6], M. Mukerji[7], P. Fernandez[8], N.J. Schork[2], V.M. Hayes[1], Indian Genome Variation Consortium.* 1) J. Craig Venter Institute, San Diego, CA; 2) The Scripps Translational Science Institute, Scripps Health and The Scripps Research Institute, La Jolla, CA; 3) Faculty of Medicine, University of New South Wales, Sydney, New South Wales, Australia; 4) The Garvan Institute of Medical Research, Sydney, Australia; 5) Namibian Blood Transfusion Services, Windhoek, Namibia; 6) Division of Medical Virology, Department of Pathology, Faculty of Health Sciences, University of Stellenbosch, Tygerberg, South Africa; 7) Insitute of Genomics and Integrative Biology (CSIR), Delhi, India; 8) Division of Urology, Department of Surgical Sciences, Faculty of Health Sciences, University of Stellenbosch, Tygerberg, South Africa.

The discovery of novel genomic variation in the Khoesan southern African population has broadened our perception of the extent of global genetic diversity. The term Khoesan (or Khoisan) collectively represents small isolated groups of forager peoples who communicate using clicking languages, but many of these groups have gone extinct. Global human migrations within and to Africa have led to extensive admixture and the emergence of contemporary populations that may carry genomic signatures of lost Khoesan lineages. The earliest arrivals into present day South Africa were southward migrating Bantu, including the amaXhosa. Centuries later, the arrival of European colonists together with slaves resulted in the founding of two admixed southern African populations, the South African Coloured and the Namibian Basters. We performed genome profiling of 70 ancestrally self-identified individuals (15 amaXhosa, 25 Coloured and 30 Basters) using Illumina HumanOmni1-Quad arrays and combined the results with data previously published for individuals from historically relevant ancestral populations including, indigenous Khoesan (Ju/'hoan), continental African (Yoruba), migrant colonists (European) and likely contributors to the Dutch East-Indian slave trade (Asian). We defined specific ancestral contributions to the amaXhosa and Basters, both showing significant Khoesan ancestry. Within our three geographically defined Coloured subgroups, we found that Khoesan admixture fractions only reach significance in subgroups located further away from the center of colonization, previously known as the Cape of Good Hope in South Africa. The most dramatic gender-specific contributions were found in the Basters, presenting with 91.7% Khoesan-derived mitochondrial and 93.3% non-African-derived Y-chromosomal DNA. The overall Khoesan contribution based on autosomal markers was most consistent within the amaXhosa (range 30–41%), then the Basters (17–40%), while most variable within the Coloured (6–57%). Contemporary populations with ancient Khoesan genomic signatures provide a unique model for studying complex global admixture patterns and will play an important role in defining the divergence between human populations.

Complete mitochondrial DNA genome sequences from the first New Zealanders: ancient DNA and the settlement of East Polynesia. *E.A. Matisoo-Smith[1,2], M. Knapp[1,2], S. Prost[1,2,3], K.A. Horsburgh[1,2,4], J. Stanton[1], H. Buckley[1].* 1) Anatomy, University of Otago, Dunedin, New Zealand; 2) Allan Wilson Centre for Molecular Ecology and Evolution, University of Otago; 3) Department of Integrative Biology, University of California, Berkeley; 4) School of Geography, Archaeology and Environmental Studies, University of Witwatersrand.

The issue of Polynesian origins has been debated since Europeans first arrived in the Pacific and the genetic evidence for their origins and migration pathway continues to be debated today. Identification of a combination of mtDNA mutations initially referred to as the “Polynesian motif” found at high frequency in Polynesian populations has provided a marker for tracking the origins of this last major human migration event. Despite the interest in identifying Polynesian origins, there has been little research on mtDNA variation within Polynesia. This is perhaps due to the reported near ubiquitous distribution of the motif within the Polynesian Triangle and the past focus on HVR sequences only. The supposed lack of mtDNA diversity in Polynesia is often presumed to be the combined result of population bottlenecks that occurred during colonising voyages and the speed and recency of colonization. We present here complete mitochondrial genome sequences of the likely founding population of Aotearoa/New Zealand recovered from the archaeological site of Wairau Bar. Of four individuals sequenced, at least three possess unique haplotypes indicating significantly more variation in the founding populations of East Polynesia that expected based on evidence from HVR data alone. These data represent the first complete mitochondrial genome sequences from ancient Polynesian voyagers and provide new insights into the genetic diversity of human populations in the Pacific at the time of the settlement of East Polynesia.

A Panel of Ancestry Informative Markers for Estimating and Correcting Potential Effects of Population Stratification in Han Chinese. *P. Qin[1], WF. Jin[1], DS. Lu[1], HY. Lou[1], JC. Wang[2], HJ. Xu[3], L. Jin[1,2], SH. Xu[1].* 1) Chinese Academy of Sciences Key Laboratory of Computational Biology, Chinese Academy of Sciences and Max Planck Society (CAS-MPG) Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shangh; 2) Ministry of Education (MOE) Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai 200433, China; 3) Department of Rheumatology and Immunology, Shanghai, Changzheng Hospital, The Second Military Medical University Hospital, Shanghai 200003, China.

Population stratification can act as a confounding factor in genetic association studies and lead to false-positive or false-negative findings. Previous studies have revealed genetic substructures in Han Chinese population, the largest ethnic group in China and composing 20% of the entire global human population. In this study, we examined 1,610 individuals with about 1 million single nucleotide polymorphisms (SNPs) and attempted to screen a panel of ancestry informative markers (AIMs) to facilitate discerning and controlling population structure in the future association studies on Han Chinese. Our analysis of the genome-wide data confirmed the north-south differentiation of Han Chinese population, accordingly, we developed a panel of 150 validated SNP AIMs which can determine northern or southern origin of each Han Chinese sample. We further evaluated the performance of the AIMs panel in association studies using both empirical and simulated data. Our results showed that this AIMs panel could have enough power for discerning and controlling population stratification in candidate gene association studies which are much cost-effective in the post-GWAS era.

3335W

Genomic demographics of the genetically isolated Amish populations of Ohio and Indiana. *L.N. D'Aoust[1], A.C. Cummings[1], L. Jiang[1], R. Laux[1], D. Fuzzell[1], L. Caywood[2], L. Reinhart-Mercer[2], M. Courtenay[2], W.K. Scott[2], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetics Rsearch, Vanderbilt University Medical Center, Nashville, TN; 2) Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL.

Founder populations, such as the Amish of Ohio and Indiana, are advantageous for genetic studies. These communities are genetically isolated because members marry primarily within their faith and have a strict lifestyle, leading to a more culturally, environmentally and genetically homogenous population. Therefore, it is hypothesized that the genetic etiology of a disease in the Amish is more likely simpler and restricted to fewer genes contributing risk. We characterized the genomic demographics of these populations to understand the genetic architecture of such isolated populations. We used data for 600,000 SNPs from 900 individuals to evaluate inbreeding coefficients, kinship coefficients, fixation index, and the number of paternal and maternal lineages present. The inbreeding coefficients calculated from the markers (average of 0.006 ± 0.011) are not similar to the coefficients determined from the pedigree structure (average of 0.014 ± 0.010). When we evaluated the kinship coefficients for each relative pair using the SNP data, they did not always match the coefficients based upon the pedigree. To determine why the estimates deviated, we evaluated the average coefficient for different types of pairs. The coefficients from the genotypes and the pedigree are respectively 0.250 ± 0.030 and 0.260 ± 0.006 for siblings, 0.250 ± 0.003 and 0.260 ± 0.004 for parent-offspring, and 0.128 ± 0.016 and 0.135 ± 0.004 for half-siblings. The average F_{ST} across the genome is 0.116 ± 0.359 for the Amish compared to the CEU HapMap samples, suggesting there may be multiple levels of inbreeding present. We identified paternal and maternal lineages from the combined pedigree of 5,437 individuals. In total, 71 paternal and 75 maternal lineages were identified, of which 37 and 54 were examined, respectively. Examination of Y chromosome markers identified three paternal lineages that include males whose alleles suggest the lineage includes unrelated males. The male members who carry the minor alleles can be related via a single male ancestor within one of these pedigrees. The mitochondrial genotypes of five maternal lineages suggest these lineages include individuals who are not maternally related. These data suggest that inbreeding is complex, and that a single figure may not accurately describe the entire population. Additionally, we can use these results to adjust analysis to properly reflect true relationships by correcting for errors in reported pedigree structure.

3336T

Jethro's descendants: a journey of 1000 years. *E. Friedman[1], J. Zidan[2], D. Ben Avraham[3], T. Maray[4], G. Atzmon[3,5].* 1) Susanne Levy Gertner Oncogenetics Unit, The Danek Gertner Institute of Human Genetics, Chaim Sheba Medical Center, 52621 Tel-Hashomer, Israel;; 2) The Oncology Department Ziv Medical Center, Zefat, Israel; 3) Departments of Medicine, Albert Einstein College of Medicine, Bronx, NY 10461; 4) Golan for Development Madjal Shams The Golan Heights; 5) Genetics, Albert Einstein College of Medicine, Bronx, NY 10461.

The Druze people enumerate ~1000000 people worldwide, share common beliefs and social practices, rarely marry outside of their faith and have a high rate of consanguinity. These features likely make the Druze people a genetic isolate. Previous attempts to define the genetic structure of the Druze people were based on unrelated individuals, primarily from Israeli residing Druze and using Y chromosome markers and mitochondrial DNA. The current study attempted to comprehensively decipher the genetic structure of geographically diverse residing Druze, based on parents-offspring trios. Forty parent-offspring trios from Beit Jan and the Golan Heights (20 each) were recruited, each trio representing a seemingly distinct geographical origin (=Hamulas). Genotyping was done using Affymetrix 6.0 platform and PCA, IBD sharing and Structure analysis as well as haplotype sharing were subsequently assessed by JMP Genomics, GERMLINE and STRUCTURE. Druze clustered with other Middle Eastern groups, and when compared with Bedouins, and Palestinians genotyped by the HGDP, the Druze formed its own distinct cluster, indicating the shared ancestry and relative isolation of each of those groups. The relative positions of the population clusters observed by PCA were confirmed by structure and IBD analysis. The closest genetic distance was noted between Golan Heights residing Druze and the Druze, Palestinian and Bedouin from HGDP panel. Haplotype and phasing are ongoing to accurately define common ancestor. This is the first study targeting Druze individuals that attempted to define common ancestor by geographical origin and facilitate future studies aimed at gene-disease interaction using the powerful tool of trios structure.

Overview of the genetic variations in the Y chromosome in the Japanese population. *Y. Sato[1,2], T. Shinka[2], A. Yamauchi[1], Y. Nakahori[2].* 1) Dept Pharmaceutical Information Science, Tokushima Univ, Tokushima, Japan; 2) Dept Human Genetics and Public Health, Tokushima Univ, Tokushima, Japan.

The modern Japanese people are widely believed to be the descendants of the Jomon and Yayoi people. There is one model to explain the formation of Japanese population called the dual structure model which hypothesizes that the indigenous people the Jomonese migrated in the northern island of Hokkaido and the Ryukyu Islands, and resided on the islands of Japan, before the Yayoi started to arrive in Kyushu (southern Japan) from the Korean Peninsula. As the Y chromosome is unable to recombine, the same type of Y chromosome is passed from father to son. Therefore, the Y chromosome is a useful tool for genealogical research. According to the haplogrouping and nomenclature system of the Y Chromosome Consortium, Japanese males mainly belong to haplogroups C, D, and O, which can be further sub-classified. Haplogroups C1 and D2 are postulated to be indigenous Japanese haplogroups, and the distributions of O2b1 and O2b* are limited to Japan and Korea. Hammer et al. have proposed that the Jomon males had the Y chromosomes with either haplogroups C or D, while Yayoi males had ones with haplogroup O from the analysis of the Ainu and Ryukyuans. Here, we hypothesized that if the abovementioned model is correct, the Y chromosome haplogroups C and D might display high frequencies on Hokkaido, and haplogroup O might display a high frequency in northern Kyusyu. In addition, the frequencies of these haplogroups might exhibit a geographical gradient in Japan. To investigate this hypothesis, we recruited 2,390 male volunteers from Hokkaido (Sapporo), northern Kyusyu (Nagasaki and Fukuoka), Shikoku (Tokushima), and Honshu (Osaka, Kanazawa, and Kanagawa) and typed their Y chromosome haplogroups. We also gathered data regarding the frequency distributions of Y chromosome haplogroups in East and Southeast Asia from the published literature. We did not detect any marked variability in the frequencies of these haplogroups among the Japanese populations. However, our results showed that haplogroup O3a4 is likely to be one of indigenous Japanese haplogroup. In conclusion, the Japanese population possesses several indigenous Y chromosome haplogroups, and their frequencies seem to have reached equilibrium.

3338W

Genome-wide SNP variation in sub-Saharan Africa is influenced by cultural and ethno-linguistic affiliation. *S. Soi[1], L. Scheinfeldt[1], C. Lambert[2], J. Hirbo[1], A. Ranciaro[1], S. Thompson[1], J. Marie Bodo[3], M. Ibrahim[4], G. Lema[5], T. Nyambo[5], S. Omar[6], C. Wambebe[7], D. Meskel[8], G. Belay[8], A. Froment[9], S.A. Tishkoff[1].* 1) Dept. Genetics and Biology, University of Pennsylvania, Philadelphia, PA, USA; 2) Cold Spring Harbor Laboratories, Cold Spring Harbor, NY, USA; 3) Malaria Research and Training Center, University of Bamako, Bamako, Mali; 4) Department of Molecular Biology, Institute of Endemic Diseases, University of Khartoum, 15-13 Khartoum, Sudan; 5) Department of Biochemistry, Muhimbili University of Health and Allied Sciences, Dar es Salaam, Tanzania; 6) Kenya Medical Research Institute, Center for Biotechnology Research and Development, 54840-00200 Nairobi, Kenya; 7) International Biomedical Research in Africa, Abuja, Nigeria; 8) Department of Biology, Addis Ababa University, Addis Ababa, Ethiopia; 9) UMR 208, IRD-MNHN, Musée de l'Homme, Paris, France.

Human genetic relationships often correspond to ethno-linguistic classification and geographic proximity. However, language shifts and historical gene flow can obscure such patterns. Because linguistic methodologies do not permit the reconstruction of relationships beyond the level of language family and archaeological evidence is often incomplete, genetic data provide an important complement in the study of modern human demographic history. To further disentangle the complex demographic questions in Africa, we have generated an expanded genome-wide set of 1.19 million single nucleotide polymorphims (SNPs) using the Illumina 1M duo array from 724 individuals from 46 diverse ethno-linguistic populations from across sub-Saharan Africa. Principal components analysis (PCA), analysis of identity by descent (IBD) tracts inferred with GERMLINE, and Bayesian cluster analysis using STRUCTURE revealed unexpectedly close relationships among linguistically and geographically disparate hunting and gathering population samples. In particular, we have identified evidence of recent common ancestry among the several East African hunter-gatherer populations, southern African San, San, eastern and western Pygmies. Our results demonstrate that recent Neolithic population movements and dynamics have not completely obscured more ancient African population structure. In addition, we are applying approximate Bayesian computation (ABC) methods using haplotype and linkage disequilibrium statistics to infer demographic histories.

3339T

Positive natural selection and recent evolutionary history in Malays. *X. Liu[1], T.H. Ong[2], L.P. Wong[2], W.T. Poh[2], N.E. Pillai[3], C.C. Khor[4], Y.Y. Teo[1,2,3,4,5].* 1) NUS Graduate School, National University of Singapore, Singapore, Singapore; 2) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 3) Life Sciences Institute, National University of Singapore, Singapore; 4) Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore; 5) Department of Statistics and Applied Probability, National University of Singapore, Singapore.

Recent human evolutionary history may be revealed through the identification of positive selection events in the human genome. Here we perform a genome-wide scan of positive natural selection in the Malay genome. While most of the signals are shown to be shared between Malay and other populations in Asia and Europe, there were some signals that appear to be exclusive to South-East Asia. The shared signals may either be due to convergent evolution, where the populations were under similar selection pressure; or more commonly, these signals could have originated from a single mutation event in the common ancestral population of these groups. To differentiate between these two situations, we used a method that locates the haplotype pattern that the advantageous allele resides on, and predicts the frequency of the positively selected allele. Haplotype forms that are remarkably consistent between the populations indicate that these populations likely carry the same functional allele that has arisen in a single mutation event prior to the time to the most recent common ancestor (TMRCA) of these populations. To perform these analyses, we estimate the TMRCA of the Malay populations along with other Southeast and East Asian populations. Subsequently, for the positive selection signals that are inferred to have originated from the same mutation events, we fine-map these signals to identify the functional variants using dense whole-genome sequence data from the 1000 Genome Projects and from the Singapore Sequencing Malay Project. The alleles identified may yield vital insights into the functional aspects that led to survival advantages in Malays and other populations.

3340F

Genetic evidence of multiple non-Asian migrations into the New World. *N. Angerhofer[1,2], S. Woodward[1,2], N. Myres[1,2], T. Steele[2], A. Nelson[2], U.A. Perego[2,3], K. Chahine[1].* 1) AncestryDNA, Provo, UT 84604, USA; 2) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT 84115, USA; 3) Dipartimento di Biologia e Biotecnologie, Università di Pavia, Pavia 27100, Italy.

Ancient migrations into the New World (North and South America) have been tied to Asia through Y chromosome (Ychr) and mitochondrial (mtDNA) affinities, where estimates of divergence place the original migrations at 15–18 kya. Recent migrations of populations to the Americas are a matter of historical record, starting with the Spanish in 1492, and with subsequent waves of Europeans, Africans and Asians. With targeted DNA testing, the evidence of these separate and distinct migrations can be detected.

During a recent survey of the nearly 45,000 Ychr haplotypes in the AncestryDNA database, a number of non-Asian haplotypes have been observed in Native American collections. Among these, a 37-loci STR non-Asian modal haplotype similar to haplogroup I was revealed to be shared between approximately 30 Central and South American samples. While they clustered together, these samples did not have close matches to known Native American haplogroups. Their time to coalescence was determined to be approximately 2000 years ago. They were distributed from Chile to Mexico, and with SNP testing, were determined to be members of Ychr haplogroup I-M26, a European haplogroup with high frequency in Sardinia and at low but significant frequencies in northern Spain, southern France, England and Ireland. Ychr SNP testing confirmed the rare M26 SNP could be used as evidence of a possible Iberian connection. Network and cluster analyses with more distant Y-STR I-M26 individuals show a strong connection to Spain and Portugal, which includes Basques and possible connections to ancient relatives in England, Wales and Ireland. It is expected that with the addition of autosomal SNP testing and analysis of linkage disequilibrium, characteristic indicators of distinct populations of post-Asian migrations into the Americas will become better defined.

The CARTaGENE Genomics Project : Population Genetics Analysis of the Founding Population of Quebec. *P. Awadalla[1,2,3], J. Hussin[1,2], Y. Idaghdour[2], A. Hodgkinson[2], J-P. Goulet[2], J-C. Grenier[2], T. de Malliard[2], V. Bruat[2], E. Gbeha[2], M. Capredon[2], E. Hip-Ki[2], Y. Payette[3], C. Boileau[3].* 1) University of Montreal, Montreal, QC, Canada; 2) CHU Ste Justine, Montreal, QC, Canada; 3) CARTaGENE Project, Montreal, QC, Canada.

European colonization of the province of Quebec began four centuries ago, with approximately 8,500 settlers, mostly of French origin. In the early settlement of Quebec, Europeans and local First Nations peoples exchanged genetic material, with the most common pattern being marriage between an aboriginal mother and a French father. After the British Conquest, between 2,000 and 4,000 Acadians and American Loyalists came to Quebec, and the French-Canadian population expanded rapidly. Today, the Quebec population comprises 7.8 million residents, of which ~80% are French speaking. In 2010, the CARTaGENE project collected data from 20,000 participants recruited throughout the province of Quebec. Genotyping data (Illumina Omni2.5M) was generated for ~1000 French-Canadians participants with a known extended pedigree. Despite their short divergence time and relatively similar geographic and environmental range, it has been demonstrated that the regional populations of Quebec are stratified and differences in disease prevalence are observed. Therefore, sampling includes individuals from three distinct regions of Quebec : the Montreal area, the Quebec city area and the Saguenay region. Here, we use this genetic data in order to explore regional population variation and study the effect of recent demographic history, admixture and migration patterns within Quebec. We further study the variation in recombination patterns and in IBD sharing and signatures of differential natural selection. Specifically, we (i) infer historical relationships between subpopulations in Quebec from genetic data; (ii) identify patterns of admixture in French-Canadians based on Native American and European source populations; (iii) compare recent breakpoints of recombination, ancestral population recombination rates and recombination hotspot location and (iv) identify differential natural selection operating in specific subpopulations of Quebec since the founding event. This work will give insight to gain a better understanding of the evolutionary forces that shaped the genomic landscape of French-Canadians and their implications in explaining differences in disease prevalence in regions of Quebec.

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: Characterizing ancestry of the GERA cohort using genome-wide data. *Y. Banda[1], M. Kvale[1], T. Hoffmann[1], S. Hesselson[1], H. Tang[3], C. Sabatti[3], D. Ranatunga[2], C. Schaefer[2], P. Kwok[1], N. Risch[1].* 1) Institute for Human Genetics, University California San Francisco, San Francisco, CA; 2) Kaiser Permanente Northern California Division of Research, Oakland, CA; 3) Department of Statistics, Stanford University, Stanford, CA.

Understanding human genetic diversity has important ramifications for all genomic analyses, including genome-wide association studies, admixture analysis and traits associated with ancestry. Primarily using Principal Components Analyses (PCA), we characterized the genetic structure in a sample of over 100,000 multi-ethnic subjects from Northern California who are part of the Genetic Epidemiology Research on Aging (GERA) cohort using 144,000 single nucleotide polymorphisms. The analysis includes approximately 84,000 whites, 8,000 Asians, 7,400 Latinos and 3,500 African Americans. We also projected subjects from the Human Genome Diversity Project onto the PC results to facilitate geographic interpretation. As in previous studies, in the analysis of the whites, Ashkenazi Jews formed a clearly distinct cluster based on the first two principal components, and individuals who are part-Jewish were also easily discerned. After removing the Jews from the analysis, the two-dimensional representation of the genetic relationships from the first two PCs closely follows the geographic distribution of the different European populations, with the first PC corresponding to a northwest-southeast cline, and the second PC to a southwest-northeast cline. In this analysis there was a continuum rather than clusters due to extensive mixing among various European Americans in the San Francisco bay area. South Asians formed a clearly distinct cluster, with apparent subgrouping likely separating Indian versus Pakistani origins. We also observed close correspondence between genetic and geographic distances when analysing the different East Asian subjects, with an apparent clustering from north to south in East Asia, consistent with extensive endogamy. Individuals of mixed East Asian-European ancestry were easily identified, and of particular interest was the observed continuous nature of a modest amount of European ancestry in individuals self-identified as Filipinos. Analysis of African Americans and Latinos revealed extensive European and African ancestry for both, and Native American ancestry for the latter, consistent with their self-reported nationality. The results obtained here are fundamental to the study of complex genetic disease in this large, population based cohort, through association studies, admixture analysis and admixture mapping, and in particular for investigating observed ethnic variation in diseases and traits.

3343F

Population diversity and history of the Indian subcontinent: Uncovering the deeper mosaic of sub-structuring and the intricate network of dispersals. *A. Basu, N. Sarkar Roy, P. P Majumder.* National Institute of BioMedical Genomics, Kalyani, India.

Past genomic studies have provided a broad picture of the peopling of the India: proposing a southern exit route through western coastline and migration from west and central Asia, through north-western corridor. We undertook a genomewide study(Illumina 1M SNP chip) comprising 367 individuals, drawn from 20 ethnic groups of India, including, Jarawa(JR) and Onge(OG) of the Andaman & Nicobar (A&N) Islands. Populations represent all geographic regions, linguistic groups and all social hierarchies within geographical/linguistic classes. Our analysis corroborated with previous studies on the existence of deep rooted population structure in India, as evidenced by a high average pairwise FST ~0.04. The average pairwise FST was extremely high(>0.1) between JR/OG and the mainland Indian populations, indicating the high differentiation between people of A&N and mainland India. The first Principal Component (PC), which accounts for 14% of the genetic variation, separates the JR and OG from the 18 mainland Indian populations. On inclusion of the Human Genome Diversity Panel(HGDP) data, the PCA shows that the JR and OG are close to the Melanesian and Papuan populations. Unlike Europe, geography alone is a poor predictor of genetic diversity and/or ancestry, as indicated by PCA, ADMIXTURE and MANTEL test indicating complex local histories. There was poor correlation between pairwise genetic distance and geographical distance(0.33). However, this correlation was high (0.41–0.76) when populations belonging to same social stratum were considered. North to south clinal variation, as reported earlier, was found for caste populations, but not for populations belonging to other social strata. Our results of admixture estimation and hierarchical clustering reveal that genetically the populations of mainland India form four ancestry clusters (cross validation error minimum(0.52) compared to other competing models): (1)TibetoBurman speaking populations of the northeast region. (2)Upper Caste groups of both northern(IE) and southern(DR) regions. (3)Austro-Asiatic(AA) speakers of central and eastern region. (4)DR speaking lower caste and tribal groups of southern region. Population ancestry analysis revealed that the AA and DR speakers have a deep-rooted ancestry and are perhaps relics of a very ancient dispersal event, perhaps the migration that entered India in the southern exit route wave. This finding is also supported by the analysis of similarity of haplotype structures.

Mitochondrial origins of the Cape Coloureds of South Africa. *K.G. Beaty[1], D.L. Phillips[1], M. Henneberg[2], M.H. Crawford[1].* 1) Lab of Biological Anthropology, Department of Anthropology, University of Kansas, Lawrence, KS; 2) Department of Anatomical Sciences, University of Adelaide, Adelaide, Australia.

Previous studies of genetic diversity have suggested that the Cape Coloureds of South Africa are a highly admixed population with genetic roots from indigenous African groups including Khoisans and later arriving Bantu speaking Xhosa farmers. Further genetic contributions came during the European colonization of South Africa, which added Dutch, French, German, and British markers to the gene pool. Slaves from Indonesia, Malaysia, Madagascar and India are also thought to have contributed to the genetic makeup of this ethnic group. This study examines the maternal contribution of each of these groups to the genetic makeup of the Cape Coloreds through sequencing of hypervariable region I of the mitochondrial DNA, and through restriction fragment length polymorphisms for haplogroup assignment and confirmation. A total of 94 individuals from Klein Karoo, South Africa were examined for this study, displaying a high level of gene diversity at 0.9663 when compared to other African groups. High frequencies of African haplogroups L1 (42.6 percent) and L2 (26.6 percent) were found. African haplogroup L0 was also detected in low frequencies, including L0d (6.4 percent), a haplogroup associated with Khoisan groups. L0a, a haplogroup associated with the Bantu expansion, was also detected at 4.3 percent. While the majority of lineages indicate an African maternal origin of Cape Coloureds, other contributions are noted through European and Eurasian haplogroups H (3.2 percent), U (4.3 percent), and R (1.1 percent). Asian haplogroup M was also found at 6.4 percent, indicating a Melanesian or Indian contribution to the Cape Coloured gene pool. This study shows the diverse maternal origin of South African Cape Coloureds.

North African Jewish and non-Jewish populations form distinctive, orthogonal clusters. *C. Campbell[1], P.F. Palamara[2], M. Dubrovsky[3], L.R. Botigué[4], M. Fellous[5], G. Atzmon[1], C. Oddoux[1], A. Pearlman[1], L. Hao[6], B. Henn[7], E. Burns[1], C. Bustamante[7], D. Comas[4], E. Friedman[3], I. Pe'er[2], H. Ostrer[1].* 1) Albert Einstein College of Medicine, Bronx, NY; 2) Columbia University, New York, NY; 3) Tel Aviv University, Israel; 4) Universitat Pompeu Fabra, Barcelona, Catalonia, Spain; 5) Cochin Institute, France; 6) University of Medicine and Dentistry of New Jersey; 7) Stanford University, Stanford, CA.

North African Jews constitute the second largest Jewish Diaspora group. Yet, their relatedness to each other, to European, Middle Eastern, and other Jewish Diaspora groups and to their former North African non-Jewish neighbors has not been well-defined. Here, genome wide analysis of five Jewish groups (Moroccan, Algerian, Tunisian, Djerban and Libyan) and comparison with other Jewish and non-Jewish groups demonstrated distinctive North African Jewish population clusters with proximity to other Jewish populations and variable degrees of Middle Eastern, European and North African admixture. These populations showed a high-degree of endogamy and were part of a larger Ashkenazi and Sephardic Jewish group. Two major sub-groups were identified by principal component, neighbor joining tree, and identity by descent (IBD) analysis - Moroccan/Algerian and Djerban/Libyan that varied in their degree of European admixture. The Libyan, Tunisian and Djerban Jewish populations showed the highest degree of within-population and cross-population IBD sharing. STRUCTURE and Xplorigin analysis demonstrated an enrichment of European ancestry in Moroccan and Algerian Jews, most likely of recent origin. By principal component analysis, all North African Jewish groups were orthogonal to contemporary populations from North and South Morocco, Western Sahara, Tunisia, Libya and Egypt. Thus, this study is compatible with the history of North African Jews - founding during Classical Antiquity with proselytism of local populations, followed by genetic isolation with the rise of Christianity and then Islam, and admixture following the emigration of Sephardic Jews during the Inquisition.

3346F

Hyper-sharing individuals in founder populations: Theory and implications to imputation strategies. *S. Carmi[1], P. Palamara[1], V. Vacic[1], T. Lencz[2], A. Darvasi[3], I. Pe'er[1].* 1) Department of Computer Science, Columbia University, New York, NY 10025, USA; 2) Department of Psychiatry, Division of Research, The Zucker Hillside Hospital Division of the North Shore-Long Island Jewish Health System, Glen Oaks, NY, 11004, USA; 3) Department of Genetics, The Institute of Life Sciences, The Hebrew University of Jerusalem, Givat Ram, Jerusalem, 91904, Israel.

Widespread sharing of long, identical-by-descent (IBD) genetic segments is a hallmark of populations that have experienced recent genetic drift. Recent progress in genotyping and sequencing technologies, coupled with new algorithms, enable now the detection of IBD segments even in large cohorts, with applications ranging from phasing and imputation through demographic inference to detection of association and positive selection. We focused on the total fraction of the genome shared IBD between arbitrary pairs of individuals. Our observations of total sharing in real cohorts suggest that this total IBD has a surprisingly wide distribution. Specifically, when considering the cohort-averaged sharing— the average total sharing between each individual to everyone else in the cohort— we repeatedly observed small groups of individuals with much more average sharing compared to others. The existence of such groups of `hyper-sharing' individuals bears important consequences to the design of sequencing studies, since, if they are selected for whole-genome sequencing, a larger fraction of the cohort can be subsequently imputed. We therefore set out to provide theoretical grounds for our empirical findings. In the Wright-Fisher model, we calculated the moments of the total sharing, and provided an approximate form for its distribution. We then investigated the average sharing between each individual to everyone else in the cohort. We found that even for very large samples, the cohort-averaged sharing approaches a normal distribution with variance that is cohort size-independent, thus implying the existence of hyper- (and hypo-) sharing individuals. We worked out explicitly the expected gain in imputation (and gene-disease association) power in sequencing studies when prioritization of samples for sequencing is IBD sharing-aware.

Analytical inference of human demographic history using multiple individual genome sequences. *H. Chen[1], D. Reich[2,3].* 1) Dept Epidemiology, Havard Sch Public Health, Boston, MA; 2) Department of Genetics, Harvard Medical School, Boston, MA 02115; 3) Broad Institute of Harvard and MIT, Cambridge, MA 02142.

A central problem in human population genetics study is to infer the past demographic history using genetic polymorphism data from present-day humans. The whole-genomic sequence data generated by new sequencing technology provide an unprecedented opportunity for population genetic studies. We present a new approach that infers the joint ancient human demography of multiple populations using multiple genomes from divergent populations. We use coalescent theory to analytically derive the joint allele frequency spectrum of multiple populations that experienced different demographic histories. Compared with the recently developed approaches, such as diffusion process approximation (dadi), sequential Markov Coalescent method (PSMC), and coalescent-MCMC (Markov Chain Monte Carlo, GPhoCS) approaches, our method has several advantages: (1) the method is computationally efficient, as the coalescent likelihood for the joint pattern of multiple populations can be obtained analytically without relying on numerical approximation of diffusion (e.g., Gutenkunst et al 2009) or computationally intensive approaches (e.g. Gronau et al 2011); (2) the method jointly analyzes more than three populations, and multiple individuals from each population, whereas previous approaches were limit to three populations (Gutenkunst et al. 2009) or one individual from each population (Gronau et al 2011; Li and Durbin 2011); and (3) detailed demographic scenarios can be incorporated into the model, including temporally-varying population sizes. We apply the method to two data sets: the first data includes three Europeans, two Asians, three Yoruba and one San sequenced using Illumina technology; and the second data set includes eight East Asians, five Northern Europeans and seven Yoruba sequenced using Complete Genomics technology. We estimate that Eurasian populations split from ancient Africans at 58,000–120,800 years ago, and the divergence time of Europeans and Asians occurred at 35,750–70,500 years ago. The inferred demographic history is generally consistent with previous studies.

3348T

Predicting the geographic origin of individuals using genome-wide SNP data. *D.J.M. Crouch, M.E. Weale.* Deparment of Medical and Molecular Genetics, King's College London, London, United Kingdom.

A capacity to predict the geographic origin of human DNA samples would have applications in forensic science, anthropology and population genetics. Over short geographic ranges, for example sub-continental regions, genetic differentiation between populations tends to be low, and the distribution of variation is clinal. Consequently, the most appropriate predictive model is one which returns continuous longitude/latitude estimates along with associated measures of uncertainty. We use the genetic covariance between individuals at known sample locations to model the spatial dependencies between allele frequencies as a function of distance. Allele frequencies at unknown locations are then imputed via this model, an approach known as Kriging, and the probability of observing the target individual's genotypes under Hardy-Weinberg Equilibrium is maximised for longitude and latitude. It is possible to extend this model by deriving the between-individual genetic covariance via haplotype information. Performance is assessed using cross-validation with European individuals from the HGDP and POPRES datasets, and we compare with alternative methods from the literature.

Y Chromosome J Haplogroups trace post glacial period expansion from Turkey and Caucasus into the Middle East. *B. Douaihy[1], D. Platt[2], M. Haber[1,3], A. Salloum[1], F. Mouzaya[1], M. Bou Dagher-Kharrat[4], G. Khazen[1], E. Matisoo-Smith[5], R.S. Wells[6], C.T. Smith[7], P. Zalloua[1,8], The Genographic consortium.* 1) Lebanese American University, Beirut, Lebanon; 2) Computational Biology Centre, IBM TJ Watson Research Centre, Yorktown Hgts, NY, USA; 3) Institut de Biologia Evolutiva (CSIC-UPF), Departament de Ciències de la Salut i de la Vida, Universitat Pompeu Fabra, 08003 Barcelona, Spain; 4) Laboratoire `Caractérisation Génomique des Plantes, Faculté des Sciences, Université Saint-Joseph, Campus Sciences et Technologies, Mar Roukos, Mkalles, BP: 1514 Riad el Solh, Beirut 1107 2050, Lebanon; 5) Allan Wilson Centre for Molecular Ecology and Evolution and University of Otago, Dunedin 9054, New Zealand; 6) The Genographic Project, National Geographic Society, Washington, DC, USA; 7) The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, UK; 8) Harvard School of Public Health, Boston, MA, USA.

Paleoclimate reconstructions have shown that several glacial refugia formed around the Mediterranean and Black Sea during the last glacial period (LGP) that dramatically affected the distribution of the populations of Eurasia and the Middle East. Post-glacial warming, beginning around 12,000 years ago, resulted in population migrations out of those refugia, and drove the Neolithic revolution. The timing and routes of these migrations and their specific regions of expansion remain elusive. The genetic signals marking the initial settlement following the LPG are also unclear. On the Y chromosome, there is significant regional variation among subhaplogroups of J within the Middle East that are informative about these events, which were investigated in more detail. 2774 samples were analyzed, including 941 newly genotyped, to characterize populations where J haplogroups have expanded geographically. Haplogroup J diversity was measured by coancestry using Y-STR haplotype effective number. Reduced Median networks were calculated for each of the J subhaplogroups and SNP coalescence times were estimated by BATWING. The J subhaplogroups' frequencies show substantial variation across the Mediterranean Basin. J subhaplogroups show little organization of their haplotypes by geography, suggesting that diversity evolved primarily within a pool of ancestral populations for a larger part of its history, then post-glacial expansions carried this diversity throughout their modern geographical range. Coalescence time estimates indicate longer evolution of J haplogroups in northern populations, in agreement with co-ancestry diversity. Population divergence time estimates are recent compared to coalescence times, supporting long evolution times prior to post-glacial expansions. Our data provide evidence for the timing and differential routes of post glacial repopulation of the region. When combined with archaeological and linguistic evidence, these genetic data allow us to reconstruct the spread of agriculture and the origins of various Neolithic cultures of the Middle East. The Neolithic expansion has been marked by haplogroups characteristic of the Middle East, with J haplogroups showing geographically differential frequency distributions and haplotype diversities. These results are suggestive of evolution within the Anatolian Peninsula and the Black Sea basin during the LGP, followed by multiple expansions taking distinct routes at different times subsequent to the LGP.

Genotyping at the DAT1 Locus; Determination of VNTR Allele Frequencies in Descendents of the Founding Families of Southwest Louisiana. *J. Drost, A. Figueroa, J. Angle.* Biology and Health Sciences, McNeese State Univ, Lake Charles, LA.

The human population of Southwest Louisiana offers a rich opportunity for genetics study because it was founded by a small number of individuals arriving independently representing a variety of ethnic backgrounds. Moreover, due to geographical and cultural isolation from other populations many current residents are direct descendants of several of these founders. Louisiana's incidence of Attention-Deficit Hyperactivity Disorder (ADHD) diagnosis in children is 14.2%, near the highest in the nation. In a pilot project we genotyped natives of southwest Louisiana to identify common VNTR alleles, which have been associated with increased risk of ADHD, among this population. DAT1 encodes the Dopamine Active Transporter (SLC6A3, MIM: 126455), a carrier protein for the reuptake of dopamine from the synaptic cleft in certain regions of the brain and a primary mechanism of dopamine regulation. A common VNTR polymorphism in the 3' untranslated region apparently influences gene expression. Repeats of the 40 base pair sequence range from 3 to 11, but the most common alleles are 10R (71.9%) and 9R (23.4%). The presence of the 10R allele has been associated with increased risk of ADHD. We sampled 80 unrelated, informed, and consenting adults who are descended from one or more of the founders arriving before the beginning of the 20th century. DNA will be isolated from whole blood, cheek cells, or hair samples. Genotyping was performed using PCR amplification and gel electrophoresis. In addition, individuals completed a questionnaire concerning ADHD diagnosis or associated phenotypes and genealogical relationship(s) to founding families. Diagnosis of ADHD was not necessary for participation as our primary interest is in assessing allele frequencies among direct descendants of the population's founders. Amplified samples are retained for sequencing to determine whether these variants are identical by descent as is assumed by the classic founder's effect model or arrived independently via different founding individuals.

3351T

A two-sex model for the admixture history of a hybrid population. *A. Goldberg, P. Verdu, N.A. Rosenberg.* Stanford University, Stanford, CA.

Admixed human populations have often experienced sex-biased admixture, in which males and females contributing to the gene pool of the admixed population are drawn in different proportions from the various source populations. Genetic variation in autosomes and sex-specific chromosomes has often been examined in order to infer patterns of sex-biased admixture, typically using statistical approaches that do not fully model the complexity of a sex-specific history of admixture. Expanding on the model of Verdu & Rosenberg (2011), we develop a model that mechanistically considers sex-specific admixture histories, in which multiple source populations contribute to the admixed population, potentially with varying contributions from male and female lineages at each generation. In an admixed population descended from two source groups, we derive the moments of the distribution of the admixture fraction from a specific source population as a function of sex-specific introgression parameters and time, separately for autosomes and sex chromosomes. Considering admixture processes that are constant in time, we demonstrate that although the mean admixture fraction from a specific source population cannot discern a sex bias in the admixture history for autosomal markers, the variance is informative about sex bias. Specifically, the long-term variance decreases as the sex bias from a contributing source population increases. We highlight a case in which different constant admixture histories produce the same autosomal variance of admixture, but consideration of the X chromosome enables the scenarios to be distinguished. Our approach can contribute to methods for inference of the history of complex sex-biased admixture processes by contrasting the distribution of admixture fractions between autosomal and non-autosomal DNA.

3352F

Admixed human genomes reveal complex migration patterns from the early spread of modern humans to the 21st century. *S. Gravel[1], J.M. Kidd[1,2], J.K. Byrnes[1], A. Moreno-Estrada[1], F. Zakharia[1], S. Musharoff[1], F.M. De La Vega[1], C.D. Bustamante[1].* 1) Genetics, Stanford University, Stanford, CA; 2) Human Genetics, University of Michigan, Ann Arbor, MI.

Populations with the slightest geographical, ethnic, or cultural differentiation often exhibit differences in their patterns of genome-wide diversity due to assortative mating. Thus admixture, defined as gene flow across preferentially mating groups, occurs in most genealogies. Whether it is considered a confounding factor (as in standard GWAS) or is directly used for mapping (as in admixture mapping), better models for admixture and population structure will result in better outcomes for medical genetics studies.

Individuals deriving recent ancestry from multiple continents represent a substantial and increasing proportion of the human population. Because of the tens of thousands of years of divergence between continental populations, we can often infer the contributions from different continental ancestries for individual loci, facilitating the interpretation of diversity patterns. We first discuss a simple Markov model that relates the time-dependent migration history to the inferred patterns of local ancestry. We use this framework to infer the timing of admixture and to differentiate between punctual and continuous models of migration: using demographic models that are consistent with both historical records and genetic data, we find evidence for continuous migration patterns in both Mexican and African-American populations.

We also present a diversity of methods for the analysis of whole-genome sequence data from admixed individuals, and apply them to 50 genomes sequenced by Complete Genomics, including 4 Mexican-Americans, 4 African-Americans and 2 individuals from Puerto Rico, together with SNP genotype data from hundreds of additional samples, as well as data recently generated by the 1000 Genomes project. We consider the allele frequency distribution, pairwise TMRCA's, and a simple extension of the recently introduced Pairwise Sequencial Markov Chain approach for demographic inference. The inferred source population demographic histories are in broad agreement with previous results for European and West-African populations, and the inferred demography for the Native source population closely follows the European one until about 20,000 years ago. Taken together, whole genome sequencing and local ancestry assignment therefore permit inferences about long-term histories of unsampled ancestral populations and highlights recent historical demographic processes that altered patterns of variation observed in admixed populations.

3353W

Quantitative characterization of the ancestry of the Estonian population. *T. Haller[1], L. Leitsalu-Moynihan[1], P.C. Ng[1,2], K. Fischer[1], T. Esko[1], K. Läll[1], A. Metspalu[1].* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Genome Institute of Singapore, Singapore.

Ancestry-related questions are increasingly getting more attention owing to the genome-wide marker information becoming available for a growing number of populations. This information can be utilized in a variety of ways ranging from the re-construction of historical events to advancing public health. Separating genetically relatively distant populations has been carried out for years. Recently the methods have gained in sensitivity by adopting haplotype-based approach and now allow comparative studies of closely related populations. The Estonian Genome Center of the University of Tartu maintains a Biobank with over 50,000 DNA and plasma samples as well as a comprehensive phenotype database (objective measurement data, health data, information on lifestyle/habits, metabolite concentrations, gene expression data etc.) for these individuals. This population-based database represents 5% of Estonia's adult population. Currently over 10,000 self-reported Estonians representing all regions of Estonia have been genotyped with genome-wide chips, and the number is expected to grow to 50,000. This allows detailed studies of the Estonian population structure in terms of ancestry and correlating the ancestry information with the phenotype information. We adopted the latest tools (SHAPEIT, ChromoPainter) together with original in-house algorithms to develop a method for quantitatively studying the Estonian population structure. Our method allows to detect what fraction of the genome of each person is inherited from which of the 19 European reference populations we use. Performing a deconvolution of these closely related genetic influences has previously remained a challenge and is addressed by our method. For each person tested the algorithm assigns percent similarity with three of the closest reference populations by performing a best fit simulation. The goodness of fit is used to estimate how much of the genetic background cannot be accounted for by the reference populations. Dissecting how well the modern time ancestry structure reflects the key historical events indicates the geographical mobility of people and displays the genetic fingerprints of the populations that have influenced Estonia throughout the history. Estonia serves as a good model for detailed ancestry studies; it is a small country located in a historically turbulent location and at the same time is a typical representative of a European population.

3354T

Demographic inference and whole genome scan for natural selection in Biaka Pygmies from Central Africa. *P.H. Hsieh[1], K.R. Veeramah[2], J.D. Wall[3], R.N. Gutenkunst[1,4], M.F. Hammer[1,2].* 1) Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, AZ; 2) Arizona Research Laboratories Division of Biotechnology, University of Arizona, Tucson, AZ; 3) Institute for Human Genetics, University of California, San Francisco, CA; 4) Department of Molecular and Cellular Biology, University of Arizona, Tucson, AZ.

African Pygmy groups reside mostly in Central African rainforests and are characterized by their short stature and predominantly hunter-gatherer lifestyle. Many Pygmy populations have been influenced by neighboring Niger-Kordofanian-speaking farmer populations through socio-economic contacts, especially since the extensive agriculture expansion from the Nigeria/Cameroon border to Southern and Eastern sub-Saharan Africa beginning ~3–5 thousand years ago. Two questions of particular interest concern 1) the population demographic dynamics of African Pygmies and the genetic consequences of the agriculture expansion, and 2) the genetic basis of adaptation to the harsh rainforest environment, in which they are exposed to not only hot and humid conditions, but also many parasites and diseases pathogens. We generated whole-genome sequences at >40X coverage for a sample of Biaka Pygmies. As a control, we also examined publicly available high-coverage whole-genome sequences data from two Niger-Kordofanian-speaking farmer populations of normal stature, the Yoruba from Nigeria and the Luhya from Kenya. To unravel the demographic history and to search for signatures of natural selection in these populations, we built a novel computational whole-genome-sequences pipeline integrating population genetic, functional, and statistical analyses. After quality control filtering, our data consist of >3.7 million SNPs that are fully called in all three populations. Through use of the model-based demographic inference tool, ∂a∂i, we found that demographic models involving recent admixture from neighboring non-Pygmy Niger-Kordofanian farmer populations to the Pygmies were significantly better than those that only featured low levels of unidirectional or bidirectional migration after divergence from a common ancestor. In light of recent findings, we also explored the likelihood of introgression between the ancestors of Biaka and archaic humans. Preliminary results from a whole-genome selection scan using multiple complementary tests, such as G2D and XP-CLR, reveal that genes involved in cell adhesion, cellular signaling, olfactory perception, and immunity were likely targeted by natural selection in the Biaka Pygmies or their recent ancestors. The present work not only demonstrates the usefulness of our computational pipeline, but also sheds new light on the history of one of the most enigmatic African populations and on the genetic basis of local adaptation.

Analysis of contributions of archaic genome and their functions in modern non-Africans. *Y. Hu[1], Q. Ding[1], Y. Wang[1], H. Zheng[1], L. Jin[1,2].* 1) MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai 200433, China; 2) Chinese Academy of Sciences and Max Planck Society (CAS-MPG) Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, People's Republic of China.

Archaic hominin admixture with modern non-Africans was detected by genome wide analysis of Neanderthal and Denisovan individuals. Compared with Africans, non-Africans share excess derived alleles with Neanderthals. Especially, Europeans and East Asians are similarly related to Neanderthals, suggesting Neanderthal gene flow to Eurasians before their split. Additional Denisovan admixture was detected in Melanesian individuals. Several models were subsequently proposed regarding time and location of admixture events. To gain better understanding in demographic and evolutionary significance of archaic hominin admixture, we implemented an algorithm to identify archaic segments, i.e., carrying locally maximized number of alleles that are only observed in non-Africans, by analyzing 1K Genome Phase I data. Totally, we identified 410,683 archaic segments in 909 non-African individuals with averaged segment length 83,460bp. In the genealogy of each archaic segment with Neanderthal, Denisovan, African and chimpanzee segments, 77~81% archaic segment coalesced first with Neanderthal, 4~8% coalesced first with Denisovan, and 14% coalesced first with neither, validating the algorithm. Interestingly, a large proportion of all the archaic segments identified shared 88.9% similarity with Neanderthal, suggesting a single major admixture with Neanderthal at 82~121kya, right after the Africa exodus of the ancestors of modern humans. Furthermore, we found that several disease associated sites with alleles specific to archaic segments, suggesting a possible contribution of Neanderthal and Denisovans to human diseases.

3356W

Anisotropic isolation by distance: the main orientations of human genetic differentiation. *F. Jay[1,2], P. Sjödin[3], M. Jakobsson[3,4], M.G.B. Blum[2].* 1) Laboratoire TIMC-IMAG UMR 5525, Université Joseph Fourier, Centre National de la Recherche Scientifique, Grenoble, France; 2) Department of Integrative Biology, UC Berkeley, Berkeley, CA; 3) Department of Evolutionary Biology, Uppsala University, Uppsala, Sweden; 4) Science for Life Laboratory, Uppsala University, Uppsala, Sweden.

Genetic differentiation among human populations is greatly influenced by geography due to the accumulation of local allele frequency differences. However, little is known about the possibly different increment of genetic differentiation along the different directions (north-south, east-west, ...). We analyzed genome-wide polymorphism data from African (n=29), Asiatic (n=26), Native American (n=9) and European (n=38) populations, and we found that the major orientations of genetic differentiation are north-south in Europe and Africa, east-west in Asia, but no preferential orientation was found in the Americas. A practical consequence of the anisotropic pattern of genetic differentiation is that the localization of an individual's geographic origin based on SNP data should be more precise along the orientation of maximum differentiation. We compared the localization of geographic origin obtained with principal component regression with a baseline method and confirmed that the largest improvement was obtained along the orientation of maximum differentiation. Our findings have implications for interpreting the making of human genetic variation in terms of isolation by distance and spatial range expansion processes.

On the use of deterministic functions for deriving approximate coalescent distributions. *E. Jewett, N. Rosenberg.* Biology, Stanford University, Stanford, CA.

Under the coalescent model, the number $n(t)$ of lineages as a function of time is nearly deterministic and is well approximated by its expected value $E[n(t)]$. In turn, this expectation is well approximated by deterministic functions that are simple and easy to compute (Slatkin and Rannala 1997; Maruvka et al., 2011). Such deterministic functions have been applied to the estimation of allele age (Slatkin and Rannala 1997; Slatkin 2000) and the estimation of effective population size (Maruvka et al., 2011). Here, we apply these deterministic functions to a variety of additional problems in estimating population divergence times and population trees, and in modeling faster-than-exponential growth. We find that deterministic approximations to $E[n(t)]$ can be used to derive accurate, computationally fast, and numerically stable approximations to coalescent probability distributions and expectations. These approximations can be very good, even when the number of lineages sampled is small. Such approximations provide alternatives to exact formulas that are computationally intractable or numerically unstable when the number of sampled lineages is moderate or large, making them ideal for applications involving large genotyping or sequencing data sets.

Exploring Population Admixture Dynamics Using Empirical and Simulated Genome-Wide Distribution of Ancestral Chromosomal Segments. *W. Jin[1], S. Wang[2], L. Jin[1,3], S. Xu[1].* 1) CAS-MPG Partner Institute for Computational Biology, Chinese Academy of Sciences, China; 2) Department of Organismic and Evolutionary Biology, Harvard University, MA; 3) School of Life Sciences, Fudan University, China.

The history and processes of admixture determine the haplotype structure and linkage disequilibrium patterns of the admixed population, which is of significant importance to medical and evolutionary studies such as identification of disease-associated genetic variants and natural selection signatures. However, most previous studies relied on simplified models that do not consider the inherent complexity of admixture process or admixture dynamics. Here we proposed two approaches to explore population admixture dynamics, and we demonstrated the approach based on distribution of chromosomal segments of distinct ancestry (CSDA) was more powerful than that based on the distribution of individual ancestry proportions by analyzing genome-wide empirical and simulated data. Analysis of 1,890 African-Americans showed that a continuous gene flow (CGF) model, in which African-Americans continuously received gene flow from European populations over about 14 generations, best explained the admixture dynamics of African-Americans among several putative models. Interestingly, we observed some African-Americans who had much more European ancestry than those under simulation, indicating substructures of local ancestries in African-American that could be resulted from individuals from some particular lineages having continuously inter-married with people of European ancestry. On the contrary, the admixture dynamics of Mexicans was more likely to be explained by a gradual admixture (GA) model in which Mexicans continuously received gene flow from both European and Amerindian populations for about 24 generations. The higher proportion of long CSDA observed in Mexican-Americans relative to Mexican-Mestizos suggested recent gene flow from European-Americans to Mexican-Americans. The genetic components of Sub-Saharan Africans in Middle Eastern populations such as Mozabite, Bedouin and Palestinian could be explained by one early admixture followed by some recent gene flow from Africans. In summary, this study not only provides new approaches to explore the admixture dynamics of admixed populations, but also advances our understanding of historical admixture processes of African-Americans, Mexicans and Middle Eastern populations.

Population History and Y-Chromsome Diversity of the Poqomchi' Maya of Eastern Guatemala. *S. Johnson[1], A. Justice[2], M. Crawford[1].* 1) University of Kansas, Lawrence, KS; 2) Department of Epidemiology, University of North Carolina at Chapel Hill.

The Poqomchi' Maya is a group of Native Americans that were peacefully converted to Christianity in the 16th century by the Spanish. This study aims to characterize the source and level of paternal admixture within the Poqomchi' Maya of Eastern Guatemala, while making inferences into their historical relationships to surrounding Central Americans. DNA was extracted from 25 Poqomchi' males and analyzed for Y-Chromosome variation and diversity compared to other Native American populations of Central America. Using SNPs that were characterized with HyBeacons® PCR probes, the presence of Native American haplogroup Q-M242 was determined to have a frequency of 90%, (the highest among all comparative populations), the majority of which, (84%)belonged to the Native American-specific lineage Q1a3a-M3. STRs (DYS-19, 385 a/b, 389 I/II, 390, 391, 392, 393, 438, and 439) were characterized on an Applied Biosystems's ABI Prism 3730 for haplogroup assignment. The Poqomchi' exhibited 25 unique haplotypes within the sample. Interestingly, neither of the Native American haplogroups C-M130 and C3b-P39, was detected. Haplotype diversity, locus diversity, and MPD were computed to characterize the intra-population variation. The Poqomchi' exhibit higher than expected haplotype diversity (0.990) compared to surrounding populations, but average gene diversity (0.569) and MPD (3.98). This difference in diversity measures is likely the result of a high occurrence of low frequency haplotypes. Mismatch analysis for STR data indicate a unimodal distribution for the frequency of pairwise differences, indicating population expansion. Slatkins Rst, R-matrix analysis, and SAMOVA were used to highlight the relationship among populations in Meso- and Central America. Results indicate that little haplotype variation is explained by geography. Despite a long history of colonization by Europeans, population decline, and forced migration, the Poqomchi' have maintained a relative isolation from non-Native populations and therefore exhibit a majority of Native American Y-lineages with little non-native admixture.

Local Ancestry Inference in the Thousand Genomes Project Admixed Populations. *E.E. Kenny[1], B. Maples[1], C. Churchhouse[2], A. Gupta Hinch[2], A. Williams[3], Y. Baran[4], S. Gravel[1], A. Moreno Estrada[1], C. Gignoux[5], F. Zakharia[1], A.W. Bigham[6], M.D. Shriver[7], A. Ruiz-Linares[8], G. Bedoya[9], T.K. Oleksyk[10], J. Dutil[12], J.C. Martinez-Cruzado[10], E. Gonzalez Burchard[5], S. Myers[2], E. Halperin[11], J. Marchini[2], C.D. Bustamante[1], The 1000 Genomes Consortium.* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Statistics, 1 South Parks Road, Oxford OX1 3TG, UK; 3) Department of Genetics, Harvard Medical School, New Research Building, 77 Ave. Louis Pasteur, Boston, Massachusetts 02115, USA; 4) School of Computer Science, Tel-Aviv University, Tel-Aviv, Israel; 5) Institute for Human Genetics, University of California San Francisco, California, USA; 6) University of Michigan, Ann Arbor, Michigan, USA; 7) Penn State University, University Park, Pennsylvania, USA; 8) Department of Genetics, Evolution and Environment. University College London, UK; 9) University of Antioquia, Medellin, Colombia; 10) Department of Biology, University of Puerto Rico at Mayagüez, Puerto Rico 00680; 11) International Computer Science Institute, Berkeley, California, USA; 12) Department of Biochemistry, Ponce School of Medicine, Ponce, Puerto Rico.

Local Ancestry Inference (LAI) from genome-scale data is an essential analysis step in biomedical genomics of mixed ancestry populations for improved power in association studies, identification of disease genes through admixture mapping and as a biomarker for disease outcome. The task of LAI is to determine the population-specific ancestry of the chromosomes of an individual, from several hypothesized source populations (i.e., a Hispanic/Latino individual may have a combination of European, African and Indigenous American ancestry). Here we present the results of the Thousand Genomes Project (TGP) Local Ancestry Inference Working Group to compare four commonly used LAI methods (LAMP-LD, HAPMIX, RFMIX and MULTIMIX) and produced high-quality LAI calls for Phase 1 TGP data from African-American (ASW), Colombian (CLM), Puerto Rican (PUR) and Mexican (MXL) populations. We first tested the accuracy of the LAI algorithms using `known-truth' simulated ASW and MXL individuals (n=10 each) and using reference panels of European, Indigenous American and African populations (n=60 each). Accuracy for each method is high when ancestral populations are genetically distinct (98.9–99.5% accuracy for ASW) but less accurate when source populations are genetically closer (93.9–95.3% accuracy for MXL). Using diploid ancestry calls at each site, we can define high confidence regions with >= 3 methods agree and improve our per method accuracy (95.5–96.4% and 99.1–99.6% for MXL and ASW, respectively) that capture 97.4% and 99.3% of the MXL and ASW sites. The consensus call at these high confidence regions gives us marginally better accuracy than any one method (96.8% and 99.7%). Applying this strategy to the TGP admixed populations, we obtain consensus calls for 99.5%, 96.5%, 96.4% and 95.2% of the ASW, PUR, CLM and MXL samples, respectively. We note the average proportion ancestries are 0.25:0.75 (European:African) for ASW, 0.47:0.04:0.49, 0.75:0.12:0.13 and 0.67:0.08:0.25 (European:African:Indigenous American) for MXL, PUR and CLM, respectively. Finally, the proportion of the genome that could not be assigned ancestry due to discordant calls between methods was 0.013, 0.049, 0.033 and 0.037 for ASW, MXL, PUR and CLM, respectively, and was strongly correlated to the proportion of short ancestry tracts (<5cM) per individual. Consensus LAI for all TGP admixed individuals are available from the TGP Phase 1 release ftp repository.

A Likelihood Ratio Test for Sex-Bias and its Application to Whole-Genome Sequencing Data of a Set of Globally-Distributed Populations. *S. Musharoff[1], J.M. Kidd[1,2], B.M. Henn[1], S. Gravel[1], B. Maples[1], K. Eilertson[3], M.C. Yee[1], H.M. Cann[4], G. Euskirchen[1], M. Snyder[1], C.D. Bustamante[1], S. Ramachandran[5].* 1) Genetics, Stanford Univ Sch Medicine, Stanford, CA; 2) Human Genetics, University of Michigan, Ann Arbor MI; 3) Bioinformatics Core, J. David Gladstone Institutes, San Francisco CA; 4) Ecology and Evolutionary Biology, Brown University, Providence RI; 5) Fondation Jean Dausset - Centre d'Étude du Polymorphisme Humain, Paris France.

The human X chromosome presents a unique opportunity to study the effect of population genetic forces. Because the X chromosome is carried in two copies in females and one copy in males, its effective population size is determined by the ratio of breeding males to females, and, as a result, the X chromosome is sensitive to sex-biased demographic processes (i.e. those involving unequal numbers of breeding males and females). Previous estimates of the level of sex-bias in human populations from Y chromosome and mitochondrial data, or from X chromosome and autosomal data, found evidence for both male bias and female bias, which may have occurred at different times during human history. Here we present a likelihood ratio test for sex-bias based on the inference of demographic parameters from genomic sequence data. Simulation studies enable us to assess the sensitivity of this test, to determine the timescales on which sex biases can be detected, and to assess the effect of sequencing coverage. We previously sequenced to moderate coverage the whole genomes of 53 individuals from 7 diverse human populations (KhoeSan, Mbuti-Pygmy, Mozabite, Pathan, Cambodian, Yakut, and Maya) drawn from the HGDP-CEPH Diversity Panel. To aid in variant calling, we have sequenced the exomes of the same individuals to high coverage. To apply our test for sex-bias to these populations, we first correct each population's site-frequency spectrum (SFS) to account for genomic variation missed due to sequencing technology using an empirical correction based on the exome sequences. We infer demographic histories from the SFS using the program dadi and we see striking differences between the observed patterns of X chromosome variation and those that are expected under the null hypothesis of no sex-bias. We perform our likelihood ratio test for sex-bias on each population separately, as well as jointly. To assess the power of this method, we use the forward simulator SFScode for a wide range of demographic scenarios including that of sex-biased admixture between modern humans and archaic humans. This characterization of the effect of demography on the X chromosome enables us to study the effects of selection, the mode of which may differ from that on the autosomes due to the X chromosome's hemizygosity in males. The test for sex-bias presented here is not limited to human or to whole-genome data and will enable demographic insights beyond those obtainable from the autosomes alone.

Population Structure and Genetic Diversity in Argentinean populations. *M. Muzzio[1,2,3], J.M.B. Motti[2,3], E. Kenny[1], L.S. Jurado-Medina[2], M.C. Yee[1], J. Beltramo[2], R. Santos[2,3], T. Cooke[1], V. Ramallo[4], M. Schawb[2], O. Cornejo[1], G. Bailliet[2], C.M. Bravi[2,3], C.D. Bustamante[1].* 1) Stanford University School of Medicine, Stanford, CA; 2) IMBICE CCT-La Plata CONICET-CICPBA, Argentina; 3) Facultad de ciencias Naturales y Museo, Universidad Nacional de La Plata, Argentina; 4) Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil.

Argentina was one of the last places peopled when humans entered the Americas. Its earliest archeological sites are dated from ~13K years b.p., and throughout its history the region has exhibited broad cultural diversity, involving both hunter-gatherer and agro-pastoral societies, different linguistic families, the Southern expansion of the Inca Empire, the arrival of the Spanish conquistadors and slave trade from Africa. More recently, Argentina has had the highest proportion of influx of transoceanic migration between ~1850 and 1940 of any Latin American country. Furthermore, the geographical distribution of immigrants was oriented towards the Pampa region of central-eastern Argentina and the Northeast, so different patterns of mixed ancestry throughout the country are expected. In this present work we aim to describe the history and structure of the Argentinean population. Thus far, we have collected DNA samples from 2904 participants from 15 dispersed regions in Argentina, from the Andean populations in the Northwest to the river lands of the Northeast. Our preliminary data includes genome-scale Illumina Exome Array 250K genotypes, plus next-generation sequencing data from uniformly spaced genomic regions targeted with a genotype-by-sequencing strategy (which covers 1.5% of the genome), for 375 participants from 9 of the 15 populations. We will identify proportions and patterns of European, African and Indigenous American ancestry in the Argentinean cohort via local ancestry inference. The first series of analyses will focus on genomic tracts of Indigenous American ancestry for fine-scale examination of sub-continental structure by comparing to a panel of 493 samples from 52 Indigenous American populations from throughout the Americas. Furthermore, this work will serve as a test of different low-cost strategies (exome genotype array vs. genotype-by-sequencing) for accurate inference of population structure in extant populations.

Rediscovering the people who greeted Columbus through mtDNA sequence analysis. *M.A. Nieves-Colon[1], E.P. Tascón-Peñaranda[2], M. Diaz-Matallana[3], I. Carrero-Gonzalez[4], F. Curbelo-Canabal[2], J. Galanther[5], M.L. Perez-Quiñones[2], H.J. Diaz-Zabala[6], C. Eng[5], O.R. Wever[7], F. Mercedes de la Cruz[8], A. Alvarez-Serrano[9], E.G. Burchard[5], J.C. Martínez-Cruzado[2].* 1) School of Human Evolution & Social Change, Arizona State University, Tempe, AZ; 2) Department of Biology, University of Puerto Rico at Mayagüez, Mayagüez, PR; 3) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogotá, Colombia; 4) Baylor College of Medicine, Houston, Texas; 5) Institute of Human Genetics, University of California, San Francisco, California; 6) Ponce School of Medicine, Ponce, Puerto Rico; 7) Department of Internal Medicine, Dr. Horacio Oduber Hospital, Oranjestad, Aruba; 8) Facultad de Ciencia y Tecnología, Universidad Central del Este, San Pedro de Macorís, Dominican Republic; 9) Museo Arqueológico Regional Altos de Chavón, La Romana, Dominican Republic.

In an effort to understand the Pre-Columbian migrations that brought the people found by Columbus to the Greater Antilles, we sequenced the mtDNA control region of 504 admixed people from the Caribbean with Native American maternal ancestry. These included 140 samples from Puerto Rico (PR), 138 samples from Honduras, and 120 samples from the Dominican Republic (DR). In addition, we obtained 49 samples from Colombia, 46 from Aruba, and a smaller number of samples from other populations in the region. Haplogroups A2 and C1 predominated in both PR and DR with joint frequencies of 88.0% and 83.1%, respectively. At the same time, median joining network analyses showed few lineages that were shared between the islands, probably as a result of limited gene flow combined with genetic drift. With the exception of two cosmopolitan control region lineages, the lineages shared between the islands always showed diversity in PR but not in DR, suggesting migrations occurred mostly in the east-to-west direction. Non-cosmopolitan lineages on both islands showed affinity with either Central or South America, with the exception of one Dominican lineage that appeared in both Central America and Aruba. In PR, where lineages were well represented, those with Central American affinity held higher diversity, suggesting that the islands were peopled first from Central America and later from South America. However, it was South American and not Central American lineages that presented signs of population expansion, consistent with the archaeological evidence that suggested the arrival of agro-ceramic cultures to the Greater Antilles from South America approximately 2,500 YBP. Consequently, most of the autosomal Native American ancestry in PR and possibly DR may be of South American origin. Complete mtDNA sequences of both a Honduran lineage related to DR, and a Venezuelan lineage related to PR, showed differences with their island counterparts. Further examination and additional samples will be necessary to refine the number, geographic origin, and the migration times for the peopling of the Greater Antilles.

3364F

Continent-wide decoupling of Y-chromosomal genetic variation from language and geography in native South Americans. *M. Nothnagel[1], L. Roewer[2], L. Gusmao[3,5], V. Gomes[3], M. Gonzalez[3], D. The way of initial habitation creates a primordial spatial pattern of human genetic variation that is subsequently modified by demographic processes. Under the assumption that most such changes follow trajectories set by climate as well as geographic and cultural conditions, some correlation between the genetic structure on the one hand, and the linguistic and geographical structure on the other, is to be expected in extant human populations even a long time after an initial colonization event and has been documented in numerous studies on European and Asian populations. In contrast, there is a notable absence of such descriptions for South America. Here, we examined Y-chromosomal genetic diversity and its relation to geographic location and linguistic classification on a continental scale in the so far largest study on South American natives, involving up to 17 microsatellite markers genotyped in a total sample of 1011 individuals representing 50 tribal populations from 81 settlements as well as single-nucleotide polymorphisms defining the founding native American phylogenetic lineages Q and C and its sub lineages. We observed a large decoupling of Y-chromosomal genetic diversity from geographical habitats and in parts from language groups on a continental scale, which is consistent with a rapid peopling of the continent and subsequent long periods of isolation of relatively small-sized tribal groups. Our results highlight the fact that a pronounced correlation between genetic and geographic/cultural structure can be expected only under very specific conditions, most of which are likely not to have been met by native South Americans.

Using Haplotypes to Infer Ancestral Origins For Recently Admixed Individuals. *K. Noto, J.K. Byrnes, N. Myres, N. Angerhofer, S.R. Woodward, C.A. Ball, K. Chahine.* AncestryDNA, Provo, UT, USA.

Identification of individual ancestral origins from genetic data is useful in many fields including admixture analysis and medical genetics. Several approaches to this task have been developed, and most rely on allele frequency differences observed at single nucleotide polymorphisms (SNPs) to assign individuals to one or more ancestral source populations. In most cases, these methods assume marker independence, treating each SNP as an independent observation. With the advent of genotyping arrays in which millions of SNPs are typed, neighboring SNPs are frequently close enough to be in linkage disequilibrium (LD). In this case the alleles observed at neighboring SNPs are strongly correlated due to shared genetic history. Using this type of data requires LD thinning to remove linked pairs of SNPs and satisfy the independence assumption. Unfortunately LD thinning also removes significant amounts of information in the data, reducing assignment accuracy. This is particularly problematic in high resolution analyses, such as identifying countries of origin within Europe. Here we explore the possibility of using phased haplotypes in place of SNPs for ancestry inference. This work is motivated by our initial observation that each SNP contributes more than twice as much ancestry information when it is part of a haplotype. What is more, some previously developed ancestry inference methods such as FRAPPE accept multi-allelic data, readily lending themselves to use with haplotypes. To examine the effect of using haplotypes on ancestry inference, we apply an algorithm based on FRAPPE to estimate ancestry proportions from SNPs alone, and then from phased haplotypes built from the same SNP set. We then compare these estimates to known sample origins. This process is repeated for two European data sets with single-origin individuals; POPRES and an unpublished set of 1000 European samples with detailed pedigrees. In both cases, all four grandparents for each sample are confirmed to be from the same country. Next, using single-origin individuals as ancestors, we use a forward simulation to construct individuals with recent admixture between various European populations and compare estimated ancestry from haplotypes or SNPs to the known mixture proportions. Finally, we assemble sets of ancestry informative markers (AIMs) from SNPs and haplotypes and assess the performance of these selected sets.

3366T

Haplotype sharing distributions for fine-scale demographic reconstruction. *P. Palamara[1], T. Lencz[2], A. Darvasi[3], I. Pe'er[1,4].* 1) Department of Computer Science, Columbia University, New York, NY; 2) The Zucker Hillside Hospital Division of the North Shore-Long Island Jewish Health System, Glen Oaks, NY, USA; 3) Division of Psychiatry Research, The Zucker Hillside Hospital, The Feinstein Institute for Medical Research, North Shore - Long Island Jewish Health System, New York, NY; 4) Center for Computational Biology and Bioinformatics, Columbia University, New York, NY.

Identical-by-descent (IBD) chromosomal segments shared by pairs of individuals can now be reliably detected in large genomic datasets of purportedly unrelated samples, and summary statistics of IBD sharing were recently shown to convey information about population-level features such as demography, natural selection and heritability of common traits. However, while key theoretical quantities of IBD sharing have been extensively investigated in the context of pedigree structures, limited literature is available to describe IBD haplotypes in pairs of unrelated individuals from arbitrary populations. We present analytical results for the relationship between haplotype sharing and demographic history. We express the distribution of IBD sharing across pairs of individuals for segments of arbitrary length as a function of the population's demography. We derive a maximum-likelihood procedure for the inference of demographic parameters, and evaluate it using several datasets of 500 synthetic individuals. Analyzing a single chromosome, we reconstruct the population size within 3% of the true size in 95% of Wright-Fisher populations. For exponentially expanding or contracting populations, the reconstructed size is within 10% of the true size for the past 100 generations. We analyze genome-wide SNP data for 500 Ashkenazi Jewish individuals. The most likely scenario we reconstructed reveals two periods of expansion, separated by a strong bottleneck. A first period of mild growth ($r \approx .02$) leads to a population of ~60,000 individuals in the 12th century A.D. Following a severe bottleneck, the reconstructed scenario includes ~300 individuals rapidly ($r \approx .28$) expanding to ~4,000,000 in the past 32 generations. This demographic profile is consistent with historical accounts for the Ashkenazi population. We further analyze 56 Kenyan Masai individuals from the HapMap 3 dataset. High levels of cryptic relatedness are pervasive in this sample. While this may suggest a strong ($r \approx -.14$) recent bottleneck in this population, we show that a model of multiple small-sized demes interacting through high migration rates, consistent with the social structure of the Masai, results in a compatible pattern of haplotype sharing. This mismatch between single-population models and historically structured demographies may explain the observed abundance of runs of homozygosity within several outbred populations. An implementation of the described methods, DoRIS, is publicly available.

3367F

Inference of population splits and mixtures from genome-wide allele frequency data. *J.K. Pickrell[1], J.K. Pritchard[2,3].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Howard Hughes Medical Institute, University of Chicago, Chicago, IL.

Many aspects of the historical relationships between populations in a species are reflected in genetic data. Inferring these relationships from genetic data, however, remains a challenging task. In this paper, we present a statistical model for inferring the patterns of population splits and mixtures in multiple populations. In this model, the sampled populations in a species are related to their common ancestor through a graph of ancestral populations. Using genome-wide allele frequency data and a Gaussian approximation to genetic drift, we infer the structure of this graph. We applied this method to a set of 55 human populations and a set of 82 dog breeds and wild canids. In both species, we show that a simple bifurcating tree does not fully describe the data; in contrast, we infer many migration events. While some of the migration events that we find have been detected previously, many have not. For example, in the human data we infer that Cambodians trace approximately 16% of their ancestry to a population ancestral to other extant East Asian populations. In the dog data, we infer that both the boxer and basenji trace a considerable fraction of their ancestry (9% and 25%, respectively) to wolves subsequent to domestication, and that East Asian toy breeds (the Shih Tzu and the Pekingese) result from admixture between modern toy breeds and "ancient" Asian breeds. Software implementing the model described here, called TreeMix, is available at http://treemix.googlecode.com.

Inferring Y Chromosome Phylogeny by Sequencing Diverse Populations. *G.D. Poznik[1,2], P.A. Underhill[3], B.M. Henn[3], M.C. Yee[3], E. Sliwerska[4], G.M. Euskirchen[3], L. Quintana-Murci[5], E. Patin[5], M. Snyder[3], J.M. Kidd[4], C.D. Bustamante[3].* 1) Program in Biomedical Informatics, Stanford University School of Medicine, Stanford, CA; 2) Department of Statistics, Stanford University, Stanford, CA; 3) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 4) Department of Human Genetics, University of Michigan, Ann Arbour, MI; 5) Human Evolutionary Genetics Unit, Centre National de la Recherche Scientifique URA3012, Institut Pasteur, Paris, France.

The male-specific region of the Y chromosome (MSY) harbors the longest stretch of non-recombining DNA in the human genome and is therefore a unique tool that enables the tracking of migrations and inference of demographic history. We have sequenced 69 male samples from nine globally diverse populations, including three African hunter-gatherer groups. Due to inefficient selection, a relatively high mutation rate, and a small effective population size, the Y chromosome is particularly subject to drift. It has accumulated large expanses of highly repetitive sequence, which pose considerable challenge within a short read sequencing paradigm. To overcome this hurdle, we have built an informatics pipeline to reliably call Y chromosome alleles from moderate coverage short read shotgun sequence data. First, we defined a callability mask, learned from the mapping quality and depth of coverage patterns in the data, and then we tuned base-pair level quality control thresholds. Based on 13,000 provisional SNP calls, we inferred a tree of the 69 sequenced Y chromosomes. Using this tree, we then called individual genotypes for each SNP with a custom-built, phylogeny-aware, EM algorithm. With these high quality calls in hand, samples were assigned haplogroup labels using standard YCC nomenclature; 29 distinct named haplogroups were represented. We find that the maximum likelihood tree we construct recapitulates the extant Y chromosome phylogeny, thus confirming the fruits of decades of work based on ascertained SNPs. Further, we resolve a major long-standing polytomy by identifying a variant for which one haplogroup retains the ancestral allele, whereas its brother clades share the derived allele, thus indicating common ancestry and uniting the latter two branches. This finding has been confirmed by genotyping a larger panel. Finally, we estimate the MSY rate of mutation recurrence and the time to the most recent common ancestor of the sampled chromosomes.

Towards understanding the population substructure and ancestry in Kuwaiti population. *R. Rajagopalan, O. Alsmadi, F. Alkayal, G. Thareja, S. John, P. Hebbar, A. Thangavel.*Dasman Genome Centre Dasman Diabetes Institute PO BOX 1180 Dasman, Kuwait 15462.

Owing to high rate of consanguinity and well known genealogy in most families, the population of Kuwait offers a great opportunity in genetic epidemiology to map recessive components of monogenic and complex disorders as well. While much has been published in rare monogenic disorders from this region, we present here for the first time the genetic makeup of Kuwaiti population in the context of genome-wide runs of homozygosity (ROH) and Identity-By-Descent (IBD) among unrelated individuals. 124 unrelated Kuwaiti individuals were genotyped using Illumina Human OmniExpress platform and more than 700,000 SNPs were used in this analysis. We used fastIBD algorithm in Beagle software [Browning & Browning, 2011] to find shared genomic regions that are IBD in this dataset and found 13,097 segments greater than 2 Mb and average length of a segment was 4.4 Mb. There were 716 long IBD segments (>10 Mb) between 360 unique pairs of individuals and the average IBD length in that subset was 23.4 Mb. 119 out of 124 individuals had at least one IBD segment that is greater than 10 Mb. We then used PLINK [Purcell S et. al. 2007] to find 3074 ROH segments that are greater than 2 Mb with mean ROH size of 3 Mb. Total ROH length ranged from 11 Mb to 533 Mb with a mean of 75 Mb and number of segments ranged from 8 to 79 with a mean of 25. To find common ROHs, we calculated the frequency of each SNP falling into an ROH segment using a sliding window approach and found 23 segments in chromosomes 1, 10 and 17 with greater than 30% of individuals having an ROH, of which 10 with greater than 40%. We also inferred regions that are homozygous-by-descent (HBD) using Beagle to compare with ROH statistics from PLINK. Though, the number of ROH segments seems to be overestimated (mostly due to error in genotype calls), the total amount of HBD is nearly the same (r2 = 0.99). Results from IBD and ROH analyses suggest the existence of both recent and ancient shared ancestry among Kuwaiti population placing them between outbred and population isolates. This could well be used in advantage to better understand the population substructure of Kuwait and in general the Arabs. With high prevalence of complex diseases like Obesity and Diabetes in the region, we hope this will also serve as a tool to find recessive components of complex diseases and may help explain some of the missing heritability.

The evolutionary history of mutations associated with leukemia. *S. Ramachandran[1], M. Kantesaria[1], A. Walia[1], J. Yang[2].* 1) Ecology & Evolutionary Biol, Brown Univ, Providence, RI; 2) Pharmaceutical Sciences, St. Jude Children's Research Hospital, Memphis, TN.

Studies of worldwide human variation have repeatedly observed genome-wide signatures predicted by simulations of a serial founder effect, in which populations expand outward from Africa through a process where each population in the expansion is formed from a subset of the previous population in the expansion. Two of the genome-wide signatures are a decrease in heterozygosity at multiallelic markers with increasing distance from Africa and increasing linkage disequilibrium with increasing distance from Africa (Jakobsson et al. 2008, DeGiorgio et al. 2009). Genome-wide association studies (GWAS) of acute lymphoblastic leukemia have observed that both incidence and response to therapy exhibit racial disparities. A recent study confirmed that response to therapy co-segregates with Native American ancestry, even after adjusting for known prognostic factors (Yang et al. 2011). We examine haplotype variation at this and other loci in the genome using genome-wide data. We find that the evolutionary history of mutations associated with leukemia is consistent with a history of hitchhiking along with beneficial alleles in linkage disequilibrium with the risk alleles found through GWAS.

3371W

Identification of regions under selection in the Gullah African American population. *P.S. Ramos[1], S. Sajuthi[2], Y. Huang[3], J. Divers[2], K.M. Kaufman[4], J.B. Harley[4], R.P. Kimberly[5], D.L. Kamen[1], C.D. Langefeld[2], M.M. Sale[3], W.T. Garvey[6], G.S. Gilkeson[1].* 1) Department of Medicine, Medical University of South Carolina, Charleston, SC; 2) Department of Biostatistical Sciences and Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC; 3) Department of Medicine and Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 4) Division of Rheumatology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 5) Department of Medicine, University of Alabama at Birmingham, Birmingham, AL; 6) Department of Nutrition Sciences and Birmingham VA Medical Center, University of Alabama, Birmingham, AL.

PURPOSE: The Gullah are a unique population of African ancestry in the U.S. In addition to their genetic and environmental homogeneity and low European admixture (less than 3.5%), a shorter genetic distance between the Gullah and Sierra Leonean tribes has also been reported, suggesting that population genetic signals, such as regions under recent selection, may be more easily detected in the Gullah than in other African American (AA) populations. Given the increased prevalence of many common diseases in AA and the increasing evidence of selection at loci associated with human diseases, identification of alleles under selection may provide insight into disease susceptibility. Since population-specific selection may cause allele frequency differences, the goal of this study was to identify regions with minor allele frequency (MAF) differences between Gullah and Sierra Leoneans. METHODS: We had available 271 Gullah and 400 Sierra Leonean samples genotyped on the Illumina Human1M and Affymetrix Genome-Wide Human SNP Array 6.0, respectively. After stringent QC was applied to each population, 185,569 SNPs common to both arrays with MAF>5% were used to compute the significance of the MAF differences between the two populations. In order to exclude MAF differences that are spurious or assay artifacts, only regions where at least two SNPs in LD showed significant Bonferroni-adjusted MAF differences were considered. RESULTS: The largest region showing significant MAF differences between the Gullah and Sierra Leoneans was the MHC at 6p21.32, where multiple SNPs show P-values between E-06 and E-13, and has previously been shown to be under selection in other populations. The region showing the most significant MAF differences was that of the complement-regulatory CUB and Sushi multiple domains 1 precursor gene (CSMD1) at 8p23.2, where several SNPs show P-values between E-06 and E-25. Interestingly, this gene has been associated with, among other traits, emphysema, multiple sclerosis, insulin resistance in AA and coronary heart disease in AA. CONCLUSION: We have identified several regions with significant allele frequency differences between the Gullah and Sierra Leoneans, suggesting that population-specific selective pressures may be operating at these loci. Given the increased prevalence of many complex traits in AA and the homogeneity of the Gullah, identification of these regions in the Gullah has the potential to elucidate disease risks in AA.

3372T

A genomewide map of Neandertal ancestry in modern humans. *S. Sankararaman[1,2], N. Patterson[2], S. Mallick[1,2], S. Pääbo[3], D. Reich[1,2].* 1) Harvard Medical School, Boston, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany.

Analysis of the genomes of archaic hominins, such as Neandertals and Denisovans, has revealed that these groups have contributed to the genetic variation of modern human populations. Yet, we know little about how these ancient mixtures have shaped the genetic structure of human populations and even less about their impact on human evolution. To answer these questions, we need a map of archaic ancestry.

Building such a map is technically challenging because of the antiquity of these gene flow events. We have developed a method based on the statistical framework of Conditional Random Fields (CRFs) that integrates single SNPs as well as haplotypes informative of ancient gene flow to give highly accurate predictions.

We applied this method to polymorphism data in European and East Asian individuals from the 1000 genomes project, in conjunction with the draft sequence of the Neandertal genome, to obtain the first genome-wide map of Neandertal ancestry. Analysis of this map leads to several novel findings:

1. We identify around 35,000 Neandertal-derived alleles in Europeans and 21,000 in East Asians.

2. We also identify over 100 Neandertal-derived alleles that are likely to have been the target of selection since introgression. One of these has a frequency of about 85% in Europe and overlaps CLOCK, a key gene in Circadian function in mammals. This gene has been found in other selection scans in Eurasian populations, but has never before been linked to Neandertal gene flow.

3. Several of the Neandertal-derived alleles identified are found among the >6,000 SNPs associated with common diseases listed in the NHGRI catalog. This list of Neandertal-derived variants include a risk variant associated with obesity and a protective variant against breast cancer.

4. Using the uncorrelated ancestries in Europe and East Asia, we can reconstruct about 600 Mb of the genome of the introgressing Neandertal.

Genetic diversity and migration history of indigenous populations from the Central Valley of Mexico. *T. Schurr[1], M. Vilar[1], R. Gomez[2], H. Zillges[1], A. Sanders[1], A. Owings[1], J. Gaieski[1], The Genographic Consortium.* 1) Dept Anthropology, Univ Pennsylvania, Philadelphia, PA; 2) Dept Toxicologia, CINVESTAV Mexico City, Mexico.

Home to the Aztec Empire, the Central Valley of Mexico was the most densely populated area of North America upon the arrival of Europeans in the early 16th century. Today, more than a million indigenous people from a number of distinct linguistic groups inhabit this region, including the Otomi (Oto-Manguean family) and the Nahua, or former Aztec (Uto-Aztecan family). Although archeologically well-studied, this complex cultural and linguistic region remains genetically understudied.

In order to assess the genetic diversity of indigenous Mexicans and infer prehistoric patterns of interaction among Mesoamerican groups, we genotyped 536 participants from twenty-three communities in four Mexican states: Guanajuato, Hidalgo, Morelos and Queretaro. Genotyping included mtDNA haplogroup and haplotype identification through control region sequencing and coding-region SNP analysis; Y-chromosome haplogroup designation through SNP and STR typing; and admixture assessment through analysis of autosomal AIMs and STRs. The resulting genotypes were compared to those of dozens of other Native American populations.

MtDNA analyses of the Otomi revealed a very high frequency (>98%) and great diversity of the four major Native American haplogroups (A2, B2, C1, D1), and also the rare D4h3. The Nahua belonged mostly to haplgroups A (75%) and B (15%). Y-chromosome analysis also showed high frequency and haplotype diversity for indigenous haplogroup Q (>70%) among the Otomi, while the Nahua were nearly 100% for that haplogroup. In addition, autosomal analysis revealed a high percentage (>75%) of indigenous AIMs in both groups. The observed genetic patterns suggest that the two populations remained genetically differentiated, even after living in proximity for several millennia. The high frequency and diversity of haplogroup A2, as compared to that in other indigenous American populations, also suggests the Central Valley may have been the center of growth and expansion for that pan-American haplogroup, one possibly associated with the domestication and spread of Mesoamerican crops such as maize. The high frequency of both haploid and bi-parental indigenous markers further suggests that the Central Valley experienced limited African and European genetic introgression in the 500 years since Spanish colonization.

Unexpected relationships and inbreeding in HapMap phase III populations. *E. Stevens[1], J. Baugher[2], M. Shirley[2], L. Frelin[3], J. Pevsner[3,4].* 1) Human Genetics, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Biochemistry, Cellular, and Molecular Biology, Johns Hopkins Univ Sch Med, Baltimore, MD; 3) Neurology, Hugo W. Moser Research Institute at Kennedy Krieger, Baltimore, MD; 4) Psychiatry and Behavioral Sciences, Johns Hopkins Univ Sch Med, Baltimore, MD.

Correct annotation of the genetic relationships between samples is essential for population genomic studies that could be biased by errors or omissions. To this end, we used identity-by-state (IBS) and identity-by-descent (IBD) methods to assess genetic relatedness of individuals within HapMap Phase III. We analyzed data from 1,397 individuals from 11 ethnic populations. Our results support previous studies (Pemberton et al., 2010; Kyriazopoulou-Panagiotopouloue et al., 2011) assessing unknown relatedness present within this population. Additionally, we present evidence for 1,657 novel pairwise relationships across 9 populations. Surprisingly, significant IBD1 values were estimated between known parents. Furthermore, significant IBD2 values were estimated in 32 previously annotated parent-child relationships. Consistent with a hypothesis of inbreeding, regions of homozygosity (ROH) were identified in which a subset overlapped those reported in previous studies (Gibson et al. 2010; Johnson et al. 2011) in the offspring of related parents. In total, we inferred 25 inbred individuals with ROH that overlapped areas of relatedness between the parents and/or IBD2 sharing at a different genomic locus between a child and a parent. Finally, 8 previously annotated parent-child relationships had unexpected IBD0 values (indicative of a deletion or genotype errors), and 10 previously annotated second-degree relationships along with 38 other novel pairwise relationships had unexpected IBD2 (indicating two separate paths of recent ancestry). These newly described types of relatedness may impact the outcome of previous studies and should inform the design of future studies relying on the HapMap Phase III resource.

Class I MHC region genetic markers have different dinamics than neutral genomic regions in Brazilian populations. *R.C.P. Toledo[1], A.C. Arcanjo[1], C.T. Mendes-Júnior[2], E.C. Castelli[3], J.A. Peña[4], R.V. Andrade[5], M.N. Klautau-Guimarães[1], S.F. Oliveira[1].* 1) Programa de Pós-Graduação em Biologia Animal, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, Distrito Federal, Brazil; 2) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, São Paulo, Brazil; 3) Departamento de Biologia Geral, Instituto de Ciências Biológicas, Universidade Federal de Goiás, Goiânia, Goiás, Brazil; 4) Departamento de Genetica y Antropología Física, Facultad de Ciencia y Tecnología, Universidad del País Vasco, Bilbao, Spain; 5) Pró-Reitoria de Pós-Graduação e Pesquisa, Universidade Católica de Brasília, Brasília, Distrito Federal, Brazil.

Brasília and Kalunga are Brazilian Midwest populations with different settlement history as well as genetic constitution. Kalunga is a rural afro-descendent population, established in the 19th century, formed by runaway afro-descendent slaves, whereas Brasília is an urban population, established in 1960 with the transfer of the capital of Brazil from the Southeast region. These populations were previously analyzed with neutral genetic markers such as AIMs, autosomic STRs, DNAmt and chromosome-Y markers which have shown, solely and altogether, that those are two distinct populations, with very different genetic structure. It has been suggested that the MHC region of the human genome might be under selection, and therefore do not behave as neutral regions. In this work, a set of loci in the Class I MHC region was analyzed to verify whether both those populations behave equally regarding markers under selection. The set of markers included five Alu insertions (MICB, TF, HJ, HG and HF) comprising the whole Class I MHC, and a 360bp sequence in the 3'UTR region of the HLA-G gene. Statistical analysis included linkage disequilibrium, haplotypic inference, population differentiation, Hardy-Weinberg Equilibrium and neutrality tests. Eight different SNPs were observed in the 3'UTR region: indel 14pb, +3003C/T, +3010G/C, +3027 A/C, +3035 C/T, +3142 G/C, +3187 G/A and +3196 G/C. All 13 loci in both populations were in HWE and Kalunga showed heterozygote excess for the AluHG locus. Brasília showed 11 3'UTR haplotypes and 21 Alu insertion haplotypes, while Kalunga presented 9 3'UTR haplotypes and 18 Alu haplotypes. The Ewens-Watterson neutrality test showed significant values only for the 3'UTR region (Brasília: F=-1.4140, $p<0.05$; Kalunga: F=-1.6354, $p<0.05$). Attempting to confirm these results, Tajima's D and Fu & Li's F tests were estimated for the 3'UTR region, but only Brasília showed significant values (D=2.1419, $p<0.05$; F=1.8458, $p<0.05$). Population differentiation test (FST) showed similarity between Brasília and Kalunga for the whole (FST = 0.01526) and separate sets (3'UTR: 0.01320; Alu: 0.01916) of markers. Therefore, there is indication of ongoing selection in the HLA-G 3'UTR, but not in the Class I MHC Alu insertions. Also, both populations are similar regarding the Class I MHC region, contrasting with results previously described using genetic markers located within genomic neutral regions. Coalescence-based Estimation of Population History in the Presence of Admixture from Genetic Variation Data. *M. Tsai[1], G. Blelloch[2], R. Ravi[3], R. Schwartz[4].* 1) Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 2) Department of Computer Science, Carnegie Mellon University, Pittsburgh, PA; 3) Tepper School of Business, Carnegie Mellon University, Pittsburgh, PA; 4) Department of Biological Science, Carnegie Mellon University, Pittsburgh, PA 15238.

Learning how modern human populations have arisen, dispersed, and intermixed since we emerged as a species is an important but challenging problem. Learning precisely how the human population is structured and how different subgroups are related to one another is not only a fundamental issue in understanding human origins, but also has practical relevance to improving models of genome evolution and better controlling for population substructure in association studies. Despite considerable attention to the general problem of identifying population substructure in large-scale variation data, the field lacks automated methods for reconstructing the relationships among population subgroups and the process by which such substructure has emerged over time (the population history). One especially challenging problem in such inference is inferring correct orders and timing of events in the presence of admixture. We describe here a novel two-step approach for joint inference of a quantitative population history in the presence of admixture from large variation datasets. The method first identifies a set of phylogenetic splits that are likely have occurred during the evolutionary history and assign each observed variation site to one of the splits. The resulting split set and the number of variation sites assigned to each split are then used to infer a model of population-level evolution describing times of the divergence and admixture events as well as admixture proportions using a coalescence-based Markov chain. To evaluate the algorithm, we generated a series of simulated data sets consisting of combinations of parental and admixed populations. On simple models of two parental and one admixed population, our algorithm reliably identifies the true population model and provides reasonable estimates of event times and admixture parameters. Performance degrades on more complicated admixture scenarios, but still shows at least 70% accuracy for four-population, two-admixture scenarios at identifying the correct model as the maximum likelihood scenario. The results suggest that automated reconstruction of complex population histories in the presence of admixture from genome-scale data is feasible, although further algorithmic improvements may be needed to infer more complicated scenarios.

Background: The Genographic Project is an international effort aimed at charting human history using genetic data. The project is non-profit and non-medical, and through the sale of its public participation kits it supports cultural preservation efforts in indigenous and traditional communities. To extend our knowledge of the human journey, interbreeding with ancient hominins, and modern human demographic history, we designed a genotyping chip optimized for genetic anthropology research. **Methods:** Our goal was to design, produce, and validate a SNP array dedicated to genetic anthropology. The GenoChip is an Illumina HD iSelect genotyping bead array with over 130,000 highly informative autosomal and X-chromosomal SNPs ascertained from over 450 worldwide populations, ~13,000 Y-chromosomal SNPs, and ~3,000 mtDNA SNPs. To determine the extent of gene flow from archaic hominins to modern humans, we included over 25,000 SNPs from candidate regions of interbreeding between extinct hominins (Neanderthal and Denisovan) and modern humans. To avoid any inadvertent medical testing we filtered out all SNPs that have known or suspected health or functional associations. We validated the chip by genotyping over 1,000 samples from 1000 Genomes, Family Tree DNA, and Genographic Project populations. **Results:** The concordance between the GenoChip and the 1000 Genomes data was over 99.5%. The GenoChip has a SNP density of approximately (1/100,000) bases over 92% of the human genome and is highly compatible with Illumina and Affymetrix commercial platforms. The ~10,000 novel Y SNPs included on the chip have greatly refined our understanding of the Y-chromosome phylogenetic tree. By including Y and mtDNA SNPs on an unprecedented scale, the GenoChip is able to delineate extremely detailed human migratory paths. The autosomal and X-chromosomal markers included on the GenoChip have revealed novel patterns of ancestry that shed a detailed new light on human history. Interbreeding analysis with extinct hominids confirmed some previous reports and allowed us to describe the modern geographical distribution of these markers in detail. **Conclusions:** The GenoChip is the first genotyping chip completely dedicated to genetic anthropology with no known medically relevant markers. We anticipate that the large-scale application of the GenoChip using the Genographic Project's diverse sample collection will provide new insights into genetic anthropology and human history.

Genetic, Genomic and Phenotypic Characterization of Qinghai Mongolians. *J. Xing[1, 2], U. Tanna[3], T.S. Simonson[2, 4], W.S. Watkins[2], D.J. Witherspoon[2], W. Wu[2], G. Qing[3], C.D. Huff[2, 5], L.B. Jorde[2], R.L. Ge[3].* 1) Department of Genetics, Rutgers, the State University of New Jersey, Piscataway, NJ; 2) Department of Human Genetics, University of Utah, Salt Lake City, UT; 3) Research Center for High Altitude Medicine, Qinghai University Medical School, Xining, Qinghai, People's Republic of China; 4) Department of Genetics, University of California in San Diego, San Diego, CA; 5) Department of Epidemiology, the University of Texas M.D. Anderson Cancer Center, Houston, TX.

Qinghai Mongolians (QH Mongolians) migrated from the Mongolian steppes to the Qinghai-Tibetan Plateau approximately 500 years ago. Living at about 3000 meters, QH Mongolians have been challenged by extreme environmental conditions similar to neighboring highland Tibetans, including metabolic demands imposed by diet, cold, and to a lesser degree, hypobaric hypoxia. Identification of adaptive genetic factors in this population could provide insight into coordinated physiological responses to these extreme conditions. In this study, we examined genetic and phenotypic variation in 42 QH Mongolian individuals. Using high-density SNP array data, we demonstrate that QH Mongolians represent a distinct population from the neighboring Tibetan, Buryat, and Han Chinese populations (Fst = 0.008 in all cases). We then performed a genome-wide selection scan in QH Mongolians and compared the selection candidates with other Mongolian and Tibetan populations. Our analyses identified a number of selection candidates that are shared between Mongolians or between Mongolians and Tibetans, including genes involved in body composition and hypoxia-related selection candidate genes previously identified in Tibetans. To understand the genomic variation and identify potential functional variants in QH Mongolians, we performed whole-genome sequencing on a QH Mongolian individual (Tianjiao1). Mitochondrial DNA (MtDNA) and Y-chromosome lineage assignment put Tianjiao1 in the H18 and Q1a1 haplogroups, respectively. Overall, we found more than 2% of the variants in the Tianjiao1 genome are not present in other populations, including more than 1,000 coding variants. Lastly, to determine the phenotypic variation in QH Mongolians, we collected a number of phenotypic traits, including levels of hemoglobin (Hb) and several metabolites. QH Mongolians have a significant lower Hb level compared to Tibetans, and the putative selected Tibetan haplotypes showed no significant association with Hb level for QH Mongolians. Overall, our study showed that QH Mongolians share genetic ancestry with Tibetan populations as well as other Mongolian populations. They present a good candidate population for studying adaptation to extreme conditions.

Paleolithic human migrations in East Eurasia by sequencing Y chromosomes. *S. Yan[1,2], C.C. Wang[1], L. Jin[1,2].* 1) MOE Key Lab of Contemporary Anthorpology, Fudan University, Shanghai, China; 2) Computational Genetics, CAS-MPG Partner Institute for Computational Biology, Shanghai, China.

Paleolithic human migrations in East Eurasia remains largely unknown due to the lack of sufficient markers derived from the mutations that occurred during that time frame. To tackle this problem, using the sequence capturing, barcoding technology and next-generation sequencing, we identified more than 4,000 new SNPs encompassing most single copy non-recombining region of human Y chromosome. New clades for haplogroups O, C, N, D, and Q could be geographically located. Especially, a few star-like expansions were unveiled, showing strong population growth. The phylogeny of Haplogroup N was radically rearranged, and all the N individuals could now be categorized into either a northern clade N1 or southern clade N2, revealing a Paleolithic migratory routes of the ancestors of Uralic speaking populations. Haplogroup C, especially the East Eurasia-dominant clade C3, could also be separated into at least two ancient clades, suggesting Paleolithic migrations in East Asia. Three major clades under O, M117+, M134xM117, and 002611+, each could be now further classified into several subclades. With these new findings, we proposed the modified the routes and dates for human populations' migration, especially those in Paleolithic time. A few Y-chromosomal expansions could now be linked to certain prehistoric cultures or ancestors of language families.

Reconstructing the history of Indigenous American populations from the Thousand Genomes Project admixed populations of the Americas. *F. Zakharia[1], M. Muzzio[1, 2, 3], K. Sandoval[1], A. Moreno-Estrada[1], S. Gravel[1], J. Byrnes[4], C.R. Guignoux[7], J.L. Rodriguez-Flores[6], B. Maples[1], W. Guiblet[5], J. Dutil[8], E.E. Kenny[1], A.W. Bigham[10], M.D. Shriver[11], . The 1000 Genomes Consortium[12], A. Ruiz-Linares[9], T.K. Oleksyk[5], J.C. Martinez-Cruzado[5], E. Gonzalez Burchard[7], C.D. Bustamante[1].* 1) Department of Genetics, School of Medicine, Stanford University, Stanford, CA, USA; 2) Facultad de Ciencias Naturales, Universidad Nacional de La Plata, 1900, Argentina; 3) IMBICE CCT-La Plata, CONICET, 1900, Argentina; 4) Ancestry.com; 5) Department of Biology, University of Puerto Rico at Mayagüez, Puerto Rico; 6) Department of Genetic Medicine, Weill Cornell Medical College, New York, NY, USA; 7) Institute for Human Genetics, University of California San Francisco, CA, USA; 8) Ponce School of Medicine, Puerto Rico; 9) Department of Genetics, Evolution and Environment. University College London, UK; 10) University of Michigan, Ann Arbor, MI, USA; 11) Penn State University, University Park, PA, USA; 12) The 1000 Genomes Project.

The Americas exhibit a rich cultural and biological diversity, including many countries with different languages, and have been deeply affected by historical events such as the arrival of the Europeans in the late 15th century. Yet little is known about the original peopling of the Americas, or about the interactions that may have taken place between the early settlers. The Thousand Genomes Project (TGP) has generated low coverage whole genome sequence, high coverage exome sequence and high quality genotype calls for three admixed populations from the Americas: Puerto Rico (PUR), Colombia (CLM), and Mexico (MXL). This dataset not only provides novel insights into these admixed populations, but also offers a unique opportunity to explore the genetics of their respective Indigenous American (IA) ancestors. To this end, we performed local ancestry deconvolution to identify tracts of IA ancestry in each of the admixed individuals in the sample. We found that the PUR, CLM and MXL populations contain an average 12%, 24%, and 47%; IA ancestry, respectively, and that 99.9%; of genomic sites are covered by at least one IA chromosome, with an average coverage of 17X, 35X, and 54X IA chromosomes for the PUR, CLM, and MXL respectively. We developed ancestry-specific (AS) extensions of both PCA and ADMIXTURE (PCA-AS and ADMIXTURE-AS) to analyze population structure considering only the IA components of ancestry in the admixed TGP genomes. We trained these methods using a large dataset comprising 493 participants from 52 IA populations across the Americas, genotyped at high density. We found that IA components in admixed individuals cluster with different linguistic groups, with the MXL and CLM appearing to be closest to Northern Amerind and Chibchan-Paezan speaking groups respectively, and the PUR near Equatorial-Tucanoan speaking populations endemic to the Amazon. Finally, we used the joint site frequency spectra of the admixed populations to make novel inferences about the demographic history of their IA ancestors. Preliminary results estimate an initial split of the MXL ancestors from the others around 12.5 kya, followed by the divergence of the PUR and CLM ancestors around 8 kya. We also found evidence of strong bottlenecking events in the PUR and CLM lineages, consistent with the low levels of heterozygosity observed in these populations.

The genetic aspect of the Slavic settlement in the East Alps region. *A. ZUPAN[1], K. VRABEC[1], T. DOV{{Cak}} DRNOV{{Sak}}EK[2], D. GLAVA{{Cak}}[1].* 1) Department for Molecular Genetics, Institute for Pathology, Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia; 2) Blood Transfusion Centre of Slovenia, Ljubljana, Slovenia.

The territory of East Alps region experienced turbulent historical events which are reflected in different archeological cultures found in this area. The archeology findings and historical writings from the sixth century A.D. revealed a sharp social transition from Roman-type social structure to unimpressive pan-Slavic social structure. The main reason for the social transition is contributed to the degradation of the Roman Empire and to the Slavic settlements. However, the historical process of the Slavic settlement in the territory of East Alps and the impact it had on the Romanized indigenous population was not convincingly resolved by the archaeological, ethnological, topological and linguistic studies. In order to provide a genetic aspect on the Slavic settlement of the East Alps region and to reconstruct past demographic events, we analyzed 42 Y-chromosome biallelic markers and 17 Y-chromosome short tandem repeats (Y-STR) in 399 Slovenians from five geographical regions. The biallelic genetic markers revealed 29 haplogroups, with the most common being R1a1a* (M198), R1b1b1a1 (xL11), I2a1 (M423) and I1* (M253). To obtain phylogenetic relationships between different populations, the biallelic and Y-STR data were compared with the data obtained from eleven Slavic and three non-Slavic populations across central Europe and Balkan. Two different Slavic clusters emerged from principal component analysis (PCA), based on frequency of bialellic markers and from multi dimensional scaling analysis (MDS), based on Y-STRs. One cluster encompassed West-Slavic groups, together with the population of Slovenia and the second encompassed the Balkan states. The genetic affiliation of Slovenian population with West-Slavic groups was additionally confirmed by the analysis of molecular variance (AMOVA) which showed the highest genetic variation among groups, when the Slovenian population was grouped together with other West-Slavic populations. The genetic data suggests a dominant North Slavic migration route into the area of East Alps region, through a process of demic diffusion, which allowed cohabitation and subsequent assimilation of indigenous Romanized population. The population genetic results from this study, when combined with archeological findings and historical writings, provide a new insight into the process of Slavic migrations into the territory of East Alps region and beyond.

Principal component analysis produces an inaccurate representation of population structure under certain conditions. *J. Bentham[1], D.L. Morris[1], D.S. Cunninghame Graham[1], C.L. Pinder[1], V. Anand[1], J.E. Wither[2], J.D. Rioux[3], M.E. Alarcón-Riquelme[4,5], T.J. Vyse[1].* 1) Department of Medical and Molecular Genetics, Division of Genetics and Molecular Medicine, King's College London, UK; 2) Toronto Western Hospital, Main Pavilion, 399 Bathurst St, Toronto, Ontario, M5T 2S8, Canada; 3) Montreal Heart Institute, Université de Montréal, 5000 rue Belanger, Montreal, Quebec, H1T 1C8, Canada; 4) GENYO, Centro de Genómica e Investigación Oncológica Pfizer, Universidad de Granada, Junta de Andalucía, Avenida de la Ilustración 114, 18007 Granada, Spain; 5) Arthritis and Clinical Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, 73104, USA.

The successes of genome-wide association studies have produced an explosion in the number of loci associated with genetically inherited diseases. Whilst many results have been replicated robustly, other loci identified appear to be false positives. Although false positive associations may be caused by various sources of systematic error, our results relate to one well-known cause of inflation of test statistics, population structure; we show that when using principal component analysis (PCA), individuals with very different ancestries may appear together, having values of zero for each principal component.

Population structure has long been recognised as a potential cause of false positives; study designs mean that subjects may be heterogeneous in ancestry, and where there are both different allele frequencies and disease prevalence between groups of subjects, spurious associations with disease may be identified. One method used to counteract this problem is to carry out PCA and use the first few principal components as covariates in logistic regression; this method relies on the principal components accurately reflecting population structure. We suggest that a proportion of false positive associations are caused by a deterministic problem encountered when applying PCA to genotype data.

We show that for the high dimensional datasets produced by genome-wide studies, PCA can fail to identify gross population outliers. Under certain conditions, the eigenvectors of subjects from different continents are superimposed on the origin of the principal component space; this is an effect of the curse of dimensionality, a set of phenomena associated with high dimensional spaces. The complete loss of information describing the ancestry of these subjects causes unacceptable inflation of the Type I error rate; counterintuitively, this effect is more likely to occur as the number of SNPs used to calculate principal components increases.We provide two examples of the effect: the first uses a dataset taken from a large genome-wide association study of systemic lupus erythematosus; the second uses simulated data. We explain how the outliers may be identified and removed; in our lupus GWAS the inflation factor was reduced from 1.9 to 1.1 by removing 200 samples found at the origin in our initial PCA.

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: Local ancestry estimations in the admixed individuals of the Genetic Epidemiology Research on Aging (GERA) cohort. *S.I. Candille[1], N.A. Johnson[1], Y. Banda[2], T. Hoffman[2], M. Kvale[2], C. Sabatti[3], S. Hesselson[2], P.Y. Kwok[2], C. Schaefer[4], N. Risch[2,4], H. Tang[1].* 1) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 2) Institute for Human Genetics, University of California, San Francisco, CA; 3) Department of Health Research and Policy, Stanford University School of Medicine, Stanford, CA; 4) Kaiser Permanente Research Program on Genes, Environment and Health, Kaiser Permanente Northern California Division of Research, Oakland, CA.

Individuals with recent ancestors from different continents have admixed genomes composed of discernible blocks of sequence inherited from genetically distinct populations. Knowledge of these blocks, their length and position within the genome enables population genetic inferences of the timing and characteristics of admixture events. Admixture mapping uses the information contained in admixed genomes to identify trait loci, for which risk variants occur at different frequencies between ancestral populations. The Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort, part of the Kaiser Permanente Research Program on Genes, Environment and Health (RPGEH), is a cohort of over 100,000 individuals recruited in Northern California. While the majority of subjects are of European ancestry, the cohort also comprises a large number of individuals presenting genetic admixture between continents including ~3000 African Americans, ~8000 Latinos, and ~1560 Filipinos. To develop a resource for population genetics and genotype/phenotype correlation studies in the GERA cohort admixed groups, we used the software SABER+ to estimate local genetic ancestry at a set of genome-wide polymorphisms for each individual. These local ancestry estimates can be used to perform admixture mapping of quantitative traits and we present our results on the mapping of several important traits displaying ethnic variation in these groups. The ethnically diverse GERA cohort represents a unique opportunity to extend the benefits of genetic research until now largely focused on populations of European descent to several admixed groups.

Multi-way admixture deconvolution using phased or unphased ancestral panels. *C. Churchhouse, J. Marchini.* Statistics, Univ Oxford, Oxford, United Kingdom.

Large collaborative projects have provided a resource of high quality genetic data on a variety of populations across the world, from a wider range of geographic locations than previously sampled including populations that are known to be admixed. An increasing number of disease association studies are being conducted in admixed individuals, such as African Americans and Latinos, and the variation in ancestry within these groups is being utilised to carry out admixture mapping. In such practices, it is important to be able to accurately decompose the population of origin along the genome of an individual with a mixed ancestral background. We have a developed a method named MULTIMIX that can perform ancestry inference in admixed individuals. MULTIMIX is novel in possessing all of the following features (a) the method can handle any number of ancestral populations, making it especially useful for analysing individuals with ancestry from three or more populations, (b) it is applicable to a dense set of genome-wide linked SNPs, (c) it will make use of phased ancestral haplotypes if they are available, but is also applicable to unphased panels of ancestral genotypes, (d) the admixed samples may be analysed as either phased or unphased, (e) the statistical model underlying our method that describes the distribution of the haplotype/genotype given the ancestry of the admixed sample makes MULTIMIX very fast to implement and capable of handling whole-genome analysis even in the case of more than two ancestral populations. We illustrate our approach using simulated data and show that we obtain up to 99.79% correct ancestry calls in European and African admixed samples and up to 99.42% in European, African and Chinese samples. We also demonstrate our method applied to real data from the HGDP and 1000 Genomes project and show that it calls 94.3% of the genome of the Mexican individuals of HapMap3 with a confidence of at least 95%.

3385F

A panel of ancestry informative markers for the South African Coloured population. *M. Daya[1], L. Van der Merwe[2], M. Möller[1], E. Hoal[1], C.R. Gignoux[3], J.M. Galanter[3], B.M Henn[3].* 1) Human Gen & Molecular Biol, Stellenbosch Univ, Cape Town, Tygerberg, South Africa; 2) Biostatistics Unit, Medical Research Council, Tygerberg, South Africa; 3) University of California San Francisco, San Francisco, California, United States of America.

Admixture is a well known confounder in genetic association studies. If genome-wide data is not available, as would be the case for candidate gene studies, ancestry informative markers (AIMs) are required in order to adjust for admixture. Previous work has shown that the South African Coloured population has 5 ancestral populations: African San, African non-San, European, South Asian and East Asian. Consequently, none of the existing published AIM sets can be applied to the population. Using genome-wide data to find SNPs with large allele frequency differences between ancestral populations, as quantified by Rosenberg et. al's *In* statistic, we developed a panel of AIMs for the South African Coloured population by experimenting with various selection strategies. Subsets of different sizes were evaluated by measuring the correlation between ancestry proportions estimated by each AIM subset with ancestry proportions estimated using genome-wide data. Since the accuracy of subsets converge with increasing size, we used linear mixed-effects modelling to select the optimal subset of markers.

3386W

A scalable pipeline for local ancestry inference using thousands of reference individuals. *C.B. Do, E. Durand, J.M. Macpherson, B. Naughton, J.L. Mountain.* 23andMe, Inc, Mountain View, CA.

Ancestry deconvolution, the task of identifying the ancestral origin of chromosomal segments in admixed individuals, is straightforward when the ancestral populations considered are sufficiently distinct. To date, however, no approaches have been shown to be effective at distinguishing between closely related populations (e.g., within Europe). Moreover, due to their computational complexity, most existing methods for ancestry deconvolution are unsuitable for application in large-scale settings, where the reference panels used contain thousands of individuals.

We describe Ancestry Painting 2.0, a modular three-stage pipeline for efficiently and accurately identifying the ancestral origin of chromosomal segments in admixed individuals. In the first stage, an out-of-sample extension of the BEAGLE phasing algorithm is used to generate a preliminary phasing for an unphased, genotyped individual. In the second stage, a support vector machine (SVM) using a specialized string kernel assigns tentative ancestry labels to short local phased genomic regions. In the third stage, an autoregressive pair hidden Markov model simultaneously corrects phasing errors and produces reconciled local ancestry estimates and confidence scores based on the SVM labels.

We compiled a reference panel of over 7,500 individuals of homogeneous ancestry, derived from a combination of several publicly available datasets and over 5,000 individuals reporting four grandparents with the same country-of-origin from the customer database of the personal genetics company, 23andMe, Inc, and excluding outliers identified through principal components analysis (PCA). In cross-validation experiments, Ancestry Painting 2.0 achieves high sensitivity and specificity (in most cases >90%) for labeling chromosomal segments across over 20 different populations worldwide. We also demonstrate the robustness of the algorithm via simulations of individuals of known local admixture, and compare Ancestry Painting 2.0 with existing state-of-the-art tools for multi-population local and global ancestry inference, including LAMP, ALLOY, PCA-ADMIX, and ADMIXTURE.

3387T

Global genome-wide variations comparisons show a generally homogeneous Levant that has been recently structured by culture. *M. Haber[1,2], D. Comas[1], P.A. Zalloua[2,3].* 1) Institut de Biologia Evolutiva (CSIC-UPF), Departament de Ciències de la Salut i de la Vida, Universitat Pompeu Fabra, 08003 Barcelona, Spain; 2) The Lebanese American University, Chouran, Beirut, Lebanon; 3) Harvard School of Public Health, Boston, MA 02215, USA.

Background: The Levant is a region in the Middle East with an impressive record of continuous human existence and major cultural developments that has been well documented since the Paleolithic. Genetic and archeological studies present solid evidence in placing the Middle East and the Arabian Peninsula as the first stepping grounds outside Africa. There is however little understanding of how the Middle East, and more precisely the Levant, was populated since the first Out of Africa Expansion, and how the Levantines genetically relate to each other and to their neighbors. **Methods:** We analyze newly generated genome-wide data from 1,341 subjects from Lebanon with complete demographic information in the context of already published data of 994 individuals from 48 global populations. We implement a series of cluster and structure-like analyses on unlinked SNPs (more than 200,000 SNPs), we also construct a co-ancestry matrix using information from haplotypes phased from more than 500,000 linked SNPs. We use this information to generate a novel population relationship tree and to identify genetic components specific to the Levantines. **Results:** We show that fine stratifications within the Levant are highly influenced by the religious affiliation of the populations within the region. We find a Levantine substructure that is distinctly split into two ancestral branches; one sharing more genetic characteristics with modern day Europeans and Central Asians while the other sharing more genetic characteristics with other Middle Easterners and Africans. Finally, we identify a Levantine component that has diverged from other Middle Easterners ~23,700–15,500 years ago during the last glacial period, and diverged from Europeans ~15,900–9,100 years ago at the start of the Neolithic. **Conclusions:** We show for the first time that the Levantines are today genetically closer to Europeans than to other Middle Easterners. We found that the Levantines and Europeans diverged at the start of the Neolithic age, giving support to a replacement model of Neolithic expansion rather than upper Paleolithic continuity of Europeans. Finally, we show that although population movements and expansions during the Epipaleolithic marked the emergence of a Levantine component and made the Levantines genetically similar, recent cultural developments, such as the inception and spread of religion, have had an impact on fine-scale population stratifications in the Levant.

Human and *Helicobacter pylori* Ancestries in Colombian Populations with Contrasting Risks of Gastric Cancer. *N. Kodaman[1], A. Pazos[2, 8], M.B. Piazuelo[2], B.G. Schneider[2], C.L. Shaffer[3], J. Romero-Gallo[2], T. de Sablet[2,7], L.E. Bravo[4], K. Wilson[2,5,7], T. Cover[3,6,7], P. Correa[2], S. Williams[1].* 1) Center for Human Genetics, Vanderbilt University, Nashville, TN; 2) Division of Gastroenterology, Department of Medicine, Vanderbilt University School of Medicine, Nashville, TN; 3) Department of Pathology, Microbiology and Immunology, Vanderbilt University School of Medicine, Nashville, TN; 4) Department of Pathology, Universidad del Valle School of Medicine, Cali, Colombia; 5) Department of Cancer Biology, Vanderbilt University School of Medicine, Nashville, TN; 6) Division of Infectious Diseases, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 7) Veterans Affairs Tennessee Valley Healthcare System, Nashville, TN; 8) Universidad de Nariño, Pasto, Colombia.

Helicobacter pylori, a chronic gastric pathogen that infects more than half of all humans, is the principal cause of gastric cancer, the second leading cause of cancer mortality worldwide. *H. pylori* infects over 90% of some Colombian populations, with individuals living in the Andean mountain region 25 times more likely to develop gastric cancer than their coastal counterparts, despite similar rates of infection. *H. pylori* strains undergo frequent recombination and thus often contain the genetic signatures of multiple ancestral populations. Previous studies have used the Bayesian clustering algorithm STRUCTURE to uncover six such populations, believed to have evolved in geographical isolation. Using multi-locus sequencing data from those studies and from *H. pylori* isolates obtained from gastric biopsies of 188 Colombian subjects, we found that Colombian strains derive mainly from three previously characterized ancestral *H. pylori*populations: ancestral Africa1 (AA1), ancestral Europe1 (AE1), and ancestral Europe2 (AE2), with most isolates containing genomic regions from all three. Distribution of strain ancestry varied with geography, with AA1 the major ancestral cluster in coastal region samples (mean=50.3%, N=78), and AE1 the major cluster in mountain region samples (mean=51.2%, N=110). We also used STRUCTURE to analyze 8181 loci from an Immunochip study of the biopsied individuals to assess human ancestry. Distributions of human ancestry also varied with geography, with mean proportions of 10.4% European, 54.4% African, and 35.2% Amerindian ancestry in the coastal region, and 13.4% European and 85.8% Amerindian ancestry in the mountain region. Proportion of Amerindian ancestry correlated strongly with the proportion of AA1, AE1, and AE2 ancestry in biopsy isolates ($r = -0.64$, $r=0.58$, $r=0.42$, respectively, with $p<0.001$ for all three). This is the first study to quantitatively assess human and *H. pylori* ancestry in a large number of Colombians. Our findings provide insight into the gastric cancer risk discrepancy between geographically stratified Colombian populations.

3389W

Deep ancestry within a Neandertal-like region on human chromosome 12. *F.L. Mendez[1], J.C. Watkins[2], M.F. Hammer[1].* 1) Arizona Research Laboratories, University of Arizona, Tucson, AZ; 2) Department of Mathematics, University of Arizona, Tucson, AZ.

The importance of the archaic ancestry of modern humans is becoming a topic of increasing interest. The identification of introgressive sequences for which a Neandertal ancestry can be assigned with confidence is essential to correctly characterize the process of introgression, understand the phenotypic consequences of introgression and study the population structure of archaic and modern humans. With a new method of analysis that provides high confidence estimates for sequences with high error rates we identify a region in chromosome 12 that has introgressed from Neandertals into modern humans, we characterize its geographic distribution and observe levels of intra-allelic variation. Furthermore, we analyze how levels of divergence change along the sequence. Consistent with previous expectations we find that the introgressive allele is mostly restricted to Eurasians, exhibits low levels of diversity and has introgressed recently into modern humans. In addition, we observe that segments of very deep divergence suggest a complex demographic scenario for the ancestry of Neandertals.

3390T

Sub-continental ancestry of admixed Caribbean populations and implications for medical genomics in the Americas. *A. Moreno Estrada[1], S. Gravel[1], M.L. Cuccaro[2], F. Zakharia[1], P. Ortiz-Tello[1], R.J. Martinez[2], J.L. McCauley[2], E.E. Kenny[1], D.J. Hedges[2], R.W. Morris[2], J.K. Byrnes[1], S. Acevedo[3], P.J. Norman[4], Z. Layrisse[5], P. Parham[4], C.D. Bustamante[1], E.R. Martin[2].* 1) Genetics, Stanford University, Stanford, CA; 2) Center for Genetic Epidemiology and Statistical Genetics, University of Miami Miller School of Medicine, Miami, USA; 3) Department of Biology, University of Puerto Rico, Mayaguez, PR; 4) Department of Structural Biology, Stanford University School of Medicine, Stanford, USA; 5) Center of Experimental Medicine "Miguel Layrisse", Venezuelan Research Institute (IVIC), Caracas, Venezuela.

Particular dynamics of admixture in the Americas have imprinted a unique genomic pattern in present day Hispanic/Latino populations. A more detailed understanding of how 500 years of admixture have shaped the genomes of Latino populations today is critical to empower medical genetic studies in admixed populations and provide important knowledge about their demographic history. While Mexican populations have been genomically characterized to some extent, genetic studies of populations from the Caribbean and South America have been largely underrepresented. To that end, we have densely genotyped 339 samples from parent-offspring triads of Caribbean-descent sampled in South Florida, US, including Puerto Ricans, Cubans, Dominicans, Haitians, Hondurans and Colombians. We combined these SNP data with other publically available genomic resources, including HapMap and 1000 Genomes data, as well as Native American SNP data from putatively ancestral populations. Global ancestry proportions, estimated using the ADMIXTURE clustering algorithm, revealed substantial variation in admixture proportions among and within Caribbean populations. To assign local, ancestry-specific haplotypes across the genome, we implemented a novel PCA-based admixture deconvolution approach (PCADMIX) for three ancestral populations. Given the optimal accuracy obtained from trio phasing, we were able to determine exact posterior probabilities along each chromosome and measure the length of tracts attributable to distinct ancestries. We observed patterns consistent with continuous influx of African ancestry across the islands and a pulse migration across populations in contact with the continental landmass. By contrast, we find less evidence for continuous flow of Native American ancestry (characterized by shorter ancestry tracts), compatible with a single migration event between 15–20 generations ago and no further contribution of Native Americans into the Caribbean. We have also used local ancestry estimates to scan the genome for ancestry-specific enriched regions potentially indicative of natural selection. Insights gained from the application of new statistical methods for admixture deconvolution will improve the design and genetic analysis of medical genomic studies in Hispanic/Latinos and other complex admixed groups, broadening the ensemble of populations included in current catalogs of human variation and contributing to reduce health disparities across the globe.

3391W

Population structure and ancestry inference under sample selection bias. *S.S. Shringarpure, E.P. Xing.* School of Computer Science, Carnegie Mellon University, Pittsburgh, PA.

Genotyping studies for detecting population structure are often constrained by economic considerations, consent etc. As a result, the genotyped sample may not be statistically representative of the underlying populations. A similar situation is encountered when samples from multiple studies are combined in an attempt to increase statistical power or for better resolution in detecting population structure. This problem is known as sample selection bias and it affects analyses by leading to results which are not consistent with the larger underlying populations. We examined the effects of different levels of sample selection bias on the performance of individual ancestry inference in simulated genotype data. Our experiments show that sample selection bias adversely affects the results of population structure analysis and ancestry inference. Our experiments on data from the Human Genome Diversity Project also show that sample selection bias can result in population structure results which can lead to different interpretations of human evolutionary history. We propose a correction for sample selection bias that is easy to implement and is effective in practice.

Genome-wide effects of sex-specific incompatibility on neutral introgression. *M. Uyenoyama.* Dept Biol, Duke Univ, Durham, NC.

A widely-used paradigm holds that while selection affects variation in a region-specific manner, all regions of the genome experience the same demographic history. This view justifies identification of outlier segments as candidates for regions that are associated, through tight linkage or epistasis, with targets of selection. On the contrary, we show that strong, sex-specific selection induced upon the introduction by migration of variants adapted to other environments generates region-specific barriers to neutral introgression. For example, an autosomal incompatibility factor that induces more severe effects in male than in female carriers can induce a higher barrier against introgression of Y chromosomes than unlinked autosomal regions, and even lower barriers to X-linked regions. Further, Y-linked factors inhibit introgression by autosomes but pose no barrier to mitochondria. These examples illustrate that sex-specific incompatibility factors can induce region-specific backward migration rates throughout the genome, even to the extent of generating higher FST in autosomal than X-linked regions, a pattern that might be interpreted as a signature of selection or sex-biased dispersal. We present analytical expressions for backward migration rates induced by sex-specific incompatibility. We then use these results to develop a coalescent-based algorithm for sampling from the exact distributions of topologies and internode lengths of the gene genealogy of a sample of neutral sites. We present preliminary results from application of our methods to genomic sequences sampled from Drosophila pseudoobscura and D. persimilis, a model system for introgression between recently diverged species for which locations of hybrid incompatibility factors have been determined by direct experiment.

3393W

Admixture Analysis of Spontaneous Hepatitis C Virus Clearance among Individuals of African-Descent. *G.L. Wojcik, P. Duggal on behalf of the International Consortium of HCV Spontaneous Resolution.* Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Background: Hepatitis C virus (HCV) is an important global public health problem with 130–170 million people worldwide chronically infected and 350,000 deaths each year. Associations between ethnicity and spontaneous viral clearance have been reported with African-Americans having a 25% lower rate of spontaneous and treatment-related viral clearance than European-Americans. Host genetics plays a large role in spontaneous clearance with significant associations in MHC and IL28B. Methods: From the International Consortium of HCV Spontaneous Resolution, we identified 451 individuals of African-descent, as determined by Principal Components Analysis (PCA). Local ancestry was estimated using LAMP (Local Ancestry in Admixed Populations), with two ancestral populations being assumed. The association between local ancestry and HCV spontaneous clearance was determined using logistic regression across the genome. Suggestive regions were then adjusted for SNP effects and a possible interaction with IL28B. Results: On average, individuals were genetically 82% of African-descent. This average is consistent with prior estimates in African-Americans. Approximately 26,000 local ancestry blocks were estimated across the genome, with no difference in average global ancestry between groups. A region on chromosome 15 had a suggestive association with spontaneous clearance in the gene SCAPER. Local ancestry of African descent conferred 1.9 times higher odds of clearance (p=5.9×10-4). When the region was adjusted for SNP effects, the top SNP was rs4886800 with an odds ratio of 1.8 (p= 0.005), and African ancestry was associated with 2.4 times the odds of clearance (p=4.4×10-5). Both signals were independent of IL28B (p>0.05). No other region approached statistical significance (p>0.0001). Conclusions: SCAPER is an S-phase cyclin A-associated protein in the endoplasmic reticulum. It is involved in recruiting cyclin A, which is essential for the progression of a cell through the S phase. Abnormal expression in the cytoplasm has been found to be associated with halted cell cycle progression and chronic HCV infection. This study demonstrates the need to estimate local ancestry and its effect on outcomes that may differ between ancestral backgrounds. The independent association of SCAPER may explain some of the ancestral differences in spontaneous resolution of HCV between African- and European-Americans and warrants further investigation.

3394T

A Genome-Wide Perspective of Population Structure and Individual Admixture in Xinjiang: Implications for Demographic History and Complex Trait Gene Mapping. *S. Xu[1], S. Li[2], D. Lu[1], P. Qin[1], H. Lou[1], W. Jin[1], X. Pan[2], L. Jin[2].* 1) CAS-MPG Partner Institute for Computational Biology, Shanghai, Shanghai, China; 2) Fudan University, Shanghai, China.

Many human populations settled at Xinjiang, China demonstrate an array of mixed anthropological features of East Eurasian (EEA) and West Eurasian (WEA), indicating a possible scenario of biological admixture between already differentiated EEA and WEA populations. However, their complex biological origin and genomic make-up, as well as their genetic interaction with surrounding populations are not well understood. In an attempt to decipher their genetic structure and population history, we conducted, to our knowledge, the first genome-wide study of four populations residing in Xinjiang. Analysis was performed using over 900,000 genome-wide single nucleotide polymorphisms (SNPs) in 200 unrelated individuals and made comparisons with 3,165 individuals representing 128 world-wide populations. Based on both genome-wide random markers and ancestry informative markers (AIMs), we demonstrated that the Kazakhs derived their ancestries from both EEA and WEA. Only modest variation in admixture proportions was observed among individuals within each population. We concluded that the present-day Xinjiang populations can be considered as admixed populations by genomic make-up, and their admixture features hold great promise to applications of admixture mapping and advance genetic-based medical research. We finally constructed a genome-wide admixture map with ancestry informative SNPs for gene discovery using admixture mapping in Xinjiang populations.

3395W

Genomics variants in the endogamous Mashadi Jewish population identified by pooled whole exome sequencing. *H. Ostrer[1], W.J. Huh[2], G. Akler[3], L. U[2], M. Popovic[4], D. Kural[4], J. Sheffield[4], E. Burns[1], G. Atzmon[1], C. Oddoux[2].* 1) Albert Einstein College Med, Bronx, NY; 2) Montefiore Medical Center, Bronx, NY; 3) Mount Sinai School of Medicine, New York, NY; 4) Seven Bridges Genomics, Cambridge, MA.

The Mashadi Jewish population is a highly endogamous group of ~20,000 members who ancestors once resided in Mashad, Iran. To understand the genetic variation within this group, whole exome sequencing was performed on four pools of 100 unrelated individuals, following capture using Nimblegen SeqCap EZ Human Exome Library v2.0 or Illumina SureSelect (2 pools each) to a coverage of 35–55-fold. Variant calls were made using GATK and found to be quantitative over the range of alleles (r ~0.90). The summary statistics demonstrated 762123 variants with 29036 mapped by ANNOVAR. Of these 538 variants had allele frequencies ≤.10 in the Mashadi Jewish population and were shown by PolyPhen2, SIFT, Mutation Taster, GERP, PhyloP to be potentially deleterious. Seventy-six demonstrated 4-fold enrichment compared to the 5400 samples in the NHLBI Exome Sequencing Project database and 6 occurred in genes known to be associated with Mendelian phenotypes (ALS2, CLCNKB, GP6, KRT14, PRR4, NR3C2). These findings demonstrate that pooled sequencing is a quantitative and cost-efficient means for generating genomic variants for previously uncharacterized populations and potentially can identify previously unknown risks for Mendelian disorders within the population.

An evaluation of genetic characteristics of two population isolates from Greece: the HELIC-Pomak and MANOLIS studies. *G. Dedoussis[1], I. Tachmazidou[2], AE. Farmaki[1], L. Southam[2], K. Palin[2], A. Kolb-Kokocinski[2], W. Rayner[2], E. Daoutidou[1], I. Ntalla[1], K. Panoutsopoulou[2], E. Tsafantakis[3], M. Karaleftheri[4], E. Zeggini[2].* 1) Dietetics-Nutrition, Harokopio Univ, Athens, Greece; 2) Wellcome Trust Sanger Institute The Morgan Building Wellcome Trust Genome Campus Hinxton Cambridge CB10 1HH; 3) Health Center, Anogeia, 74051 Crete, Greece; 4) Health Center, Exinos, 67300 Xanthi, Greece.

The study of low-frequency and rare variants can be empowered by focusing on isolated populations, in which rare variants may have increased in frequency and linkage disequilibrium tends to be extended. Sequencing is efficient in isolates, because variants are shared in extended haplotype contexts, supporting accurate imputation. Here we assess sample sets collected from two Greek populations: the Pomak villages are a set of religiously-isolated mountainous villages in the North (population size 11,000) with high incidence of metabolic-related phenotypes (eg. Hypertension >23%; hyperlipidemia >16%) of cardiovascular disease; Anogia is a mountainous village on Crete, with high levels of longevity (population size 4,000). 747 and 1118 individuals respectively were typed on the Illumina OmniExpress platform. We calculated genome-wide IBS statistics to assess the degree of relatedness and compared it with the general Greek population (707 samples with OmniExpress data, TEENAGE study). We additionally calculated the proportion of individuals with at least one “surrogate parent” as a means for accurate long-range haplotype phasing and imputation, as proposed by Kong et al, Nature Genetics 2008. We find 1–1.4% of individual pairs with pi-hat>0.05, and ~0.4% with pi-hat>0.1 in the isolates compared to 0% in the general Greek population. We also find that ~80%-82% of subjects have at least one surrogate parent in the isolates, compared to ~1% in the outbred Greek population. We have established the HELIC-Pomak and MANOLIS cohorts as genetic isolates and we are currently whole-genome sequencing 250 individuals to enable imputation and subsequent association testing. This approach has the potential to identify novel robust associations with disease-related complex traits.

Genomic variants in the Dominican population identified by whole exome genotyping using Affymetrix Axiom Arrays. *C. Oddoux[1], C. Cambell[2], L. U[1], H. Ostrer[2].* 1) Montefiore Medical Center, Bronx, NY; 2) Albert Einstein College of Medicine, Bronx, NY.

The Dominican population is an admixed population with native, African, and European origins. To understand the genetic variation within this group, whole exome genotyping was performed on 192 unrelated individuals, using the Affymetrix Axiom array. The summary statistics demonstrated 319,284 variants with 260,478 mapped by ANNOVAR. Of these 10,995 variants had allele frequencies ≤10 in the Dominican population and were shown by PolyPhen2, SIFT, MutationTaster, LRT, or PhyloP to be potentially deleterious the majority showing four-fold or greater enrichment as compared to the 5400 samples in the NHLBI Exome Sequencing Project database and variants were observed in 1110 genes known to be associated with Mendelian phenotypes. These findings demonstrate that whole exome genotyping using Axiom arrays is a cost-efficient means for generating genomic variant frequencies for previously uncharacterized populations and potentially can identify previously unknown risks for Mendelian disorders within the population.

3398T

A Population-Based Study and Subsequent Disclosure of Autosomal Recessive Disease-Causing Mutations in a Founder Population. *J.X. Chong[1], R.L. Anderson[1], R. Ouwenga[1], D.J. Waggoner[1,2], C. Ober[1,3].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Pediatrics, University of Chicago, Chicago, IL; 3) Obstetrics and Gynecology, University of Chicago, Chicago, IL.

The decreasing costs of exome and whole genome sequencing have resulted in a renaissance for identifying Mendelian disease mutations, and for the first time it is possible to survey the distribution and characteristics of these mutations in large population samples. We conducted carrier screening for all autosomal recessive mutations known to be present in 1,644 members of a founder population, the Hutterites of South Dakota, and revealed surprisingly high carrier frequencies for many of these mutations. By utilizing the rich demographic, genetic, and phenotypic data available on these subjects and simulations in the exact pedigree that these individuals belong to, we show that the majority of mutations were likely introduced into the population by a single Hutterite founder and then drifted to the high frequencies observed. In addition, we find that carriers of the same founder mutation often share extremely small segments (<0.5Mb) of the mutation-bearing haplotype, which has implications for homozygosity mapping approaches used in founder populations. We further show that while there is an increased incidence of autosomal recessive diseases overall, the mean carrier burden is likely to be lower in the Hutterites than in the general population. Finally, based on simulations, we predict the presence of 30 or more undiscovered recessive mutations among these subjects, which would at least double the number of AR diseases that have been reported in the Hutterites to date. Given the potential clinical and reproductive relevance of the genotypes discovered during this project, we initiated a phased approach to disclosure of results, which included assessment of attitudes towards disclosure of carrier information, an educational program, and a consent process that would allow us to disclose genetic results to participants in our studies who desired this information. We also met directly with individuals and families to share information related to medically actionable diseases that were present in themselves or their family. Overall, ~80% of individuals who participated in the educational program signed consent forms for the release of their carrier status for 14 diseases.

Deep-coverage whole genome sequencing of 100 Qatari reveals elevated prevalence of population-specific variants linked to disease. *J.L. Rodriguez-Flores[1], K.A. Fakhro[2], N.R. Hackett[1], J. Salit[1], J. Fuller[1], J.A. Malek[2], R. Badii[3], A. Al-Marri[3], L. Chouchane[2], R.G. Crystal[1], J.G. Mezey[1,4].* 1) Dept of Genetic Medicine, Weill Cornell Medical College, New York, NY; 2) Dept of Genetic Medicine, Weill Cornell Medical College, Doha, Qatar; 3) Hamad Medical Corporation, Doha, Qatar; 4) Dept of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

The Arabian Peninsula is the migration crossroads between Africa and Eurasia, and hence is an important part of the story of human genetic variation. The Qatari population is a broad sample of the genetic variation in the region, including individuals of Bedouin (Q1), Persian (Q2), and African (Q3) ancestry. The Q1 population is of particular interest because of a high rate of consanguinity within the population, with long runs of homozygosity in the genome. In order to study the effects of extreme consanguinity on the Qatari genome while sampling the complete spectrum of population genetic variation, we selected for whole genome sequencing 100 Qatari with varying degrees of Bedouin ancestry. Over half the individuals selected for sequencing are of primarily Bedouin ancestry (>70%), with the rest having varying proportions of Bedouin admixture, and eight being highly admixed (<50% Q1, Q2 or Q3). Each genome was sequenced to >30x depth using Illumina paired-end 100bp reads, these reads were mapped to the GRCh37 human reference using BWA and variants were called using a pipeline based on GATK. We identified an overall higher proportion of homozygosity in the Q1, with a median homozygosity in coding regions higher than Q2, Q3 and all 1000 Genomes Project populations. Using a manually curated version of the OMIM database, we identified multiple heterozygous carriers for recessive variants linked to severe childhood-onset Mendelian disorders with prevalence up to 2%. Four of these variants were observed only in one sub-population (Q1, Q2 or Q3), and hence the sub-population allele frequency was higher than for the general population. Examples include an arterial tortuosity variant at 4% prevalence in Q1, and a retinitis pigmentosa variant at 5% prevalence in Q2. Of these two, only the retinitis pigmentosa variant was previously observed in the 1000 Genomes project (1% prevalence in Europe). Analysis of identity-by-descent showed shared ancestry of the local haplotypes flanking these variants, indicating a common founder origin. We hypothesize that these observations are a combined result of a founder effect in the population and a high rate of consanguinity, resulting in an unusually high prevalence of a severely deleterious mutation within a subpopulation that frequently intermarries. This whole genome dataset can serve as a foundation for future studies of genomics in Qatar and the Arabian Peninsula.

Single gene disorders in Western India: Cohort of high risk group. *C. Ankleshwaria, J. Sheth, H. Patel, J. Lekshami, F. Sheth.* Biochemical and Molecular Genetics, Frige's Institute of Human Genetics, Ahmedabad, Gujarat, India.

Present study comprises of 755 cases referred for various single gene disorders from 2007 to 2012. This includes 313 (41.45%) for β-Thalassemia, 139 (18.41%) for Cystic fibrosis (CF), 116 (15.36%) for Spinal Muscular Atrophy (SMA) and 74 (9.80%) for Duchenne Muscular Dystrophy (DMD), 32(4.23%) for Spinocerebellar Ataxia (SCA), 24(3.17%) of Achondroplasia, 22 (2.91%) of Fragile- X, 20(2.64%) of Albinism and 15(1.98%) of Huntington The most common mutation observed in β-Thalassemia was IVS 1, 5 (G-C) in 108(34.50%) followed by FS 41/42 in 33(10.54%), 619 bp deletion in 32(10.22%), FS 8/9 in 25(7.98%) and IVS 1, 1 (G-T) in 27(8.62%) cases. For CF, δf508 was observed in 24(17.26%), R117H in 3(2.15%), heterozygous forδf508 and S549N in 1(0.71%). For SMA, exon 7 and exon 8 of SMN1 and SMN2 was deleted in 57(49.13%), only exon 7 in 3(2.58%) cases of SMN1, only exon 8 in 3(2.58%) cases of SMN1, only exon 7 of SMN2 gene in 3(2.58%) cases and exon 7and 8 of SMN2 gene in 1(0.86%) case. For DMD, single exon deletion was observed in 10(13.51%) cases, 2 exon deletion in 6(8.10%), three exon deletion in 14(18.91), four exon deletion in 6(8.10%) and remaining 38(51.35%) showed multiple exon deletions. Of 32 cases suspected with SCA, 1(3.12%) was found with SCA 1, 8(25%) with SCA 2, 3(9.37%) with SCA 3. For Achondroplasia, 3(12.5%) cases were found to have G1138A and 2(8.33%) were found to have G1138C in heterozygous status. Cases suspected with Fragile-X, only 3(13.63%) were confirmed to have more than 100 repeats of CGG. For Albinism, R278X was the most common mutation with heterozygous status in 5(33.33%) and homozygous in 5(33.33%) cases. For Huntington, 6(40%) of 15 were found to have increased CAG repeats confirming the disease status. Overall study demonstrates that β-Thalassemia, CF, SMA and DMD are the most common single gene disorder and national screening planning may be needed to attenuate the burden of these diseases in addition to carrier screening and prenatal diagnosis.

Study on the distribution of rare genetic variations in the French Canadian population. *S. Girard[1,2], L.-P. Lemieux Perreault[1], I. Mongrain[1], G. Lettre[3], J. Rioux[3], M. Phillips[3], S. de Denus[3], G.A. Rouleau[4], J.-C. Tardif[3], M.-P. Dube[1,3].* 1) Université de Montréal, Montreal, Quebec, CanadaCentre de Pharmacogénomique Beaulieu-Saucier Université de Montréal 5000, rue Belanger Est Montreal, Quebec H1T 1C8; 2) CHUM Research Center, Y-3624, Pav JA-de-Sève 2099 rue Alexandre-de-Sève, Montreal, Qc; 3) Institut de Cardiologie de Montréal 5000, rue Bélanger Montréal (Québec) H1T 1C8; 4) Centre Hospitalier Universitaire Sainte-Justine Research Center, Montréal, Québec, Canada.

Several studies have recently demonstrated that unlike common genetic variations, rare genetic variants have a unique distribution profile specific to each population. Until recently, it was not possible to conduct population studies on the distribution of rare variants due to limitations linked to technologies and the number of identified rare variants. Using a specifically designed genotyping platform to identify variations in exons (Illumina ExomeChip), we examined the distribution of rare variations in a cohort of over 10,000 individuals (the Montreal Heart Institute Hospital Cohort). Among this cohort, we compared the prevalence of rare variations in 7713 individuals of French Canadian origin to those of European populations (1000 genome project and NHLBI GO Exome Sequencing Project). We subdivided the French Canadian population samples according to the birthplace of the four grandparents of the individuals. Using the geographical coordinates of the birthplace, we kept only individuals whose grandparents were born less than 25km apart. Using a MDS plot, we were able to identify a divergent subpopulation that characterizes the Charlevoix-Saguenay region, a known geographic isolate. The distribution of selected rare variants from this region was found to be distinct from the rest of the French Canadian population. This allows us to better characterize the founder effect specific to the French-Canadian population in addition to improving our understanding of the evolution of allele frequencies of rare variations.

We initiated the largest population genetic study of Y-chromosomal genetic variation in South American natives to date. A total of 1011 individuals, representing 50 tribal populations from 81 settlements, were genotyped for up to 17 short tandem repeats and up to 16 single-nucleotide polymorphisms (Y-SNPs), defining native American phylogenetic lineages Q and C and their sub lineages. We report upon the detection of a novel Native American founding lineage C-M217 (C3*) in different tribal and linguistic groups from Ecuador (Kichwa, Waorani). This finding is intriguing in view of the high prevalence of the same haplogroup in Central, East and North East Asia, and its concurrent absence from North America. Possible scenarios include (i) later migratory waves that quickly passed the existing populations in North America, and (ii) long-distance contact with East Asia. The introduction of C3* chromosomes into South America from Eastern Asia by sea, either along the American West coast or across the Pacific could revitalize the hypothesis for the origins of New World ceramics found in coastal Ecuador from the Japanese Jōmon culture. The striking differences observed between the C3* Y-STR haplotypes of Ecuadorians and Asians on the one hand and between the tribes within Ecuador on the other would be explicable in terms of a long divergence time after the arrival and the process of tribalization.

Single Nucleotide Variation Analysis of Protein Domain Signatures of Human Genes. *J. Freudenberg.* Ctr Human Gen, Feinstein Inst Med Res, Manhasset, NY.

We recently proposed a simple method to estimate relative density of nonsynonymous SNVs (rdnsv) in a set of genes as compared with its expectation (Freudenberg et al., PLoS ONE 7(6): e38087, 2012). In short, rdnsv is estimated by correcting the ratio between nonsynonymous SNVs (nsSNVs) per nonsynonymous site and synonymous SNVs (sSNVs) per synonymous site for the bias of synonymous sites towards transitions in the genetic code and different mutation rates for transitions and transversions. We then fit a linear regression model to rdnsv over different SNV allele frequency bins. The y-intercept of this model (rdnsv0) predicts rdnsv for an allele frequency close to 0, which can be interpreted as the proportion of nonsynonymous sites where mutations may segregate with a frequency notably greater 0. The slope of the model further determines rdnsv for the allele frequency close to 1 (rdnsv1), which measures the proportion of nonsynonymous sites where nsSNVs may reach fixation. We now apply our method to evaluate the levels of nsSNVs among the 30 most prevalent Pfam domain signatures in the human genome, using different published exome sequencing datasets. The greatest rdnsv estimates are displayed by PF00067:Cyt_P450, PF00005:ABC_transpt-like, and PF00001:GPCR_Rhodpsn. Interestingly, Cyt_P450 and ABC_transpt-like stand out by high rdnsv0 and small rdnsv1 estimates, indicating many sites where nonsynonymous SNVs may segregate at low frequency, but few sites where they may reach high frequency or fixation. In contrast, the sequence annotated by PF00001:GPCR_Rhodpsn displays both high rdnsv0 and rdnsv1 estimates. This domain signature is typically found in olfactory receptors, where nonsynonymous variants easily reach high frequency due to relaxed constraint. On the other end of the spectrum, we find the smallest rdnsv0 and rdnsv1 estimates for the domain signatures PF07714:Tyr_pkinase, PF00069:Se/Thr_pkinase, and PF00076:RRM_RNP1. These protein domains play important signaling roles in many cell types, which may explain their high levels of constraint and reduced tolerance even for rare variants. Importantly, our results are consistent across parameters and SNV datasets. In particular, similar estimates of rdnsv are obtained by the approximative strategy that multiplies the observed ratio between nsSNVS and sSNVs with the factor f'=0.4 and other strategies that consider the exact numbers of synonymous, nonsynonymous, transition, and transversion sites.

Investigating the evolution of deleterious mutations in the major histocompatibility complex as a potential explanation for frequently observed HLA-disease associations. *T.L. Lenz[1], D.M. Jordan[1], S.R. Sunyaev[1,2].* 1) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA.

Understanding the evolution of disease-causing mutations in the genome is a key objective in human genetics and evolutionary medicine. The accumulating evidence for a growing number of disease variants from genome-wide association studies raises the question as to how these causal variants evolve and are maintained in human populations despite their usually deleterious effects. Both neutral as wells as selective processes have been proposed to counteract purging of disease variants. Here we investigate these processes for one of the most gene-dense regions in the human genome, the major histocompatibility complex (MHC). While this genomic region on the short arm of chromosome 6 appears to harbor an unexpected large fraction of disease variants, it exhibits also an exceptional level of heterozygosity, which is thought to be maintained by pathogen-mediated balancing selection on the antigen-presenting HLA genes in this region. It has therefore been suggested that high levels of haplotypic heterozygosity in the MHC region provide a `shelter' for deleterious mutations by limiting expression of their homozygous phenotype and thus inhibiting purging mechanisms. This scenario would explain the otherwise unexpected high frequencies of deleterious mutations in this region and thus the frequent association of the MHC region with genetic disorders and diseases. Here we use frequency information of sequence variants from 5,379 human exomes, publicly available through the exome variant server of the NHLBI GO Exome Sequencing Project, to investigate the frequency of deleterious sequence variants in the MHC region at an unprecedented depth. This dataset comprises 17,538 protein-coding genes with nearly 900,000 amino acid-altering point mutations (SNPs). From this dataset we identify computationally predicted deleterious mutations inside and outside the MHC region and compare the observed frequency distribution of such mutations in the MHC region against simulated gene sets from the rest of the genome. We then employ forward simulations to identify the most likely evolutionary scenarios that have led to the observed distribution of damaging sequence variants in the MHC region. Our results thus shed light on the processes governing the evolution and maintenance of deleterious sequence variants in the human genome.

Quantifying the Degree of Purifying Selection in Genes Associated with Nephrotic Syndrome. *M.G. Sampson[1,4], M. Kretzler[2,4], H.M. Kang[3,4].* 1) Dept. of Pediatrics & Communicable Disease-Nephrology; 2) Dept. of Internal Medicine-Nephrology; 3) Dept. of Biostatistics; 4) University of Michigan Ann Arbor, MI.

Background: Studying the genetic basis of nephrotic syndrome (NS), a disease resulting from protein loss through the urine due to abnormalities of the glomerular filtration barrier, has resulted in the discovery of both rare and more common variants in genes associated with increased risk of disease. However, the contribution of genetic variation to the pathogenesis of NS cases remains unknown in the majority of cases. Given the observation that deleterious single nucleotide variants (SNV) in disease genes tend to undergo purifying natural selection, defining the degree of this selection in known and candidate NS genes may help to identify disease-associated loci in subjects with this disease. Leveraging genome-wide SNV data from the 1000 Genomes Project (1000G) coupled with functional prediction software, we developed and implemented a number of novel and known methods to quantify the degree of purifying selection on genes associated with NS and compared them genome-wide.**Methods:** Using 1000G data, we measured the frequency of non-synonymous SNV present in coding regions across the genome and used functional prediction software to stratify them as deleterious or benign. We then created two metrics of selection: 1) number of SNV/kilobase ("Suppressed Mutation") & 2) percentage of SNV that are private ("Enriched Rare Variants"). Using a Wilcoxon rank sum test, we contrasted the difference of frequency spectrum between benign and silent mutations for 17,506 genes across the genome and established the quantile in which the 12 NS-associated genes were located.**Results:** The NS genes demonstrating most enrichment for rare variants were *APOL1* (.008 quantile of all genes tested), *LAMB2* (.016 quantile), and *TRPC6* (.036 quantile). The NS genes with the strongest suppression of deleterious SNV were *INF2* (.008 quantile), *MYH9* (.011 quantile), and *ACTN4* (.045 quantile). *INF2* had a 66x lower rate of deleterious vs benign SNV.**Conclusions:** Multiple NS genes exhibit evidence of strong negative selection, suggesting that deleterious SNV in these genes are likely functional and could have large effects. This can be further investigated by sequencing these genes in NS-cohorts large enough to pick up rare, deleterious SNV. Additionally, annotating NS-candidate genes with these metrics of purifying selection may help prioritize genes for further study.

3406T

An Assessment of Population Stratification in Rare Variant Association tests Using an Analytic Model of Joint Site Frequency Spectra. *M. Reppell[1], M. Zawistowski[1], D. Wegmann[2], R. Weyant[1], P.L. St Jean[3], M.G. Ehm[3], M.R. Nelson[3], J. Novembre[4], S. Zöllner[1,5].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI, USA; 2) School of Life Sciences, École polytechnique fédérale de Lausanne, Lausanne, Switzerland; 3) Quantitative Sciences, GlaxoSmithKline, RTP, NC, USA; 4) Department of Ecology and Evolutionary Biology, University of California-Los Angeles, Los Angeles, CA, USA; 5) Department of Psychiatry, University of Michigan, Ann Arbor, MI, USA.

Understanding the role rare variation plays in disease etiology is a fundamental question in human genetics today. A critical step in determining valid genotype-phenotype relationships is properly accounting for population structure. The impact of population stratification and necessary correction methods for gene-based association tests are not well understood. To address this we devised a novel analytical model for the Joint Site Frequency Spectrum (JSFS) of two populations, extending the classic hierarchical beta model of population allele frequencies. This model captures patterns of rare variant diversity observed in real sequence data without requiring explicit demographic assumptions, as would be necessary in a coalescent-based approach. We calibrated our model using data from 202 drug target genes sequenced in 14,001 individuals, with a particular focus on accurately modeling singletons, and simulated datasets with different degrees of population stratification by sampling case and control at different proportions from two populations. Gene-based association tests that combine information from multiple rare alleles into a single statistic can be broadly divided into those that accumulate rare variant counts within individual samples (for example, CMC and CMAT), and those that combine statistical evidence across individual markers (for example, SKAT). Interestingly, the P-value inflation induced by population stratification differs substantially between the two classes of rare variant tests: tests that combine evidence across markers typically have a higher rate of false positives than tests that combine variants across genes. This behavior is well predicted by summary statistics that quantify the burden and sharing of rare variants across populations. We further demonstrate that genomic control as currently defined is unable to properly correct for test statistic inflation, but find that an alternative control that uses observed test statistic variance accounts well for over- or under dispersion in gene-based test statistics. A better understanding of how population stratification affects rare variant association tests, and how to properly correct it, is critical for determining the role rare variants play in disease development.

Estimating and Interpreting F_{ST}: the Impact of Rare Variants. *G. Bhatia[1,2], N. Patterson[2], S. Sankararaman[2,5], A.L. Price[2,3,4].* 1) Harvard-Massachusetts Institute of Technology (MIT) Division of Health, Science and Technology, Cambridge, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 4) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 5) Department of Genetics, Harvard Medical School, Boston, MA.

F_{ST} is a widely used tool for studying population structure, but many different definitions, estimation methods and interpretations exist in the literature. Thus, wide variation in published estimates of F_{ST} is important to understand. For example, the F_{ST} between European (CEU) and East Asian (CHB) populations is 0.111 when estimated from HapMap3 data, but only 0.052 when estimated from 1000 Genomes data (1kG). While, changes in F_{ST} from sequencing data might be expected from including rare variants we show that this is largely through bias introduced by the estimation method and not population genetic factors. We describe a method that is shown to avoid these biases. We consider three specific aspects of estimation: (1) defining F_{ST} for a single SNP, (2) combining estimates of F_{ST} across multiple SNPs, and (3) selecting the set of SNPs used in the computation. Correcting for differences in each of these aspects of estimation yields estimates of F_{ST} that are much more concordant between genotype and sequence data. For example, our estimate of F_{ST} between CEU and CHB from 1kG is 0.106, only slightly lower than the HapMap3 estimate. This decrease is due to ascertainment bias of SNPs included in the HapMap3 project, not to properties of rare variants. In general, F_{ST}at rare variants in a population will be sensitive to demographic events affecting that population. When comparing CEU to CHB, for example, we show that rare variants in CEU and CHB have higher F_{ST} than common variants. This is consistent with the influence of strong bottlenecks on F_{ST} at rare variants. We note that ascertainment in an out-group—for example, Yoruba (YRI)—will remove this frequency dependence of F_{ST}. Finally, we show that single-SNP estimates of F_{ST} based on a common definition (Weir and Cockerham 1984) can become inflated in a setting of very different sample sizes. This inflation can result in false-positive signals of natural selection. Indeed, we show that in a recent study of selection that compared 1,890 African-American and 113 YRI samples, (Jin et al. 2011), F_{ST} estimates at 9 of the 10 reported novel loci are inflated by the disparity in sample size, and, after correction, only 7 of these 10 loci remain nominally significant. This suggests that caution is warranted when using this definition to rank single-SNP estimates of F_{ST}. Our results indicate that a careful protocol is needed for producing F_{ST} estimates. We provide such a protocol.

3408T

Are rare and common variant stratification patterns the same? *E. Genin[1,2], M-C. Babron[1,2], M. de Tayrac[1,2], D.N. Rutledge[3], E. Zeggini[4].* 1) U946 Genetic variability and human diseases, INSERM, Paris, France; 2) Institut Universitaire d'Hématologie, Univ Paris Diderot, Paris, France; 3) AgroParisTech, Paris, France; 4) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

If the population stratification of common variants has been extensively studied on empirical data, this is not the case for rare variants. Rare variants are more likely than common variants to be under moderate levels of negative selection and/or to have arisen recently and be population-specific. It is thus plausible that rare variants could exhibit stratification patterns different from common variants. With the development of high-throughput sequencing, the role of rare variants in diseases can now be tested in association studies. To avoid false positive associations, it is important to understand how rare variants are stratified and how to adjust for their stratification in association tests. Using the WTCCC1 Affymetrix 500K genome scan data, we show that the stratification patterns of rare and common variants are indeed different. The top principal component extracted from the rare variant category shows poor correlations with any principal component or combination of principal components from the low frequency or common variant categories. These results could suggest that a suitable solution to avoid false positive association due to population stratification would involve adjusting for the respective PCs when testing for variants in different allele frequency categories. However, we found this was not the case both on type 2 diabetes case-control data and on simulated data. Indeed, adjusting rare variant association tests on PCs derived from rare variants does no better to correct for population stratification than adjusting on PCs derived from more common variants. Mixed models perform slightly better for low frequency variants than PC based adjustments but less well for the rarest variants. These results call for the need of new methodological developments specifically devoted to address rare variant stratification issues in association tests.

3409W

Variant frequency and the scale of population structure. *P. Raska, O. De la Cruz Cabrera.* Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Proper characterization of population structure is important for understanding current and historical demographics of human populations and for adjusting for this structure when conducting tests of genetic association. Principal component analysis (PCA) has proven effective for this purpose. Adding kernel methodology to PCA brings with it two added benefits, the possibility of dealing with non-linear structure and the convenient notion of kernel bandwidth. Here we make the connection between kernel bandwidth and variant frequency as both being delimiters of the scale of population structure that can be characterized. We investigate the effect of variant frequency on inferred population structure through simulation. The underlying hypothesis is that rare variants, which tend to be shared only between individuals with more recent common ancestry, will tend to reveal structure at a smaller scale, while common variants, which can be shared by unrelated individuals, reveal differences at a larger scale. Conversely, common variants will not vary sufficiently to inform on smaller scale variation and rare variants will be less informative than common variants for larger scale variation. The latter becomes obvious with the realization that it would not be possible to infer the relative distances between subpopulations on the basis of completely private variants. We further hypothesize that as the geographic region under consideration is reduced, rare variants will become more common reaching an optimum frequency at which the variant will be most informative for the regional population structure. Finally,we predict that the population structure that is present for common and rare variants will differ not only in scale but also within the finer scale of rare variants, where selective forces may have shaped population structure independently of the neutral drift pattern represented by common variants. What population structure is best characterized by variants of different frequency is a question of paramount importance with the advent of next generation sequencing. In rare variant association analyses, now becoming common with the availability of sequencing data, the type of confounding structure present in the data may not be well represented nor controlled for by common variants. This study wishes to address this question and in so doing, give guidelines for population stratification control in the new era of genetic association studies.

Male-specific common CNVs and complex gender differences in CNV detected among 808 olfactory receptor loci, in 150 phenotypically normal individuals from the 1000 Genome Project. *F. Shadravan.* None, San Francisco, CA.

Gender differences due to both autosomal and sex chromosomes play a pivotal role in the human genetic identity and are also manifested in many genetic disorders. In this study their effects on copy number variation (CNV), the gain or loss of genomic materials, which is also known to cause some diseases were explored. As the olfactory receptor (OR) repertoire comprises the largest human gene family, it was selected for this study. The CNV genotypes came from open access data, studying 808 OR loci in 150 phenotypically normal individuals from the 1000 Genome Project. Out of 808 loci studied, 188 pseudogenes and 134 genes showed a total of 4,595 CNVs, and their analysis revealed the following two novel findings: 1- Detection of 22 gene duplications among nine OR loci in subtelomeric region of chromosome X in 13 out of 57 males, while absent in 93 females studied. One of these loci was located between two genes previously identified as part of a “gay genes” region. 2- Detection of significant gender differences in OR pseudogenes, and not OR genes, in which the male genome showed more CNVs, among 494 non-common variants detected in 260 OR loci; whereas the comparison of 4,101 common CNV variants detected among 62 OR loci did not show any significant differences among the genders, either between OR pseudogenes or genes (the standard Bonferroni correction was used for multiple testing). Using a CNV public database for sick children (ISCA), the application of these findings for improving clinical molecular diagnostics was discussed through showing an example of gender differences in CNV among kids with autism. Additional clinical relevance is discussed, as the most CNV-enriched polymorphic OR cluster in the human genome, located at chr 15q11.2, was found near the PWS/AS bi-directionally imprinted region associated with two well-known mental retardation syndromes. In light of finding recent gender differences among OR pseudogenes, an indirect role for OR processed pseudogenes in the embryonic development of primate brain is proposed. It is based on their parent-of-origin regulatory suppression of their intact counterpart genes, thus switching off temporally a more primitive mental cognitive system based heavily on olfaction and pheromones, as seen in most mammals to allow the development of a newer cognitive system based on a larger brain in primates. Syndromic mental retardation consequently might arise due to developmental delays in this switching process.

Transcriptome sequencing across seven diverse populations characterizing novel transcript isoforms and allele-specific expression. *H.A. Costa[1], A.R. Martin[1], J.M. Kidd[2], B.M. Henn[1], M.C. Yee[1], F. Grubert[1], S.B. Montgomery[1], H.M. Cann[3], M.P. Snyder[1], C.D. Bustamante[1].* 1) Stanford University School of Medicine, Department of Genetics, Stanford, CA, 94305; 2) University of Michigan School of Medicine, Department of Human Genetics, Ann Arbor, MI, 48109; 3) Foundation Jean Dausset, Centre d'Etude du Polymorphisme Humain, Paris, 75010, France.

RNA sequencing studies enable the characterization and quantification of the full complement of coding elements within the human genome. These transcribed elements play an important role in human evolution and phenotypic diversity. Present studies have shed insight into novel transcript structures and transcript variability in individual populations. However, in order to obtain a more complete understanding of how gene expression variation influences complex human phenotypes and to better understand overall human diversity, further studies investigating under-sampled and isolated populations are necessary. Thus, we have sequenced the genomes and mRNA fractions of 45 lymphoblastoid cell lines from seven populations within the Human Genome Diversity Project. These populations include: San Bushmen of southern Africa, Mbuti Pygmies of central Africa, Mozabites of north Africa, Pathans of central Asia, Cambodians of east Asia, Yakut of Siberia, and Mayans of Mexico. This cohort of populations mirroring major human migratory routes will enable us to leverage the robust and quantitative nature of RNAseq to identify novel transcript isoforms as well as rare transcripts and sites of allele-specific expression. Preliminary results reveal ~100 novel transcript isoforms significantly expressed across several individuals, with several showing population unique expression. Additionally, functional annotation of a subset of these isoforms shows enrichment in metabolism and immune response genes. Further analysis will be required to correlate these variants with functional significance. This dataset will allow for the characterization of human transcriptome variation across diverse populations.

African Genome Variation Project. *I. Tachmazidou[1], F. Ayele[2], C. Pomilla[1,3], J. Asimit[1], D. Gurdasani[1,3], R. Nsubuga[4], D. Shriner[2] on behalf of the APCDR investigators.* 1) Wellcome Trust Sanger Insitute, Hinxton, United Kingdom; 2) Center for Research on Genomics and Global Health, Bethesda, US; 3) Department of Public Health, University of Cambridge, Cambridge, United Kingdom; 4) MRC/UVRI Uganda Research Unit on AIDS, Uganda.

Genome-wide association studies in populations from sub-Saharan Africa (SSA) are eagerly anticipated, but there is a paucity of genetic data to inform powerful study design. Pronounced genetic diversity across ethnic groups within SSA, in conjunction with low levels of LD and differences in haplotype structure, give rise to statistical genetics challenges when designing and conducting genomic epidemiology studies. The African Genome Variation Project is a collaboration across the African Partnership for Chronic Disease Research (www.apcdr.org), which aims to facilitate large-scale genetic association studies in diseases of relevance to SSA populations by providing insight into the genetic variation landscape of different ethnic groups. To achieve this, we have genotyped 100 unrelated individuals from each of 12 ethnolinguistic groups on the 2.5 million SNP Illumina platform. This project has been designed to provide a currently unavailable genome-wide view of common variation and a framework for statistically imputing genetic variants for genome-wide association studies in anticipation of future larger-scale whole-genome sequencing endeavours in relevant populations. We are actively examining: 1) the allele frequency spectrum of variants on the chip; 2) patterns of LD and haplotype structure; 3) the utility of the 2.5M Illumina platform for relevant populations; 4) imputation-based approaches aiming to increase genetic association study power; 5) analytical challenges and the need for new statistical genetics methods to address them; 6) the data as a valuable resource for the scientific community; 7) collaboration and synergies among contributing parties; and 8) the set-up of a research framework and resource for additional analyses, for example studies of natural selection, mapping genetic variation to linguistic and demographic differences, and evaluating powerful approaches for trans-ethnic meta-analysis and fine-mapping. We find that between 1.32 and 1.39 million SNPs have MAF>0.05 and that between 200 and 270 thousand SNPs are monomorphic in the individuals examined. We also find that there are high levels of redundancy on the chip, as calculated based on pairwise correlation between variants in each ethnolinguistic group. We will be submitting all genotype data to the European Genotype Archive (EGA). These data will be available to bona fide researchers under a managed access procedure, in keeping with ethical approval for the samples utilised.

3413W

Inference of genetic ancestry using genotype data from a single individual. *C. Chen[1], S. Lee[2], S. Pollack[1,2,3], D. Hunter[1,4], P. Kraft[1,2,4], J. Hirschhorn[3,5,6,7,8], A. Price[1,2,3].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 5) Division of Genetics, Children's Hospital, Boston, MA; 6) Division of Endocrinology, Children's Hospital, Boston, MA; 7) Program in Genomics, Children's Hospital, Boston, MA; 8) Department of Genetics, Harvard Medical School, MA.

Existing methods to infer genetic ancestry generally require raw genotypes from a large set of individuals. Applications in personal genomics and genetic association studies motivate inference of genetic ancestry using raw genotypes from just a single individual, given the logistical challenges surrounding the sharing of raw genotypes, and because the samples in a particular study may have insufficient diversity or may have family structure which can impede ancestry inference. Here, we present methods and software to infer genome-wide ancestry using genotypes from a single individual by predicting principal components (PCs) with SNP weights pre-computed from external reference panels of genotypes. Notably, the reference panels of genotypes do not need to be shared for predicting ancestry. The predicted PCs can be transformed into ancestry from continental populations such as West Africans, East Asians and Europeans, or more closely related subpopulations such as Northwest Europeans (NW), Southeast Europeans (SE) and Ashkenazi Jews (AJ). We used 394 samples from HapMap 3 continental populations and 6,546 European Americans from Framingham Heart Study SHARe data as our external reference panels of genotypes. We applied our method to two independent data sets: 49 African Americans from HapMap 3 (ASW) and 1,636 European Americans from a study of bipolar disease (BD). We used results from PCA incorporating genotypes from external reference panels as our gold standard. For ASW samples, the predicted first PC obtained using pre-computed SNP weights attained an R^2 of 1.00 (95% CI: 1.00 to 1.00) while first PC obtained using genotypes from ASW samples alone attained an R^2 of 0.32 (95% CI: 0.16 to 0.44), which reflects the confounding effects of family structure in ASW samples on ancestry inference. For BD samples, the predicted ancestry attained 98% accuracy when assigning individuals to categories of NW, SE, and AJ ancestry. However, the ancestry obtained using genotypes from BD samples alone attained only 51% accuracy, which reflects the lack of diversity in the BD samples. In a study of simulated phenotypes with population stratification (max. $\chi^2 = 71.5$, corrected $P = 8.5\times10^{-12}$), application of our method was sufficient to correct for population stratification (max. $\chi^2 = 21.3$, corrected $P > 0.05$). In summary, we present the first publicly available software that use genotypes from a single individual to provide accurate estimates of genetic ancestry.

3414W

A Unified Model of Meiosis Combining Recombination, Non-Disjunction, Interference and Infertility. *H.R. Johnston IV, D.J. Cutler.* Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

Human male and female recombination rates and patterns differ greatly across the broad scale of human chromosomes. Rates of infertility and non-disjunction differ widely between males and females. No simple cause is known for these observations. To this end, we have created a unified model of meiosis that combines recombination, non-disjunction, interference and fertility. The model correctly predicts the rate of fertility, trisomy 21 occurrences and the number and, most interestingly, the different patterns of recombination between the sexes. The model we create is based on the observation that chiasmata are the mechanism that enables the normal segregation of chromosomes during meiosis. Non-disjunction is the result of a failed segregation event. In our model, non-disjunction occurs both when no chiasmata are present between pairs of non-sister chromatids as well as when multiple chiasmata are present close together between pairs of non-sister chromatids. Other elements of our model include having no chiasmata occur between sister chromatids as well as concluding male meiosis immediately while arresting female meiosis between birth and the mother's age at conception. This period of arrest requires that females begin with far more chiasmata than males. It also allows for physical interference to initiate from anywhere on a chromosome arm. In males, this initiation event is always telomeric. These elements combine to generate the unique patterns of recombination in each gender that have, heretofore, not been explained. They also generate the unique patterns of non-disjunction and infertility, helping to explain why these phenomena are seen far more often in eggs relative to sperm. Overall, this model argues that gross differences between male and female patterns of non-disjunction, infertility, and recombination are substantially the result of the period of meiotic arrest during oogenesis.

Landscape of DNA methylation in meningiomas. *F. Gao[1], L. Shi[1], J. Russin[2], L. Zeng[1], X. Chang[1], T. Chen[2], S. Giannotta[2], D. Weisenberger[3], G. Zada[2], W. Mack[1,2], K. Wang[1].* 1) Zilkha Neurogenetic Institute, USC, Los Angeles, CA; 2) Department of Neurosurgery, USC, Los Angeles, CA; 3) Epigenome Center, USC, Los Angeles, CA.

Meningiomas are central nervous system tumors that originate from the meningeal coverings of the brain and spinal cord. The vast majority of meningiomas are pathologically benign or atypical, but 3–5% of them become malignant. Several studies have investigated the genetics of meningiomas, but the key molecular pathways involved in malignant transformation remains enigmatic. Additionally, the extent of epigenetic alterations in malignant meningioma remains unknown, despite previous studies on benign/atypical meningiomas. Here we explored the landscape of DNA methylation in 19 meningiomas (11 benign, 4 atypical and 4 malignant). Compared to benign tumors, atypical and malignant tumors show increasing trends of global hypomethylation. Clustering analysis using DNA methylation data readily separates malignant tumors from atypical and benign tumors (but not between benign and atypical tumors), implicating that the DNA methylation pattern may serve as a diagnostic biomarker for malignancy. Biological pathway analysis on genes differentially methylated in malignant and benign tumors suggested that the glioma-related pathway is significantly enriched (p=0.002). Genes hypomethylated at promoters show a general increase of expression level in malignant meningiomas, whereas genes with hypermethylated CpG islands (such as *HOXA6* and *HOXA9*) coincide with the binding sites of polycomb repressive complex (PRC) in early developmental stage. Most of the genes with hypermethylated CpG islands at promoter regions were suppressed in both malignant and benign meningiomas, suggesting the switching of epigenetic machinery on gene silencing from PRC binding to DNA hypermethylation. One exception is *MAL2*, which is highly expressed in normal brain tissue and benign meningiomas, but silenced in malignant tumors, suggesting that DNA hypermethylation of *MAL2* represents de novo gene silencing induced by DNA methylation in malignant meningiomas. In summary, our results suggested that malignant meningiomas have distinct DNA methylation patterns than benign and atypical meningiomas, and that some of the differentially methylated genes may serve as diagnostic biomarkers or candidate causal genes for malignant transformation.

A Panel of Epigenetic Biomarkers of NSCLC Identified from a Comprehensive Microarray-based DNA Methylation Analysis. *S.Cheng Guo[1], X.Tian Wang[1], J.Bin Xu[2], Felix.Li Jin[1], J.Cun Wang[1].* 1) human genetics, Ministry of Education Key Laboratory of Contemporary Anthropology School of Life, shanghai, China; 2) Department of Cardiac and Thoracic Surgery, Changhai Hospital, Shanghai, China.

Lung cancer, a complex disease involved both genetic and epigenetic changes, is the leading cause of cancer deaths worldwide. Aberrant DNA methylation status is an important event in lung cancer initiation.So DNA methylation has emerged as a highly promising biomarker for early cancer screening or diagnosis. The analysis of DNA methylation-based biomarkers is rapidly advancing, and a large number of potential biomarkers have been identified. However, the sensitivity and specificity of a single site still can't meet the need of the clinical diagnosis or screening, and thus exploring the best combination or biomarker panels to benefit clinical detection precision is pressing. In this study, DNA methylation profiling data of 400 non-small cell lung cancer (NSCLC) associated samples, which included 294 NSCLC, 99 cancer adjacents, and 7 normal lung tissues with detailed clinical information, were obtained. All the datasets were background-corrected and normalized separately, then merged and conducted quantile normalization collectively. Batch effect analysis tools, ComBat, was used to eliminate the batch effect existing in combined datasets. Four different methods based on PCA, Decision tree, LDA, and SVM were used to make clinical classification. Four genes (NTSR-1, GALR1, AGTR1, SLC5A8) was uncovered highly methylated in NSCLC with methylation rates of 61%, 47%, 31%, and 27%, respectively, while no methylation signal was found in normal lung tissues. Hypermethylation of NTSR1 was significantly associated with cancer metastasis (P = 0.0012) and subtype (P = 0.000892). Hypermethylation of GALR1 was also significantly associated with subtype of lung cancer (P = 1.55e-09). Multiple classification methods showed combined DNA methylation biomarkers had great power to distinguish NSCLC from adjacent cancer tissues with average sensitivity and specificity of 92.9% and 96.4% at least after 10 fold cross validation. Another dataset from our lab confirmed the methylation of galanin receptor subtype 2 (GALR1), with a similar methlyation rate of 66%, whose hypermethyaltion in promoter region has been identified in several other cancers and caused its gene inactivation. we have developed a ComBat-Meta pipeline to analyze the array-based methylation data and found four hypermethylated genes in caucasian NSCLC patients with high sensitivity and specificity. The methylation status of two of them was further confirmed in Chinese NSCLC patients.

Methylome Correlation Structure in Human Aging Brain. *G.P. Srivastava[1,2,3], M.L. Eaton[3,4], B.T. Keenan[1,2,3], L.B. Chibnik[1,2,3], J.A Schneider[5], M. Kellis[3,4], D.A. Bennett[5], P.L. De Jager[1,2,3].* 1) Neurology, Harvard Medical School, Boston, MA; 2) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Departments of Neurology and Psychiatry, Brigham and Women's Hospital, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA 02142; 4) Computer Science and Artificial Intelligence Laboratory (CSAIL), Massachusetts Institute of Technology, Cambridge, MA; 5) Rush Alzheimer's Disease Center, Rush University Medical Center, Chicago IL.

DNA methylation is one of the most studied epigenetic marks. The human genome has a non-uniform distribution of approximately 22 million CpGs mostly concentrated in apparently nonfunctional repetitive elements and a tiny fraction of functionally important genomic regions such as CpG islands. Though methylation of CpG sites at single nucleotide resolution and in CpG dense regions like CpG islands is well studied, inter-CpG relation in terms of their methylation and the correlation structure amongst methylation of different CpG sites across the genome is not well understood. We used genome-wide DNA methylation profiles from 748 frozen human post-mortem brains using Illumina 450K HD infinium technology to explore the correlation structures in the brain's methylome: one-half of samples were used in the discovery screen and the second half of subjects were used for replication. We find that the methylation of neighboring CpGs within a certain physical distance is strongly correlated, and we define such areas of high correlation in “cis” as a methylation block (mBlock). We propose a flexible and efficient definition for an mBlock and have developed an algorithm to explore all such mBlocks along with their boundaries and other characteristics. Limiting the analysis to regions deeply explored with our beadset (density >= 5 CG/kb, 146,041/460,067(~1\4) beadset content) and applying our definition of >75% of probe pairs with r >=0.5, we find 20,355 CG sites distributed in 2,537 mBlocks; 13.9% of surveyed CGs fall in an mBlock. The replication samples validate this correlation structure: r^2=0.996 when comparing the extent of correlation within each mBlock defined in the discovery sample set to that of the replication sample set. The mean mBlock size is approximately 2 kb ranging from 52 bp to ~263 kbps, but large outliers are noted. mBlocks are found throughout each chromosome. Strong correlation of mBlocks in "trans” is also noted and is being characterized. Overall, we provide a methodology for empirical data reduction in DNA methylation data that (1) provides an approach to estimating the number of independent loci sampled by the Illumina beadset in brain to facilitate downstream analysis, (2) enables the design of future, more efficient and informative content for beadsets or other CG screening strategies, and (3) offers one insight into the structure of the methylome that could highlight functional units found in the tissue of cell type being sampled.

Quantifying and Normalizing Methylation Levels in Illumina Arrays. *H. Xu[1], D. Ryu[1], S. Su[2], X. Wang[2], R. Podolsky[3], V. George[1].* 1) Dept Biostatistics, Georgia Health Sciences University, Augusta, GA; 2) Georgia Prevention Center, Georgia Health Sciences University, Augusta, GA; 3) Ctr Biotechnology & Genomic Medicine, Georgia Health Sciences University, Augusta, GA.

Illumina has developed a 450K BeadArray for examining methylation levels genomewide and enabling methylome-wide association studies. Most analyses of Illumina methylation arrays depend on β, the proportion of total signal that is methylated. Little attention has been paid to finding a summary measure that has good statistical properties for testing for differential methylation. Further, little attention has been paid to the potential need to normalize these data. We proposed the N-value, a type of weighted logistic transformation of that accounts for signal variability among beads.Analyses based on the N-value appear to be more robust based on an obesity data set as well as based on simulations.

Bone health at age 49–51 years is associated with *IGF2* DNA methylation levels in the Newcastle Thousand Families Study cohort. *C. Potter[1], J.C. McConnell[1], L. Barrett[1], R.M. Francis[2], M.S. Pearce[3], C.L. Relton[1].* 1) Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, United Kingdom; 2) Regional Medical Physics Department, Freeman Hospital, Newcastle upon Tyne, United Kingdom; 3) Institute of Health & Society, Newcastle University, Sir James Spence Institute, Newcastle upon Tyne, United Kingdom.

Purpose: Inter-individual variation in DNA methylation is believed to play a role in the development and progression of common complex diseases. The hypothesis that both global and gene-specific DNA methylation is associated with bone health at age 49–51 years was investigated in this study. **Methods:** Markers of global DNA methylation (LINE-1 and LUMA) and *IGF2*promoter methylation were quantified by Pyrosequencing in peripheral blood-derived DNA samples from 215, 127 and 203 individuals, respectively, from the Newcastle Thousand Families Study (NTFS). Associations between DNA methylation and contemporary DXA-based measures of bone health, namely femoral neck shaft angle (NSA), bone mineral density (BMD) and bone area of the hip and lumbar spine, were examined. Data were analysed using linear regression, adjusted for significant covariates (including sex, height and/or weight). Presented regression coefficients indicate the unit increase in the outcome variable (NSA:°c, BMD: g/cm2, area: cm2) per unit increase in methylation (% or ratio). No corrections were made for multiple testing. **Results:** *IGF2* methylation demonstrated a significant association with hip BMD (coefficient (95% CI): 0.003 (0.000, 0.006), p=0.045), the significance of which was attenuated following adjustment for weight (0.002 (0.000, 0.005), p=0.075). Upon stratification for sex, a significant association was demonstrated in females (0.004 (0.001, 0.007), p=0.012) but not males (-0.001 (-0.006, 0.005), p=0.762). There was no evidence of a statistical interaction between *IGF2* methylation and sex upon hip BMD. *IGF2* methylation also demonstrated association with spine BMD (0.003 (0.000, 0.007), p=0.042), which was again attenuated following adjustment for weight and sex (0.003 (0.000, 0.006), p=0.066) and upon stratification for sex (females: 0.004 (-0.002, 0.009), p=0.175, males: 0.003 (-0.001, 0.007), p=0.195). Neither LINE-1 nor LUMA global DNA methylation was associated with hip or spine BMD. Bone area (hip, spine and total) and NSA were not associated with any measure of DNA methylation. **Conclusions:** *IGF2* DNA methylation demonstrated associations with hip and spine BMD in the NTFS population, particularly in females. However, these associations did not appear to be wholly independent of known covariates. Hence, further work is required in larger datasets to elucidate a possible causal relationship.

3420T

NSD1 mutations in Sotos syndrome alter the DNA methylation landscape of genes involved in somatic growth and neuronal transmission. *R. Weksberg[1, 2], H. Jin[2], Y. Chen[2], D. Grafodatskaya[2], M. Inbar-Feigenberg[1], BHY. Chung[3], C. Cytrynbaum[1], S. Choufani[2].* 1) Div Clin & Metabolic Gen, Hosp Sick Children, Toronto, ON, Canada; 2) Program in Genetics and Genome Biology, Hosp Sick Children, Toronto ON, Canada; 3) University of Hong Kong, Hong kong.

Sotos syndrome (OMIM 117550) is a rare genetic overgrowth disorder associated with malformations and neurodevelopmental problems including intellectual and behavioural issues. Individuals with Sotos syndrome are haploinsufficient for NSD1 (nuclear receptor-binding SET domain protein 1), a histone lysine methyltransferase important for multiple aspects of normal development. Recently, NSD1 was shown to bind near various promoter elements, regulating multiple genes via interactions with H3K36me and RNA polymerase II. These data suggest a potential role for NSD1 in regulating transcription initiation via epigenetic mechanisms such as DNA methylation (DNAm). We utilized a novel approach to identify the functional impact of NSD1 mutations on the methylome of patients with Sotos syndrome. Bisulfite modified blood DNA from 6 NSD1 mutation- positive cases was investigated by genome-wide profiling of DNAm using the Illumina Human Infinium 27K microarray covering the promoter of 14500 genes. Differential DNAm analysis using Mann-Whitney and FDR identified a total of 1285 CpG sites with loss of DNAm and 54 CpGs with gain of DNAm that were significantly different (>10%) compared to controls (n=36). To investigate whether these DNAm differences are NSD1 specific, we examined the DNAm profiles of 2 other overgrowth syndromes Simpson-Golabi-Behmel syndrome (n=5) with mutations in GPC3 and PTEN Hamartoma Tumor syndrome (n=6)with mutations in PTEN using data from the Illumina 27k array. Differential DNAm analysis did not identify any significant DNAm at any of the 27578 CpG sites in these two disorders compared to controls. These data suggest that DNAm changes at specific gene promoters occur in concert with NSD1 haploinsufficiency. Using ingenuity pathway software, we discovered that the significant candidate CpG sites associated with NSD1 mutations are enriched within two main functional networks: mass growth and neurotransmission. These networks are highly relevant to the clinical manifestations observed in patients with Sotos syndrome and highlight the relevance of such DNAm changes. This is the first report of a functional effect of the NSD1 haploinsufficiency on the DNA methylation landscape. Further work is currently underway to identify common sequence motifs in the promoters of genes with altered DNAm signatures in NSD1 haploinsufficiency that will be critical for the characterization of genome-wide binding targets for NSD1.

Aberrant expression of DNA methylation, cellular proliferation and DNA repair genes in gastric carcinogenesis? *D.Q. Calcagno[1], F. Wisnieski[1], T.B. Brilhante[1], C.O. Gigek[1], E.S. Chen[1], M.F. Leal[1], S. Demachki[2], P.P. Assumpcao[3], R. Artigiani[4], L.G. Lorenco[5], R.R. Burbano[6], M.A.C. Smith[1].* 1) Disciplina de Genética, Departamento de Morfologia e Genética, UNIFESP, São Paulo, Brazil; 2) Servico de Anatomia patologica, Hospital Universitário João de Barros Barreto, UFPA, Belém, Brazil; 3) Servico de Cirurgia, Hospital Universitário João de Barros Barreto, UFPA, Belém, Brazil; 4) Departamento de Patologia, UNIFESP, São Paulo, Brazil; 5) Disciplina de Gastroenterologia Cirúrgica, Departamento de Cirurgia, UNIFESP, São Paulo, Brazil; 6) Laboratório de Citogenética Humana, Instituto de Ciências Biológicas, UFPA, Belém, Brazil.

Aberrant DNA methylation contributes significantly to the development and progression of gastric cancer, one of the leading causes of cancer death worldwide. A greater understanding of methylation status into these processes are necessary to help in gastric cancer patient treatment. The methylation status is controlled and mediated mainly by DNA methyltransferases (DNMT1, DNMT3A and DNMT3B) and methyl-CpG binding domain proteins (MeCP2, MBD1, MBD2, MBD3 and MBD4). We compared quantitative reverse transcriptase PCR real time in eighteen gastric tumors and their paired non-neoplastic gastric tissue samples or gastric tissue from health patients to examine the expression of DNMT1, DNMT3A, DNMT3B, MeCP2, MBD1, MBD2, MBD3 and MBD4. mRNA. We also investigated PCNA, Ki67 and MGMT gene mRNA expression, proliferative biomarkers and repair gene, respectively. In present study, DNMT1A and PCNA were overexpressed in gastric tumors than gastric tissue from health patients (U= 81, p=0.0196; U=5, p=0.0307, respectively). Additionally, we also observed that DNMT3A and Ki67 were overexpressed in paired non-neoplastic gastric tissue than gastric tissue from health patients (U=6, p=0.0443; U=11, p= 0.0029; respectively). Moreover, DNMT3A, MBD1, MBD2, MBD3, MBD4 and MGMT mRNA expression were reduced in gastric tumors than their paired non-neoplastic gastric tissue (W= 112, p=0.016; W= 108, p=0.027; W= 96, p=0.048; W= 109, p=0.027; W= 107, p=0.0210; W=79, p=0.0143, respectively). These results suggested that early onset gastric cancer involves an increase of mRNA expression of DNMT1A, DNMT3A, PCNA and Ki67. In the future, the aberrant mRNA expression of DNMT1A, DNMT3A, MBD1, MBD2, MBD3, MBD4, PCNA, Ki67, and MGHT may become valuable diagnostic and prognostic markers as well as potential therapeutic targets for gastric cancer.

Novel MicroRNAs and Epigenetic Biomarkers for Gastrointestinal Stromal Tumors (GIST). *D. Glavac[1], M. Ravnik-Glava{{cak}}[1,2].* 1) Department of Molecular Genetics, Faculty of Medicine, University of Ljubljana, Vrazov trg 2, 1000, Ljubljana, Slovenia; 2) Institute of Biochemistry, Faculty of Medicine, University of Ljubljana, Vrazov trg 2, 1000, Ljubljana, Slovenia.

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal neoplasms in the gastrointestinal tract. A small minority of GISTs are associated with hereditary syndromes. Large-scale screening of multiple types of molecular aberrations (e.g., mutations, copy number variations, DNA methylations, gene expressions, microRNA expressions) becomes increasingly important in the prognosis and study of cancer, including GISTs. GIST is primarily defined by activating mutations in the KIT or PDGFRA receptor tyrosine kinases. The mutations cause functional changes in KIT and PDGFRA proteins, usually leading to ligand-independent dimerization and constitutional activation. Whereas oncogenic KIT or PDGFRA mutations seem vital to promoting neoplastic transformation, additional genetic and epigenetic alterations are probably required to explain the wide spectrum of clinical behaviour in GIST. In our retrospective study of 126 patients with GIST we investigated KIT and PDGFRA mutational status and further evaluated novel potential biomarkers found by whole genome methylation studies and microRNA microarray analysis. We identified aberrant methylation status using eleven methylation-sensitive CpG islands in GIST with and without mutations. CIMP (CpG islands methylator phenotype, which is defined as methylation involving more than three gene promoters) was present in almoust all GIST without mutation, although there was no statistical difference between GIST with or without gene mutations. On the other hand, CIMP was found in 45 % of GIST with c-kit or PDGFRA gene mutations. In terms of risk categories, CIMP was present in 50% of low-risk GIST and in 60 % of high-risk GIST. Aberrant methylation of multiple gene promoters, as well as the c-kit and PDGFRA genes, therefore plays an important role in the tumorigenesis of GIST. Thirty-five miRNAs were found to be differentially expressed in terms of localization and mutation status. Differential expression was further analysed and confirmed for six miRNAs by qRT-PCR in 39 additional GISTs. Differentially expressed miRNAs were functionally mapped to KIT/PDGFRA signalling and G1/S-phase transition of the cell cycle, revealing several predicted miRNA/mRNA interactions for nine gene targets from KIT/PDGFRA signalling. MicroRNAs and their regulation of gene expression in a tissue-specific manner have also potential application for use as therapeutic targets or disease biomarkers.

The epigenetic alteration of PPP1R3C in the colorectal cancer. *S.K. Lee[1], J.W. Moon[1], J. Kim[2], H.S. Kim[1], S.H. Park[1].* 1) Dept Anatomy, KOREA Univ, Seoul, South Korea; 2) Dept of General Surgery, Korea Univ, Medical Center, Seoul, South Korea.

Epigenetic DNA methylation is an alternative mechanism to genetic events lead to the inactivation of gene expression. The promoter hypermethylation of gene has been frequently observed during the pathogenesis of colorectal cancer (CRC). We analyzed the methylation profile of 27,578 CpG sites spanning more than 14,000 genes in 20 CRC and 20 adjacent non-tumor containing tissues with methylation bead chip array technology. We identified 125 CpG sites located in promoter CpG islands that were significantly hypermethylated in CRC compared with adjacent normal tissues ($p<0.0001$). Protein phosphatase 1 regulatory subunit 3C (PPP1R3C) is one of hypermethylated genes at the CpG island in CRC tissues. PPP1R3C contributes to glycogen accumulation and is reported the reduced mRNA expression in 35–59% of the melanoma cell lines compared to melanocytes correlated with a high proportion of promoter methylation. We verified the down expressed PPP1R3C in CRC tissues using reverse transcription polymerase chain reaction. Moreover, we figured out the hypermethylated status of PPP1R3C in 3 CRC cell lines compared with normal colon cell line through methylation bead chip array at the 10 promoter CpG sites. The down-regulated expression level of PPP1R3C was also observed both mRNA and protein levels in 2 CRC cell lines, DLD1 and LoVo and the suppressed expression was recovered by treatment of 5-Aza-2'-deoxycytidine, a DNA methyl-transferase inhibitor. These results show that promoter methylation of PPP1R3C gene is frequently occurred and gene silencing may play a remarkable role in colon carcinogenesis.

3424T

EGCG applications on HT-29 and MCF-7 cell lines and evaluation of tumor suppressor gene methylation. *O. Ozer[1], Y.K. Terzi[1], O. Darcansoy Iseri[2], Z. Yilmaz Celik[1], F.I. Sahin[1].* 1) Department of Medical Genetics, Baskent University Faculty of Medicine, Ankara, Turkey; 2) Baskent University Institute of Transplantation and Gene Sciences, Ankara, Turkey.

Cathechins are most active constituents of green tea which include epigallocatechin 3-gallate (EGCG), epigallocatechin, epicatechin-3-gallate (ECG), and epicatechin. EGCG is an antitumor molecule and it shows this activity by binding to the active center of methyl transferase enzyme. Previous studies showed that EGCG decreased DNA hypermethylation and is a potential anti-cancer drug for cancer prevention or treatment. Promoter hypermethylation is a basic mechanism of gene silencing especially for tumor suppressor and DNA repair gene inactivation. It has been shown that methylation of promoter regions impressed in different stages of carcinogenesis. In this study, we aimed to analyze the effect of EGCG on methylation status of tumour suppressor genes in cancer cell lines, HT-29 and MCF-7. MTT assay was utilized to determine EGCG concentrations for each cell line. HT-29 and MCF-7 cells were incubated with 10μM, 20μM and 50μM, and 1μM, 5μM and 10μM EGCG for 48 hours, respectively according to the MTT results. Following incubation with or without EGCG, DNA was isolated from control and study cells. Methylation status was determined by a commercially available methylation spesific MLPA kit, ME002 tumour suppressor-2 probe mix (MRC Holland, Amsterdam, the Nederlands) for 25 different tumor suppressor genes, according to the manufacturer's instructions. In initial samples, promoter regions of CDH13, GATA5 and RARB genes were found to be hypermethylated in the MCF7 cell line. WT1, CHFR, ESR1, and PAX5 genes were hypermethylated in the HT-29 cell line in addition to these three genes. Change in methylation status was not detected in our study samples after EGCG application. Our results suggested that methylation status of tumor suppressor genes did not change with different EGCG doses. As it has been clearly shown that methylation is an important epigenetic factor on behavior of cancer cells and a potential target for epigenetic therapy, further studies would be more informative with different cancer cell lines and large gene methylation profiles to arrive at definite conclusions.

3425T

Methylation, mutational and expression analysis of IL6, IL8 and IL1B on the different tumor tissues. *M. Poulin, A. Meyer, G. Gonzalez, J. Xu, L. Yan.* EpigenDx, Hopkinton, MA.

Interleukins are a group of cytokines that were first seen to be expressed by white blood cell. Inflammatory pathways stimulated by cytokines which are meant to defend the organism against infection and injury, can promote an environment which favors tumor growth and metastasis. Supporting this is the fact that alteration in their expression have been shown to correspond with increased incidence of a variety of cancers. We have isolated the DNA from ten tumor tissues and their adjacent normal tissue from four different tumor types; ovarian, breast, colon and cervical. By utilizing a combination of bisulfite sequencing, quantitative mutation analysis, and expression analysis, we show that there are distinct patterns of methylation levels between IL6, IL18 and IL1B in each of the cancers observed. IL18 showed a dramatic decrease in promoter methylation in all tumor types. In IL6, specific regions within the promoter are differentially methylated inter- as well as intra-genetically. The normal tissue distal promoter shows very high levels of methylation while the proximal promoter methylation levels are very low. When the distal promoter is examined between normal and tumor tissue, there is a distinct hypomethylation observed in all types with the greatest difference being in ovarian and breast tumors. There is very little variation between the normal and tumor tissues in the proximal promoter. IL1B methylation is very variable, where certain cancers and regions within the promoter show hypermethylation while others show hypomethylation. We have also analyzed a number of SNPs within these genes and show a possible correlation with the methylation and /or expression of the genes and the SNP genotypes. These data may provide information that would develop biomarkers for different cancers.

Methylation Profiling of Tumor Suppressor Genes in Invasive Ductal Breast Carcinoma. *Y.K. Terzi[1], F.I. Sahin[1], O. Ozer[1], Z. Yilmaz Celik[1], B. Demirhan[2], M.C. Yagmurdur[3].* 1) Department of Medical Genetics, Baskent University Faculty of Medicine, Ankara, Turkey; 2) Department of Pathology, Baskent University Faculty of Medicine, Ankara, Turkey; 3) Department of General Surgery, Baskent University Faculty of Medicine, Ankara, Turkey.

Breast cancer is the most common cancer and one of the leading causes of cancer death in females worldwide. Genetic and epigenetic changes play pivotal roles in the development and progression of breast cancer. One important epigenetic mechanism is the methylation of genomic DNA. CpG-islands are located in or near the promoter region or other regulatory regions of approximately 50% of human genes. Many tumors have excessive methylation of CpG islands. Silencing of tumor suppressor genes through promoter hypermethylation is known to be a common event in carcinogenesis, including breast cancer. Its reversible nature makes methylation an attractive biomarker for better diagnosis and prognosis. In this study, we examined the promoter methylation status of 25 tumor suppressor genes in formaline fixed parafin embedded tissues from 18 patients diagnosed with invasive ductal carcinoma. Methylation status was determined by a commercially available methylation specific MLPA kit, ME002 tumour suppressor-2 probe mix (MRC Holland, Amsterdam, the Nederlands) for 25 different tumor suppressor genes, according to the manufacturer's instructions. According to our analysis results, GATA5, CDH13, BRCA2, MSH6, CD44 and CDH13 were found to be hypermethylated in invasive ductal breast carcinoma tissues. Promoter hypermethylation of these genes in breast carcinoma tissues, except GATA5, has been reported previously. We found hypermethylation of GATA5 promoter in 3 of the tissues in the current study. Although altered expression of GATA5 has found to be associated with different tumors, its function in human cancers including breast cancer is not well defined yet. Methylation of tumor suppressor genes is known as an early hallmark of carcinogenesis. Determining the methylation status of genes in different types of breast cancer tumors will help us to unravel disease pathogenesis, and be able to anticipate the prognosis. In addition, identified genes can be used as early biomarkers in preventive medicine.

Whole genome bisulfite sequencing of acute lymphoblastic leukemia cells. *P. Wahlberg[1], J. Nordlund[1], O. Karlberg[1], C. Bäcklin[2], U. Liljedahl[1], E. Forestier[5,4], M. Gustafsson[2], G. Lönnerholm[3,4], A-C. Syvänen[1].* 1) Molecular Medicine, Department of Medical Sciences, Uppsala University, Sweden; 2) Cancer Pharmacology and Computational Medicine, Department of Medical Sciences, Uppsala University, Sweden; 3) Department of Children's and Women's Health, Uppsala University, Sweden; 4) For the Nordic Society of Pediatric Hematology and Oncology (NOPHO); 5) Department of Medical Biosciences, University of Umeå, Umeå, Sweden.

Acute lymphoblastic leukemia (ALL) is the most common pediatric cancer in the developed countries. With modern treatment protocols children with ALL have a good prognosis, but for unknown reasons, approximately 20% of patients do not respond to treatment. DNA methylation of CpG sites plays an important role in cell differentiation and establishment of cell identity by regulation of gene expression. Aberrant methylation patterns have been observed in a wide variety of cancers. We and others have previously documented large differences in the DNA methylation patterns of ALL epigenomes compared to control immune cells, and common methylation patterns have been identified in ALL subtypes. Because of its importance for cellular function, abnormal methylation patterns could play a major role in ALL pathogenesis. Hence, epigenomic analysis can shed light on specific genes and pathways involved in ALL pathogenesis. Bisulfite sequencing is considered as the golden standard for methylation analysis and offers in combination with high-though sequencing the possibility to determine genome-wide cytosine methylation levels at base-pair resolution. In addition, bisulfite sequencing provides information on haplotype-specific methylation. To determine the patterns of methylation in ALL cells we have generated whole genome bisulfite sequencing data at high coverage to characterize in detail the methylomes of four samples, representing different subtypes of ALL. We will present a detailed view of the methylation patterns in the four bisulfite-sequenced ALL patients together with analysis of RNA-Seq data that we will use to infer how methylation affects transcription. We will also investigate the occurrence of allele-specific methylation and its role in allele-specific gene regulation.

3428T

Integrative genomic and epigenomic profiling of bladder cancer. *A. Woloszynska-Read[1], D. Wang[2], L. Yan[2], Q. Hu[2], J. Wang[2], W. Bshara[3], J. Conroy[4], K. Guru[5], C. Morrison[3], S. Liu[2], D.L. Trump[6], C.S. Johnson[7].* 1) Cancer Prevention and Population Science, Roswell Park Cancer Institute, Buffalo, NY; 2) Biostatistics & Bioinformatics, Roswell Park Cancer Institute, Buffalo, NY; 3) Pathology, Roswell Park Cancer Institute, Buffalo, NY; 4) Center for Genomic Medicine, Roswell Park Cancer Institute, Buffalo, NY; 5) Urology, Roswell Park Cancer Institute, Buffalo, NY; 6) Medicine, Roswell Park Cancer Institute, Buffalo, NY; 7) Pharmacology and Therapeutics, Roswell Park Cancer Institute, Buffalo, NY.

Bladder cancer (BC) is among the most common and prevalent malignancies worldwide, and has remained so for over 30 years. The development of BC is associated with the accumulation of multiple genetic and epigenetic changes. The aim of this study was to characterize BC tissues comprehensively using state-of-the-art DNA methylation and genome sequencing methods, and conduct integrative analyses to identify chromosomal regions affected by genetic and/or epigenetic changes contributing to invasive phenotypes of the disease. We performed a new generation DNA methylation profiling study of 106 bladder tumors and 52 adjacent normal tissues. Our initial findings demonstrate that DNA methylation patterns of more than 450K interrogated CpG loci reliably distinguish tumor and non-malignant bladder tissues, with tumors characterized by global hypermethylation in CpG islands and hypomethylation in CpG shores, shelves, and open seas. Unsupervised clustering of DNA methylation profiles using a recursively portioned mixture model (RPMM) revealed three distinct DNA methylation clusters for BC tissues. The Wilcoxon signed-rank test and the Wilcoxon rank-sum test were used to evaluate differences in DNA methylation β-values for each probe between 52 tumors and 52 matched adjacent-non-malignant tissues, and between the independent 54 tumors and the same 52 non-malignant tissues, respectively. We identified a unique core set of differentially methylated genes enriched for homeobox transcription factors and cell-cell adhesion pathway. Using exome sequencing data from a subset of samples profiled by 450K array, we identified a number of genes harboring non-silent somatic mutations, with MLL2 mutated in more than 40% of tumors. Our study is the first to report MLL2 as a frequent target of somatic mutation in BC. MLL2 is a chromatin modifying protein involved in gene expression and epigenetic control of active chromatin states, and MLL2 mutation may have an effect on DNA methylation patterns in BC. Mutation screening on a set of discovered mutated genes in the remaining samples is currently ongoing to integrate the observed mutations with DNA methylation clusters. We are also examining the clinical and pathologic stage and history of these tumors to discern potential genetic and epigenetic associations. This study could reveal important genomic and epigenomic differences between BC and bladder non-malignant tissues, and define diagnostic, prognostic, and therapeutic targets.

Differential and sex-specific DNA methylation of the placental *LEP* promoter in early onset preeclampsia. *K. Hogg[1], J.D. Blair[1], M.S. Peñaherrera[1], K. Louie[1], P. von Dadelszen[2], W.P. Robinson[1].* 1) Dept. of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Dept. Obstetrics and Gynaecology, University of British Columbia, Vancouver, BC, Canada.

Preeclampsia is a common disorder characterized by poor placentation, maternal hypertension and proteinuria and is often associated with fetal intrauterine growth restriction (IUGR). Maternal biomarkers of preeclampsia include elevated plasma leptin and placental *LEP* expression is upregulated. We previously showed that the *LEP* gene promoter is differentially methylated in an imprinted manner in placenta. We hypothesize that altered DNA methylation in the placental *LEP* promoter provides a molecular mechanism for altered expression in these patients. To measure methylation of CpG dinucleotides within the *LEP* promoter, bisulphite pyrosequencing was performed in third trimester placentae from control (n=111), early onset preeclampsia (EOPET; n=19), late onset preeclampsia (LOPET; n=18) and IUGR (n=13) pregnancies. Candidate CpGs were selected based on their proximity to the transcription start site (TSS), TATA box, SP1 and C/EBP transcription factor binding motifs, and a hypoxia response element (HRE). Raw methylation values were adjusted for gestational age and data was additionally stratified by infant gender. *P*-values were adjusted for multiple comparisons. Hypomethylation of the *LEP* promoter was observed in EOPET placentae compared to controls, but not LOPET or IUGR cases. A >10% loss of methylation was observed at CpG sites +9, +14 and +20 bp upstream of the TSS ($P<0.001$). At the TSS (-1; $P<0.01$), and the SP1 (-19) and C/EBP (-51) binding sites, there was a >5% loss of methylation. No methylation change was observed proximal to the HRE (-115,-118). Upon gender-stratification, methylation of the CpG site contained within the C/EBP consensus sequence was significantly hypomethylated in females ($P<0.01$) but not males, compared to controls. Hypomethylation of the placental *LEP* promoter in EOPET, possibly due to loss of methylation of the imprinted allele, may be a mechanism by which *LEP* gene expression is altered in these placentas. Leptin is known to promote proliferation and survival of trophoblast cells, therefore methylation differences may be explained by differing cell populations. The absence of methylation changes in LOPET confirms the differing underlying etiology between early and late onset preeclampsia. Lack of change in IUGR placentas suggests that growth restriction is not a contributory factor. Finally, these results indicate placental sexual dimorphism that may confer altered susceptibility and/or adaption to pathological events.

3430T

A Genome-wide DNA Methylation Association Study of Young-Onset Hypertension in Han Chinese Population of Taiwan. *K.M. Chiang[1,4], H.C. Yang[2], J.W. Chen[3], W.H. Pan[4].* 1) Institute of Biomedical sciences, Academia Sinica, Taipei, Taiwan; 2) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan; 3) National Yang-Ming University School of Medical and Taipei Veterans General Hospital, Taipei, Taiwan; 4) Institute of Biomedical Science, Academia Sinica, Taipei, Taiwan.

Hypertension is a common and complex disorder. Young-onset hypertension (YOH) may be a more feasible target disorder to investigate than the late-onset one due to its stronger genetic component. We performed a two stage genome-wide Methylation association study to map YOH susceptibility methylated loci. In the first stage, we analyzed 45 YOH cases and 45 normotensive controls with age, sex and BMI adjusted in all the analyses. In the second stage, an independent set of 205 YOH cases and 205 normotensive controls were used to validate the findings from the first stage. Illumina HumanMethylation450 BeadChip (> 485,000 methylation sites) was used to generate the β value, which is proportional to the degree of methylated state of any particular loci. SAS and PARTEK Genomic Suit were used for further statistical analyses. We will also integrate the genome-wide CNVs and gene expression data with methylation data to see the functional effect of methylation. Illumina HumanHap 550K Genotyping BeadChip was used for CNV calling and Phalanx Human OneArray v5.1 (30,275 transcripts) was used to measure the whole genome gene expression profiles. In addition to the single locus tests, we will also perform the gene set analyses based on 4277 Gene Ontology categories, 299 BioCarta pathways and 128 KEGG pathways. Several gene sets have been identified in our study.

3431T

Genome wide DNA methylation profiling of monozygotic twins discordant for trisomy 21. *A. Letourneau[1], M.R. Sailani[1], F. Santoni[1], D. Robyr[1], P. Makrythanasis[1], A. Sharp[2], S.E. Antonarakis[1,3].* 1) Genetic Medicine & Development, University of Geneva Medical School, Geneva, Switzerland; 2) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, NY 10029 USA; 3) iGE3 institute of Genetics and Genomics of Geneva, Switzerland.

DNA methylation is essential in mammalian development and has an effect in gene expression. We have hypothesized that methylation differences induced by trisomy 21 (T21) contribute to the phenotypic characteristics and heterogeneity in T21. In order to determine the methylation differences in T21 without the interference of the genomic variation, we have used fetal fibroblasts from monozygotic twins discordant for T21. We also used fibroblasts from monozygotic twins concordant for T21, normal monozygotic twins without T21, and unrelated normal and T21 individuals as controls. We applied Reduced Representation Bisulfite Sequencing (RRBS) to generate nucleotide resolution of DNA methylation based on high throughput sequencing (HiSeq 2×100bp) between each pair of twins. An initial analysis of MZ twins discordant for T21 identified 66,491 differentially methylated C nucleotides out of 2,316,600 interrogated nucleotides (DMCs) (FDR<0.01 and at least 25% methylation difference per C) of which 38%, 21%, and 41% reside in gene bodies, promoters, and intergenic regions respectively. The KEGG gene ontology analysis of genes harboring DMCs, showed an enrichment for embryonic morphogenesis (BH_FDR=1.8E-8), neuron differentiation (BH_FDR = 5.6E-7), and cell projection organization (BH_FDR = 2.7E-6); pathway analyses showed an enrichment for genes involved in cancer (BH_FDR=7.6E-5), MAPK signaling (BH_FDR=2.4E-4), and axon guidance (BH_FDR=2.7E-3). The study of methylation differences in monozygotic twins discordant for genomic abnormalities is a promising approach to understand the molecular mechanisms of aneuploidies.

3432T

Genome-wide quantitative DNA methylation analysis of imprinted DMRs in patients with Beckwith-Wiedemann Syndrome by MALDI-TOF MS technology. *T. Maeda, K. Jozaki, H. YAtsuki, K. Higashimoto, H. Soezima.* Biomolecular Sciences, Faculty of Medicine, Saga University, Saga, Saga, Japan.

Beckwith-Wiedemann Syndrome (BWS) is a genomic imprinting disorder characterized by macroglossia, macrosomia, and abdominal wall defect and a predisposition to embryonal tumor in childhood. Dysregulation of imprinted growth regulatory genes due to epimutation, such as loss of methylation at KvDMR (KvDMR-LOM) and gain of methylation at H19-DMR (H19DMR-GOM) within 11p15.5, is the major cause of BWS. It has been reported that BWS with the epimutation also showed hypomethylation at imprinted differentially methylated regions (DMRs) outside of 11p15.5 including ZAC and GNAS loci. However, there has been no report of a genome-wide analysis of imprinted DMRs in BWS patients. In this study, we performed quantitative DNA methylation analysis of 34 imprinted DMRs scattered throughout human genome in 47 BWS patients (37 with KvDMR-LOM, 10 with H19-GOM) by MALDI-TOF MS technology. We also used pyrosequencing to confirm the aberrant methylation detected by MALDI-TOF MS. A strong correlation between the results of MALDI-TOF MS and that of pyrosequencing was found (p = 1.6 × 10-77). By the genome-wide analysis, we identified aberrantly methylated DMRs outside of 11p15.5, which were not reported previously, in both patients with KvDMR-LOM and H19DMR-GOM. In patients with KvDMR-LOM, 14 of 37 patients (37.8%) showed the ectopic aberrant methylation, and about half of patients showed it at plural DMRs. It has been reported that most of all the ectopic aberrant methylation was hypomethylation and occurred at maternally methylated DMRs. However, our result showed hypermethylation at both maternally and paternally methylated DMRs. In patients with H19DMR-GOM, 3 of 10 patients (30.0%) showed the ectopic aberrant methylation. Six showed hypermethylation at either or both of IGF2-DMR0 and IGF2-DMR2, suggesting coordinate biallelic expression of IGF2 by H19-DMR and IGF2-DMR0 and/or IGF2-DMR2. Frequency of the ectopic aberrant methylation among all DMRs analyzed in KvDMR-LOM patients (3.73%) was significantly higher than that in H19DMR-GOM patients (1.03%) (p = 0.0199, chi-square test). Since it is considered that KvDMR-LOM and H19DMR-GOM occur during pre- and post-implantation, respectively, the significant difference suggested that methylation of imprinted DMRs was relatively unstable in pre-implantation stage in comparison with post-implantation stage.

Epigenomic features and transcription factor binding sites associate with hotspots of genomic instability in human germline and in cancer. *C. Coarfa[1], C.S. Pichot[2], A.R. Jackson[1], A. Tandon[1], S. Raghuraman[1], S. Paithankar[1], A.V. Lee[3], S.E. McGuire[2], A. Milosavljevic[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX; 3) Pharmacology and Chemical Biology, University of Pittsburgh, Pittsburgh, PA.

Mechanisms of copy-number and other structural variation in human germline and in somatic cancer cells are poorly understood. A large fraction of mutability that selectively affects specific hotspots not associated with NAHR remains to be explained. We recently demonstrated strong association of selective structural mutability with genomic hypomethylation (Li et al, PLoS Genetics 2012 8(5) e1002692). The hypomethylation associates with structurally polymorphic and fast-evolving loci. Rare CNVs occurring in the genomes of individuals diagnosed with schizophrenia, bipolar disorder, and developmental delay and de novo CNVs associated with autism are significantly more concentrated within the hypomethylated loci. We here extend these original findings in the following two directions. (1) To increase resolution and scope, we analyze fifty mate-pair sequencing genome profiles from the pilot 1000 Genome Project and high-resolution breakpoint maps derived by sequencing thirty breast and prostate cell lines and tumor samples, including six mate-pair profiles derived in the course of this project. Analysis of these independent data sets confirms that genomic breakpoints originating in human germline strongly associate with germline-specific genomic hypomethylation in contrast to cancer-associated somatic structural variants which do not. (2) To examine potential role of factors other than methylation, we analyze the variants in the context of the Human Epigenome Atlas, ENCODE, and Cistrome databases, including a total of over 250 relevant epigenomic profiles and transcription factor binding maps. We find that structurally mutable loci in germline associate with ChIP-seq binding sites of Suz12, a key member of the PRC2 Polycomb complex, with H3K27me3 and H3K9me3 histone marks regulated by PRC2 and with ChIP-seq binding sites of other transcription factors regulating the two histone marks. The breakpoints in breast cancer associate with different sets of transcription factor binding sites and epigenomic marks and are particularly concentrated around distal active enhancers. HER2- and HER2- breast cancer cell lines also show distinct distributions of genomic breakpoints. In summary, the observed patterns of association suggest roles for the epigenome and transcription factors in selective structural mutability both in germline and in somatic cells.

3434T

DNA methylation influences lipid and adipokine profiles. *M.A. Carless, H. Kulkarni, D.L. Rainwater, A.G. Comuzzie, M.C. Mahaney, J. Blangero.* Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX, 78227-5301.

Lipid and adipokine imbalances are a critical component of obesity and metabolic syndrome, which are strong risk factors for cardiovascular disease, the leading cause of death worldwide. Although blood lipid levels are heritable, known genetic effects explain only 10–15% of variance within these traits so we set out to identify epigenetic factors that might contribute to variance in lipid and adipokine levels. Using Illumina HumanMethylation450 BeadChips, we generated genome-wide methylation profiles for 1,200 Mexican American individuals from the San Antonio Family Heart Study. In a preliminary subset of 404 individuals, we estimated heritability and performed association analysis of serum lipid and adipokine concentrations using quantitative DNA methylation levels at 482,419 CpG sites. In total, 5,016 CpG sites (~1%) were found to be heritable after Bonferroni correction for multiple tests ($p<1.04\times10^{-7}$). Several associations that approached significance were seen between DNA methylation and serum levels of high density (HDLC) and low density (LDLC) lipoprotein cholesterol, triglycerides, adiponectin and leptin. Notably, triglyceride levels were suggestively associated with methylation in *STARD13* ($p=6.35\times10^{-6}$), a gene previously implicated in lipid variation and metabolic syndrome, as well as with methylation in *GULP1* ($p=1.56\times10^{-5}$), a gene implicated in cellular lipid homeostasis. These genes were also suggestively correlated with HDLC levels, showing an opposite direction of effect. LDLC was suggestively associated with methylation in *PTRF* ($p=4.3\times10^{-6}$), a gene implicated in lipodystrophy. Methylation within *TTC7B* ($p=1.10\times10^{-6}$), a gene implicated in obesity, stroke and cardiovascular disease, and methylation within *FOXA1* ($p=2.30\times10^{-6}$), which may be involved in adipogenesis, were suggestively associated with adiponectin levels. Leptin levels were suggestively associated with methylation in *ASAM* ($p=1.50\times10^{-5}$), a gene involved in adipocyte differentiation and diet-induced obesity. Several other, potentially novel associations were seen, including methylation within genes having transcriptional or translational regulatory functions. We are currently analyzing additional samples and phenotypes to further investigate the role of DNA methylation in lipid and adipokine variation. The identification of genes influencing such variation will contribute to our understanding of the pathophysiology of obesity, metabolic syndrome and cardiovascular disease.

3435T

Identification of epigenetic markers underlying increased risk of type 2 diabetes in South Asians: the EpiMigrant Pilot Study. *A. Drong[1], C. Blancher[1], M.R. Jarvelin[2,3,4,5], C.M. Lindgren[1], P. Elliott[2,3], M.I. McCarthy[1,6], J.S. Kooner[7], J.C. Chambers[2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Epidemiology and Biostatistics, Imperial College London, London, United Kingdom; 3) MRC-HPA Centre for Environment and Health, Imperial College London, London, United Kingdom; 4) Institute of Health Sciences, University of Oulu, Oulu, Finland; 5) National Institute of Health and Welfare, Oulu, Finland; 6) Oxford Centre for Diabetes Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 7) National Heart and Lung Institute, Imperial College London, London, United Kingdom.

Type 2 diabetes (T2D) is 2–4 times more common in South Asians than Europeans; this difference in susceptibility is not accounted for by differences in physical activity, diet, obesity or known genetic variants. We report a pilot epigenome-wide association study (EWAS) designed to explore epigenetic factors contributing to increased risk of T2D amongst South Asians. We investigated 45 South Asian men participating in the London Life Sciences Population (LOLIPOP) study, and recruited from GP lists in London (UK). At baseline (age=50.9±9.1 years), all individuals were normal glucose tolerant (NGT, glucose<7mmol/L and HbA1c<6.0%). During follow-up 7.0±0.9 years later, 15 subjects remained NGT, while 30 developed T2D (glucose≥7mmol/L and HbA1c≥6.5%). Of the 30 people with incident T2D, 15 were previously undiagnosed and not on treatment (U-T2D), while 15 had been clinically diagnosed and were on treatment (T-T2D). Whole blood was collected at baseline and follow-up: genomic DNA was extracted from all 90 samples in one batch. Percent methylation (beta) at 485,577 sites was profiled with the Infinium HM450 BeadChip, excluding signals with detection $p<0.01$ and markers with >5% failure rate. We investigated association of DNA methylation with incident T2D and potential confounders including age, body mass index, drug treatment, white blood cell count (WBC) and white cell subsets using linear models. We measured the inflation of associations $\lambda=\text{mean}\beta^2/\text{var}(\beta)$, where β is the regression coefficient. In the baseline samples, we found global differences in beta between incident T2D and controls (U-T2D vs NGT: λ=1.60; T-T2D vs NGT: λ=2.10). In contrast betas were similar between U-T2D and T-T2D (λ=1.01). To assess the impact of aging we compared baseline to follow-up samples as Δbeta per marker; we again found marked differences in Δbeta between people who developed T2D and those who remained NGT (U-T2D vs NGT: λ=1.51; T-T2D vs NGT: λ=1.51). Beta values closely associated with age (λ=2.29) and with white cell differentials (lymphocytes: λ=5.18; neutrophils: λ=2.30; eosinophils: λ=1.59), but not with total WBC or BMI. Associations of beta with T2D persisted after adjustment for these confounders (U-T2D vs NGT: λ=1.46; T-T2D vs NGT: λ=1.97). Our findings support the hypothesis that epigenetic markers may predict or influence risk of T2D in South Asians, but reveal important confounding effects that will need to be controlled for in the design of future T2D EWAS.

Epigenome-wide association analysis identified aging alteration of DNA methylation level in the genes related to metabolic pathways. *H. Kitajima, K. Yamamoto.* Division of Genome Analysis. Research Center for Genetic Information., Medical Institute of Bioregulation, Kyushu University, Fukuoka, Fukuoka, Japan.

Aging affects various physiological processes and increases susceptibility to diseases. Whether aging alters DNA methylation level, whether genetic polymorphism affects aging-related epigenetic change, and how the aging-related epigenetic change influences disease traits are of great interest. To settle this matter, we performed epigenome-wide association study by analyzing approximate 450K DNA methylation sites using the blood sample of total 384 subjects in Japanese general population. We conducted multistage association analysis between DNA methylation level and age by adjusting with sex and body mass index using general linear model for 96 subjects in each step. We identified 10 age-associated methylation sites which showed P-value < 0.001 in every four sets. The P-value of these sites in combined set (384 subjects) reached conservative Bonferroni threshold (P-value < 1.05×10^{-7} accounting for 473,864 tests). The location of these sites were as follows; the 2 sites (5.8×10^{-36} and 1.5×10^{-15}) in *ELOVL2* which is included in the n-3 polyunsaturated fatty acid (PUFA) metabolic pathway, the 2 sites (2.3×10^{-29} and 1.9×10^{-29}) in *FHL2*, the one site (1.2×10^{-20}) in *OTUD7A*, the 2 sites (9.3×10^{-20} and 4.6×10^{-16}) in *KLF14* which is associated with diabetes mellitus, the one site (2.5×10^{-18}) in *TRIM59*, the one site (4.1×10^{-15}) in *UBE2D2*, *CXXC5*, the one site (1.9×10^{-13}) in 16q24 locus. We further investigated disease association of the age-associated DNA methylation level in terms of hypertension, diabetes mellitus, and dyslipidemia. The one methylation site in *ELOVL2* significantly associated with hypertension (P-value = 4.4×10^{-4}). This association newly highlighted the relationship between the hypertensive state and the n-3 PUFA metabolic pathway which is related to the serum high-density lipoprotein cholesterol level. In addition, we found that the methylation levels of one site in *KLF14* and the one site in *OTUD7A* are significantly association with the genotype of nearby SNPs (linear regression P-value = 3.2×10^{-7} and 3.2×10^{-7}, respectively). Our findings imply that aging and its individual difference would be understood through an extent of epigenetic change of genes involved in metabolic pathways which are essential for maintenance of cellular activity.

Alterations in methylation status of immune response genes promoters in cell-free DNA during a hemodialysis procedure in patients with diabetic nephropathy and in non-diabetic subjects. *M. Korabecna[1, 2], E. Pazourkova[1, 2], A. Horinek[1, 2], M. Mokrejsova[3], V. Tesar[2].* 1) Faculty of Medicine in Pilsen, Charles University in Prague, Pilsen, Czech Republic; 2) First Faculty of Medicine, Charles University in Prague, Prague, Czech Republic; 3) Third Faculty of Medicine, Charles University in Prague, Prague, Czech Republic.

Background: Elevations of cell-free DNA (cfDNA) concentrations during hemodialysis (HD) sessions were reported in numerous studies. In this study, we focus on methylation status of promoters of 24 immune response genes at the level of plasma cfDNA and their alterations provoked by the HD process in patients with diabetic nephropathy (DN). 20%-40 % of patients with diabetes mellitus (DM) develop DN which belongs to one of the most frequent causes of HD therapy. Then the HD therapy itself could highly modify patient's immune system. Methods: We isolated plasma cfDNA from 20 patients with DN and from16 non diabetic patients before and after a HD session. We examined also cfDNA from 10 healthy volunteers two times per day with 4 h interval. The extent of promoter methylation of 24 genes involved in immune response was examined using the EpiTect Methyl qPCR Array Inflammatory Response and Autoimmunity and cluster analysis (SABiosciences, Qiagen). We compare results obtained in DN patients with methylation patterns in healthy controls and non- diabetic HD patients using STATISTICA software ver.10. Results: We described significant changes in promoter methylation of genes IL17C, IL7, IL13 and IL15 that were promoted in consequence of DN patient's blood contact with artificial surfaces of dialyzer. In interdialytic interval we found significant differences between DN patients and healthy subjects in three genes only (IL13RA1, EDG3 and IL7) but after a HD procedure significant alterations were found in 50% of examined genes. The only highly significant difference between DN and non-diabetic hemodialyzed subjects immediately after HD session was found in the promoter methylation in the IL12B gene which is one of candidate type I diabetes susceptibility gene. Conclusion: The method provides the new tools for evaluation of immune system activity in HD patients. The results can be further correlated with clinical data to contribute to understanding the complex pathogenesis of renal failure and its treatment. Supported by grants no. Genome-wide DNA methylation study of obesity and type 2 diabetes. *D. Zhou, D. Zhang, Z. Zhang.* Bio-X Institutes, Key Laboratory for the Genetics of Developmental and Neuropsychiatric Disorders (Ministry of Education), Shanghai Jiao Tong University, shanghai, China.

Obesity and type 2 diabetes are complex metabolic diseases, which affected by both environmental and genetic factors. Epigenetic effects, especially DNA methylation, may play very important role in the occurrence and development processes. In this study, we used high-fat diet induced obese and diabetic model mice as experimental material, and used two genome-wide methylation sequencing technology (MeDIP sequencing and MSCC sequencing) to investigate the changes of DNA methylation in the process of obesity and diabetes. We found that the genes, which involved in MAPK pathway, insulin pathway and cancer pathway, have significant changes in DNA methylation.

Density of inter-individual epigenome variation uncovered by integrative epigenome mapping at single base resolution. *J.J. Lambourne, S. Busche, V. Adoue, T. Kwan, M. Caron, G. Bourque, M. Lathrop, T. Pastinen.* McGill University, Montreal, Quebec, Canada.

Combination of human epigenomic data with transcriptome analyses has principles of tissue specificity and at increased pace assigned function to non-coding DNA elements. Large-scale efforts have mostly focused on revealing principles of tissue differentiation and demonstrated enrichment of phenotype associated genetic variants at non-coding functional elements. Previous studies have linked thousands of such variants also to expression quantitative traits and more recently to population variation in chromatin and transcription factor binding. Epigenome Mapping Centre at McGill (EMC-McGill) is pursuing understanding of tissue-specific epigenomic signatures applying next-generation sequencing (NGS) based approaches ChIP-seq. of chromatin marks, strand-specific RNA-seq. and whole genome bisulphite-seq. (methylC-seq.). To address contribution of inter-individual sequence and epigenomic variation to genome function, EMC-McGill is carrying out detailed epigenome mapping in primary cells related and unrelated donors. In pilot studies we compared low coverage (5x) methylC-seq. to Illumina 450K to interrogate inter-individual CpG-methylation variation and its correlation to other functional genomic data (ChIP-seq./RNA-seq). Overall, >100x more interindividual methylation variation was revealed by methylC-seq. Unbiased methylation seq. observed substantially higher genome methylation as compared to estimates based on targeted 450K analyses, while at all overlapping sites the methylation estimates were (r2 = 0.85 to 0.90) concordant even at low seq. coverage. Furthermore, expression phenotypes correlate substantially better with methylC-seq. as compared to Illumina 450K. On-going analyses are targeted to derive precise estimates of the additional functional genomic variation at chromatin at expression states achieved by methylC-seq. as well as extension of the single-base intergrative analyses to multiple human primary cells including longitudinal sampling in population. Early results suggest that studies applying targeted tools may not appreciate full spectrum of epigenomic variation in populations.

Allelic-dropout during PCR in the promoter of an imprinted gene potentially caused by interaction between G-quadruplex structures and DNA methylation. *M.A. Kennedy[1], A.J. Stevens[1], S. Stuffrein-Roberts[1], A. Gibb[1], K. Doudney[1], A. Bagshaw[1], A. Aitchison[1], M.R. Eccles[2], V.V. Filichev[3], P.R. Joyce[4].* 1) Dept Pathology, University of Otago, Christchurch, Christchurch, New Zealand; 2) Department of Pathology, University of Otago, Dunedin School of Medicine, Dunedin, New Zealand; 3) Institute of Fundamental Sciences, Massey University, Palmerston North, New Zealand; 4) Department of Psychological Medicine, University of Otago, Christchurch, New Zealand.

While exploring genetic variability in the maternally imprinted human gene MEST, which plays a role in development and maternal behaviour(1–3), we discovered three SNPs in a CpG island located at the 5' end of the gene(4). These SNPs are in total linkage disequilibrium, such that there are two haplotypes in the human population. When these SNPs were typed in many subjects we observed a non-Mendelian pattern whereby only one haplotype was detectable in each subject, never both, despite the use of multiple methods. Experiments in which genomic DNA from different subjects was mixed prove that the assays were capable of detecting both haplotypes simultaneously(4). The absence of observed heterozygotes was most likely due to allelic dropout of one allele, although dropout of different alleles in different subjects was puzzling. We tested the effect of methylation in PCRs where amplified products for both MEST haplotypes were mixed to mimic heterozygous templates, and found that artificially methylated templates dropped out of these reactions. This suggested that DNA methylation is important in dropout, but alone this seems unlikely to completely account for it. Sequences in the MEST promoter region appear capable of forming non-B DNA structures known as G-quadruplexes (G4). Circular dichroism and native gel electrophoresis with oligonucleotides confirmed that at least three MEST promoter regions are capable of forming marked G4 structures, and that the corresponding complementary strands for each region were capable of forming a different secondary structure known as an i-motif. These data lead us to suggest that methylated DNA causes stabilization of G4 structures in vitro, leading to polymerase blockage and allelic dropout of the imprinted allele. This would account for the loss of different alleles in different subjects. Proof of this awaits an assay that does not suffer allelic dropout, so the parental status and methylation pattern of lost alleles can be ascertained. If this model proves correct, it also raises the question of whether in vivo interactions between DNA methylation and G4 or i-motif structures can occur. 1. Lefebvre et al. Genetics of Global DNA Methylation Patterns in Adipose Tissue from Twins and Its Effect on Gene Expression and Disease: The MuTHER Study. *E. Grundberg[1,2], E. Meduri[1,2], J.K. Sandling[1], A.K. Hedman[3], S. Keildson[3], J. Nisbet[1], M. Sekowska[1], A. Wilk[1], A. Barett[3], K.S. Small[1,2], J.T. Bell[2], E.T. Dermitzakis[4], M.I. McCarthy[3,5,6], T.D. Spector[2], P. Deloukas[1].* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 4) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 5) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Churchill Hospital, Oxford, United Kingdom; 6) Oxford National Institute for Health Research Biomedical Research Centre, Churchill Hospital, Oxford, United Kingdom.

Functional approaches to interpret disease-associations identified in GWAS are in high demand. Many of the disease-associated variants map to non-coding DNA and as a result functional association studies of transcriptome in human tissues targeted to the disease of interest have elucidated layers of impact for common SNPs.As DNA methylation is known to be an important regulator of gene expression the approach is now being expanded to include epigenomic data as well. To this end, we used the IlluminaHumanMethylation450 array to profile 662 adipose tissue samples derived from well phenotyped female twins from the MuTHER project - a major resource ofdetailed genomic (HapMap2) and transcriptomic(IlluminaHT-12)data from multiple tissues.As the majority of the profiled cytosine sites were invariable across individuals we restricted analysis to the 34,685 (10%) most informative sites. Both genome-wide heritability analysis and simple correlations of methylation levels within and between twin pairs (r_{MZ}= 0.96, r_{DZ}=0.94, $r_{unrelated}$=0.92) confirmed evidence for DNA methylation being heritable. To map the underlying genetic (regulatory) effect we performed methylationQTL (mQTL) analysis and found an abundance of common variants (MAF >5%) acting in *cis* with top associations enriched in close proximity to the site (median distance 9kb). The majority (71%) of the cytosine sites associated with an mSNP at 1% FDR were located in CpG islands, shores or shelves. By combining the *cis*-mQTL data with *cis*-eQTLs we noted that 7.6% of the associations were directly overlapping, indicating genetic regulation of gene expression being mediated through DNA methylation.This degree of overlap (~8%, 1% FDR) was further confirmed by association analysis directly comparing methylation patterns of CpG sites in gene promoters with gene expression scores of corresponding genes on the IlluminaHT-12 expression array where an excess of negative correlations ($beta_{median}$=-0.03) was noted. Finally, preliminary observations of a first attempt to integrate disease associations (NHGRI GWAS catalogue) with adipose-derived methylome data indicate an enrichment of mSNPs overlapping with disease loci associated with estrogen-dependent diseases and traits such as age of menarche, ovarian and breast cancer. On-going analysis includes utilizing the twin design to map familial (genetic and common environment) and unique environmental effect of the methylome.

A methylome-wide MBD-seq study followed by replication in a total of 3,000 schizophrenia case-control samples identifies new disease biomarkers. *K.A. Aberg[1], J.L. McClay[1], S. Nerella[1], S.L. Clark[1], G. Kumar[1], W. Chen[2], A.N. Khachane[1], G. Gao[2], L.Y. Xie[1], A. Hudson[1], J. Bukszar[1], C.M. Hultman[3], P.F. Sullivan[3,4], P.K.E. Magnusson[3], E.J.C.G. van den Oord[1], Swedish Schizophrenia Consortium.* 1) Sch Pharmacy, Ctr Biomarker Res & Personalized Med, Virginia Commonwealth Univ, Richmond, VA; 2) Department of Biostatistics, School of Medicine, Virginia Commonwealth University, Richmond, VA, USA; 3) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 4) Department of Genetics, University of North Carolina at Chapel Hill, NC, USA.

We performed a methylome-wide association study (MWAS) of DNA extracted from whole blood in a schizophrenia case-control sample of 1,500 individuals. We applied the methyl-binding domain 2 sequencing (MBD-seq) approach to enrich for the methylated fraction of the genome followed by next-generation sequencing, which allows for investigation of 30.6 million CpGs in the human genome. To analyze this massive dataset, we developed an analysis pipeline specifically for MBD-seq that includes alignment, quality control (QC), novel estimators for calculating CpG coverage, data reduction combining highly correlated CpGs into blocks, principal component analysis, association testing, bioinformatics annotation and network analysis. The top findings were replicated in an independent schizophrenia case-control sample of 1,500 individuals using targeted pyrosequencing.

After QC and data reduction, 4.2 million high quality blocks were left for methylome-wide association (lambda of 1.013). In contrast to similarly sized GWAS for schizophrenia, our MWAS showed a number of highly significant findings with top p-values of 5.10E-10 and 110 blocks (450 CpGs) with p-values < 9.9E-7. Among the top results were differentially methylated blocks located in: *TBC1D22A* (p=5.10E-10), *PKDREJ* (p= 3.41E-09), *LRRC37A3* (p= 5.10E-09) and *SATB1* (p-value=3.27E-08).

Bioinformatic analyses of the top findings indicate that CpGs associated to schizophrenia are rarely located in CpG islands (<0.1%) but commonly are located in introns (>63.7%). Although replication is still ongoing, several genes on the top list have already replicated including *SATB1, ETS2*, *PHACTR3* and *FNDC3B*. Interestingly, when conducting network analysis, many of the genes among the top results clustered into the same networks. One such example includes the replicated genes *SATB1* and *ETS2*, which interact to regulate chromatin modeling and gene expression. A gene under regulation of the *SATB1/ETS2* network is *BCL2*, which recently was associated with schizophrenia in a large GWAS-meta analysis.

Our replicated results represent one of the first sets of CpG sites identified through MWAS that potentially can be used to improve treatment, diagnosis and disease etiology for schizophrenia patients.

3443T

Genome-wide estimation of DNA methylation heritability in CD4+ T-cells from 80 families. *D. Absher[1], L. Waite[1], H. Tiwari[2], D. Arnett[3].* 1) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 2) Dept. of Biostatistics, University of Alabama at Birmingham, Birmingham, AL; 3) Dept. of Epidemiology, University of Alabama at Birmingham, Birmingham, AL.

DNA methylation is a potent regulator of transcription and is influenced by genetic and environmental factors. Genome-wide studies are now underway to identify DNA methylation patterns that are associated with common human diseases and their risk factors. However, the relative impact of genetic and environmental influences on locus-specific DNA methylation has not been well characterized, and controlling for these influences in epigenetic association studies is crucial to their success. To assess the heritability of CpG methylation and to distinguish allele-specific DNA methylation or methyl-QTLs from more complex epigenetic inheritance patterns, we measured DNA methylation at >480,000 CpGs in CD4+ T-cells from >400 individuals in >80 famiiles. The MHC locus on chromosome 6 was among several regions that displayed enrichment for heritable DNA methylation, and we identified strong cis effects from local genetic variants, as well as inheritance patterns that were independent of local DNA sequence.

3444T

Epigenetic Second Hit on Genebody of PKD1 Leads to Cystic Kidney in ADPKD. *J. Bae[1,2], Y. Woo[3], J. Lee[1], J. Park[3], Y. Kim[2].* 1) KNIH, Osong, ChungCheongbukdo, South Korea; 2) YGI, Seoul, South Korea; 3) Sookmyung W. University, Seoul, South Korea.

Autosomal dominant polycystic kidney disease (ADPKD) is a genetic disorder mostly caused by mutations in PKD1, possibly in a “two-hits” mechanism. To identify the disease-causing mutations of the PKD1 in cyst patients, both genomic and cDNA sequences were examined. Although the PKD1 genomic sequences of the patients revealed an inactivating mutation in some patients, no inactivating mutation was found in the expressed alleles of the PKD1. However, the levels of PKD1 expression were greatly diminished in the patients. To test whether epigenetic modification plays a role in ADPKD pathogenesis, we performed genome-wide methylation affinity purification sequencing (MIRA-Seq) analysis on 3 ADPKD patient cystic kidney samples and examined the disease-associated aberrant DNA methylations. Intriguingly, PKD1 gene was one of the most significantly hypermethylated genes in the patients along with other key regulators of Notch and Wnt signaling pathways, indicating an epigenetic silencing as the second inactivating mechanism of PKD1. The hypermethylation regions were observed as large blocks on several chromosomal locations and mostly enriched in the genebody areas, which showed negative correlation to the expression levels of the associated genes. The epigenetic regulation of the cyst development was further confirmed by the retarded cyst formation of MDCK cells in an in vitro 3D cyst culture system upon treatment of DNA methylation inhibitors, accompanied with the upregulation of the PKD1 expression. Taken together, DNA methylation changes of PKD1 and related regulatory genes in ADPKD appear to promote kidney cyst development.

3445T

Altered DNA Methylation in Preeclamptic Placentas. *J.D. Blair[1,3], R.K.C. Yuen[1,3], P. von Dadelszen[2,3], W.P. Robinson[1,2,3].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Department of Obstetrics and Gynaecology, University of British Columbia, Vancouver, British Columbia, Canada; 3) Child and Family Research Institute, Vancouver, British Columbia, Canada.

Preeclampsia (PET) is one of the leading causes of maternal death in the world. It is clinically characterized by hypertension and proteinuria. Physiologically, it is suspected to be initiated by poor placental invasion and maternal artery remodeling. This creates a hypoxic environment, causing abnormal placental gene expression and increased apoptosis in syncytiotrophoblast, which then leads to vascular endothelial damage in the mother. Many of the molecular aspects of PET are still unknown. Epigenetic processes, such as DNA methylation, that are associated with regulation of gene expression may play a role in the molecular etiology of PET. We hypothesize there will be altered DNA methylation of biologically significant genes in placental samples from pregnancies affected by PET. Samples in this study included 10 chorionic villi samples from placentas affected by early-onset preeclampsia (EOPET) and 10 gestational age matched controls. Using the Illumina Infinium HumanMethylation450 BeadChip, we surveyed the DNA methylation status of 450,000 CpG sites across the genome. Using strict criteria of >15% absolute average DNA methylation difference and <5% false discovery rate, 267 CpG sites were significantly different. Interestingly, all of the significant CpGs were hypomethylated in the EOPET samples compared to controls. Most of the significant CpG sites were located in the gene body or in a CpG island shore, rather than in the CpG island of a promoter. Significant genes were followed up bioinformatically using MEME Suite to identify recurrent transcription factor binding motifs, DAVID to investigate enrichment of gene function and STRING to elucidate protein-protein interactions among the significant genes. DNA methylation and gene expression of several candidates are also being confirmed in a larger cohort. . Numerous genes with altered DNA methylation were biologically significant including those associated with i) trophoblast invasion and differentiation (ADAM12, TIMP3, CSF1R), ii) hypoxia (BHLHE40, STC2, PKM2, IDH2) and iii) genes that have previously been shown to be differentially expressed in preeclamptic placentas (CYP11A1, LEP, PAPPA2, GNA12). Hypomethylation of trophoblast-related and hypoxia-related genes suggest DNA methylation plays a significant role in the EOPET development and may be useful for diagnostic purposes. Future studies should focus on elucidating the underlying molecular mechanisms for these changes.

Highly abnormal methylation of the placental genome in the CBAXDBA model of pregnancy failure. *S. Brown, E. Bonney, L. Brown.* Dept OB/GYN, Univ Vermont, Burlington, VT.

When female mice of the inbred strain, DBA/2 (DBA/2F) are mated with CBA/J males (CBA/JM), few fetal resorptions are noted. However, when the opposite mating is performed (CBA/JF X DBA/2M), up to 50% of pregnancies are resorbed by gestational day 12–14. Because of this, CBA/JF X DBA/2M matings have served as a model system for miscarriage for many years; however, there is no molecular understanding of the cause for fetal loss. F1 embryos from CBA/JF X DBA/2M matings are genetically identical to F1 embryos from DBA/2F X CBA/JM matings, making it unlikely that genetic differences between embryos contribute to the differential rate of loss. Therefore, it is assumed that pregnancy loss is in some way mediated by the maternal environment. As an alternative hypothesis, we have considered the possibility that there may be parent of origin (imprinting) differences between the two classes of genetically identical embryos. In this model, parent of origin (epigenetic) differences (as opposed to maternal environment) would contribute to pregnancy failure. To test this model, we performed a microarray-based analysis of methylation of placental DNA of E9.5 embryos at ~15,000 sites on chromosome 7. We show that DBA/2F XCBA/JM (healthy) embryos have highly consistent methylation profiles, while CBA/JF XDBA/2M (loss-prone) embryos show a striking degree of variability of methylation at thousands of loci, reflecting a highly disordered epigenome. This was assessed by determining the variance of signal intensity across 7 microarray data sets for all ~16K loci. We then compared the mean variance of the two groups using a z test and confirmed a striking degree of variability of methylation in loss-prone pregnancies at E9.5. When the same experiment was performed at E8.5, we found less striking but still highly significant evidence for disordered methylation in the loss prone (CBAXDBA) embryos. Given what is known about the establishment of methylation during embryogenesis, the methylation abnormalities that we see are likely to have been present since implantation, and this suggests that the abnormalities are intrinsic to the embryo. Alternatively, the CBA/J maternal environment may act to alter methylation long before any overt evidence of pregnancy failure. Future experiments will be aimed at understanding whether methylation abnormalities are truly intrinsic to the embryo or depend on the maternal environment.

DNA Methylation Profiles of Paediatric Obsessive Compulsive Disorder (OCD). *D.T Butcher[1], G.L Hanna[2], D.R Rosenberg[3], R. Weksberg[1,4,5], P.D. Arnold[1,6].* 1) Genetics & Genome Biology, Sickkids Research Inst, Toronto, Ontario, Canada; 2) Department of Psychiatry, University of Michigan, Ann Arbor, Michigan, USA; 3) Psychiatry and Behavioral Neuroscience, Wayne State University School of Medicine, Detroit, Michgan, USA; 4) Department of Paediatrics and the Institute of Medical Sciences, University of Toronto, Toronto, Ontario, Canada; 5) Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 6) Department of Psychiatry, The Hospital for Sick Children, Toronto, Ontario, Canada.

Obsessive-Compulsive disorder (OCD) is a complex, common and debilitating psychiatric disorder. Heritability estimates range from 40% to 65% suggesting that genetic factors play a role in this disorder. However, there are other potential important determinants, such as epigenetics contributing to the OCD phenotype. Epigenetic mechanisms, such as DNA methylation, have increasingly been shown to be important in the etiology of other complex disorders. We hypothesized that there are alterations in DNA methylation patterns in paediatric OCD compared to controls. We used a novel genome-wide approach to identify epigenetic variants in children with OCD. Although few epigenetic studies have been conducted using saliva DNA, epigenetic biomarkers have identified parallel DNA methylation alterations in blood and brain of patients with neuropsychiatric disorders.

Analysis of blood DNA methylation patterns in 10 paediatric OCD patients compared to 10 controls identified both gain and loss of methylation at a number of CpG sites. Candidate DNA methylation alterations identified in this initial investigation are highly relevant to the OCD phenotype and include altered DNA methylation in promoters of genes in glutamate signalling, myelin synthesis and lipid transporters. An expanded cohort of genome-wide DNA methylation profiles for 20 blood and 20 saliva of paediatric OCD patients compared to tissue, age and sex-matched controls is being generated using the Illumina 450K Infinium Methylation BeadChip array. Saliva DNA was collected using Oragene•Dx saliva kits (DNA Genotek). Data is analyzed using the IMA package in R and Genome Studio software from Illumina. Methylation differences of greater than or less than 15% between groups and $p<0.05$ defined candidate genes are being selected for validation using targeted pyrosequencing.

The identification of epigenetic modifications in children with OCD will lead to improved understanding of the pathophysiology and molecular mechanisms leading to this disorder. These epigenetic alterations could provide early diagnostic biomarkers for OCD which may influence treatment strategies, including both pharmacological and cognitive behavioural therapy. Such a personalized medicine approach has the potential to provide tremendous benefits to patients suffering from OCD.

Complete or partial loss of methylation at the *GNAS* locus identified in patients referred for molecular diagnosis of pseudohypoparathyroidism type 1a. *G.S. Charames[1], S.J. Steinberg[1,2], B.A. Karczeski[1], M.A. Levine[3,4], G.R. Cutting[1,5].* 1) Johns Hopkins DNA Diagnostic Lab, Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Division of Endocrinology and Diabetes, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Department of Pediatrics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 5) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD.

Pseudohypoparathyroidism (PHP) type 1 is a heterogeneous disorder characterized by resistance to parathyroid hormone. Patients with PHP-1a show impaired responsiveness to additional hormones, plus a constellation of physical findings called Albright Hereditary Osteodystrophy (AHO) that include brachydactyly, short stature and ectopic ossification. Some family members have only AHO and normal hormone responsiveness, a variant termed pseudopseudohypoparathyroidism (PPHP). By contrast, patients with PHP-1b have a more limited phenotype and typically have only PTH resistance and few, if any, features of AHO. PHP type 1 is caused by mutations that reduce expression or function of the imprinted *GNAS* gene, which encodes several proteins including the alpha subunit of the heterotrimeric G protein Gs that couples hormone receptors to activation of adenylyl cyclase. Gsα is biallelically expressed in most tissues, but in some tissues only the maternal allele is transcribed. While both PHP-1a and PPHP are caused by *GNAS* coding region mutations on the maternally-derived and paternally-derived coding regions, respectively, PHP-1b is associated with epigenetic defects, including complete loss of methylation at the *GNAS* exon 1A (e1A) differentially methylated region (DMR), which reduce transcription of the maternal Gsα allele in imprinted cells. Recently, partial loss of e1A methylation has been reported in some patients suspected to have PHP, but the implications of this molecular modification are not known. This report describes a cohort of 116 patients with presumed PHP-1a who were referred to our clinical lab for *GNAS* analysis and were mutation-negative. We examined *GNAS* e1A DMR in these patients by either bisulfite Sanger sequencing or bisulfite pyrosequencing to assess methylation status. Normal methylation is greater than 35% at ^{me}CpG, based on 1SD of the mean of normal controls; complete loss of methylation is less than 5%. Ten patients had a complete loss of e1A methylation suggesting that they actually had PHP-1b. Moreover, 5 subjects had a partial loss of e1A methylation (5–35% methylation). Our results suggest that e1A methylation defects are not uncommon in patients with presumed PHP-1a, and approximately 10% may have PHP-1b. Moreover, the spectrum of methylation defects in *GNAS*, including partial loss of e1A methylation, is more extensive than previously recognized. The clinical and molecular implications of these findings deserve further study.

DNA Methylation of *ADCYAP1R1* is associated with childhood asthma in Puerto Ricans. *W. Chen[1], N. Boutaoui[1], Y.Y. Han[1], J. Brehm[1], C. Schmitz[1], E. Acosta-Perez[2], M. Cloutier[3], D. Calvert[4], S. Thornton-Thompson[4], D.B. Wakefield[3], M. Alvarez[2], A. Colón-Semidey[2], G. Canino[2], J.C. Celedón[1].* 1) Division of Pulmonary Medicine, Allergy and Immunology, Children's Hospital of Pittsburgh of the University of Pittsburgh Medical Center, Pittsburgh, PA; 2) Behavioral Sciences Research Institute, University of Puerto Rico, San Juan, PR; 3) Department of Pediatrics, University of Connecticut Health Center, Farmington, CT; 4) Connecticut Children's Medical Center, Hartford, CT.

Background: Puerto Ricans share a disproportionate burden of asthma and are often exposed to high levels of stress and violence. Psychosocial stress has been associated with asthma morbidity in children, but little is known about the underlying biological mechanism. Ressler et al recently reported that methylation of the gene encoding the receptor for adenylate-cyclase activating polypeptide 1 (*ADCYAP1R1*) is associated with posttraumatic stress disorder (PTSD) in adults. We hypothesized that methylation of *ADCYAP1R1* is associated with childhood asthma in Puerto Rican (PR) children. **Methods**: Pyrosequencing assays were used to assess methylation of four CpG sites in *ADCYAP1R1* using DNA from white blood cells in 1,001 PR children (including children with [cases, n=550] and without [controls, n=451] asthma) recruited in Hartford (CT) and San Juan (PR). 1 ug of DNA for each sample was bisulfite-converted using the EZ-96 DNA Methylation-Gold kit ™ deep well format (Zymo research, Orange, CA). PCR was performed using diluted bisulfate-converted DNA and *ADCYAP1R1* primers. CpG analysis was performed using PyroMark Q24 software (Qiagen, Valencia, CA). T test and chi-square test were applied for bivariate analyses. Logistic regression was used for the multivariate analysis, which was adjusted for age, gender, household income and (for the combined cohort) study site. **Results**: Among all participants, higher methylation of a CpG site in the promoter of*ADCYAP1R1* is associated with an increased risk of asthma (odds ratio per 5% increase in methylation=1.011, 95% confidence interval=1.002–1.020, P=0.013). Similar results were obtained in a confirmatory analysis excluding two cases with extreme methylation levels (OR= 1.011, 95%CI=1.001–1.020, P=0.022). **Conclusions**: Epigenetic modification of *ADCYAP1R1* may play an important role in the etiology of asthma in PR children. The interaction between psychosocial stress, DNA methylation and childhood asthma merits further examination.

The Role of DNA Methylation in Cognitive Decline and Alzheimer's Disease. *L.B. Chibnik[1,2,3], B.T. Keenan[1,3], G. Srivastava[1,2,3], M.L. Eaton[3,4], A. Meissner[3,5], J.A. Schneider[6], M. Kellis[3,4], D. Bennett[6], P.L. De Jager[1,2,3].* 1) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Brigham & Women's Hospital; 2) Harvard Medical School; 3) Broad Institute of MIT and Harvard; 4) Computer Science and Artificial Intelligence Laboratory, MIT; 5) Department of Stem Cell and Regenerative Biology, Harvard University, Harvard Stem Cell Institute; 6) Rush Alzheimer's Disease Center, Rush University Medical Center.

The DNA methylome captures the transcriptional potential of a cell or tissue: hyper-methylation of a promoter region is typically a mark of a closed chromatin conformation, which prevents transcription. Differential methylation of validated Alzheimer's disease (AD) susceptibility loci could influence their effect. We assess the state of chromatin at the regions of the genome around validated loci to identify CpG sites that correlate with AD disease measures. We utilized data from two longitudinal cohorts, the Religious Order Study and Rush Memory and Aging Project. DNA methylation profiles were generated in samples of dorsolateral prefrontal cortex using Illumina HumanMet450K beadset. We analyzed CpG sites within 25 kb of 10 validated AD susceptibility genes. The outcomes of interest were episodic memory decline (EMD), quantified as residual slope from a linear mixed effects model, a count of neuritic amyloid plaques (NP) and diagnosis of AD (dxAD). We assessed the association between the outcomes and extent of CpG methylation at each site as well as between the AD SNPs and methylation using linear regression. 357 CpGs were tested with a significance threshold for the primary outcome (dxAD) of p<0.0001. A total of 748 subjects, with a mean (SD) age of death of 88.0 (6.6), were included in the analysis. Intriguing results were seen for AD genes BIN1 and EPHA1. Methylation level of the top CpG site at BIN1 (cg04019522), which lies in the gene body, is significantly associated with all three outcomes, dxAD (p=3.6×10-5), EMD (p=0.0006) and NP (p=3.4 x10-5). The best CpG site at EPHA1 (cg26960083) lies just 313 bp from the transcription start site and is associated with dxAD (p=3×10-5), marginally with EMD (p=0.03) but not NP (p= 0.29). In both cases, CpGs are hypermethylated in AD relative to non-demented subjects. Given our modest sample size, the validated SNPs within these genes are not associated with the outcomes in our data (ps>0.05). These observations suggest that, within known AD susceptibility genes, the level of methylation in the brains of older individuals may be related to pathophysiological processes associated with AD and may play a role in influencing gene expression from susceptibility loci.

Distinct DNA Methylation Signature in Ovarian Cancer Histological Subtypes. *M.S. Cicek[1], D.C. Koestler[2], B.L. Fridley[1], S.M. Armasu[1], K.R. Kalli[3], M.C. Larson[1], R.A. Vierkant[1], B.J. Winterhoff[4], J. Chien[5], J.B. Fan[6], M. Bibikova[6], B. Klotzle[6], G. Konecny[7], V. Shridhar[8], J.M. Cunningham[8], E.L. Goode[1].* 1) Dept. of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Dept. of Community and Family Medicine, Dartmouth Medical School, Lebanon, NH; 3) Dept. of Medicine, Mayo Clinic, Rochester, MN; 4) Dept. of Obstetrics and Gynecology, Mayo Clinic, Rochester, MN; 5) Dept. of Cancer Biology, University of Kansas, Kansas City, KS; 6) Illumina Inc, San Diego, CA; 7) Dept. of Medicine, UCLA, Los Angeles, CA; 8) Dept. of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Ovarian cancer is a heterogeneous disease; however, it is considered clinically as one disease and treatment is dependent upon tumor stage and grade rather than histologic subtype. Among the most common subtypes of ovarian cancer (high grade serous (70%), low grade serous (5%), endometrioid (10%), clear cell (10%), and mucinous (3%)) there is increasing evidence that various histologic subtypes have different genetic risk factors and outcome. In this study, we tested the hypothesis that the ovarian histologic subtypes have different methylation profiles. We performed genome-wide DNA methylation assays (Infinium HumanMethylation450 BeadChip) on a discovery set of fresh frozen invasive epithelial ovarian cancer tumors from the Mayo Clinic (n=326) to identify methylation signatures that differentiate histological subtypes. In particular, we applied a semi-supervised recursively partitioned mixture modeling (SS-RPMM) strategy to identify methylation signature that can distinguish clear cell subtype from serous, mucinous and endometrioid subtypes. A clear cell methylation profile consisting of an optimal number of 22 CpG loci was identified based on a cross-validation procedure. The identified CpG loci in this methylation profile were correlated with gene expression (Agilent whole human genome 4×44K expression arrays), and CpG methylation was negatively correlated with gene expression at *FGFRL1, KCNH2, ATXN2, NDRG2,* and *SLC16A11*. Replication analysis is underway in two independent set of samples. Preliminary data suggest that we have identified an epithelial ovarian cancer clear cell methylation signature. Future studies will evaluate the relationship between methylation profile and outcome. This clear cell methylation signature will not only help us better understand heterogeneity in ovarian histological subtypes but may also open new treatment targets that might specifically help clear cell ovarian cancer patients.

3452T

Identifying new biomarkers for alcohol use behaviors in a methylome-wide MBD-seq study. *S.L. Clark[1], K.A. Aberg[1], S. Nerella[1], G. Kumar[1], J.L. McClay[1], W. Chen[2], L.Y. Xie[1], A. Hudson[1], G. Gao[2], J. Bukszar[1], C.M. Hultman[3], P.K.E. Magnusson[3], P.F. Sullivan[3,4], E.J.C.G. van den Oord[1], Swedish Schizophrenia Consortium.* 1) Center for Biomarker Research and Personalized Medicine, School of Pharmacy, Virginia Commonwealth University, Richmond, VA, USA; 2) Department of Biostatistics, School of Medicine, Virginia Commonwealth University, Richmond, VA, USA; 3) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 4) Department of Genetics, University of North Carolina at Chapel Hill, NC, USA.

Methylation studies of alcohol phenotypes have historically been restricted to candidate genes in very small sample sizes. More recent studies have taken a methylome-wide approach but have only focused on <450k methylation sites and only in small samples. This study makes a huge leap forward by using next generation sequencing to screen the 30.6 million human methylation sites for association with drinking behaviors. We performed methylome-wide association studies (MWAS) in a sample of ~700 individuals using two phenotypes related to alcohol habits, including if participants ever used alcohol and in what frequency they drink. To investigate all CpGs in the human genome, we enriched for the methylated genomic fraction using a methyl-CpG binding domain (MBD) protein capture system (MethylMinerTM kit from Invitrogen) followed by next generation sequencing (MBD-seq). Each sample had, on average, 67.7 million reads, to yield a total of 4.19 trillion reads for all ~700 individuals. After quality control and collapsing highly correlated CpGs into smaller “blocks”, 4.2 million high quality blocks were left for methylome-wide association testing with the phenotypes of ever using alcohol (lambda of 1.04) and frequency of alcohol use (lambda of 1.01). The MWAS showed a number of highly significant findings with a top p-value of 3.30E-09 and 68 blocks (160 CpGs) with p-values < 9.9E-06. Among the top results were blocks located in, for example, ELOVL2 (p=5.47E-08) and PDE4B (p-value = 9.10E-07) for ever using alcohol and ATF1 (p-value = 1.95E-07) for frequency of alcohol use. PDE4B has previously been linked to alcohol response while ELOVL2 and ATF1 have been associated with comorbid psychiatric disorders. A network analysis was performed to examine if any of the top results cluster into the same network. For example, ATF1 and another top finding, RASGRF1, exist in a known Nerve Growth Factor (NGF) pathway. When this pathway is chronically exposed to alcohol the NGF-stimulated phosphorylation and activation of MAP kinases is enhanced. We are currently replicating the top findings in an independent sample of 560 individuals using targeted pyrosequencing. Once the results are replicated, we will have ascertained the first collection of CpG sites identified using MWAS for alcohol use behaviors.

Smoking reduces DNA methylation levels at multiple genomic loci. *P. Deloukas[1], L. Tsaprouni[1], T-P. Yang[1], J. Bell[2], K.J. Dick[3], S. Kanoni[1], C. Nelson[3], E. Meduri[1,2], F. Cambien[4], C. Hengstenberg[5], J. Erdmann[6], H. Schunkert[6], A.H. Goodall[3], W.H. Ouwehand[7,7], T. Spector[2], N. Samani[3].* 1) Human Genetics, Wellcome Trust Sanger Inst, Cambridge, United Kingdom; 2) Department of Twin Research and Genetic Epidemiology, King's College London, UK; 3) Department of Cardiovascular Sciences, University of Leicester & National Institute for Health Research Leicester Cardiovascular Biomedical Research Unit, Glenfield Hospital, Leicester, UK; 4) INSERM UMRS 937, Pierre and Marie Curie University and Medical School, Paris, France; 5) Klinik und Poliklinikfür Innere Medizin II, Regensburg, Germany; 6) Universität zu Lübeck, Medizinische Klinik II, & Deutsches Zentrum für Herz-Kreislauf-Forschung, Lübeck, Germany; 7) Department of Haematology, University of Cambridge and National Health Service (NHS) Blood and Transplant, Cambridge, UK.

Smoking is a major risk factor in most common diseases impacting mortality. Genome wide association studies have clearly linked nicotine dependence and smoking behaviour to increased risk of cardiovascular, pulmonary and malignant diseases whilst recent evidence show that global DNA methylation is influenced by smoking behaviour. We assessed methylation patterns in peripheral-blood DNA in 464 individuals (Cardiogenics study) of which 285 are current or ex-smokers with the use of the Illumina Human Methylation 450K BeadChip. A linear model analysis confirmed an effect of smoking on methylation in two previously reported genes: Coagulation factor 2 (F2RL3) and G-protein coupled receptor 15 (GPR15). F2RL3 was significantly associated with methylation in smokers (p=2.8×10-17 at FDR=1.65×10-12) which replicates the association reported earlier this year. GPR15 was also associated with smoking history ($p=2.51\times10^{-18}$ at $FDR=1.72\times10^{-13}$). We obtained 62 signals at a nominal p value 10^{-6} corresponding to 13 loci. Interestingly, one of the top signals is in a region of chromosome 2 (233283397–233285959) located close to the neuronal acetylcholine receptor subunit D (CHRND) gene. We then undertook replication in an independent sample of 356 Twins from the TwinsUK registry which comprises 145 current or ex-smokers. After applying Bonferroni correction 19 probes representing 12 loci which included F2RL3, GPR15 and the chromosome 2 region, replicated at $p < 8.06\times10^{-4}$. Levels of methylation were reduced in smokers in all replicating loci; for example all seven probes covering the chromosome 2 region ($p=6.48\times10^{-10}$ - 1.81×10^{-22}). Interestingly, this trend was reversed when we examined people that had stopped smoking (data from TwinsUK study only). Finally, we assessed the intersection between methylated QTLs (metQTLs; $p < 10^{-3}$) versus the top 62 probes from the linear model analysis described above. Both F2RL3 and the chr2 (233283397–233285959) region had a metQTL in blood associated with methylation. However, GPR15 did not have any metQTL at genome wide significance.

3454T

DNA hypomethylation of *INS-IGF2* and *BACH2* in affected individuals within discordant monozygotic twins suggests a role for epigenetic influences in type 1 diabetes susceptibility. *E. Elboudwarej[1], H. Quach[1], P. Ramsay[1], J. Lane[2], E. Sinclair[4], L. Criswell[4], P. Fain[3], J. Jeffrey[3], G. Eisenbarth[3], L. Barcellos[1], J. Noble[2].* 1) Genetic Epidemiology and Genomics Laboratory, Division of Epidemiology, School of Public Health, UC Berkeley, Berkeley, CA; 2) Children's Hospital Oakland Research Institute, Oakland, CA; 3) University of Colorado Health Sciences Center, Barbara Davis Center for Childhood Diabetes, Denver, CO; 4) University of California, San Francisco, Department of Medicine, San Francisco, CA.

Type 1 diabetes (T1D) has a substantial genetic risk component, with the strongest risk attributable to Human Leukocyte Antigen (HLA) genes in the Major Histocompatibility Complex (MHC). Traditional genetics cannot completely explain susceptibility, as evidenced by varying levels of disease discordance among monozygotic (MZ) twin pairs. In this matched case-control study, seven MZ twin pairs, T1D discordant for 8 to 20 years, were examined for differences in DNA methylation (DNAm) at more than 480,000 CG dinucleotides (CpGs) across the genome using DNA from peripheral blood samples. An additional set of five HLA matched, T1D discordant siblings, was analyzed as a replication dataset. Initially, measures of methylation were investigated as averages across all sites within three pre-selected regions: Whole-genome (global), T1D-associated genes (non-MHC), and MHC region genes. Among twin pairs, both T1D-associated and MHC region methylation were significantly lower in affected twins ($p < 0.05$). For site-specific analyses, CpGs of interest were analyzed individually, or were averaged across sites within a gene when appropriate. A total of 14 sites in 12 MHC region genes, and 7 sites in 5 T1D-associated genes (*INS-IGF2*, *BACH2*, *IL2*, *IL2RA*, and *TNFAIP3*) demonstrated significant differences in methylation between the affected and unaffected twin of each pair ($p < 0.05$). Differentially methylated genes were consistently hypomethylated in the affected twin when compared to the unaffected twin. To address the question of whether or not differences in the candidate loci might be attributable to specific cell populations, methylation was examined in the following cell subsets from a single unrelated individual: CD14+ monocytes, CD19+ B lymphocytes, and both CD4+ naïve and memory T lymphocytes derived from peripheral blood. While methylation of sites within *BACH2* and *IL2RA* showed high variability across the four cell types, *INS-IGF2*, *IL2*, and *TNFAIP3* profiles were identical. Results suggest that DNA methylation differences in T1D-associated genes distinguish affected from unaffected individuals in MZ twin pairs but not discordant siblings. Epigenetic influences may partially explain some of the missing heritability for T1D risk.

Migration and DNA methylation: a comparison of methylation patterns in type 2 diabetes susceptibility genes between Indians and Europeans. *H.R. Elliott[1], G.K. Walia[2], A. Duggirala[3], A. Groom[1], S.U. Reddy[3], G.R. Chandak[3], V. Gupta[2], M. Laakso[4], J.M. Dekker[5], M. Walker[1], S. Ebrahim[2,6], G. Davey Smith[7], C.L. Relton[1], The RISC consortium.* 1) Newcastle University, Newcastle-upon-Tyne, Tyne and Wear, United Kingdom; 2) South Asia Network for Chronic Disease, Public Health Foundation of India, New Delhi, India; 3) Centre for Cellular and Molecular Biology, Council of Scientific and Industrial Research, Hyderabad, India; 4) University of Eastern Finland, Finland; 5) VU University Medical Centre of Amsterdam, Netherlands; 6) Department of Epidemiology and Population Health, London School of Hygiene and Tropical Medicine, London, United Kingdom; 7) MRC Centre for Causal Analyses in Translational Epidemiology, Department of Social and Community Medicine, University of Bristol, Bristol, United Kingdom.

Introduction Type 2 diabetes is a global problem that is increasingly prevalent in low and middle income countries including India, partly attributed to increased urbanisation. Genotype clearly plays a role in type 2 diabetes susceptibility. However, the role of DNA methylation and its interaction with genotype and metabolic measures is poorly understood. This study aimed to establish whether methylation patterns of type 2 diabetes implicated genes differ between distinct Indian and European populations and/or change following rural to urban migration in India.**Methods** Quantitative DNA methylation analysis in Indians (Urban and Rural dwelling siblings recruited in Lucknow and Hyderabad) and Europeans using Sequenom® EpiTYPER™ technology was undertaken in three genes: ADCY5, FTO and KCNJ11. Metabolic measures and genotype data were also analysed to assess their relationships with DNA methylation.**Results** Consistent differences in DNA methylation patterns were observed between Indian and European populations. Mann-Whitney U tests showed DNA methylation was lower in the European group compared to the Urban Indian group for all three loci tested: ADCY5 median difference 6.3% (z= 17.72, p= 2.831e-70); FTO median difference 2.7% (z= 15.44, p= 9.495e-54); KCNJ11 median difference 1.5% (z= 14.60, p= 2.787e-48). Methylation differences were also observed between populations within India. In Europeans, SNPs were analysed for an additive effect using non parametric trend tests. An increase in HDL of 0.07 mmol/L was observed when the minor allele of ADCY5 rs17295401 was present (trend test: z= 2.66, p= 0.008). HDL showed a 0.16 mmol/L average increase per minor allele of FTO rs16952479 (trend: z= 2.62, p= 0.009). Fasting insulin was on average 0.45 mU/L higher (trend: z= 2.52, p= 0.012) and BMI was on average 0.53 units higher (z= 2.82, p= 0.005) per minor allele of FTO rs9939609. HDL showed a 0.16 mmol/L average decrease per minor allele of KCNJ11 rs1800467 (trend: z= -3.33, p= 0.001). However, these observations were not linked to local variation in DNA methylation levels. No differences in methylation patterns were observed in urban-dwelling migrants compared to their non-migrant rural-dwelling siblings. **Conclusions** Analysis of DNA methylation at three type 2 diabetes susceptibility loci highlighted geographical and ethnic differences in methylation patterns. These differences may be attributed to genetic and/or region-specific environmental factors.

DNA methylation alterations associated with autism spectrum disorders. *D. Grafodatskaya[1], R. Rajendram[1], Y. Lou[1], D.T. Butcher[1], L. Senman[2], C. Windpassinger[3], W. Roberts[2], S.W. Scherer[4], R. Weksberg[5].* 1) Gen & Genome Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Autism Research Unit, Hosp Sick Children, Toronto, ON, Canada; 3) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 4) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, Canada; 5) Institute of Medical Sciences, University of Toronto, Toronto, Canada.

Autism spectrum disorders (ASD) are a group of childhood neurodevelopmental disorders typically diagnosed at 2–3 years of age and characterized by three areas of behavioral impairment: social interactions, communication and repetitive behaviors. Since known genetic factors account for only subset of ASD cases and environmental risk factors have been implicated, it is likely that epigenetics plays a significant role in ASD etiology. Epigenetics refers to heritable changes in gene expression occurring without altered DNA sequence. DNA methylation (DNAm) is the best studied form of epigenetic regulation. The objective of this study was to identify ASD-associated DNAm alterations in the blood of such individuals. Genome-wide DNAm was assessed in 12 blood samples from ASD cases and 12 controls at ~27,000 CpG sites using the Illumina 27K platform. To identify DNAm variants associated with ASD, we selected CpG sites with DNAm changes of at least 10%, compared to controls. Using this approach we identified 7 CpGs with loss and 5 CpGs with gain in ASD vs controls. Further, in order to assess the relevance of DNA methylation changes identified in blood to brain, we compared DNAm levels at the 13 CpG sites referred to above to 150 brain samples of neurologically normal individuals run on the same microarray platform (Gibbs et al. 2010). To narrow the list of candidates we selected CpGs with: 1) similar levels of DNAm in blood and brain in controls, 2) no outliers in the brain similar to the outliers levels in the blood of ASD cases. Two rare variants with gain of DNAm at CpG sites within promoters of arylsulfatase A (ARSA) and phosphatidylcholine transfer protein (PCTP) genes survived this comparison. DNAm at these two loci were validated and replicated in extended cohorts using targeted DNAm analysis. Our data support a role for epigenetic variants in ASD etiology and demonstrate the feasibility of identifying such epigenetic variants in clinically accessible tissues such as blood.

A population-based method for identification of differential methylation regions among samples. *C.L. Hsiao[1], C.S.J. Fann[1], C.J. Chang[2].* 1) IBMS, Academia Sinica, Taipei, Taiwan; 2) Graduate Institute of Clinical Medical Sciences, Chang-Gung University, Taiwan.

The epigenetic variation, specifically variation in DNA methylation, has been proven to be involved with gene regulation and may make a significant contribution to the missing heritability. Advances of genomic technologies have placed us in a position to initiate large-scale studies of DNA methylation. The epigenome-wide association studies present novel opportunities for understanding the role of DNA methylation in pathogenesis but with new challenges that are not encountered previously. The differential methylation regions (DMRs) represent genomic regions with different methylation statuses among multiple samples. Successfully recognizing DMRs without given any phenotypic information could help to understand variations of methylation status changes in a given population, either among individuals or between different conditions, e.g. different tissue types or tumor-normal samples. Previously many supervised methods have been studied, and we propose a novel unsupervised approach to directly analyze methylation intensity data across a large set of samples to identify DMRs, with no need for prior single-sample analysis. This approach is a region-based method that takes into account the correlations of methylation levels between nearby probes which may introduce a high rate of false positive for point-wise method in simulation studies. In a real data study, 25 methylation data profiling by genome tiling array (NimbleGen Human 2.1M array) are employed, including 5 samples each of normal liver, frontal cortex, spleen and colon, and 5 samples of colon tumor. More than 5,000 DMRs with at least 15% of samples having different methylation patterns in comparison with the rest of the samples have been identified. The changes of methylation status on these DMRs are highly associated with the specific tissue types and tumor/normal colon samples. The results show that our newly proposed method is useful in identification of differential methylation regions among samples.

Genetics and epigenetics of PON1 in Mexican-American children. *K. Huen, K. Harley, P. Yousefi, A. Bradman, L. Barcellos, B. Eskenazi, N. Holland*. Center for Environment al Research and Children's Health (CERCH), School of Public Health, University of California, Berkeley, CA.

Children's susceptibility to environmental toxicants may depend on multiple factors including early life exposures, genetics, and gene-environment interactions. CHAMACOS is a longitudinal birth cohort study of low-income Mexican-American farmworker families in California. We followed 601 pregnant women and their children and found that *in utero* exposures to pesticides were associated with abnormal birth and neurodevelopmental outcomes (Eskenazi et al,2004, 2007, 2010; Young et al, 2005; Bouchard et al, 2011). We also demonstrated that these health effects depend on phenotype and genotype of paraoxonase (PON1), a multifunctional enzyme involved in detoxification of organophosphate pesticides and oxidative stress (Holland et al, 2006; Huen et al, 2009;2010 Eskenazi et al, 2010; Harley et al, 2011). Previously, we sequenced the *PON1* gene in our Mexican-American subjects and identified several new functional polymorphisms (Huen et al, 2011). These polymorphisms as well as haplotypes containing multiple SNPs only explained an additional 2–4% of PON1 activity compared to well-known SNPs$PON1_{192}$ and $PON1_{-108}$ considered individually. Although coding SNP $PON1_{192}$ accounts for >70% of variation of substrate-specific paraoxonase activity, only a small portion of the variation (~25%) of PON1 enzyme quantity is explained by promoter SNP $PON1_{-108}$. We sought to determine whether epigenetic mechanisms such as DNA methylation in the *PON1* gene (assessed by Illumina 450K Methylation BeadChip) may also significantly influence PON1 quantity (measured by arylesterase activity) in CHAMACOS children at birth and 9 years of age (n=104). We interrogated 18 CpG sites in the *PON1* gene located in shores, shelves, and CpG islands. DNA methylation, particularly in several south shore and CpG island sites, was strongly associated with PON1 quantity ($p<0.005$) in 9 year olds but not in newborns. Furthermore, we observed significant allele-specific differences in methylation with the promoter SNP $PON1_{-108}$. Epigenetic changes were associated with PON1 quantity yet it remains unknown whether factors like environmental exposure influence these alterations. In future studies we will examine the relationship between early life exposures and DNA methylation in the *PON1* gene to determine whether epigenetics mediate the effects of exposure on PON1 variation.

Comprehensive DNA Methylation Profiling of 3.7 million CpGs with the SureSelect Target Enrichment System. *K. Jeong[1], M. Corioni[1], F. Useche[1], A. Shafer[3], E. Haugen[3], B. Novak[1], S. Happe[2], D. Roberts[1], J. Stamatoyannopoulos[3], E. LeProust[1]*. 1) Genomics Division, Agilent Technologies, Santa Clara, CA; 2) Genomics Division, Agilent Technologies, Cedar Creek, TX; 3) Dept. of Medicine, Univ. of Washington, Seattle, WA.

DNA cytosine methylation is a critical epigenetic modification involved in human diseases such as cancer and imprinting disorders. Various cellular processes including gene regulation, embryonic development, X chromosome inactivation, and chromatin remodeling are strongly associated with DNA methylation changes. Next-generation sequencing combined with sodium bisulfite treatment allows identification of methylation changes at single base resolution. However, whole genome bisulfite sequencing is prohibitively expensive. Additionally, many of the regions in whole genome bisulfite sequencing are in repetitive regions, and provide very little useful information. In many cases, the researcher is only interested in profiling a subset of biologically relevant regions. To address these needs, we have developed SureSelect Methyl-Seq, which combines Agilent's SureSelect Target Enrichment platform with bisulfite sequencing to detect methylation changes. Our Methyl-Seq design targets human genomic CpG sites within CpG islands/shores, promoters, known differentially methylated regions (DMRs) and previously determined regulatory regions. This comprehensive design covers 84Mb making it well suited to study cancer-, tissue-, and stem cell-specific DMRs. SureSelect Methy-Seq is also optimized for different sizes of custom designs. Here we describe the SureSelect Methyl-Seq workflow and demonstrate efficient target enrichment and precise methylation level detection. Further, we show high concordance with whole-genome bisulfite sequencing of known model systems. We also describe the detection of tissue and cancer specific DMRs in various samples including formalin fixed paraffin embedded tissues.

The development of a method for in-solution hybrid capture of bisulfite-converted DNA for targeted bisulfite sequencing of 175 ADME genes. *M. Kals[1], M. Ivanov[2], M. Kacevska[2], A. Metspalu[1], M. Ingelman-Sundberg[2], L. Milani[1]*. 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden.

DNA methylation is one of the most important epigenetic alterations involved in the control of gene expression. Bisulfite sequencing (BS-seq) of genomic DNA is currently the only method to study DNA methylation patterns at the single-nucleotide resolution. Hence, next-generation sequencing (NGS) of bisulfite-converted DNA is the method of choice to investigate DNA methylation profiles at the genome-wide scale. Nevertheless, sequencing of hundreds of human methylomes is still a very expensive task. At the same time, researchers often would like to investigate not the whole methylome but only a subset of genes of interest. Thus, the use of DNA target enrichment techniques together with bisulfite conversion of DNA could allow researchers to restrict the analyzed region of human epigenome. We successfully developed a novel protocol for the hybrid capture of bisulfite converted gDNA using custom Agilent SureSelect Target Enrichment system. In the pilot experiment, we initiated the protocol with 4 gDNA samples isolated from adult human livers and prepared 4 bisulfite-converted NGS libraries, which were enriched for 4 Mb genomic region of interest covering non-repetitive intervals of coding and regulatory regions of 175 ADME genes which are involved in the metabolism and distribution of drugs. The proposed method was validated by pyrosequencing and the Illumina HumanMethylation450 assay, and both techniques were highly consistent with the NGS BS-seq results. Sequencing of these target enriched bisulfite libraries on Illumina HiSeq2000 allowed us to reliably quantify methylation levels of more than 60% of the CpG sites in the selected genes. The number of common CpG sites for all 4 samples was more than 45,000; the median coverage varied between 36–77x and the mean CpG methylation level was 57–60%. Data analysis revealed that specific CpG sites are variably methylated among individuals and this variability is found in almost all ADME genes assessed. Such variable DNA methylation patterns provide valuable information regarding ADME gene regulation and aid in understanding inter-individual differences in drug metabolism and transport.

Association of Fetal-Derived Hypermethylated RASSF1A Concentrations in Placenta-Mediated Pregnancy Complications. *S. Kim[1], M. Kim[1], S. Park[1], D. Lee[1], J. Lim[1], J. Han[2], H. Ahn[2], J. Chung[2], M. Ryu[1, 2]*. 1) Laboratory of Medical Genetics, Medical Research Institute, Cheil General Hospital and Women's Healthcare Center, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, KwanDong University college of Medicine, Seoul, Korea.

Objective: The purpose of this study was to evaluate whether the fetal-derived hypermethylated RASSF1A concentration in maternal plasma is altered during pregnancy in pregnancies complicated with placental dysfunction manifested by intrauterine growth restriction (IUGR), preeclampsia (PE), or placental previa (PP) and whether any possible alternation can be detected in susceptible subjects before onset of the clinical disease. Methods: We performed real-time quantitative PCR to quantify RASSF1A concentrations before and after methylation-sensitive restriction digestion in maternal plasma at 7 to 40 gestational weeks of normal pregnancies (n = 161), IUGR (n = 43), PE (n = 22), PP (n = 10), and non-pregnant women (n = 20). Results: A positive correlation was observed between fetal-derived hypermethylated RASSF1A concentration and gestational age for all patient groups ($r = .624$; $P < .001$ for IUGR, $r = .381$; $P = .042$ for PE, $r = .606$; $P = .010$ for PP, $r = .560$; $P < .001$ for controls). The median concentration of hypermethylated RASSF1A was increased as early as at 10 to 13 weeks of gestation. Hypermethylated RASSF1A concentration in the second trimester (15 to 27 weeks) was significantly higher in patients who subsequently developed IUGR ($P = .002$), PE ($P < .001$) or PP ($P < .001$) than in controls. Conclusion: This study first demonstrated an increased concentration of fetal-derived hypermethylated RASSF1A sequences according to advancing gestation and before the onset of the clinical manifestation of pregnancy complications secondary to placental dysfunction such as IUGR, PE and PP. Hypermethylated RASSF1A in maternal plasma may be considered as a potential biomarker to detect placental-medicated pregnancy complications, regardless of fetal gender and polymorphism.

Epigenome Wide Association Study of Rheumatoid Arthritis. *I. Koh[1], J. Kim[1], J. Yoon[1], B. Kim[1], I. Park[1], K. Kim[1], Y. Kim[1], R. Huh[1], B. Han[1], S. Bae[2], J. Bae[1], J. Lee[1].* 1) KNIH, Osong, Chungcheongbukdo, South Korea; 2) Hanyang University, Seoul, Korea.

In addition to genetic factors, various environmental factors have been associated with the pathogenesis of autoimmune disease. One of major environmental factors related is epigenetic modification. To identify causative epigenetic aberration in autoimmune disease, we performed DNA methylation profiling of 76 Rheumatoid Arthritis (RA) patients against 14 healthy control by methyl binding protein affinity purification-Sequencing (MBD-Seq) and Illumina 450k DNA methylation beadarray in blood and synovium fluid CD4+ T cell. Epigenome profiling reveals that T cell development related pathway was most significantly enriched in differentially expressed gene set. Next, we identified Differential Methylation Site (DMS, p-value less than 10^{-7}). Top3 DMS include development related transcription factor, T cell development related transcription factor and angiotensin binding protein playing a role in autoimmune disease. In addition to DMS identification, we compared marker identified from Genome Wide Association Study (GWAS) data with epigenetic modification profile. we tested 7 top significant SNP loci confirmed from 3 independent GWAS data, which only revealed that the strongest marker HLA-DRB1(Odds Ratio=2.51, p-value=$4.9*10^{-23}$) showed significant difference in DNA methylation (p-value = 0.069), whereas other 6 marker didn't showed any significant methylation change. Thus, HLA-DRB1 locus was single common target for both genome and epigenome modification. Further study on common target of genome-epigenome will be discussed.

DNA methylation analysis of iPS cells using whole-genome bisulphite sequencing. *D.S. Lee[1,2,5], J.Y. Shin[1,4], Y.S. Ju[1,2,3,5], J.I. Kim[1,2,4,5], P. Tonge[6], M. Puri[6], A. Nagy[6,7], J.S. Seo[1,2,3,5].* 1) GMI, Seoul national university, Seoul, Seoul, South Korea; 2) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul 110-799, Korea; 3) Macrogen Inc., Seoul 153-023, Korea; 4) Psoma Therapeutics Inc., Seoul 110-799, Korea; 5) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul 110-799, Korea; 6) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Ontario M5G 1×5, Canada; 7) Department of Molecular Genetics, University of Toronto, Toronto M5S 1A8, Canada.

iPS cells have several advantages for stem cell research and regenerative medicine including a potentially limitless supply of patient-matched cells for cell-based therapies without the requirement for human embryonic donor tissue. iPS cells may be used for therapeutics, in vitro modelling of human complex diseases, and drug development. Somatic cell reprogramming involves epigenetic remodelling of chromatin architecture including methylation, conferring iPS cells with characteristics similar to embryonic stem (ES) cells. However, it remains unknown whether the re-establishment of an ES-cell-like DNA methylation pattern occurs throughout the genome, and how the methylation pattern changes during the reprogramming process. To address these questions, we utilized a secondary inducible reprogramming system developed in mouse using piggyBac-mediated transposition of the four reprogramming factors. Here we report whole-genome DNA methylation profiles at single-base resolution for mouse ES cells, secondary mouse embryonic fibroblast (MEF), secondary factor independent iPS cells induced from these MEFs, and cells undergoing reprogramming at Day 8, using whole genome bisulphite sequencing. Hiseq 2000 was used for the whole genome sequencing, and Bismark was used as an alignment tool. We defined differentially methylated regions (DMRs) and partially methylated domains(PMDs) in CpG, CHG, and CHH context. iPS cells show significant reprogramming variability, including somatic memory and aberrant reprogramming of DNA methylation.

Advanced genome-wide methylome profiling and analysis of leukemia reveals novel epigenetic dynamics. *S. Li, A. Akalin, F. Garrett-Bakelman, A. Melnick, C. Mason.* Weill Cornell Medical College, New York, NY.

Understanding the molecular mechanisms that lead cancer is one of the most important aspects of cancer research. Previous studies have shown that aberrant cytosine methylation patterning is a hallmark of acute lymphoblastic leukemia (AML). DNA cytosine methylation is a critical epigenetic modification that regulates gene expression and mediates cellular differentiation states. Current high-throughput methods for examination of the epigenome, such as reduced representation bisulfite sequencing (RRBS), ameliorate the cost of sequencing after bisulfite treatment, but limit the number of regions that can be examined. Here, we report biochemical and bioinformatics improvements in the RRBS method, creating a new technique called enhanced RRBS (ERRBS) and a R package methylKit which can quickly analyze genome-wide cytosine methylation profiles from high-throughput bisulfite sequencing experiments. We applied the protocol and performed differential methylation analysis on AML samples. Our method shows an improved conversation efficiency of the non-methylated cytosines (>99.5%). We found an increased number (11–61%) of CpG sites that can be detected and quantified in all areas: CpG islands, promoters, CpG shores, introns, and exons. We applied methylKit to stratify the AML patients based on the methylation dynamics. Moreover, we effectively determined the differentially methylated regions (DMRs) and CpG sites (DMCs) using a hidden markov model (HMM) that revealed new regions of the genome that are altered in AML.

Differential Methylation of Colorectal Adenomas of the Right Side. *J. Li[1], D. Koestler[1], J. Baron[1], A. Dietrich[1], G. Tsongalis[2], L. Butterly[2], M. Goodrich[2], C. Marsit[1], J. Moore[1], A. Andrew[1], A. Srivastava[3].* 1) Geisel School of Medicine, Dartmouth College, Lebanon, NH; 2) Dartmouth-Hitchcock Medical Center, Lebanon, NH; 3) Brigham and Women's Hospital, Boston, MA.

Colon polyps are growths on the surface of the colon, which are generally asymptomatic, but have the potential of progressing to cancer. Recent work has demonstrated that colonoscopy reduces mortality for cancers on the left, but not on the right side of the colon, suggesting that there are important biological differences between the right- and left-sided precursors of colon cancer. We hypothesized that the phenotypic differences between right- and left-colon polyps may be due to their underlying DNA methylation signatures. To evaluate side-specific differences in DNA methylation status, we obtained primary polyp tissue (n=65 left-sided, n=70 right-sided polyps), removed at the baseline screening colonoscopy from consenting New Hampshire Colonoscopy Registry (NHCR) participants who were diagnosed with a conventional adenoma. DNA extracted from the primary tissue was then subjected to epigenome-wide methylation assessment using the Illumina HumanMethylation450 BeadChip, which profiles the methylation status for >485,000 CpG loci. A principal component analysis (PCA) applied to the methylation data revealed that the first principle component, which explains the largest amount of variability in methylation across the array, was significantly associated with colon polyp side (p=0.007). Furthermore, examining methylation differences across the array revealed 57,795 (12.2%) loci that were associated with left/right colon polyp side (p<=0.05) and 168 loci below the Bonferroni threshold (p<=1.06e-7). Among significant loci, a greater than expected proportion was associated with genes regulating cell growth, mitotic cycle, oncogenic transformation, or had prior evidence of modification in cancer. Unexpectedly, the percentage of the probes that located on the CpG islands among the entire array was 30.8%, while percentage of CpG loci among the significant probes associated with side was only 18.2%. Our results suggest both gene-specific and genome wide differences in DNA methylation between left and right colon-adenomas. Molecular characterization of these lesions will help elucidate the basis of the side-specific differences in polyps and help to identify potential molecular markers of lesion subtypes that may require different screening intervals.

Methylation quantitative trait loci and epigenetic networks underlying asthma-related traits. *L. Liang[1], S.A.G. Willis-Owen[2], K.C.C. Wong[2], A. Binia[2], G. Davies[3], J.M. Hopkin[3], I. Yang[4], T.M. Pastinen[5], D.A. Schwartz[4], G. Abecasis[6], G.M. Lathrop[7], M.F. Moffatt[2], W.O.C.M. Cookson[2].* 1) Departments of Epidemiology and Biostatistics, Harvard School of Public Health, Boston, MA 02115; 2) National Heart and Lung Institute, Imperial College, London SW3 6LY, UK; 3) Institute of Life Science, School of Medicine, Swansea University, UK; 4) University of Colorado School of Medicine and National Jewish Health, Denver, CO; 5) Departments of Human and Medical Genetics, McGill University and Génome Québec Innovation Centre, Montréal, Canada; 6) Center for Statistical Genetics, Dept. of Biostatistics, SPH II, Ann Arbor, MI; 7) CEA / Centre National de Genotypage, 91057 Evry, France.

Epigenetic variation in the methylation of DNA at CpG islands (CGI) is related to the regulation of transcription. The extent of epigenetic variation in the human genome and its relevance to common diseases are not known. We studied methylation status in asthmatic nuclear families genome-wide at 27,000 CGI in DNA from peripheral blood leukocytes (PBL). We show here that major components of variation in methylation quantitative trait loci (meQTL) included age, sex and the shared family environment. We observed true genetic influences (meSNPs) on methylation status at 10% of loci. In order to establish the utility of genome-wide meQTL association studies (GMAS) to common diseases we show mapping of meQTL with genome wide significance to multiple phenotypes. We found and replicated meQTL associations to the total serum IgE concentration ($P<10^{-11}$) the top four of which accounted for 21.5% of the IgE variation, compared to 1–2% seen in GWAS studies of the same trait. Cigarette smoking showed replicated associations to loci influencing coagulation. Genome function is mediated through interactive networks of genes and regulatory elements, and we further show here the presence of strongly co-ordinated regulation of meQTL in the form of 30 scale-free meQTL correlation networks (meQTN). Enrichment analysis identified meQTN modules that could be attributed to peripheral blood neutrophils, lymphocytes, monocytes and eosinophils ($P<10^{-81}$ to 10^{-350}). These and other modules were enriched by loci associated to asthma and the total serum IgE ($P<10^{-16}$ to 10^{-104}). Hubs in these networks define potential therapeutic targets for manipulating cell-specific immune function in asthma and other common inflammatory diseases.

Activation of silenced tumor suppressor genes in prostate cancer cells by a novel energy restriction-mimetic agent. *H. Lin[1,2,4], Y. Kuo[2], Y. Weng[3], I. Lai[2], T. Huang[3], S. Lin[1], D. Niu[4,5], C. Chen[2].* 1) Department of Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan and Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 2) Division of Medicinal Chemistry, College of Pharmacy, The Ohio State University, Columbus, OH 43210, U.S.A; 3) Human Cancer Genetics Program, The Ohio State University, Columbus, OH 43210, U.S.A; 4) Institute of Clinical Medicine, National Yang-Ming University, Taipei, Taiwan; 5) Department of Pediatrics, Taipei Veterans General Hospital, Taipei, Taiwan.

BACKGROUND. Targeting tumor metabolism by energy restriction-mimetic agents (ERMAs) has emerged as a strategy for cancer therapy/prevention. Evidence suggests a mechanistic link between ERMA-mediated antitumor effects and epigenetic gene regulation. METHODS. Microarray analysis showed that a novel thiazolidinedione-derived ERMA, CG-12, and glucose deprivation could suppress DNA methyltransferase (DNMT)1 expression and reactivate DNA methylation-silenced tumor suppressor genes in LNCaP prostate cancer cells. Thus, we investigated the effects of a potent CG-12 derivative, CG-5, vis-à-vis 2-deoxyglucose, glucose deprivation and/or 5-aza-deoxycytidine, on DNMT isoform expression (Western blotting, RT-PCR), DNMT1 transcriptional activation (luciferase reporter assay), and expression of genes frequently hypermethylated in prostate cancer (quantitative real-time PCR). Promoter methylation in these genes was assessed by pyrosequencing analysis. SiRNA-mediated knockdown and ectopic expression of DNMT1 were used to validate DNMT1 as a target of CG-5. RESULTS. CG-5 and glucose deprivation upregulated the expression of DNA methylation-silenced tumor suppressor genes, including GADD45a, GADD45b, IGFBP3, LAMB3, BASP1, GPX3, and GSTP1, but also downregulated methylated tumor/invasion-promoting genes, including CD44, S100A4, and TACSTD2. In contrast, 5-aza-deoxycytidine induced global reactivation of these genes. CG-5 mediated these epigenetic effects through transcriptional repression of DNMT1, which was associated with reduced expression of Sp1 and E2F1. SiRNA-mediated knockdown and ectopic expression of DNMT1 corroborated DNMT1's role in CG-5-mediated modulation of gene expression. Pyrosequencing revealed differential effects of CG-5 versus 5-aza-deoxycytidine on promoter methylation in the genes examined. CONCLUSIONS. These findings reveal a previously uncharacterized epigenetic effect of ERMAs on DNA methylation-silenced tumor suppressor genes, which may foster novel strategies for prostate cancer therapy.

3468T

Patterns of SNP-based genome-wide heritability of methylation in four brain regions. *J. Listgarten, G. Quon, C. Lippert, D. Heckerman.* Microsoft Research, Los Angeles, CA., 90024.

We used a mixed model to investigate the extent to which genetic variation in DNA sequence explains variation in CpG dinucleotide methylation in data from 150 individuals for four brain regions. In particular, our goals were to investigate what role cis-DNA sequence plays in influencing methylation, what an optimum definition of cis (i.e., locality) is in this context, and whether CpG dinucleotides with heritable methylation were more likely to be associated with particular classes of genes. We found that 5–7% of CpG sites assayed were heritable, with a median narrow-sense heritability of 21% (and a mean of 3.5% over all sites) when using an optimal cis window of 50kb. We also found good concordance across brain regions. Our percentage of significant sites is similar to work by Bell et al., who found that 6.3% of CpG sites tested had significant QTLs, although they found a mean genome-wide heritability of 18%, higher than ours, unsurprisingly given that they used a twin-based correlation estimate. Finally, we show that the set of genes potentially targeted by these methylation loci are enriched in human leukocyte antigen (HLA) genes, which are important in a variety of developmental and immune processes. Our estimates of heritability are conservative, and we suspect that the number of heritable loci will increase in the near future as the methylome is assayed across a broader range of tissue and cell types and the density of the tested loci is increased.

Statistical Models to Predict DNA Methylation Level across Different Tissues in Human. *B. Ma[1], E. Wilker[2], S.A.G. Willis-Owen[3], K.C.C. Wong[3], A. Baccarelli[1,2], J. Schwartz[1,2], W.O.C.M. Cookson[3], K. Khabbaz[4], M.A. Mittleman[1], M.F. Moffatt[3], L. Liang[1,5].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Department of Environmental Health, Harvard School of Public Health, Boston, MA; 3) National Heart and Lung Institute, Imperial College, London SW3 6LY, UK; 4) Division of Cardiothoracic Surgery, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA; 5) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

Variation in DNA methylation is important to cell differentiation and is known to be associated with aging, cancers and complex diseases. Although studies have shown that methylation patterns are highly conserved across tissues, there are substantial between-tissue variations that characterize tissue-specific DNA methylation patterns. In this investigation, we found that for individual loci the methylation difference between tissues is highly consistent and reliably reproducible across multiple individuals. Following this finding, we developed a statistical model for each CpG site to predict methylation level in one tissue based on the methylation level in another tissue. Using data from two ongoing studies: (1) In a study for childhood asthma, 39 individuals with methylation measured in both peripheral blood leukocytes (PBL) and EBV transformed lymphoblastoid cell lines (LCL) using the Illumina Infinium HumanMethylation27 array that covers 27,000 CpGs, and (2) In a study for atrial fibrillation, 14 individuals with methylation measures in 3 tissues (atrium, internal mammary artery and peripheral leukocytes) using Illumina Infinium HumanMethylation450 array that covers more than 480,000 methylation sites on the genome, we found that our method can greatly improve accuracy for cross tissue prediction (correlation square R2 increases from 0.81 (raw correlation R2) to 0.97 for blood->artery prediction, from 0.83 to 0.99 for blood->atrium prediction and 0.92 to 0.99 for LCL->PBL prediction based on cross-validation). These results indicate that methylation level in target tissue can be predicted using methylation measured in different tissues. We showed that methylation status at multiple CpG sites can be combined to further improve the prediction performance. This implies that using relatively easy accessible tissues (e.g. blood), large scale epidemiology investigations that target hard-to-access tissues could become feasible and non-invasive disease screening using epigenetic profile may also be achievable.

Comparative DNA methylation in TrkB gene across brain regions of suicide completers. *G. Maussion, B. Labonté, C. Ernst, A. Diallo, J. Yang, N. Mechawar, G. Turecki.*Department of Psychiatry, Douglas Hospital, McGill University, Montreal, QUEBEC, Canada.

TrkB gene codes for a receptor of BDNF. Previous studies by our group indicate that a subgroup of suicide completers have low expression levels of TrkBT1, an isoform which has no tyrosine kinase domain and is highly expressed in astrocytes. In previous studies, we observed epigenetic modifications in the TrkB promoter, which partially explained TrkB-T1 low expression level in brain tissue from suicide completers. The general aim of this study was to investigate DNA methylation throughout the TrkB-T1 gene sequence and adjacent genomic regions which could be responsible for the significant deregulation in TrkB-T1. Twelve low TrkB-T1 expressor suicides and 12 normal TrkB-T1 expressor controls were investigated. DNA was extracted from BA8/9, and the methylation fraction was pulled down by Methylated DNA immunoprecipitation. Microarray studies were performed using custom-made Agilent arrays tiling the whole TrkB gene and adjacent genomic sequence. After statistical correction for multiple testing, 9 DNA sequences located in TrkB gene were identified hypermethylated in frontal cortex of suicide completers. Four out of nine probes matched with intronic regions of TrkB gene whereas the five remaining probes corresponded to TrkB-T1 3'UTR sequence. These data are in agreement with the hypothesis of a transcript-specific deregulation through DNA methylation. We focused on the probes differentially methylated in this DNA region and validated them by clone sequencing of bisulfite treated DNA. Intergenic and extragenic regions present differential methylation between groups. Additional studies need to assess the functional significance of these findings. As DNA methylation is known to be region specific, we also aim to analyse the methylation pattern TrkB gene in the hippocampus where gene deregulations have been shown in brain from suicide completers.

Methylomic Variation In Alzheimer's Disease. *J. Mill[1], K. Lunnon[1], M. Volta[1], R. Smith[1], J. Powell[1], Y. Patel[1], N. Buckley[1], J. Cooper[1], C. Troakes[1], V. Haroutunian[2], S. Lovestone[1], L. Schalkwyk[1].* 1) SGDP Research Centre, Institute of Psychiatry, King's College London, London, United Kingdom; 2) The Mount Sinai School of Medicine, New York, USA.

Although the neuropathological changes associated with AD have been well characterized in post-mortem brain tissue, little is known about either the underlying etiology of the disorder or the precise mechanisms behind disease progression. In this project we aim to look beyond the traditional genetic and neuropathological etiological approaches to AD by testing the hypothesis that epigenetic phenomena play a crucial role in the development of the disorder. We have examined genome-wide patterns of DNA methylation across multiple brain-regions and blood, obtained from the same patients, using several complementary methylomic technologies (MeDIP-seq and Illumina 450K arrays) using samples from two well-characterized AD cohorts from the UK and US. We have identified several AD-associated differentially-methylated regions (DMRs); interestingly, some DMRs are observed in specific brain regions and others are common across tissues. We have also assessed cross-tissue patterns of allele-specific DNA methylation, identifying cis-acting genetic effects on epigenetic status in specific regions of the brain. Finally, we are using immunohistochemistry to quantify 5-methylcytosine, 5-hydroxymethylcytosine, 5-formylcytosine and 5-carboxylcystosine in tissue from AD patients and controls, and employing laser-capture microdissection to examine methylomic changes in purified populations of neurons and microglia from affected patients and controls. Ultimately we aim to integrate our methylomic data with other genomic, transcriptomic and proteomic data being collected from the same samples to undertake a truly integrative approach to the etiology of AD.

Cytosine modifications and cellular sensitivity to chemotherapeutics. *E.L. Moen[1], X. Zhang[2], S.M. Delaney[1], L.A. Godley[1], M.E. Dolan[1], W. Zhang[2].* 1) Department of Medicine, University of Chicago, Chicago, IL; 2) University of Illinois at Chicago, IL.

Covalent cytosine modifications, 5-methylcytosine and 5-hydroxymethylcytosine, occur in CpG dinucleotides throughout the human genome with genetic and environmental influences contributing to inter-individual differences. Our objective is to characterize inter-individual variation in cytosine modifications and investigate its contribution on gene expression and pharmacologic phenotypes, such as cellular sensitivity to chemotherapeutics. The International HapMap Project lymphoblastoid cell lines (LCLs) are an attractive model to address these questions at a genome-wide level due to publicly available genotype and gene expression datasets. In addition, our laboratory has gathered drug phenotype data for 14 chemotherapeutic agents. Thus, overlaying global cytosine modification data onto these existing datasets allows us to study how epigenetic variation affects cellular response to chemotherapeutic agents. We used the Illumina Infinium 450K HumanMethylation Beadchip array to measure cytosine modification levels at >485,000 CpGs. In this study, we included 73 unrelated African (YRI - Yoruba people from Ibadan, Nigeria) and 60 European ancestry (CEU - Caucasians from Utah, US) LCLs. After several filtering steps, we analyzed 283,540 CpGs and found that most of the inter-individual variation occurred outside of CpG islands, at CpGs in shores and shelves. Using gene expression data from the Affymetrix Human Exon Array, which measures the expression of 17,284 transcripts, we discovered 3,049 cis-acting modified cytosine-gene expression relationships at FDR<0.01. Interestingly, we saw both positive and negative associations between cytosine modification and gene expression. As expected, high levels of cytosine modification in gene promoter regions were more likely to be associated with negative gene expression. Conversely, high levels of cytosine modifications within the gene body were to more likely to be associated with positive gene expression. Importantly, cytosine modification heterogeneity and its consequences on gene expression contribute to variation in cellular response to chemotherapeutics. For example, a methylation locus in the gene body of PARD3 was found to significantly associated with both cisplatin and carboplatin IC50 in the YRI samples. These investigations will further our understanding of mechanisms of resistance to chemotherapeutic drugs.

3473T

Aberrant promoter hypermethylation of MMP16 gene in the colorectal cancer. *J. MOON[1], S. LEE[1], J. KIM[1], G. YOU[1], J. LEE[1], J. KIM[2], H. KIM[1], S. PARK[1].* 1) Anatomy, College of Medicine, Korea University, Seoul, South Korea; 2) Department of General Surgery, Korea University Medical Center, Seoul, South Korea.

We evaluated the methylation profile of 27,578 CpG sites spanning more than 14,000 genes in paired 20 colorectal cancer (CRC) tissues with methylation bead chip array-based technology. In array data, we confirmed 739 CpG sites as aberrant DNA methylation ($p<0.0001$) and 125 CpG sites was located in promoter region. There were strongly hypermethylated in CRC more than adjacent normal tissue ($p<0.0001$). Among these genes, matrix metallopeptidase 16 (MMP16, MT3-MMP) was one of the top-ranking methylation genes in 20 CRC tissues ($p<0.0001$). MMP16 involves ternary complex formation on the cell surface and possess the potential to promote melanoma invasion. To confirm the correlation between methylation and expression, we investigated the mRNA expression level of MMP16 by RT-PCR and western in CRC tissues compared adjacent normal tissues. The low expression level of MMP16 gene was correlated by about 30% on methylated CRC tissues. In addtion, MMP16 was down-expressed in three hypermethylated CRC cell lines. Futhermore, the mRNA expression of MMP16 in CRC cells was restored after 5-aza-2'-deoxycytidine treatment. In conclusion, our result revealed that the promoter hypermethylation of MMP16 is frequently present in CRC, may play role in colorectal cancer invasion. For understanding of MMP16 methylation effects, we are analyzing the correlation between hypermethylation of MMP16 onto CRC risk factor as migration and invasion.

Deep sequencing reveals allelic and parental inheritance patterns of genome-wide DNA methylation in large number of nuclear pedigrees with schizophrenia. *R.A. Ophoff[1,2,3], N. Plongthongkum[4], T. Wang[1], Y. Zhang[1], K.R. Van Eijk[3], R.S. Kahn[3], M.P.M. Boks[3], S. Horvath[2], K. Zhang[4].* 1) Center for Neurobehavioral Genetics, Semel Inst of Neuroscience, Univ California Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, UCLA, Los Angeles; 3) Department of Psychiatry, University Medical Center Utrecht, The Netherlands; 4) Department of Bioengineering, UCSD, San Diego.

In an effort to study genome-wide epigenetic profiles and their inheritance patterns in the context of a neuropsychiatric disorder, we examined allelic DNA methylation in 22 nuclear pedigrees consisting of two parents, a proband affected with schizophrenia and one or two unaffected siblings. These subjects represent a relatively large number of potential informative meioses that can be used to robustly decipher epigenetic patterns of inheritance at a genome-wide scale, thereby facilitating genetic studies of disease susceptibility of complex traits. Using genomic DNA from whole blood we employed methylation sequencing with bisulfite padlock probes targeting >550,000 CpG sites genome-wide. After bisulfite treatment we generated libraries of 96 subjects and used barcodes for multiplexing of all samples simultaneously for data collection on a HiSeq2000 sequencer. We generated an average of 3Gbps of data per sample, and called an average of 504,825 CpG sites per subject, with >80% of the samples having over 450,000 CpG sites called. The sequence data identified more than 150,000 SNPs per subject allowing for genetic analysis and allelic-specific studies. As part of the initial data analysis we performed a mid-parent offspring analysis to estimate the heritability of CpG methylation. Our results suggest that 13.4% of CpGs with variable methylation profiles have strong evidence for a heritable component of which 60% could be explained by allelic variation at the CpG site itself. Thus far we have no evidence of chromosomal clustering of these CpGs. We also performed methylation QTL (mQTL) analysis and observed robust evidence of *cis* regulation of DNA methylation. We detected a general trend of increased *cis*-association signal closer to the CpG site with more than 50% of mQTLs within 2 kb of the methylated site. Overall, allele specific methylation (ASM) patterns within the pedigrees, show the strongest evidence for sequence-dependent ASM when SNPs are located within the CpG site itself. We are currently expanding our analyses to include patterns of imprinting, parent-of-origin and age effects. Examining the effect of disease status on CpG methylation to uncover possible biology underlying disease susceptibility completes our study.

Methylation Pattern of Twin Groups with Behcet's Syndrome. *M. Ozkilic[1], B. Shamloo[1], G. Celikyapi Erdem[1], E. Seyahi[2], H. Yazici[2], E. Tahir Turanli[1,3].* 1) Dr. Orhan Öcalgiray Molecular Biology-Biotechnology and Genetics Research Center, Istanbul Technical University, Istanbul, Turkey; 2) Department of Rheumotology, Cerrahpasa School of Medicine, Istanbul University, Istanbul, Turkey; 3) Molecular Biology and Genetics Department, Science and Letter Faculty, Istanbul Technical University, Istanbul, Turkey.

Objective: Behçet's Syndrome (BS) is a multisystem vasculitis of unknown etiology. HLA-B51 is the strongest marker associated with BS. Phenotypic discordance between BS monozygotic twins points to involvement of epigenetic or environmental factors in the etiology. We hypothesized that global methylation profile are different between discordant BS twins. Global methylation levels were compared among concordant and discordant 4 MZ and 4 DZ BS twins with age-gender matched healthy MZ and DZ twins (n=8). Methods: DNA was isolated from venous blood of BS and control twins. DNA was digested into nucleotides and then nucleotides converted to nucleosides. Global methylation value was obtained by injecting digested DNA samples to HPLC and separating nucleosides including dC and 5-mdC. The area below the peaks was recorded. Tests were triplicated, 5-mdC: dC ratio for each of the samples was calculated (%RSD= 7%). Authentic dc and 5-mdc was used as standard for the experiment to determine and compare dC:5-mdC ratios. The average values were compared between groups using student T test analyses. Results and Conclusions: The difference between 5-mdC: dC ratio was found to be more correlated with each other in healthy control twins compared to the discordant BS twins (P= 0.02847). However the global methylation level did not change with the disease status such that both BS (mean= 0.032 sd=0.006) and control MZ/DZ (mean= 0.030 sd=0.001) twins found to have similar total methylation levels. This finding is in agreement with previous studies on the level of global DNA methylation level in human genome, but it is in contrast with another study in which decreased global methylation was shown in SLE pairs of discordant MZ twins. We are further analyzing our sample for locus specific methylation and we are including other disease control twins such as SLE and FMF into our dataset.

Integrated analysis of genome-wide DNA methylation and gene expression in post-mortem schizophrenia brain samples. *R. Pidsley, J. Viana, C. Troakes, S. Al-Sarraj, L. Schalkwyk, J. Mill.* Institute of Psychiatry, London, London, United Kingdom.

Schizophrenia is a severe psychiatric disorder characterised by psychotic symptoms and cognitive deficits. Recent work suggests that epigenetic factors regulating gene expression, including DNA methylation, may play a role in the molecular aetiology of the disorder. Patterns of DNA methylation and gene expression are tissue-specific, so brain tissue is optimal for the identification of methylomic and transcriptomic changes associated with schizophrenia. In this study, DNA and RNA were extracted from a unique collection of well-characterised, neuropathologically dissected human post-mortem brain samples: frontal cortex (n=47) and cerebellum (n=47) samples, comprising 23 schizophrenia patients and 24 healthy controls. Genome-wide methylation and expression analyses were performed using the Illumina Infinium Human Methylation450 BeadChip and the Illumina HumanHT-12 v4 Expression BeadChip, respectively. Integrated analyses to test for genome-wide association between DNA methylation, gene expression and schizophrenia are ongoing. Initial results show tissue-specific, genome-wide significant differences in DNA methylation between cases and controls at numerous loci. I will report on these results, which give an insight into the role of epigenetics in schizophrenia, and on the results of the integrated analysis, which will provide additional information about the underlying biological mechanism of association.

Determination of methylation profile in patients with schizophrenia. *B. Rukova[1], R. Staneva[1], S. Hadjidekova[1], D. Nikolova[1], V. Milanova[2], D. Toncheva[1].* 1) Department of Medical Genetics, Sofia, Bulgaria; 2) Department of Psychiatry, Sofia, Bulgaria.

Schizophrenia is a severe chronic mental disorder that affects most of the higher brain functions. Its prevalence is estimated on about 1% worldwide. The classical symptoms occur in several other psychiatric disorders, which makes difficult the exact diagnoses. Schizophrenia is a serious social and economic healthcare problem. Currently, there is no etiological treatment. DNA methylation is a major epigenetic modification. It is a biochemical process that is important for normal organismal development and cellular differentiation. DNA methylation stably alters the gene expression pattern in cells. This modification can be inherited through cell division. Materials and methods: We analyzed age matched pools of 220 schizophrenia patients and 220 healthy controls. We've performed high-resolution genome-wide methylation array analysis (Agilent 1×244K). We've analyzed the methylation status of 27800 CpG islands of both groups to identify methylation profile differences. Results: Our experiments show significant difference in the methylation profile between patients and controls. In patients group we established 59 hypermethylated genes and 37 hypomethylated genes, compared to healthy controls. Some of these hypermethylated genes play a role in neuronal development, methylation and mediation of neuronal impulses like ESPNP, GNMT,BHLHE23,CRELD2. Some of the hypomethylated in patients genes like PROX1, FGF13 and GABBR1 take part in neuronal development, signal transmission and cell growth. Conclusions: Our data suggest that there is a major differences in methylation profile between patients and controls. This dysregulation can play a critical role in schizophrenia pathogenesis. Association of CpG island shore methylation in peripheral blood with disease state and SNP variants in the MLH1 region in colorectal cancer patients. *A. Savio[1,2], M. Lemire[3], M. Mrkonjic[1,2], S. Gallinger[1,2,4,5], B. Zanke[6], T. Hudson[3], B. Bapat[1,2,7].* 1) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON; 2) Samuel Lunenfeld Research Institute, Toronto, ON; 3) Ontario Institute for Cancer Research, Toronto, ON; 4) Ontario Familial Colorectal Cancer Registry, Cancer Care Ontario, Toronto, ON; 5) Department of Surgery, University of Toronto, Toronto, ON; 6) Ottawa Hospital Research Institute, Ottawa, ON; 7) Department of Pathology, University Health Network, Toronto, ON.

Epigenetic gene silencing via hypermethylation of CpG islands in tumor cells contributes to colorectal cancer (CRC) development. We previously demonstrated that SNPs (rs1800734, rs749072, and rs13098279) in the MLH1 (MutL homolog 1) gene region are associated with MLH1 promoter CpG island methylation, loss of MLH1 protein expression, and tumor microsatellite instability (MSI). Recent studies have identified less CpG-dense "shore" regions flanking many CpG islands. These CpG island shores often exhibit distinct methylation profiles between different tissues and normal versus tumor cells of patients. To date, most studies have focused on somatic methylation events within tumor tissue while few have examined the contributions of peripheral blood cell (PBC) methylation changes to CRC risk. To address whether MLH1 methylation in PBCs is correlated with tumorigenesis we utilized Illumina methylation microarrays to measure genome-wide methylation at 450,000 CpG sites in DNA extracted from PBCs of 884 CRC cases and 845 healthy controls. Analysis of chromosome 3p21 revealed that a CpG island shore 1 kb upstream of MLH1 incurs significantly lower methylation in CRC patients than controls. When stratified by SNP genotypes of rs1800734, rs749072, and rs13098279, individuals with wild-type genotypes incur significantly higher PBC CpG island shore methylation than heterozygous or homozygous variant individuals in both CRC cases and controls. CpG island shore methylation also decreases significantly with increasing age in cases and controls. This is the first study of its kind to integrate PBC methylation at a CpG island shore with SNP genotype status in CRC cases and controls. We have found decreased methylation in CRC patients, individuals possessing variant SNP alleles, and older individuals. This decreased methylation at the MLH1 CpG island shore may indicate genomic instability possibly predisposing to CRC.

The DNA methylation landscape of human placenta. *D. Schroeder[1], H. Yu[2], P. Lott[2], D. Hong[1], C. Walker[3,4], I. Korf[2], J. LaSalle[1,2,4].* 1) Medical Microbiology and Immunology, UC Davis, Davis, CA; 2) UC Davis Genome Center, UC Davis, Davis, CA; 3) Obstetrics & Gynecology, UC Davis School of Medicine, Sacramento, CA; 4) UC Davis M.I.N.D. Institute, UC Davis School of Medicine, Sacramento, CA.

As genome-scale DNA methylation sequencing technologies have improved it has become apparent that tissue-specific methylation can occur not only at promoters, enhancers, and CpG islands but also over larger genomic regions. In most human tissues, the vast majority of the genome is highly methylated (>70%). However, genomic sequencing of bisulfite-treated DNA (MethylC-seq) has revealed large partially methylated domains (PMDs) in some human cell lines. PMDs can cover as much as 40% of the genome in fetal lung fibroblasts and are associated with gene repression and inactive chromatin marks. We have previously demonstrated PMDs in human SH-SY5Y neuroblastoma cells and shown that tissue specific PMDs define a subset of neuronally expressed genes with synaptic functions. However, to date only cultured cells and some cancers have shown evidence for PMDs, suggesting that PMDs may not be observed in normal human tissues.

Here we performed MethylC-seq in full-term human placenta, discovering the first normal human tissue showing clear evidence of PMDs. Similar to our observations in cultured human cells having PMDs, RNA-seq analysis confirmed that genes in PMDs are repressed in placenta. Using a hidden Markov model, we mapped placental PMDs genome-wide and compared them to mapped PMDs of two other human cell lines (IMR90 and SH-SY5Y). GO analysis showed that genes in placental PMDs had tissue-specific functions and that combining PMD information from multiple cell and tissue types increased the statistical significance of the tissue-specific GO terms. A deeper analysis of DNA methylation patterns in placenta showed that methylation levels in promoter CpG islands were actually higher for genes within PMDs, despite the lower overall methylation of surrounding regions, perhaps due to protection from active demethylation of CpG islands in PMDs. These results suggest that PMDs are a developmentally dynamic feature of the methylome that is relevant for understanding not only cancer but also normal tissue development. Future investigations of human placenta by MethylC-seq may be informative for finding epigenetic biomarkers of diseases such as neurodevelopmental disorders.

Methylation Quantitative Trait Loci (mQTL) are Consistently Detected across Ancestry, Age and Tissue Type. *A.K. Smith[1], V. Kilaru[1], M. Kocak[2], L.M. Almli[1], K.B. Mercer[3], E.B. Binder[4], K.J. Ressler[1,3], F.A. Tylavsky[2], K.N. Conneely[5].* 1) Psychiatry & Behavioral Sciences, Emory University, Atlanta, GA; 2) Department of Preventive Medicine, University of Tennessee Health Science Center, Memphis, TN; 3) Howard Hughes Medical Institute, Chevy Chase, MD; 4) Max-Planck Institute of Psychiatry, Munich, Germany; 5) Department of Human Genetics, Emory University, Atlanta, GA.

Individual genotypes can result in different patterns of DNA methylation. These methylation Quantitative Trait Loci (mQTLs) influence methylation across extended genomic regions and may underlie direct SNP associations or gene-environment interactions. mQTLs have been identified in multiple tissues and cohorts, but only a limited number are consistent across studies. We hypothesize that the detection of mQTLs will vary with ancestral population, age, and tissue type. To explore this, we analyzed 7 datasets that varied by race (Caucasian [CC] vs. African American [AA]), age (neonate vs. adult) and tissue type (blood vs. 4 regions of postmortem brain) with genome-wide DNA methylation (HumanMethylation27 BeadChip) and SNP data (Illumina or Affymetrix arrays). SNPs that were common to all arrays (~90k), had a MAF <.05 and did not deviate significantly from HWE ($p<.00001$) were included. Methylation probes that contained SNPs were excluded. We tested for mQTLs by performing linear regressions of methylation levels at each CpG site on SNP genotypes within 50kb under an additive model, controlling the false discovery rate at .05. We identified 591 mQTLs in CC umbilical cord blood (N=87), 116 in AA cord blood (N=87), 146 in AA adult blood (N=90), 380 in CC pons (N=125), 332 in CC cerebellum (N=119), 520 in CC frontal cortex (N=133) and 707 in the CC temporal cortex (N=127). Significant overlap of mQTLs was observed between all pairs of sample groups ($p<2.4\times10\text{-}13$). For example, rs2066992 (interleukin 6; IL6) associates with genotype-dependent DNA methylation of IL6 CpG sites in 6 of the 7 datasets evaluated ($1.18\times10\text{-}11<p<5.5\times10\text{-}5$). The highest rates of overlap were observed within the 4 brain regions (31–61%) and in comparisons of adult whole blood and cord blood samples (32–44%), even with the differences in race and age of samples. Overlap between blood and brain datasets was lower (15–34%) but still highly significant. The SNP-CpG relationships that were common between at least 1 blood and 1 brain dataset were enriched for biological functions including cell growth and signaling, cardiovascular development and disease, hematological development and disease, tissue and organism development, neurological and psychological disorders and hereditary disorders. These data provide insight into the mechanisms by which SNPs impact gene regulation and supports the notion that peripheral blood may be a reliable correlate of physiological processes in other tissues.

Whole-genome methylation analysis- new insights in BEN molecular ethiology. *R. Staneva[1], B. Rukova[1], I. Dimova[1], S. Hadzhidekova[1], O. Boyanova[1], M. Polenakovic[2], V. Stefanovic[3], R. Cukuranovic[3], V. Djonov[4], A. Galabov[5], D. Toncheva[1].* 1) Department of Medical Genetics, Medical University of Sofia, Sofia, Bulgaria; 2) Macedonian Academy of Sciences and Arts, Skopje, The Former Yugoslav Rrepublic of Macedonia; 3) Faculty of Medicine, Institute of Nephrology, University of Nis, Nis, Serbia; 4) Institute of Anatomy, University of Bern, Bern, Switzerland; 5) Institute of Microbiology, Bulgarian Academy of Sciences.

BACKGROUND: Balkan endemic nephropathy (BEN) represents a chronic progressive interstitial nephritis in striking correlation with uroepithelial tumors of the upper urinary tract. The disease has endemic distribution in the Danube river regions in several Balkan countries and in some endemic regions shows markedly predominance of affected females. DNA methylation is a primary epigenetic modification that is involved in major processes such as cancer, genomic imprinting, gene silencing etc. Epigenetic tests can prove to be the bridge between environmental factors and genetic background in BEN development. MATERIALS AND METHODS: Age matched pools of 19 female BEN patients and 33 healthy female controls from nonendemic regions were created as well as age matched pools of 30 male BEN patients and 31 healthy male nonendemic controls from Serbian ancestry. We've performed high-resolution genome-wide methylation array analysis on Agilent Human CpG island Microarray(1×244K). The data was analyzed by Agilent Genomic Workbench Lite v.6.5.0.18. RESULTS: We compared methylation status of the affected group and unaffected group by our own software, applying stringent criteria. In the female group 198 gene-related CpG islands showed disparity in methylation status between affected and unaffected individuals verus 228 CpG islands in male group. We further compared the males and females data and 26 CpG islands proved to be common for both groups. In both female and male patient group some transmembrane ion chanells, zinc-finger proteins, TNF-path related proteins,enzymes and DNA-modification proteins were hypomethylated. Hypermethylation in both patient groups showed some nuclear receptor proteins, cytoskeletal proteins and protein kinases. CONCLUSIONS: Data obtained from our experiments suggest that dysregulation of cytoskeletal proteins, transcription factors, transmembrane ion channels as well as proteins involved in DNA-splicing and cell proliferation can be key mechanism in BEN pathogenesis. These results are in unison with the key pathological alterations in BEN and further elucidate the precise molecular mechanism behind BEN development. Acknowledgements: funded by project DMU03/35 by Bulgarian Ministry of Education and Science, project IZ73Z0_ 127949 of SCOPES, SNSF, Switzerland.

Genome-wide differences in DNA methylation identified in children with Williams-Beuren Syndrome. *E. Strong[1], D. Butcher[2], C.B. Mervis[3], C.A. Morris[4], R. Weksberg[1,2], L.R. Osborne[1,5].* 1) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Program in Genetics and Genome Biology, SickKids Research Institute, Toronto, Ontario, Canada; 3) Department of Psychological and Brain Sciences, University of Louisville, Louisville, KY; 4) Department of Pediatrics, University of Nevada School of Medicine, Las Vegas, NV; 5) Department of Medicine, University of Toronto, Toronto, Ontario, Canada.

Williams-Beuren Syndrome (WBS) is a neurodevelopmental disorder caused by the hemizygosity of 26 genes on chromosome 7q11.23. People with WBS exhibit an array of cognitive and behavioral features including intellectual disability, social disinhibition, anxiety, deficits in visuospatial construction and attention deficit hyperactivity disorder, but the neurobiological basis for these symptoms remains unknown. Several genes within the deleted region have been associated with epigenetic complexes or mechanisms. BAZ1B is a component of the ISWI family of ATP dependent chromatin remodelling complexes WINAC, WICH and B-WICH. The general transcription factors GTF2I and GTF2IRD1 have been shown to interact with the histone deacetylase HDAC3. Furthermore, WBSCR22, an as yet uncharacterised protein, contains an S-adenosyl-methionine binding motif, typical of methyltransferases. Deletion of one or more of these genes could result in altered epigenetic pathways, which may contribute to the phenotypic presentation of WBS. To explore the possibility of disrupted epigenetic pathways in WBS, we assessed genome-wide DNA methylation levels using the Illumina HumanMethylation450 array. Comparison of whole blood DNA from a discovery cohort of 14 male children with WBS and from 10 age- and sex-matched controls, identified 635 statistically significant differentially methylated CpG dinucleotides (minimum beta value ±0.17 and adjusted $p<0.05$), corresponding to 263 unique genes, one large gene cluster and many inter-genic regions. We identified a significant gain of methylation across the protocadherin cluster, a 700kb gene cluster of neuronal cell-adhesion proteins, located on chromosome 5q31. Furthermore, we identified altered CpG methylation within several genes involved in synaptic plasticity and/or axon guidance. This is the first report of aberrant genome-wide DNA methylation in WBS and our results suggest that one or more genes within the 7q11.23 deleted region modify the epigenome at specific loci. We have identified aberrant DNA methylation across numerous genes with neurological functions, potentially implicating many additional genes and pathways outside the 7q11.23 region in the neurological phenotypes of WBS. Further validation of these findings through the analysis of additional DNA samples and correlation with gene expression is currently underway.

Genome-wide Profiling of 5-Formylcytosine in Embryonic Stem Cells. *K.E. Szulwach[1], C.X. Song[2], Q. Dai[2], Y. Fu[2], P. Liu[3], L. Li[1], Y. Li[1], G.L. Xu[3], C. He[2], P. Jin[1].* 1) Dept Human Gen, Emory Univ, Atlanta, GA; 2) Dept Chem and Inst Biophysical Dynamics, Univ of Chicago, Chicago, IL; 3) Group of DNA Metabolism, State Key Laboratory of Molecular Biology, Inst of Biochem and Cell Biology, Shanghai Inst for Biol Sciences, Chinese Academy of Sciences, Shanghai, China.

TET-family proteins oxidize 5-methylcytosine (5mC) stepwise to 5-hydroxymethylcytosine (5hmC), 5-formylcytosine (5fC), and 5-carboxylcytosine (5caC). 5fC and 5caC can be excised by the DNA glycosylase TDG, implicating 5mC oxidation in active DNA demethylation. Here we have developed and implemented a novel method for the enrichment of 5fC by coupling selective chemical reduction of 5fC with subsequent biotin tagging and streptavidin-mediated affinity capture, thereby enabling its genome-wide mapping. We applied this method to map the genomic distribution of 5fC in embryonic stem cells (ESCs) in parallel with 5hmC. Our results demonstrate that 5fC-enriched regions of the genome are depleted of 5mC concomitant with an increased frequency and abundance of 5hmC compared to 5hmC-marked regions, suggesting that specific mapping of 5fC allows for further refinement of genomic elements that are subjected to oxidation, more so than mapping 5hmC alone. Genomic and epigenomic annotation of 5fC-enriched regions demonstrated that they occur more frequently than expected at distinct gene regulatory elements, including known Tet1 binding sites, H3K4me1 marked putative enhancers, and sites of DNase I hypersensitivity, as compared to 5hmC. Additional profiling of 5fC in *Tdg*-null mouse ESCs revealed accumulation of 5fC at known Tet1 binding sites as well as p300 bound loci, CTCF binding sites, and a subset of transcription start sites. Examination of the sequence content within 5fC-enriched regions specific to *Tdg*-null ESCs revealed reduced CpG frequency and GC content, indicating that local sequence context influences oxidation of 5mC and TDG-dependant removal of 5fC at defined gene regulatory regions. Our results establish a novel methodology for genomic profiling of 5fC, providing the first genome-wide view of this mark, and suggest important roles for TET-mediated 5mC oxidation coupled with TDG-dependant removal of 5fC at defined gene regulatory elements.

Extremely preterm infants are epigenetically different from term infants at birth and an epigenetic legacy of preterm birth may remain at 18 years of age. *C. Theda[1,2], M. Cruickshank[2], A. Oshlack[2], P. Sheehan[1], R. Saffery[2], P. Davis[1,2], LW. Doyle[1,2], J. Craig[2].* 1) Royal Women's Hospital, Melbourne, Australia; 2) Murdoch Children's Research Institute, Melbourne, Australia.

Extremely preterm infants (born at less than 28 weeks gestation) have more short and longterm ill-health than term infants. Preterm birth and medical interventions are stressful for the infants affecting early postnatal nutrition and growth. Environment, stress and nutrition can persistently alter gene regulation, not through changes in DNA sequence but through epigenetic changes that are mitotically heritable. Epigenetic state is programmed early in development but can undergo modification during life. Our aim was to investigate whether (i) infants born premature are epigenetically different from those born at term and (ii) if prematurity leaves an epigenetic legacy detectable later in life. We examined genome wide DNA methylation profiles after extracting DNA from dried blood spots of 12 extremely preterm infants and 12 term probands obtained at birth and 18 years. DNA methylation was quantified using the Illumina Infinium Human Methylation 450 BeadChip array covering 485,000 genome wide CpGs. After stringent quality control, exclusion of X/Y probes and probes targeting known polymorphisms, 349,013 probes remained for statistical analysis. Combined analysis of birth and 18 yr samples identified 112 differentially methylated probes (DMPs; significant at $p<0.05$ after adjustment for multiple testing) comparing preterm and term probands. We identified 1,546 DMPs using birth samples only and detected no significant DMPs using only 18 yr samples. To explore a potential long term effect of premature birth on DNA methylation, we also analyzed the top 1,500-ranked sites (by odds) from the 18 yr samples: multidimensional scaling and clustering dendrograms revealed that this set of probes separates both birth and 18 yr samples according to proband groups. Of the 112 significant DMPs identified during the combined analysis, 16 probes overlapped with the top 1500-ranked probes using the 18 yr samples and 104 probes overlapped with the significant DMPs identified in birth samples. Our results indicate: (i) significant DNA methylation differences at birth comparing premature and term infants; possibly a gestational age effect; (ii) a distinct subset of methylation differences that are present at birth and persist to 18 years. While our results are preliminary and the numbers small, they are the first report of long term epigenetic effects of prematurity. Replication of the reported findings and functional analysis of genomic sites of interest are underway.

Genome Wide Detection and Analysis of CpG Dinucleotide Methylation in Cancer Fatigue Studies. *D. Wang[1], H. Lee[1], W. Xiao[2], C. Hsiao[1], H. Kim[1], R. Dionne[1], L. Saligan[1].* 1) NINR/NIH, Bethesda, MD, USA; 2) CIT/NIH, Bethesda, MD, USA.

Objectives: DNA methylation is an epigenetic mechanism involved in transcriptional regulation in development and cellular differentiation. Aberrant methylation patterns have been observed in a large number of human cancers. In this study, we investigated the role of DNA methylation in fatigue progression in men with non-metastatic prostate cancer receiving localized external beam radiation therapy (EBRT). Methods: We have applied Methyl Binding Domain (MBD)-seq method to peripheral blood DNA of 8 patients at the baseline (pre-treatment) and midpoint (21 days after receiving ERBT) when fatigue severity normally peaks. Methylated DNA was first precipitated by binding to the methyl—CpG binding domain of human MBD2 protein, then subjected to next-generation sequencing via 36-bp single-end module on the Genome Analyzer IIx (Illumina, San Diego, CA). The sequencing data were further analyzed including data processing, quality control, normalization and statistical analysis. The genes that were most differentially methylated after EBRT were investigated by comparing the expression profiles and changes of expression were confirmed with qPCR. Results: A total of 40 to 50 million reads were generated for each DNA sample, of which 73% to 80% could be mapped uniquely to the reference human genome (NCBI 37/hg19). Reads that were unambiguously mapped to a single location in the reference human genome were extended to 200 bp and hits were counted in every 25 bp bin which then led to peak identification. After filtering, we observed 350,000 to 490, 000 non-overlapping peaks with significant evidence of methylation in each DNA sample, of which 40,000 to 180,000 were found to be unique in the same patients between the baseline and midpoint of the EBRT. We further investigated the relationship between the methylation profiles and gene expression levels for the genes with most differentially methylated regions in at least half of the patients (4 out of 8). We could confirm the role of DNA methylation in transcriptional regulation of gene expression. Conclusion: This study is the first to provide a large scale and unbiased analysis of changes in DNA methylation occurring just 21 days after EBRT initiation in peripheral blood of men with non-metastatic prostate cancer. Based on the methylation profile changes along with their associated gene expression changes in these patients, we could suggest the role of DNA methylation in fatigue progression after EBRT.

Prediction of total serum IgE using genome-wide methylation profile. *X. Wang[1], S.A.G. Willis-Owen[2], K.C.C. Wong[2], A. Binia[2], G. Davies[3], J.M. Hopkin[3], G.M. Lathrop[4], M.F. Moffatt[2], W.O.C.M. Cookson[2], L. Liang[1,5].* 1) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 2) National Heart and Lung Institute, Imperial College, London SW3 6LY, UK; 3) Institute of Life Science, School of Medicine, Swansea University, UK; 4) CEA / Centre National de Genotypage, 91057 Evry, France; 5) Departments of Epidemiology, Harvard School of Public Health, Boston, MA 02115.

DNA methylation at CpG sites is an important epigenetic modification that may regulate gene expression. There is a growing interest in understanding how the methylation inheritance contributes to the development of complex diseases or traits. It has been shown that methylation modification may influence individual asthma risk and related phenotypes. The primary purpose of this study is to comprehensively assess—by using genome-wide DNA methylation data as markers—the contribution of epigenetic effects on asthma related quantitative traits. Results of variance component analyses on our data indicated that a considerable proportion of phenotypic variation in total serum IgE (an important biomarker for asthma) can be explained by the variation in epigenetic markers. To evaluate the clinical utility of epigenetic markers, we then constructed and compared various prediction models by including top ranked methylation loci from the genome-wide association scan, together with selected sets of known genetic markers from published genome-wide association studies (GWAS). A new prediction model based upon Best Linear Unbiased Prediction (BLUP) was further proposed where all CpG sites (on the Illumina Infinium 27K methylation array) were simultaneously modeled. The overall prediction accuracies of the proposed methods were extensively evaluated via the cross-validation analysis. We observed a significant increase of correlation coefficient between actual and predicted IgE level when methylation markers were included (from 0.32 before to 0.57 after including methylation data). By using an independent sample based on Illumina 450K methylation array, we also assessed the performance of cross platform prediction using methylation markers. Taken together, results from this study suggest that DNA methylation has important influence in asthma and it explains much larger variability in IgE level than known genetic variants (2% due to top genetic markers in large GWAS vs. 15% due to top 3 CpG sites). Our comprehensive assessment suggests that methylation has great potential in prediction of clinical phenotypes.

Epigenomic Profiling of Autism Spectrum Disorder. *C.C.Y. Wong[1], L.C. Schalkwyk[1], E.L. Meaburn[1,4], A. Ronald[1,4], T.S. Price[1], R. Plomin[1], D.H. Geschwind[3], J. Mill[1,2].* 1) MRC SGDP Centre, King's College London, Institute of Psychiatry, London, U.K; 2) University of Exeter, U.K; 3) UCLA Department of Neurology. 710 Westwood Plaza. Los Angeles, CA 90095-1769. USA; 4) Birkbeck, University London, U.K.

Autism Spectrum disorder (ASD) is a group of common, complex neurodevelopmental disorders characterized by marked etiological heterogeneity. Evidence from twin and family studies suggest that ASD has a strong heritable component, supported by the identification of several susceptibility loci and the growing body of literature demonstrating the association of de novo and inherited copy number variations (CNVs) with disease. Recent evidence also implicates a role for epigenetic variation in the etiology of ASD. In this study, we first performed epigenomic profiling using Illumina 27K Methylation arrays in whole blood samples from a unique set of MZ twins discordant for ASD and ASD-related traits (n=53 twin pairs; 106 individuals). We identified a number of significant disease-relevant differentially methylated genes and enrichments of disease-related biological networks within discordant MZ pairs as well as between cases and controls. Second, we performed DNA methylation profiling in post-mortem brain tissues from multiple brain regions obtained from the Autism Tissue Program and the London Brain Bank. Illumina Infinium 450K Human Methylation arrays and Agilent Methylation SureSelect target enrichment combined with ultra-deep bisulfite sequencing were used. We observed significant DNA methylation differences between cases and controls using both approaches with several potential ASD-associated epigenetic biomarkers located in the vicinity of genes previously implicated in psychiatric disorder.

Microarray-Based Genome-Wide Analyses of DNA Methylation in Hematological Malignancies. *Y. Yang[1], H. Mei[1], L. Edelmann[1], A.J. Sharp[1], I. Peter[1], V. Najfeld[2], C.R. Geyer[3], J.F. DeCoteau[3], S.A. Scott[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY 10029; 2) Department of Pathology, Mount Sinai School of Medicine, New York, NY 10029; 3) Cancer Stem Cell Research Group, University of Saskatchewan, Saskatoon, SK, Canada, S7N 4H4.

Aberrant DNA methylation is directly involved in human imprinting disorders and is a hallmark of many cancers, including hematological malignancies. Genome-wide methylation analysis can be achieved using microarrays following either methylated DNA immunoprecipitation (MeDIP) or bisulfite modification. Our aim was to assess the MeDIP-based Human DNA Methylation Microarray (MeDIP-array; Agilent Technologies) using 16 hematological cancer cell lines by comparing results to those derived from the Infinium HumanMethylation450 BeadChip (BC-array; Illumina), a quantitative bisulfite-based array. A high correlation for all 16 samples was observed between MeDIP- and BC-array data when comparing overlapping 1kb genomic intervals (0.83±0.04). Bisulfite sequencing of 9 differentially methylated regions in AML193 cells showed stronger correlation with BC-array (0.99) than MeDIP-array (0.90); however, the BC-array correlation was different depending on which type of probe chemistry was assessed (Type I Infinium: 0.94; Type II Infinium: 0.84). Reassessment of BC-array data based on probe type indicated that Type II probes consistently performed with a reduced dynamic range compared to Type I probes, which necessitated additional normalization. Hierarchical clustering of the identified methylation profiles indicated that both MeDIP- and BC-array could generally distinguish disease subtypes (AML, CML, ALCL, BL, PCL) among the tested cell lines; however, the BC-array data was a more accurate predictor, particularly when clustering only by promoter region methylation. After subtracting the methylated genes detected in peripheral blood specimens from 36 healthy multi-ethnic controls, 373 to 3139 genes with promoter methylation were identified among the five different disease subtypes, and 92 were methylated across all 16 cell lines. Additionally, treatment of AML193 cells with a DNA methylation inhibitor, 5-aza-2'-deoxycytidine, resulted in a prominent reduction in detected methylation by both MeDIP- and BC-array (MeDIP log2 ratio median: 0.50 vs 0.34; BC beta value median: 0.86 vs 0.67). Taken together, these data indicate that both MeDIP- and BC-arrays are useful for studying whole-genome methylation profiles and identifying genes aberrantly silenced by promoter methylation in hematological and other malignancies. However, the inability to accurately quantitate DNA methylation levels by MeDIP-array may be a limitation depending on study design and research question.

Discovery of Cross-Reactive Probes in the Illumina Infinium HumanMethylation450 Microarray: A Cautionary Tale. *Y. Chen[1,5], M. Lemire[2], S. Choufani[1], D.T. Butcher[1], D. Grafodatskaya[1], B.W. Zanke[2,3], R. Weksberg[1,4].* 1) Genetics and Genome Biology Program, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 3) Clinical Epidemiology Program, Ottawa Hospital Research Institute, Ottawa, Canada; 4) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 5) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada.

DNA methylation, an important type of epigenetic modification in humans, participates in crucial cellular processes such as embryonic development, X-inactivation, genomic imprinting and chromosome stability. Several platforms have been developed to study genome-wide DNA methylation. Many investigators in the field have chosen the Illumina Infinium HumanMethylation microarrays for its ability to reliably assess DNA methylation following bisulfite conversion. We have recently reported that 6–10% of probes on the Illumina Infinium HumanMethylation27K microarray are cross-reactive, co-hybridizing to alternate sequences that are highly homologous to the intended targets.

Here we report our findings on the new Illumina array, the Infinium HumanMethylation450K microarray which has >17-fold increase in coverage spanning multiple genomic regions, compared to the 27K array which covers only promoter regions. We analyzed data from the 450K methylation profiles of 489 males and 357 females from the control cohort of the Assessment of Risk for Colorectal Cancer Tumours in Canada (ARCTIC) project. Among the autosomal CpG sites that displayed significant methylation differences between males and females, we observed an enrichment of cross-reactive probes co-hybridizing to the sex chromosomes. This can lead investigators to mistakenly infer the existence of significant autosomal sex-associated methylation differences. Based on the sex methylation analysis, we concluded that ~5% of the probes are potentially cross-reactive. In addition, we found a number of probes targeting polymorphic CpGs (i.e. SNPs overlapping CpG sites). The methylation levels detected by these probes are simply the reflection of underlying genetic polymorphisms and thus could be misinterpreted as true signals.

The existence of cross-reactive probes and polymorphic CpGs in the Illumina microarrays reflecting homologous/repetitive sequences and SNPs in the human genome can confound data obtained from these microarrays. Therefore, investigators should exercise caution when significant associations are found on these platforms. A list of all the cross-reactive probes will be made available to the scientific community. Finally, our data suggest that biological interpretation of significant microarray findings continue to be validated by a second independent method such as sodium-bisulfite pyrosequencing.

Epigenetic changes in response to common environmental compounds. *V. Labrie[1], I. Rezaian[2], S. Konigorski[3], N. Miller[4], Y. Li[2], C. Austin[4], R. Tice[5], M. Xia[4], A. Ngom[2], L. Rueda[2], R. Kustra[3], A. Petronis[1].* 1) Krembil Family Epigenetics Laboratory, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) School of Computer Science, University of Windsor, Windsor, Ontario, Canada; 3) Division of Biostatistics, University of Toronto, Toronto, Ontario, Canada; 4) National Institutes of Health Chemical Genomics Center, Rockville, Maryland, USA; 5) National Toxicology Program, National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina, USA.

Environmental chemicals have the potential to impact disease susceptibility, and thereby pose an important public health concern. The mechanisms through which environmental contaminants influence human health are not well-defined and studies examining the biological effects of environmental chemicals will facilitate disease prevention and management. We have initiated a large-scale study to examine the possibility that environmental agents target the epigenome. As a preliminary investigation, we established the experimental parameters that are necessary for our study. Genome-wide changes in DNA methylation were examined in human cells exposed to several agents that are known to induce epigenetic alterations. A series of times points and concentrations were tested to identify the optimal design for the study of epigenetic effects of chemical agents. Furthermore, certain genomic regions were found to be consistently more affected by the chemical compounds. This study is a first-step in understanding how environmental chemicals can impact the epigenome and affect genomic functions relevant to the etiology of complex diseases.

Regulatory network of microRNA action - miR-199a in health and diseases. *S. Gu, Y.K. Suen, W.Y. Chan.* School of Biomedical Sciences, The Chinese University of Hong Kong, HKSAR, Hong Kong.

It is well-known that microRNAs (miRNAs) affect gene expression by regulating the translation of mRNAs. However, how miRNAs are regulated is less studied. The well-conserved human miR-199a plays important roles in different systems. MiR-199a is encoded by two loci in the human genome, miR-199a-1 on chromosome 19 and miR-199a-2 on chromosome 1. Both loci encode the same miRNA. Past studies showed that miR-199a behaves quite differently in different systems and diseases. The cause of this diverse action of the miRNA is not clear. However, it is likely caused by different regulation of the two genomic loci and variable targets of the miRNA in different cells and tissues. We used miR-199a as a model in order to elucidate the mechanism(s)that underpins miRNA actions. Previous studies showed that the promoters of both miR-199a-1 and -2 were hypermethylated resulting in silencing the expression of miR-199a in testicular germ cell tumors (TGCTs). In addition, transcription factor REST was observed to bind to the promoter of both miR-199a genes, raising the possibility that it might also be involved in controlling the expression of the miRNA in TGCTs. Contrary to the observations in TGCTs, miR-199a-2 was showed to have lower methylation levels in glioma patient samples comparing to the normal brain, while the methylation status of miR-199a-1 remained unchanged. The decreased methylation level of miR-199a-2 might explain the higher expression levels of miR-199a in glioma patients. In mesenchymal stem cells, expression of miR-199a was up-regulated during the differentiation process. This might be controlled by transcription factor Twist1. Previous studies showed that Twist1 binds to the promoter of DNM3OS, the intron of which contains the miR-199a-2 locus, and the elevated levels of miR-199a during stem cell differentiation may be due to the activating effect of Twist1 binding. Besides its upstream regulators, we also studied the activities of miR-199a by identifying its downstream targets. Observations indicated that the targets of miR-199a in different tissues are likely to be different resulting in different effects of the miRNA. By studying the mechanisms that control the expressions of miR-199a and its various downstream targets in different systems, we hope to illustrate the complexity of miRNA biology and indications of future directions for miRNA research.

Gold nanoparticles (AuNPs) cause variation in the level of methylation in H3K4 and H3K9. *A. Polverino[1], A. Iuliano[1,7], L. Cristino[1,4], R. Imperatore[2,4], A. Longo[5], G. Carotenuto[5], S. De Nicola[6], M. Piscopo[3], L. Fucci[3], E. Vitale[1].* 1) Cybernetics, CNR, Pozzuoli, Naples, Italy; 2) Institute of Biomolecular Chemistry CNR, Pozzuoli Naples, Italy; 3) Department of Structural and Functional Biology University of Naples, Naples Italy; 4) Endocannabinoid Research Group; 5) Institute of Biomaterials, CNR of Portici, Naples, Italy; 6) National Institute of Applied Optics (INOA) of the CNR Pozzuoli, Naples Italy; 7) Department of Institutional Studies Parthenope University Naples.

Histones are small basic proteins that play important roles in DNA packaging. A 10 nm DNA fiber is wrapped around a core of histones H2A, H2B, H3 and H4, forming a nucleosome, the first level of DNA condensation in chromatin. Histone methylation of specific lysine residues regulates the opening and closing of chromatin and has been proposed as a stable epigenetic marker that directs biological functions. Mitotically heritable epigenetic modifications have been reported to affect transcriptional regulation and to play key roles in human pathology, including inflammatory and neoplastic disorders. Here we characterize the effects of gold nanoparticles (AuNPs) and their uptake by human neuroblastoma cells SH-SY5Y in order to characterize their effects and optimize their use as potential drug delivery vehicles. We explored alterations in chromatin structure by analyzing the level of H3K4 and H3K9 methylation. We selected colloidal gold as our nanoparticle of choice, primarily because of its characteristic stability as well as its advantageous spectral properties. AuNPs have a diameter of approximately 2 nm and an absorption spectrum with a peak at 350 nm and their emission shifts from green to red upon forming clusters of approximately 200 nm in diameter. The clustered particles have a broad emission spectrum ranging from 400 to 600 nm. SH-SY5Y cells were incubated with AuNPs from 1 to 100 ng/ml for one hour, histones were extracted and dimethyl H3K4 and dimethyl H3K9 were quantitated by Western immunostaining. Histone H3 Lys 4 dimethylation positively correlates with transcription rate and Lys 9 dimethylation is associated with transcriptional repression. Cells treated with AuNP 100 ng/ml, 10 ng/ml and 5 ng/ml nanoparticles had a lower level of H3K4 dimethylation than controls (48%, 29,4% and 15%, respectively). Nanoparticle concentrations of 2 ng/ml and 1 ng/ml had no effect. Conversely, we observed a 50% increase of H3K9 dimethylation upon treatment with 100 ng/ml nanoparticles but no effect with 10 ng/ml and 5 ng/ml. Of note, treatment with 2 ng/ml and 1 ng/ml nanoparticles resulted in lower levels of H3K9 dimethylation (25,3% and 29,2%, respectively). Our data suggest an epigenetic modification of the genome, which correlates with a global gene expression decrease. However, cellular effects due to AuNPs appear to decrease proportionally to nanoparticle concentrations.

Gene methylation and allelic expression imbalance of the CYP1A2 and CYP3A4 genes in human livers. *J. Shi[1], W. Shou[1,2], Z. Niu[1], Y. Wang[1], K. Zhang[1], W. Huang[1,2].* 1) Department of Genetics, Shanghai-MOST Key Laboratory of Health and Disease Genomics, Chinese National Human Genome Center at Shanghai, Shanghai, 201203, China; 2) Rui Jin Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai 200025, China.

The CYPs play a critical role in the drug metabolism and contribute to the therapy outcome. CYP1A2 has an important function in the metabolism of caffeine as well as of several clinically important drugs. CYP3A4 are involved in the metabolism of 45–60% of all currently used drugs and a variety of other compounds. The large inter-individual difference in CYP1A2 and CYPP3A4 expression was well known. However, the underlying causes for these variations were not known. Epigenetic modifications and allelic expression imbalance have been found to influence the expression and activity of human CYP genes. Thus, we investigated the allelic expression imbalance and the methylation status of CYP1A2 and CYP3A4 genes in Chinese population. 25.0% of the rs2470890 heterozygote in CYP1A2 gene and 9.7% of the rs33972239 heterozygote in CYP3A4 gene showed allelic expression imbalance. The total hepatic CYP1A2 mRNA level correlated with the allelic ratio, the individual with a low ratio tended to have a low mRNA expression level. The lower extent of methylation associated to a higher CYP3A4 mRNA expression level was observed in four CpG sites located 25kb upstream of the translational start codon of CYP3A4. Our study suggested that the cis-acting variants might be involved in the regulation of CYP1A2 and the regulation of CYP1A2 might be different in populations, and provided more evidence of epigenetics playing a role in regulating the expression of CYP3A4. Our results present a new insight into the large inter-individual difference in CYP1A2 and CYP3A4 gene expression.

6q24 Transient neonatal diabetes mellitus: 16 years of data collection. *I. K. Temple[1,2], S. Kabwama[1], L. Doherty[1,3], S. Ennis[1], E. Cook[1], L. Harrison[2], S. Ellard[4], S. Flanagan[4], A. T. Hattersley[4], J. P. H. Shield[5], D. J. G. Mackay[1,3].* 1) Human Genetics and Genomic Medicine, Faculty of Medicine, University of Southampton, Southampton, Hampshire, United Kingdom; 2) Wessex Clinical Genetics Service, Princess Anne Hospital, University Hospital Southampton NHS Foundation Trust, UK; 3) Wessex Regional Genetics Laboratory, Salisbury District Hospital, Salisbury NHS Foundation Trust, Salisbury, UK; 4) Institute of Biomedical and Clinical Science, Peninsular College of Medicine and Dentistry, University of Exeter, Exeter UK; 5) Institute of Child Life and Health, University of Bristol, Bristol, UK.

Introduction: TNDM due to genetic aberrations at 6q24 is the commonest cause of diabetes presenting within the first week of life. TNDM predisposes to diabetes mellitus in later life. We report on the clinical presentation of 164 confirmed cases, the largest worldwide cohort of 6q24 TNDM cases. Data were collected from referring physicians by questionnaire completed at the time of referral. Results: The mean age of presentation was 8 days with a mode on day 1. On average, babies recovered by 4.5 months with a mode of 2 months. Birth weight had a normal distribution with a mean of 1997g but ranged from 3370g to 1050g with most babies born at term. Data analysis showed a positive correlation between age of presentation and both higher birth weight and longer gestation (p=0.04 and p = 0.007 respectively). 34% had paternally inherited duplications at 6q24, 37% had paternal uniparental disomy 6 (pUPD6) and 29 % had a maternal hypomethylation at 6q24 (44% isolated at 6q24, 46% with loss of methylation at multiple loci (28% due to ZFP57 mutations and 18% with hypomethylation at multiple loci of unknown cause)). No significant difference between the three genetic abnormalities (duplication, pUPD6 and methylation) was identified in terms of presentation of diabetes. However, analysis of variance (ANOVA) identified a significant difference (p=0.009) between the three genetic subgroups in terms of number of congenital abnormalities with babies with a duplication at 6q24 having a statistically lower number of congenital abnormalities compared to those with pUPD6 and hypomethylation (p=0.022 and p=0.020 respectively). For individual anomalies there were statistically significant differences for macroglossia and umbilical hernia. We also showed that patients with a loss of methylation at multiple imprinted loci (TND HIL (ZFP57/unknown)) had significantly more congenital abnormalities compared to patients with methylation loss at only 6q24(p=0.005). The IVF rate for babies with an epigenetic cause was 12% (2/17) compared with 0/46 in the other genetic subgroups. Conclusions: These results define the clinical presentation of 6q24 TNDM. The results also indicate a genotype phenotype correlation that patients with TNDM due to duplications at 6q24 have fewer associated congenital abnormalities. Furthermore congenital abnormalities are more common in those with loss of methylation affecting multiple imprinted loci than those with isolated hypomethylation at 6q24.

Genome-wide profiling of human uniparental tissues to search for novel imprinted genes. *S. Wen[1,2], W. Wan[1], A. Balasa[3], S. Mahadevan[4], Z. Liu[3,5], IB. Van den Veyver[1,2,3,4].* 1) OB/GYN, Baylor College of Medicine, Houston, TX; 2) Mol Hum Gen, Baylor College of Medicine, Houston, TX; 3) Pediatrics, Baylor College of Medicine, Houston, TX; 4) TBMM, Baylor College of Medicine, Houston, TX; 5) Neurology, Baylor College of Medicine, Houston, TX.

Purpose: Imprinted genes are preferentially/exclusively expressed from one parental allele. Many known imprinted genes are essential for embryonic and placental development. Their imprinting status is often associated with allele-specific CpG methylation of nearby differentially methylated regions (DMR). In this study we searched for novel imprinted genes by genome-wide DNA methylation profiling comparing DNA from androgenetic complete hydatidiform moles (AnCHM) and normal placenta. Methods: Genomic DNA was extracted from six AnCHM and six term placentas, bisulfite treated and hybridized to an Illumina Infinium Methyl27 array, which allows simultaneous characterization of the methylation status of 27,578 CpGs. For data analysis, we first examined a training data set of 129 CpGs located within 18 well-characterized imprinted DMRs. Based on behavior of these CpGs in AnCHMs and placentas, we defined criteria for candidate novel CpGs as follows: (1) p<0.01119; (2) beta values in placenta between 0.35 to 0.77; (3) beta-value difference between AnCHM and placenta is at least 0.15; (4) CpGs are located on autosomes. After identification of candidate imprinted genes, their allele-specific expression patterns were validated in four human trios by identifying informative expressed single-nucleotide polymorphisms (SNPs) in parental DNAs and assessing them for mono-allelic expression in cDNA of offspring placentas by RT-PCR. Results: We identified 592 candidate paternally methylated CpGs and 207 candidate maternally methylated CpGs. After defining a DMR as a genomic region smaller than 4kb, 576 candidate paternally imprinted genes and 142 candidate maternally imprinted genes remained. From these, we selected 24 genes for validation based on their p-value and a known or putative function relevant to human placenta. We identified mono-allelic expression of the SMPD3 gene, which encodes sphingomyelin sphingomyelinases 3. SMPD3 plays an important role in embryonic development and inactivation of Smpd3 in mice causes dwarfism and other developmental defects. Conclusion: Differential methylation profiling of AnCHM is an efficient method to identify imprinted loci in human placenta. We are continuing to validate other identified candidate imprinted loci in human trios.

Next generation bisulfite analysis around a 2.2 kb ICR1 deletion in 11p15.5 reveals variable hypermethylation explaining reduced penetrance in BWS families. *J. Beygo[1], V. Citro[2], D. Prawitt[3], M. Heitmann[1], K. Rademacher[1], B. Horsthemke[1], A. Riccio[2], K. Buiting[1].* 1) Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany; 2) Department of Environmental Science, Second University of Naples, Caserta 81100, Italy; 3) Zentrum für Kinder und Jugendmedizin, Universitätsmedizin Mainz, Mainz, Germany.

The congenital overgrowth disorder Beckwith-Wiedemann Syndrome (BWS) is caused by epigenetic or genomic alterations affecting one or both of the two imprinting control regions ICR1 or ICR2 on chromosome 11p15.5 which are normally methylated only on the paternal or the maternal allele, respectively. In rare cases BWS is caused by a maternally transmitted microdeletion affecting CTCF binding sites in the ICR1, which results in loss of IGF2 imprinting and BWS. Using MLPA (multiplex ligation-dependent probe amplification) we identified a microdeletion in peripheral blood from a female patient presenting with classical features of BWS. The deletion was also found in the healthy mother, maternal aunt and maternal grandfather of the patient. Interestingly, sequence analysis of the deletion breakpoints revealed that the 2.2 kb microdeletion is identical on the nucleotide level to a familial case reported by Prawitt *et al.*(2005). The deletion abolishes the CTCF binding sites 4 and 5 and fuses CTCF3 and 6 within the repeats B5 and B1. In order to find out how this 2.2 kb deletion and other deletions of the ICR1, which have been reported before (Sparago *et al.* 2004 and 2007; Cerrato *et al.* 2005; De Crescenzo *et al.* 2011), affect the DNA methylation in affected and unaffected deletion carriers we performed high resolution methylation analysis using next generation bisulfite sequencing on the 454 GS Junior System in six families to obtain highly quantitative DNA methylation. In three families with a 1.8 kb deletion and one family with a 1.4 kb deletion, which all show complete penetrance, we observed strong hypermethylation of adjacent CpGs and CTCF binding sites after maternal transmission of the deletion. In contrast, affected and unaffected family members with a maternally inherited 2.2 kb deletion had slight or no hypermethylation, respectively. These studies suggest that the 2.2 kb deletion can, but must not lead to a gain of methylation on the maternal allele, thus explaining the reduced penetrance in these two families.

3497T

A noncoding imprinted RNA, MESTIT1 is essential for the repression in cis of KLF14. *S. Horike, M. Meguro-Horike.* Advanced Science Research Center, Kanazawa University, Kanazawa, Ishikawa, Japan.

Imprinted genes on human chromosome 7 are thought to be involved in Russell-Silver syndrome (RSS). However, involvement of the known imprinted genes in RSS has yet to be established. Interestingly, previous study identified a noncoding imprinted RNA, *MESTIT1*, which is located intronic of *MEST* at 7q32. This gene is transcribed from the paternal allele only in the opposite direction to the *MEST* gene. However, the function of this noncoding imprinted RNA, *MESTIT1*, has remained unclear. In this study, we investigated some of its basic feature. We found that *MESTIT1* was exclusively localized in the nucleus, like other nuclear-retained RNAs, *45S* precursor rRNAs, imprinted ncRNA *Airn*. In addition to the basic analyses of *MESTIT1*, functional testing would be very important to determine whether the *MESTIT1* can be crucial imprinting elements and act in cis throughout the 7q32 imprinted cluster to silence protein-coding genes. Towards the dissection of the molecular basis of imprinted gene clusters, we have previously established monochromosomal hybrids containing individual human chromosomes of defined parental origin. In our study, a human chromosome 7 in the monochromosomal hybrids was tagged with pSV2*neo*, so that the marked chromosome could be successfully transferred into mouse A9 cells. Furthermore, the paternal or maternal copies of human chromosome 7 were transferred independently from A9 cells into DT40 cells by microcell fusion. DT40 cells exhibit high frequency homologous recombination between exogenous DNA templates and their chromosomal counterparts. This enables the efficient targeted modification of individual human chromosomes, too. In this study, we created modified human chromosome 7 carrying a targeted deletion of the *MESTIT*1 with the use of DT40 cells. We showed that deletion of the *MESTIT1*on the paternal chromosome results in the de-repression in cis of the normally silent paternal allele of *KLF14.* Our finding provided an important aspect for a detailed understanding of the mechanisms of long-range control gene activity within chromosomal domain.

3498T

MeCP2 is required for chromatin higher-order structure and dynamics at the imprinted 15q11-q13 locus. *M. Meguro-Horike[1], D.H. Yasui[2], W. Powell[2], J.M. LaSalle[2], S. Horike[1].* 1) Advanced Science Research Center, Kanazawa University, Kanazawa, Ishikawa, Japan; 2) Dep. of Medical Microbiology and Immunology, UC Davis, USA.

Deletions of 15q11-q13 on the paternal chromosome 15 cause Prader-Willi syndrome, whereas maternal deletions cause Angelman syndrome. Parental differences in DNA methylation at PWS-IC have a crucial role in genomic imprinting of 15q11-q13, as well as differences in DNA replication timing, histone modifications, chromosome nuclear organization, and mitotic recombination frequencies. However, despite progress in molecular characterization of 15q11-q13 rearrangements and imprinting mechanisms, the molecular pathogenesis of the autism phenotype resulting from maternal 15q11-q13 duplications remains largely unknown. Currently, no cell culture model exists for maternal 15q11-q13 duplication observed in autism cases, so our microcell-mediated transfers of a maternal chromosome 15 into human SH-SY5Y neuronal cells are expected to be a novel and essential experimental system for further understanding 15q11-q13 epigenetics in autism. Our 15q duplication neuronal model revealed that by quantitative RT-PCR transcript levels of *NDN*, *SNRPN*, *GABRB3*, and *CHRNA7* were reduced compared to expected levels despite having no detectable alteration in promoter DNA methylation. Since 15q11-q13 alleles have been previously shown to exhibit homologous pairing in mature human neurons, we assessed homologous pairing of 15q11-q13 by fluorescence in situ hybridization (FISH). Homologous pairing of 15q11-q13 was significantly disrupted by 15q duplication. To further understand the extent and mechanism of 15q11-q13 homologous pairing, we mapped the minimal region of homologous pairing to a ~500 kb region at the 3' end of*GABRB3* which contains multiple binding sites for chromatin regulators MeCP2 and CTCF as well as long-range interactions with the imprinting control region. Using RNA interference, we show that MeCP2 and CTCF are required for the homologous pairing of 15q11-q13 during neuronal maturational differentiation. In addition to the 15q11-q13 homologous trans interactions, we demonstrate that parental allele-specific chromatin structure at 15q11-q13 are regulated by PWS-IC and methyl-CpG binding proteins such as MeCP2. These data support a model where 15q11-q13 genes are regulated epigenetically at the level of both inter- and intra-chromosomal associations and that chromosome imbalance disrupts the epigenetic regulation of genes in 15q11-q13.

DNA methylation analysis of reciprocal genome-wide UPDs to define imprinted differentially methylated regions in the human genome. *K. Nakabayashi[1], A.M. Trujillo[2], C. Tayama[1], V. Romanelli[2], P. Lapunzina[3], M. Kagami[4], H. Soejima[5], H. Ogata[6], F. Court[2], D. Monk[2], K. Hata[1].* 1) Dept Maternal-Fetal Biol, Natl Res Inst for Child Health and Development, Tokyo, Japan; 2) Cancer Epigenetic and Biology Program, Institut d'Investigació Biomedica de Bellvitge, Barcelona, Spain; 3) Instituto de Genética Médica y Molecular, Universidad Autónoma de Madrid, Madrid, Spain; 4) Dept of Mol Endocrinol, Natl Res Inst for Child Health and Development, Tokyo, Japan; 5) Div of Mol Genet & Epigenet, Facult of Med, Saga Univ, Saga, Japan; 6) Dept of Pediatrics, Hamamatsu Univ, School of Med, Hamamatsu, Japan.

Genomic imprinting, an epigenetic phenomenon whereby genes are differentially expressed according to their parental origin, is shown to be crucial for placental development and fetal growth in mammals including humans. Most of well-characterized imprinted loci have been found to contain a germline differentially methylated region (DMR) harboring allelic DNA methylation inherited from the male or the female gamete. Several germline DMRs have been shown to govern imprinted gene expression and methylation of post-zygotic (secondary) DMRs as a cis-acting imprinting-control region (ICR). Epimutation at ICRs in humans has been shown to cause a number of imprinting disorders. We and others have previously identified rare mosaic genome-wide paternal and maternal uniparental disomy (UPD) cases among cohorts diagnosed to be Beckwith-Wiedemann and Silver-Russell syndromes, respectively. Profiling and comparison of the DNA methylation patterns of such UPD cases successfully detected the majority of known DMRs and also lead to identify novel DMRs such as FAM50B-DMR and ZFP597-DMR. In this study, we subjected the blood genomic DNA of genome-wide paternal and maternal UPD cases to illumina 450K methylation BeadChip analysis to further define the regions of known DMRs in the human genome. Among over 45,000 probes, we identified 382 probes for 32 DMRs in 20 known imprinted loci. This information will facilitate to further elucidate the genomic and epigenomic signatures of DMRs as well as to characterize the extent of epimutation(s) at DMRs in imprinting disorder cases.

The imprinted *C15orf2* gene in the Prader-Willi syndrome region encodes a nuclear pore complex associated protein. *L.C. Neumann[1], Y. Markaki[2], E. Mladenov[3], D. Hoffmann[4], K. Buiting[1], B. Horsthemke[1].* 1) Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany; 2) LMU München, Biozentrum Martinsried, Department Biologie II, Martinsried, Germany; 3) Institut für Strahlenbiologie, Universitätsklinikum Essen, Essen, Germany; 4) Abteilung für Bioinformatik, Zentrum für Medizinische Biotechnologie, Universität Duisburg-Essen, Essen, Germany.

The Prader-Willi syndrome (PWS) region in 15q11q13 harbors a cluster of imprinted genes expressed from the paternal chromosome only. Whereas loss of function of the *SNORD116*genes appears to be responsible for the major features of PWS, the role of the other genes is less clear. One of these genes is *C15orf2*, which has no orthologs in rodents but appears to be under strong positive selection in primates.

C15orf2 encodes an 1156 amino acids protein with six nuclear localization sequences. To find out more about the function of C15orf2, we used protein BLAST analysis and the InterProScan signature recognition search. With both tools we found a highly significant similarity of C15orf2 to the nuclear pore complex (NPC) protein POM121. Using the Invitrogen Flp-In system we generated a stable cell line that expresses FLAG-tagged C15orf2 upon doxycycline induction. By immunocytochemistry in expression-induced cells we found C15orf2 located at the nuclear periphery, where it co-localized with NPCs and nuclear lamins. At very high expression levels we observed invaginations of the nuclear envelope. Extending these observations to three-dimensional structured illumination microscopy (3D-SIM), which achieves an eight-fold improved volumetric resolution over conventional imaging and can resolve single NPCs, we saw that C15orf2 is located at the inner face of the nuclear envelope where it strongly associates with the NPC. Additionally, in nuclear envelope isolation and fractionation experiments we detected C15orf2 in the NPC and lamina fractions.

These experiments for the first time demonstrate that C15orf2 is part of the NPC or its associated molecular networks. After consultation with the Human Genome Nomenclature Committee we propose to assign a new name to *C15orf2*: *Nuclear pore associated protein 1* (*NPAP1*).

The `Language Gene' FOXP2 is not Imprinted. *A.C. Thomas, J.M. Frost, F. Khadem, P. Stanier, G.E. Moore.* University College London, Institute of Child Health, London, United Kingdom.

The Forkhead-box protein P2 (FOXP2) was identified as the first gene to be linked to an inherited form of language and speech disorder, namely developmental verbal dyspraxia (DVD) in the three generational `KE' family. DVD causes impaired selection and sequencing of coordinated orofacial movements that are required for speech and individuals show deficits in linguistic and grammatical processing. FOXP2 is a transcriptional repressor that is widely expressed in the fetal and adult brain (as well as other tissues) where it is thought to regulate the expression of genes in the cortical, basal ganglia and cerebellar circuits. We wanted to test the theory that FOXP2 may be an imprinted gene. It's location on chromosome 7 (7q31) makes it within fairly close proximity to a known imprinted region and additionally there is evidence for a differential parent-of-origin expression effect with regard to FOXP2, although recent genetic evidence has come to light that conflicts with this data. FOXP2 is a highly conserved protein and so finding an informative SNP for imprinting analysis was challenging. Initially we tried to perform imprinting analysis using the heterozygous point mutation found in members of the KE family (R553H) but FOXP2 is not expressed in blood so we were unable to do so. Subsequently we carried out imprinting analysis in brain and liver using rs12705977 in the 3' Untranslated Region of FOXP2. Methods used involved sequencing of genomic DNA to identify individuals informative (heterozygous) for this SNP followed by RNA extraction, DNase treatment, Reverse Transcriptase-PCR and subsequent sequencing of the corresponding tissues. In all cases FOXP2 was bi-allelically expressed therefore verifying that it is not imprinted in these tissues. This finding would imply that the origin of speech is too important to have evolved through imprinting or through haplo-insufficiency.

Evaluation of gene expression profile of chromatin modification enzymes in ACP02 and ACP03 gastric cell lines. *J.C. Santos[1,2], R.R. Burbano[3], M.L. Ribeiro[1,2].* 1) Sao Francisco University Medical School, Braganca Paulista, Sao Paulo, Brazil; 2) Universidade Estadual de Campinas, Genetics and Molecular Biology Post Graduation Program; 3) Human Cytogenetics Laboratory, Institute of Biological Sciences, Federal University of Pará, Belém-PA,Brazil.

Gastric cancer is one of the leading causes of cancer-related deaths worldwide. Two main gastric cancer histotypes, intestinal and diffuse, are recognized. Although most of the described genetic alterations have been observed in both types, it has been proposed that these two tumor types might result from different epigenetic pathways. Regarding this subject, in the recent years, much attention has focused on modifications of chromatin because their critical role in regulation gene expression and their active involvement in a number of cellular processes. Additionally, it is well known that epigenetic alterations such as aberrant expression of histone-modifying enzymes have been implicated in tumorigenesis. Since the knowledge of the events that lead to these alterations in cancer cells in vivo is still limited, the study of cancer cell lines is useful in solving this problem. Thus the aim of this work was to evaluate the mRNA expression profile of 84 chromatin modification enzymes in two Brazilian cell lines obtained from primary gastric adenocarcinoma. The cell lines were previously obtained from two patients with gastric cancer, including one diffuse type (ACP02) and one intestinal type (ACP03). After cellular growth (48h), the samples were evaluated by real-time PCR using the Human Epigenetic Chromatin Modification Enzymes RT^2 Profiler™ PCR Array. The expression was normalized with mRNA obtained from a normal tissue. Our data revealed that 26% of the genes were up-regulated and 24% down-regulated, in both ACP02 and ACP03. The up-regulation was exclusively observed among 55% of histone methyltransferases. On the other hand, the down-regulation was found among 46% of histone deacetilases, 43% histone phosphorylation and 34% of histone demethylases. The data from the present study contribute to characterize these new cell lines, and also indicate both shared the same pattern of expression of chromatin modification enzymes.

Expression patterns of histone acetylation modifier genes in gastric cancer. *F. Wisnieski[1], D.Q. Calcagno[1], M.F. Leal[1], T.B. Pontes[1], C.O. Gigek[1], E.S. Chen[1], S. Demachki[2], L.G. Lourenço[3], P.P. Assumpção[2], R. Artigiani[4], R.R. Burbano[5], M.A.C Smith[1].* 1) Department of Morphology and Genetics, UNIFESP, São Paulo, São Paulo, Brazil; 2) Service Surgery, University Hospital João de Barros Barreto, Belém, Pará, Brazil; 3) Department of Surgical Gastroenterology, UNIFESP, São Paulo, São Paulo, Brazil; 4) Department of Pathology, UNIFESP, São Paulo, Brazil; 5) Laboratory of Human Cytogenetics, UFPA, Belém, Pará, Brazil.

Gastric cancer is the fourth most prevalent cancer and the second cause of cancer-related deaths worldwide. Brazil has the fourth highest rate of gastric cancer in Latin America. The degree of acetylation of specific lysine residues in the tails of nucleosomal core histones plays an important role in the regulation of gene expression through chromatin structure. The acetylation of histone residues by histone acetyltransferases (HATs) leads to increased gene activity, whereas deacetylation by histone deacetylases (HDACs) results in chromatin condensation, making gene sequences inaccessible to transcription factors. Alterations in the pattern of histone modification can affect genome structure and integrity and, therefore, disrupt normal patterns of gene expression. Moreover, such histone alterations could be causal factors in cancer. The aims of this study were to compare the expression of two classes of chromatin-modifier genes (HDACs - *HDAC1*, *HDAC2*, *HDAC3* and HATs - *GCN5* and *PCAF*) between primary gastric adenocarcinoma and adjacent non-tumor tissues and to identify possible associations between the expression of these genes and clinicopathological features. Gene expression was evaluated by RT-qPCR in 38 gastric tumor and the matched non-tumor tissues from individuals of Brazil. Before evaluate HDACs and HATs expression, four bioinformatics tools (NormFinder, geNorm, BestKeeper and DataAssist) were used to assess the suitability of five possible reference genes (*ACTB*, *B2M*, *GAPDH*, *18SrRNA* and *RPL29*) for gastric samples. The best combination of reference genes was *GAPDH-B2M*. *HDAC1*, *HDAC3* and *GCN5*expression did not differ between tumor and non-tumor gastric tissues. *HDAC2* expression was significantly higher in tumor tissue compared to adjacent non-tumor tissue (p=0.04), whereas*PCAF* expression was significantly lower in tumor tissue compared to adjacent non-tumor tissue (p=0.01). In addition, *HDAC2* expression was higher in intestinal-type than diffuse-type gastric cancer (p=0.04). These findings suggest that *HDAC2* and *PCAF* may be possible biomarkers for the diagnosis of gastric cancer or useful targets for gene therapy.

3504T

The enzyme holocarboxylase synthetase mediates biotin-independent gene-silencing through the recruitment of histone deacetilases in the nucleus of human cells. *I. Trujillo, T. Barrios-García, S. Reyes-Carmona, I. Meneses-Morales, A. Leon-Del-Rio.* Biologia Molecular, Universidad Nacional Autonoma de Mexico, Mexico, Mexico City, Mexico.

The enzyme Holocarboxylase synthetase (HCS) plays a major role in metabolism catalyzing the biotinylation and activation of five biotin-dependent carboxylases in human cells. We demonstrated that HCS is also an obligate participant in biotin-mediated transcription control of multiple genes through the activation of a cGMP-dependent signal transduction pathway. The finding of HCS in the cell nucleus lead to suggest it could control gene expression through a mechanism based on histone biotinylation. However, this hypothesis has been recently challenged by the finding that biotin is not a natural histone modification. Using polytene chromosomes of D. melanogaster as a model we found HCS is a heterochromatin-associated protein that co-localizes with the transcription repressive epigenetic mark H3K9met3. In this work we explore the hypothesis that nuclear HCS is involved in gene silencing by determining the transactivation effect of a GAL4-HCS hybrid on the expression of a luciferase reporter gene in human HepG2 cells. Our results show that GAL4-HCS acts as a transcriptional repressor whose activity can be reversed by the non-specific HDAC inhibitor trichostatin A (TSA). To test the hypothesis that HCS could mediate transcriptional repression by interacting with HDACs we performed pull-down assays with recombinant GST-HCS and 35S-Met-HDACs. The results showed that HCS can interact with different histone deacetilases in vitro. Co-inmunoprecipitation of HepG2 nuclear proteins using an antibody anti-HCS allowed us to demonstrate that this enzyme is associated to HDACs in the nucleus of human cells in vivo. To explore if the role of HCS as a repressor of transcription requires of its biotinylation activity we introduced amino acid sequence changes in the active site of the enzyme, mimicking the mutations found in patients with severe HCS deficiency. The mutant HCS proteins promoted transcriptional repression of the reporter gene as efficiently as the wild type HCS. We propose that nuclear HCS mediates events of transcriptional repression through a novel biotin-independent mechanism which involves the recruitment of HDACs to the promoter of target genes.

Epigenetic Variation Among Humans. *M. Kasowski[1], F. Grubert[1], S. Kyriazopoulou-Panagiotopoulou[1], A. Kundaje[2], J. Li[1], D. Spacek[1], M. Snyder[1].* 1) Stanford University, Stanford, CA; 2) MIT, Cambridge, MA.

We previously showed that variation in transcription factor binding is an important mechanism leading to global differences in gene expression among humans. It is currently unknown to what extent differences in histone marks also contribute to expression variation between people. Histone proteins possess a variety of covalent modifications (e.g., methylation and acetylation) that correlate with the activation state of genes and functions of noncoding elements. Epigenetic modifications influence expression in part by altering chromatin structure, including accessibility of enhancers to transcription factors. Therefore variations in these marks may give rise to variations in transcription factor binding and gene expression. We are investigating global variation in epigenetic marks among individuals, its genetic basis, and influence on expression. Specifically, we have employed ChIP-Seq to map histone marks associated with a variety of functional elements genome wide in 12 HapMap individuals, and are correlating variations in these marks with transcription factor binding and RNA-Seq data. This study is expected to provide fundamental insights into the role of epigenetic variation in human phenotypic diversity.

Expression of mouse Lin28 gene is epigenetically regulated by histone modification. *A. Pang, A. Title, O.M. Rennert.* Laboratory of Clinical and Developmental Genomics, NICHD/NIH, Bethesda, MD.

The RNA-binding protein Lin28 is considered to be a “stemness” marker. It has a positive regulatory role on cell proliferation, which is partly mediated by the enhancement of translation of genes involved in cell growth. Additionally it blocks the maturation of microRNA let-7 that functions in tumor suppression. The expression of Lin28 gene predominantly occurs in pluripotent cells and cancer cells. Nevertheless, the regulation of Lin28 gene expression has not been thoroughly studied. We hypothesized the cell-limited expression of Lin28 is regulated epigenetically. We examined whether the absence of Lin28 expression in mouse cells resulted from the methylation of Lin28 promoter DNA. Bisulfite-sequencing analysis did not reveal a correlation between its promoter DNA methylation and expression of Lin28 gene. Consistent with this observation, Lin28 expression was not reactivated in non-Lin28 expressing cells, such as NIH/3T3 cells, after treatment with 5-aza-2'-deoxycytidine. We next examined if Lin28 expression was regulated by histone acetylation. Treatment of NIH/3T3 cells with the histone deacetylase inhibitor trichostatin A (TSA) led to the reactivation of Lin28 expresssion. In addition, the promoter region of Lin28 gene became more sensitive to nuclease digestion after TSA treatment, suggesting that Lin28 expression was mediated by the relaxation of chromatin. In agreement with these findings, we observed a significant enrichment of H3K9ac and reduced occupancy of H3K9me2 at the Lin28 promoter region in TSA-treated NIH/3T3 cells and in undifferentiated P19 embryonal carcinoma cells. The opposite pattern of histone modification was found in untreated NIH/3T3 cells and differentiated P19 cells. Taken together, our results identify that Lin28 expression in mouse cells is epigenetically regulated by histone modification.

Transcriptional and epigenetic variation in human induced pluripotent stem cells. *N. Kumasaka[1], F. Rouhani[1], L. Vallier[2], A. Bradley[1], D. Gaffney[1].* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Stem Cell Institute, University of Cambridge.

Human induced pluripotent stem cells (hIPSCs) are a potentially powerful system for developing cellular models of human disease. However, significant epigenetic and transcriptional differences may occur between hIPSCs derived from different tissues and different individuals. Identifying the sources of this variation, and their relative importance in determining the transcriptional and epigenetic landscape of hIPSCs is important for understanding the biology of cellular reprogramming, and for informing efforts to improve the quality and differentiation potential of hIPSC lines. Here we perform RNA-seq, ChIP-seq for a panel of 4 histone modifications and FAIRE-seq on hIPSCs derived from skin fibroblasts, keratinocytes and endothelial precursor cells across a number of different, healthy donor individuals and from a human embryonic cell line (H9ESC) for comparison. We compared epigenetic and transcriptional variability between and within tissues and individuals using a novel statistical framework based on Bayesian hierarchical negative-binomial model. Our approach allows us to estimate over-dispersion for each transcript using the entire data set while adjusting for known experimental biases, such as GC content, as covariates. Our results suggest that, although a small number of genes are consistently differentially expressed between hIPSCs and hESCs, very few of these are specific to their tissue of origin. We suggest that transcriptional memory of the progenitor cell type in hIPSCs is a relatively rare phenomenon.

The ratio of *IGF2/IGF2R* in chorionic villus samples as a biomarker for birth weight. *C. Demetriou[1, 2], A. Thomas[1], M. Ishida[1], S. Abu-Amero[1], R. Aggarwal[3], D. Peebles[3], A. Syngelaki[4], K. Nicolaides[4], L. Regan[2], G.E. Moore[1].* 1) Clinical and Molecular Genetics Unit, Institute of Child Health, University College London, UK; 2) Department of Obstetrics and Gynaecology, St. Mary's Campus, Imperial College London, UK; 3) Institute for Womens Health, University College London, UK; 4) Harris Birthright Research Centre for Fetal Medicine, King's College Hospital, London, UK.

Fetal growth and development is a complex process driven by both genetic and environmental factors. Although many genes are involved, of particular interest are imprinted genes that are monoallelically expressed in a parent-of-origin fashion. Insulin-like growth factor 2 (*Igf2*) and one of its receptors, (*Igf2r*) are examples of direct interaction between paternal and maternal imprinted genes in mice involved in growth regulation. *Igf2* promotes growth enhancement while *Igf2r* sequesters IGF2 and therefore restricts the growth promoting actions of IGF2. In this study, the expression levels of *IGF2* and *IGF2R* were investigated using real-time PCR in 260 human chorionic villus samples (CVSs) obtained at 11–13 weeks of gestation. The expression levels of *IGF2*, *IGF2R* and *IGF2/IGF2R* ratio were correlated with fetal growth parameters such as birth weight (BW) and crown-rump length (CRL). Expression of *IGF2* and *IGF2R* was standardised against the *L19* housekeeping gene and fitted to appropriate regression models. The analysis of the data was performed correcting for confounding factors such as gender, maternal weight and gestational age. *IGF2* CVS expression showed a significant positive correlation with both BW (p=0.004) and CRL (p=0.007). A similar positive association was observed between the expression levels of *IGF2R* and BW (p=0.006) and CRL (p=0.03). Babies that were small for gestational age (N=50) had a significantly lower *IGF2* expression levels compared to normal babies (N=145) (p=1.1e-07) and a significantly lower *IGF2/IGF2R* ratio (p=3.8e-09). This suggests that the low IGF2 levels could be causing the small size at 11–13 weeks and is predictive of <10% birth weight babies at term. Babies that were large for gestational age (N=65) had significantly higher *IGF2R* expression levels compared to normal babies (p=0.02), suggesting that these babies are releasing more IGF2R in order to remove IGF2 and hence avoid further increase in size. This is the first study that has looked at the expression of *IGF2* and*IGF2R* in human CVS and the first report of a positive correlation with growth parameters such as BW and CRL.

Genome Wide Studies of Methylation in the Mouse Frontal Cortex Reveals Novel Imprinted Differential Methylated Regions and Non-CG Methylation. *C. Barr[1,2], W. Xie[3], Y. Feng[1], K. Wigg[1], E. Dempster[1,4], L. Gomez[1], J. Eubanks[1], B. Ren[3].* 1) Genes & Development, Toronto Western Hosp, UHN, Toronto, ON, Canada; 2) Programme in Neurosciences and Mental Health, The Hospital for Sick Children, Toronto, ON, Canada; 3) Ludwig Institute for Cancer Research, University of California San Diego, CA; 4) Institute of Psychiatry, Kings College London, London UK.

Current data support approximately 90 validated imprinted genes in mice, but a recent study indicated that this number may be well over 1,000. Many of the genes are imprinted in a tissue/cell type specific pattern and little is known of these genes. Previous evidence indicates that imprinted genes influence the development of specific brain regions and we sought to identify imprinted genes contributing to the development of the frontal cortex. We created crosses and reverse crosses of mouse strains to determine the parent-of-origin of expressed genes. We used next generation sequencing of RNA (RNA-seq), chromatin immunoprecipitation to histone modifications (ChiP-seq), and bisulfite sequencing (MethylC-Seq) of DNA from the frontal cortex of the adult F1 mice to identity transcripts and epigenetic markers with parent-of-origin effects. Using a FDR of .01, and requiring that the same parent-of-origin bias was evident in 6 biological replicates, we identified known imprinted genes as well as novel patterns of expression for known imprinted genes. We also identified 109 novel transcripts with parent-of-origin effects. Using Methyl-seq we correctly identified known differentially methylated regions (DMRs) as well as 23 novel DMRs most within known imprinted regions. Interestingly, we found significant amounts of non-CG methylation in frontal cortex (35% of methylation), some showing evidence of imprinting. We confirmed the finding of non-CG methylation in 6 additional brain regions and spinal cord but not in other differentiated tissues. None of the novel imprinted transcripts that we identified using RNA-seq were marked by a DMR or by chromatin patterns that were indicative of imprinting. Further, pyrosequencing of a subset of the novel candidates did not replicate their imprinted expression. The results thus do not support the existence of many more imprinted genes than previously identified in frontal cortex and suggest a potential bias in RNA-seq data. The finding of significant amounts of non-CG methylation was surprising given that this epigenetic mark previously documented only in ES cells, preimplantation embryos and oocytes, and was thought to be a marker of pluripotency. The role of this epigenetic mark in human brain is currently under investigation.

3510T

An integrated analysis of DNA methylation, histone modifications and gene expression in monozygotic twins discordant for psoriasis identifies disease-associated genes. *R. Lyle[1], K. Gervin[1], G.D. Gilfillan[1], M. Hammerø[1], H.S. Hjorthaug[1], A.O. Olsen[2], T. Hughes[1], J.R. Harris[3], D.E. Undlien[1].* 1) Department of Medical Genetics, Oslo University Hospital, Oslo, Norway; 2) Department of Dermatology, Oslo University Hospital and University of Oslo, Oslo, Norway; 3) Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway.

Psoriasis is a common, chronic inflammatory immune-mediated disease, which affects mainly the skin, but also the joints. The worldwide prevalence ranges between 1–11.8% depending on ethnicity and geographical area. Psoriasis has a strong genetic component with an estimated heritability of 66%. However, additional environmental and/or epigenetic factors are thought to be important, as concordance rates among MZ twins are only 35–72%. The aim of this study is to identify epigenetically dysregulated genes which are associated with psoriasis. We investigated the epigenetic component of psoriasis using high-throughput bisulfite sequencing (RRBS), ChIPseq (H3K4me3 and H3K27me3) and RNAseq to explore the extent of DNA methylation, histone modifications and gene expression differences in CD4+ cells isolated from 20 pairs of monozygotic (MZ) twins discordant for psoriasis. This approach enables an integrated analysis of the interplay between DNA methylation, histone modifications and gene expression and identifies disease-associated epigenetic patterns and dysregulated genes. This pinpoints potential susceptibility genes and pathways dysregulated in psoriasis. This is the first study to systematically integrate DNA methylation, histone modifications and gene expression in discordant MZ twins in order to reveal and understand the epigenetic component of disease.

3511T

Monozygotic male twins with loss of methylation at DMR2 but discordant for clinical features of Beckwith Wiedemann syndrome. *J. Lazier, M.A. Thomas.* Department of Medical Genetics, University of Calgary, Calgary, Alberta, Canada.

Beckwith Wiedemann Syndrome (BWS) is characterized by overgrowth, hemihyperplasia, neonatal hypoglycemia, abdominal wall defects, macroglossia, ear pitting, and an increased risk of embryonal tumours. Several cases of discordant monozygotic (MZ) twins for BWS have been reported, with a disproportionate number of female twins with a loss of methylation (LOM) at DMR2. Understanding the mechanisms underlying the phenotypic differences in MZ twins will help understand variability in this condition. We present the tenth known case of male monozygotic twins who are discordant for clinical features of BWS. Pregnancy was by natural conception with no complications. One twin was born larger than the other, with a weight of 2.72 Kg (<97%ile) and was noted to have a large umbilical cord. He was treated for hypoglycemia for days 3–5, with spontaneous recovery. He had macroglossia and a nevus flammeus on his forehead. He was later noted to have hemihyperplasia affecting his right arm. The other twin had a birthweight of 2.3kg (50%ile). He had a fainter nevus flammeus than his brother, but did not have neonatal hypoglycemia, macroglossia or hemihyperplasia. Genetic testing confirmed monozygosity and showed that both had LOM at DMR2 in their serum.

Several mechanisms have been proposed to account for the discordant phenotypes, including non-random X-inactivation in females, although this has been questioned. Differences in either new mutations or methylation changes in other genes likely play a role. Weksberg *et. al*, (2002) proposed that DMR2 LOM either predisposes to twinning and discordance, or discordance is caused by unequal splitting of the inner cell mass during a twinning event. DMR2 LOM has also been seen repeatedly in the blood of an unaffected twin, but usually not also in the buccal swab. This may be caused either by allo-transfusion (due to shared blood flow in placenta) or migration of affected blood cell precursors from the yolk sac to both twins (Bliek, 2009).

We will perform further investigation from their buccal swabs which may help provide new evidence into modifying factors affecting expression.

Acquired Epigenetic and Chromosomal Instability Alterations are Present in Adults Who Experienced Childhood Sexual Abuse: A Discordant Monozygotic (MZ) Twin Study. *T. York[1], J. Brumelle[2], J. Juusola[2], K. Kendler[3], E. Eaves[1,3], A. Amstadter[3], S. Aggen[3], K. Jones[4], S. Latendresse[3], A. Ferreira-Gonzalez[2], C. Jackson-Cook[1,2].* 1) Human and Molecular Genetics, Virginia Commonwealth Univ, Richmond, VA; 2) Pathology, Virginia Commonwealth Univ, Richmond, VA; 3) Psychiatry, Virginia Commonwealth Univ, Richmond, VA; 4) Neodiagnostix, Inc, Rockville, MD.

Childhood sexual abuse (CSA) is a traumatic event associated with an increased lifetime risk for developing psychiatric disorders, as well as several age-related health problems such as cardiovascular and respiratory disease. We hypothesize that the latent health consequences of CSA exposure are biologically mediated by acquired somatic epigenetic and chromosomal alterations that persist into adulthood. To test this hypothesis we collected blood specimens from female adult MZ twins (17 pairs, 34 individuals) who were DISCORDANT for a history of CSA. Acquired chromosomal changes were measured using the cytokinesis-block micronucleus (MN) assay on stimulated lymphocytes, which allows for scoring of numerical and structural acquired chromosomal anomalies. Epigenetic alterations were quantified by methylation profiles in bisulphite converted DNA using the Illumina Infinium Methylation 450K BeadChip, which interrogates over 480K genome-wide cytosines. Female MZ twins exposed to CSA (CSA+) exhibited a 1.63-fold average increase in their frequency of MN compared to their nonexposed cotwins (Paired t-test, t_{16}=2.65, P=0.017). This increase primarily reflected the impact of CSA exposure since no additional effects of familial or environmental factors were noted after controlling for the effect of CSA exposure. The observed co-twin divergence in MN frequencies increased with age, suggesting that the biological effects of CSA on adult MN formation may be cumulative. Extrapolating from normative twin data, the observed increase in MN in the CSA+ twins was calculated to be consistent with a 9.9 year biological age increase compared to their unabused MZ co-twins. Divergence in methylation profiles were also seen between the discordant identical co-twins. Acquired changes were detected for 465 sites (FDR of 15%). The majority of these differences (393 sites or 84.5%) were attributable to hypomethylation in the CSA+ twins, suggesting that these abused twins may have activation of normally inactivated genomic regions. The hypomethylated cytosines were preferentially located in sites outside of CpG islands, in CpG shores or “open sea” sequences (Binomial test P=0.063). These data support a direct link between CSA exposure and both epigenetic and chromosomal instability frequencies in adults and provide a foundational basis for future investigations to understand whether and how these DNA-based changes might mediate the association between CSA and adult disease outcomes.

3513T

Genome-wide DNA methylation and gene expression analyses of monozygotic twins discordant for intelligence levels. *CC. Yu[1], M. Furukawa[1], K. Kobayashi[1], C. Shikishima[2], PC. Cha[1], J. Sese[3], H. Sugawara[4], K. Iwamoto[5], T. Kato[4], J. Ando[6], T. Toda[1].* 1) Division of Neurology/Molecular Brain Science, Kobe University Graduate School of Medicine, Kobe, Japan; 2) Keio Advance Research Centers, Keio University, Tokyo, Japan; 3) Department of Computer Science, Graduate School of Information Science and Engineering, Tokyo Institute of Technology, Tokyo, Japan; 4) Laboratory for Molecular Dynamics of Mental Disorders, RIKEN Brain Science Institute, Saitama, Japan; 5) Department of Molecular Psychiatry, Graduate School of Medicine, the University of Tokyo, Tokyo, Japan; 6) Faculty of Letters, Keio University, Tokyo, Japan.

Human intelligence, as measured by intelligence quotient (IQ) tests, demonstrates one of the highest heritabilities among human quantitative traits. Nevertheless, studies to identify quantitative trait loci responsible for intelligence face challenges because of the small effect sizes of individual genes. Phenotypically discordant monozygotic (MZ) twins provide a feasible way to minimize the effects of irrelevant genetic and environmental factors, and should yield more interpretable results by finding epigenetic or gene expression differences between twins. Here we conducted array-based genome-wide DNA methylation and gene expression analyses using 17 pairs of healthy MZ twins discordant intelligently. ARHGAP18, related to Rho GTPase, was identified in pair-wise methylation status analysis and validated via direct bisulfite sequencing and quantitative RT-PCR. To perform expression profile analysis, gene set enrichment analysis (GSEA) between the groups of twins with higher IQ and their co-twins revealed up-regulated expression of several ribosome-related genes and DNA replication-related genes in the group with higher IQ. To focus more on individual pairs, we conducted pair-wise GSEA and leading edge analysis, which indicated up-regulated expression of several ion channel-related genes in twins with lower IQ, and up-regulated expression of IGF-1 in twins with higher IQ. Our findings implied that these groups of genes may be related to IQ and should shed light on the mechanism underlying human intelligence.

Analysis of expressed SNPs identifies new genes escaping X-chromosome inactivation and variable extents of expression from the inactive X. *A. Cotton[1], B. Ge[2], T. Pastinen[2], C. Brown[1].* 1) University of British Columbia, Department of Medical Genetics, Life Sciences Institute, Molecular Epigenetics Group, Vancouver, British Columbia, Canada; 2) McGill University and Genome Québec Innovation Centre, Department of Human and Medical Genetics, McGill University Health Centre, McGill University, Montréal, Québec, Canada.

X-chromosome inactivation (XCI) results in the transcriptional silencing of most, but not all, genes on one X chromosome. Genes which escape XCI are candidates to explain the phenotype of X-aneuploides and sex-specific disease susceptibilities. Cis-acting silencing is also observed for imprinted genes and recent genome-wide studies of expressed SNPs have revealed considerable allelic imbalance (AI), in which two alleles of the same gene show large differences in the level of expression. As the majority of X-linked genes are subject to XCI, these genes would be expected to show AI in females with non-random XCI which would in turn allow for the identification of genes subject to or escaping from XCI. X-linked AI was examined using the Illumina Human1M-duo BeadChip in 190 samples (99 female and 91 male) from three populations (CEPH, YRI and primary fibroblasts). By combining multiple probes across genes, a single AI score was calculated for 725 X-linked genes. In the female fibroblast samples, an average 97% of genes showed bi-allelic expression leading to the conclusion that these samples had random XCI. In 31 lymphoblast samples (27 CEPH and 4 YRI), more than half of the X-linked genes were found to have mono-allelic expression, suggesting XCI in these females was not random. Using only those females with substantial non-random XCI, AI scores were converted into an XCI status for 374 X-linked genes, 81% of which showed the same XCI status as previously established. Of the 52 genes with no previous data, 36 were demonstrated to be subject to XCI and 11 escaped from inactivation. An additional 5 novel genes were found to escape from X-chromosome inactivation in some females but were subject in others demonstrating a pattern of expression known as variable escape from XCI. Data from different cell types, different populations and families, allows investigation of potential sources of such variability. Interestingly, in the populations where all females showed random XCI, genes with mono-allelic expression were still detected. X-linked AI analysis has not only provided new data on which genes escape from XCI, but also direct information about the wide-range of expression level on the inactive X relative to the active X chromosome. Overall, the study of AI for X-linked genes provides the opportunity to increase our understanding of the silencing of one X chromosome during XCI, and thus how cis-acting silencing can contribute to variations in disease.

Investigating the role of the WICH chromatin remodeling complex in maintaining facultative heterochromatin at the human inactive X chromosome through targeted deletion of the BAZ1B gene using zinc finger nuclease technology. *A.E. Culver-Cochran, B.P. Chadwick.* Biological Science, Florida State University, Tallahassee, FL.

X chromosome inactivation (XCI) is the mammalian from of dosage compensation that balances the levels of X-linked gene expression between the sexes. Early in female development, transcription from one X is shut down as the chromosome is repackaged into facultative heterochromatin. Once established, the same X is maintained as the inactive X chromosome (Xi) throughout subsequent somatic cell divisions. While much is known about the initiation of XCI, our understanding of how the Xi chromatin is faithfully maintained through each cell cycle is limited. We have identified the multifunctional Williams syndrome transcription factor (WSTF) as a protein that transiently associates with the Xi as it is replicated in late S-phase, and, therefore, is a prime candidate for maintaining XCI. WSTF acts at the Xi as a component of the WSTF-ISWI chromatin remodeling complex (WICH). Interestingly, we have found that WICH and two other proteins implicated in heterochromatin maintenance, γ-H2A.X and BRCA1, sequentially associate with the Xi, suggesting that each plays a unique role in maintaining the chromosome's epigenetic signature. In order to assess the role of WICH at the Xi, we used zinc finger nuclease (ZFN) technology to disrupt the WSTF encoding BAZ1B gene on chromosome 7q11. A pair of active ZFNs were designed to exon-7 and were subsequently introduced into a female diploid hTERT-immortalized cell line along with a promoter-trap repair template that completely replaced the exon. Two clones were isolated that had successfully removed both alleles of exon-7, and three independent clones were identified that had replaced one allele and disrupted the open reading frame of the second allele by non-homologous end joining. We are actively investigating the impact of WSTF loss on the Xi by examining changes to chromatin structure and X-linked gene expression.

DNA methylation profiling in X;autosome translocations supports a role for repeat elements in the spread of X chromosome inactivation. *A. Sharp, N. Bala, M. Brahmachary, P. Garg, C. Borel.* Genetics & Genomics Sci, Mount Sinai Sch Med, New York, NY.

X chromosome inactivation (XCI) is an epigenetic mechanism that silences in cis the majority of genes on one of the two X chromosomes in females. However, a significant fraction of genes remain expressed from the inactive X and thus `escape' XCI. Several previous studies have shown differential densities of certain types of common repeat elements associated with genes subject to versus those that escaping XCI, suggesting that the spread of XCI might be regulated by these repeats. However, due to the non-random distribution of genes that escape XCI and the unusual evolutionary history of the X chromosome, it has been unclear if the correlation between repeat elements and escape from XCI is a functional one. In order to test the hypothesis that the spread of X chromosome inactivation shows sequence specificity, we have analyzed the spread of XCI into autosomal chromatin by performing DNA methylation profiling in six unbalanced X;autosome translocations using Illumina 450k beadchips. Using promoter hypermethylation as a robust epigenetic signature to measure the spread of XCI, we have determined the inactivation status of 1,189 autosomal genes after translocation onto the inactive X. Subsequent sequence analysis comparing the prevalence of common repeats and DNA motifs in translocated autosomal genes that are either subject to or escape the spread of XCI shows that the density of many repeat elements, including LINEs, Alus, ERVs and MIRs, is significantly correlated with local susceptibility to the XCI signal. This association between repeat density and silencing of autosomal genes by XCI recapitulates similar observations made on the X chromosome, suggesting a causal relationship between DNA sequence features such as common repeats and the spread of XCI. These data support Mary Lyon's `repeat hypothesis', suggesting a functional role for repetitive elements in the XCI process.

Tools for epigenetic research. *L. Apone, P. Liu, G. Lohman, E. Cantor, B. Langhorst, D. Munafo, C. Sumner, E. Yigit, L. Merrill, F. Stewart, T. Evans, E. Dimalanta, T. Davis.* New England Biolabs, Inc., Ipswich, MA.

Epigenetics is the study of heritable changes in gene expression that occur without a change in the primary DNA sequence. These changes, which include DNA methylation and histone protein modification, are reversible, responsive to environmental stimuli and add layers of complexity to the human genome. Epigenetic changes occur predominately through protein DNA interactions. Identifying and mapping these interactions is key to understanding how changes in the epigenome affect human health and disease. The chromatin immunoprecipitation assay (ChIP) is one of the most powerful tools available to map DNA protein interactions. When coupled with high throughput DNA sequencing (ChIP-Seq), genome wide, protein interaction maps can be generated. Although a powerful technique, the use of ChIP-Seq has been hampered by the difficulty in obtaining sufficient quantities of input DNA. To overcome this challenge we have developed a library construction method using novel NEBNext® reagents and adaptors with a low DNA input requirement. The method is quick, easy and compatible with multiple high throughput sequencing platforms. In addition, the use of NEBNext® multiplex oligos allows the sequencing of multiple ChIP-Seq samples in a single sequencing run. Taken together, the improvements to library construction, the versatility of platform choice and the ability to multiplex, will aid researchers in overcoming some of the hurdles to using ChIP-Seq in epigenetic research.

Sex-influenced epigenetic effects in chromosomal rearrangements. *J. Kapalanga[1,2,3], D. Wong[2,3], N. Nwebube[1], A. Gandy[2,3].* 1) Dept Pediatrics, Genetics, Grey Bruce Health Services, Owen Sound, ON, Canada; 2) Dept Pediatrics, Dalhousie University, Halifax, NS, Canada; 3) Summerside Medical Center, Summerside, PE, Canada.

Balanced chromosomal rearrangements can be associated with an abnormal phenotype; conceivably due to break-point involvement of loci and regions of the genome that are critical in gene or genomic function. Abnormal phenotypes in balanced translocation carriers have been attributed to microdeletions, microduplications, gene disruptions and position effects at the break points. The aforementioned mechanisms may not be the only explanation for abnormal phenotypes in chromosomal rearrangements. Epigenetic influences could be another explanation. We report the effect of sex on phenotype in individuals with familial chromosomal rearrangements in different regions of the genome. The chromosomal rearrangements, viz; 46, XY, inv(11)(p15.4q12).ish inv(11)(pter+qter+), t(14;17)(q32.32;qter) and 47, +mar(12) were observed in 3 families and across three generations. An analysis of clinical data resulted in the identification of 9 individuals with balanced chromosomal rearrangements or supernumerary marker chromosomes (SMC). Four of the 9 individuals had abnormal phenotypes and all 4 were male, while all 5 individuals with normal phenotypes were female. While studies have shown that there are more mothers than fathers in translocationor SMC families, no studies have reported a sex effect on microdeletions, microduplications, gene disruptions and position effects associated with balanced chromosomal rearrangements. We, therefore, hypothesize that sex-influenced epigenetic mechanisms are an explanation for the observed sex related differences in phenotypic effects of balanced chromosomal rearrangements. DNA methylation and histone modification studies are being undertaken to characterize the epigenetic mechanisms.

The relationship between paternal uniparental disomy and clinical features in patients with Beckwith-Wiedemann syndrome. *O. Yasufumi, K. Jozaki, T. Maeda, H. Yatsuki, K. Higashimoto, H. Soejima.* Division of Molecular Genetics and Epigenetics, Department of Biomolecular Sciences, Faculty of Medicine, Saga University, Saga, Japan.

(Background and purpose) Beckwith-Wiedemann syndrome (BWS) is an imprinting disorder characterized by macroglossia, macrosomia, abdominal wall defect and a predisposition to embryonal tumor in childhood. Approximately 20% of patients with BWS show the paternal uniparental disomy (UPD) of chromosome 11. The patients with UPD were mosaic of normal cells and UPD cells, leading to hypertmethylation at H19-DMR and hypomethylation at KvDMR within 11p15. 5 imprinted region. UPD of BWS has genetic diversity such as the various ratio of mosaicism and the various extent of UPD region. The aim of this study is to clarify the relationship between the genetic diversity and clinical manifestations in BWS patients caused by UPD. (Subjects and methods) We analyzed 25 of BWS patients with UPD (male 9, female 16). The mosaic ratio was evaluated by tetranucleotide repeat markers from 11p15.5 and calculated as follows: (k-1)/(k+1) × 100; where k is the ratio of the peak height of ratios of paternal allele to maternal allele. The extent of UPD was evaluated by Affymetrix® Human SNP array 6.0. MassARRAY analysis was performed to search the methylation of 35 imprinted differentially methylated regions (DMRs) scattered throughout genome. Based on these results, we statistically analyzed the relationship between the diversity of UPD and clinical information. (Result) The mosaic ratio ranged from 28% to 99%;, and was 60% or more in 16 cases. As for the extent of UPD, the recombination breakpoints existed within chromosome 11p in 19 cases, and spread into the 11q in two cases. The smallest UPD region was 2.7 Mb, including both H19-DMR and KvDMR. The largest UPD region was whole genome, i.e., genome-wide paternal UPD (GWU), which was detected in four patients. In the methylation analysis, the hypermethylation at H19-DMR and the hypomethylation at KvDMR were seen in all cases according to the mosaic ratio. In addition, the majority of other imprinted DMRs showed aberrant methylation in all GWU cases. There was no correlation between the mosaic ratio and the extent of UPD. We found negative correlations between the mosaic ratio and fetal-placental weight ratio, and between the extent of UPD and gestational age. Furthermore, an increased incidence of tumor development correlated with the extent of UPD. (Conclusion) The genetic diversity of UPD may affect the BWS phenotypes including gestational age, placentation, and tumor development.

Streamlined chromosome conformation capture workflow for the studies of human β-globin gene control by locus control region. *C. Woo, C. Liu, S. Dong.* Life Technologies, 850 Lincoln Centre Drive, Foster City, CA.

The human genome is organized non-randomly in the nucleus. The three-dimensional chromosome structure and interaction represent the final outcome of genetic and epigenetic interplays and provide the basis for gene regulation. We developed a streamlined workflow to convert such physical interactions between genomic loci to quantifiable DNA sequences by real time PCR. The improved workflow has shortened sample to readout time from five to two days, yielding an average of 22ug of 3C library from 5×10e6 cells. Real time PCR also provides interaction profiles in high resolution. The human β-globin gene family on Chromosome 11, which consists of five isoforms, is expressed sequentially during development, as enhanced by the locus control region (LCR) 60kb away. Using the improved workflow, we measured the detailed interactions between LCR region and β-globin isoforms and correlated the interaction with gene expression levels in two cell lines: a β-globin expressing erythroleukemia cell line (K562) and non-expressing lymphoblast cell line (GM06990) in relation to LCR conformation. The results confirmed the different LCR interaction in expressing and non-expressing cell lines. Quantitative interaction analysis of the data further refined the enhancer functioning domain and revealed the strong correlation of high expression with strong interaction with LCR, indicating that β-globin gene expression was controlled by the looping interaction between the LCR enhancer and the target genes.

Micro-RNAs in the Sclera: Role in Ocular Growth Regulation and Implications for Myopia. *R. Metlapally[1], P. Gonzalez[2], F.A. Hawthorne[3], K. Tran-Viet[3], C.F. Wildsoet[1], T.L. Young[2,3].* 1) School of Optometry, University of California at Berkeley, CA; 2) Duke Eye Center, Durham, NC; 3) Duke Center for Human Genetics, Durham, NC.

Purpose: The enhanced ocular enlargement underlying myopia is driven by a signaling cascade that originates in the retina and ultimately determined by scleral (outer coat) extracellular matrix remodeling. miRNAs regulate gene expression by pairing with the 3' UTR of target sequences and serve as nodes of signaling networks. The role of miRNAs in scleral remodelling is unknown. We hypothesized that the sclera, like most tissues, expresses miRNAs and that some play active roles in eye growth regulation. **Methods:** Scleral samples were obtained from normal human fetal donor eyes (24 wk), representing rapidly growing eyes, as well as adult (age-matched) donor eyes (n=6, each group). RNA was extracted using the miRVANA kit and genome-wide miRNA profiling performed using the Agilent Human miRNA Microarray platform. To obtain miRNA target predictions, Microcosm, TargetScan and PicTar algorithms were used. Select collagen-specific miRNAs were validated using Taqman® MicroRNA Assays in samples from posterior and peripheral scleral regions (n=7, each group). Microarray data were analyzed using R (http://www.r-project.org), and quantitative PCR data with 2^-deltaCt method. **Results:** Human sclera expressed several miRNAs and many were differentially expressed, higher in rapidly growing fetal eyes ($p<0.01$, min $p= 6.5\times10^{11}$). Increased expression of collagen-specific mir-214, let-7c, let-7e, mir-103, mir-107, and mir-98 in fetal tissue was also demonstrated (fold changes 1.5 to 4, $p<0.01$) in follow-up experiments. In the validation experiments no significant differences were observed in miRNA expression between posterior and peripheral regions, for either age group. **Conclusions:** To our knowledge, this is the first comprehensive study of miRNA expression in human sclera. The sclera expresses several miRNAs, some of which show age-related differential regulation, consistent with a role in ocular growth regulation. Corresponding genome-wide mRNA profiling and analyses of correlations with micro-RNA signatures are underway to characterize the pathways involved, by way of exploring the potential role for miRNAs in ocular growth regulation in general and mechanisms underlying myopia development more specifically.

3522T

DNA combing assay for detection of contraction-dependent facioscapulohumeral muscular dystrophy (FSHD1). *F.Z. Boyar[1], P. Chan[1], V. Sulcova[1], D. Tsao[1], R. Owen[1], P. Walrafen[2], C.D. Braastad[3], M. Jocson[3], W. Sun[1], A. Anguiano[1], C.M. Strom[1].* 1) Department of Genetics, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA; 2) Diagnostics Division, Genomic Vision, Paris, France; 3) Athena Diagnostics Inc., Worcester, MA.

FSHD, the third most common muscular dystrophy, is an autosomal dominant disorder with a prevalence of 4–10 per 100,000. It is characterized by often asymmetric progressive weakness of facial, scapular and upper arm muscles. FSHD1 is associated with the contraction of the D4Z4 region (3.3 kb repeat motif that contains DUX4, double homeobox 4, gene) at the subtelomeric region of 4q35 and activation of the normally epigenetically silenced DUX4. Patients carry 1–10 copies of D4Z4 on the 4qA allele, while normal individuals harbor 11–100 copies. Contractions of the partner 4qB allele or a homologous region on chromosome 10q26 are non-pathogenic. Detection of truncated D4Z4 and diagnosis of FSHD1 have been based on Southern blot which provides only an approximate size of the fragment of interest. Here we report a method for analysis of the D4Z4 region using DNA combing for direct visualization, recognition and measurement of the pathogenic 4qA allele. DNA combing and southern blot results showed complete concordance in a series of DNA plugs from normal and abnormal peripheral blood samples tested with the former providing a specific number of D4Z4 repeat elements. DNA combing assay was also performed directly on fresh blood and FSHD1 cell lines. Our findings underscore the utility of DNA combing assay for more accurate measurement of the D4Z1 locus on the pathogenic 4qA allele and diagnosis of FSHD1. It may also be applicable in the study of other disorders associated with copy number variation or repeat expansion and contraction. This represents the first successful validation of a molecular combing assay in a United States commercial laboratory.

3523T

RNA editing of the *SDHB* transcripts (C to U) in peripheral blood monocytes. *R.T. Taggart, J.D. Tario, K.H. De Jong, P.K Wallace, B.E. Baysal.* Dept Pathology, Roswell Park Cancer Institute, Buffalo, NY.

RNA editing is an epigenetic mechanism of gene regulation involving programmed enzymatic recoding of a RNA transcript. Targeted C to U RNA editing is performed primarily by APOBEC3 family of cytidine deaminase enzymes. Only a few endogenous gene transcripts of C to U editing are known. We described previously a recurrent stop codon mutation, C136T (R46X), in a fraction of succinate dehydrogenase subunit B gene, *SDHB*, transcripts in peripheral blood mononuclear cells (PBMCs). Similar mutations in the SDH subunits in germ line cause hereditary paraganglioma tumors. We describe here screening of cell types where *SDHB* editing occurs using a novel quantitative PCR assay for the measurement of mutated 136T versus wild-type 136C transcripts in cold-aggregated or CD14-column purified monocytes from peripheral blood and in various cell lines. We also measured expression of APOBEC3 family of enzymes.

Significant fraction of *SDHB* RNAs carries the 136T mutation in monocyte enriched populations (mean=6.3%; range 2.5–9.2%; n=4). *SDHB* editing is very low in lymphocyte enriched populations (mean=1.7%; range=1.3–2.2%; n=4) and absent in fibroblast line X269/8 and lymphoblastoid cell lines (<1%). Monocytic differentiation of HL60, THP1 and U937 cell lines by vitamin D exposure, as confirmed by flow cytometry, induces no *SDHB* editing. qRT-PCR analysis of APOBEC3 enzymes reveals that APOBEC3A, APOBEC3C and cytidine deaminase enzymes are expressed at least 5-fold more in monocyte-enriched PBMCs than in monocyte-depleted cells. The expression of other APOBEC3 enzymes is either very low in monocyte-enriched PBMCs (APOBEC3B, -3DE,) or decreased relative to monocyte-depleted PBMCs (APOBEC3F, -3G, -3H).

The *SDHB* gene is downregulated by site-specific C to U RNA editing in peripheral blood monocytes. SDH (mitochondrial complex II) is subject to tissue-specific dosage reduction by epigenetic mechanisms including genomic imprinting of *SDHD* and RNA editing of *SDHB*. Constitutive hypoxic phenotype of paraganglioma tumors suggests that these epigenetic changes may enhance hypoxia sensitivity and survival in normal cells.

FTO levels affect RNA modification and the transcriptome. *T. Berulava[1], M. Ziehe[2], L. Klein-Hitpass[3], E. Mladenov[4], J. Thomale[3], U. Rüther[5], B. Horsthemke[1].* 1) Institut für Humangenetik, Universitätsklinikum Essen, Hufelandstrasse 55, 45122 Essen, Germany; 2) Analytical and Environmental Chemistry, Humboldt-Universität zu Berlin, Brook-Taylor-Str.2, 12489 Berlin, Germany; 3) Institut für Zellbiologie (Tumorforschung), Universitätsklinikum Essen, Hufelandstrasse 55, 45122 Essen Germany; 4) Institut für medizinische Strahlenbiologie,Universitätsklinikum Essen, Hufelandstrasse 55, 45122 Essen, Germany; 5) Institut für Entwicklungs- und Molekularbiologie der Tiere (EMT) Heinrich-Heine-Universität, Universitätsstr.1, 40225 Düsseldorf Germany.

A block of single nucleotide polymorphisms (SNPs) within the intron 1 of the *FTO* (fat mass and obesity associated) gene is associated with variation in body weight. Previous works suggest that increased expression of *FTO* leads to increased body weight, although the underlying mechanism has remained unclear. The gene encodes a 2-oxoglutarate-dependent RNA demethylase, which has been shown to demethylate 3meU, 3meC, 1meA *in vitro* and 6meA *in vitro* and *in vivo*. To elucidate the function of FTO we examined the consequences of altered FTO levels in cultured cells and murine brain. Here we show that a knockdown of *FTO* in HEK293 cells affects the transcripts levels of genes involved in the response to starvation, whereas overexpression of FTO affects the transcript levels of genes related to RNA processing and metabolism. Changes in transcripts levels may reflect changes in transcript stability depending on the degree of adenine methylation. Subcellular localization of FTO further strengthens the notion that FTO is involved in RNA processing and metabolism. Using immunocytochemistry and confocal laser scanning microscopy, we detected FTO in nuclear speckles and - to a lesser and varying extent - in the nucleoplasm and nucleoli of HEK293, HeLa and MCF-7 cells. Moreover, RNA modification analyses of total brain RNA revealed that loss of Fto affects the 3-methyluridine/uridine and pseudouridine/uridine ratios. We conclude that altered levels of FTO have multiple and diverse consequences on RNA modifications and the transcriptome.

3525T

Prioritizing candidate functional SNPs at GWAS loci using epigenomic datasets from ENCODE. *K.S. Lo[1,2], C.D. Palmer[3,4], J.N. Hirschhorn[3,4], G. Lettre[1,2].* 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Université de Montréal, Montréal, Québec, Canada; 3) Children's Hospital Boston, Boston, MA, USA; 4) Broad Institute, Cambridge, MA, USA.

INTRODUCTION: Genome-wide association studies (GWAS) have identified hundreds of coding but mostly non-coding single nucleotide polymorphisms (SNPs) associated with complex human diseases and traits. At most GWAS loci, the SNPs that causally influence gene products and thus phenotypic variation remain unknown. Epigenomics could help clarify some of these findings by prioritizing functional follow-up through the discovery of regulatory elements.

METHODS & RESULTS: To identify functional variants at the 180 loci associated with adult height by the GIANT Consortium (Lango Allen et al., Nature, 2010), we used epigenomic data compiled by the Encyclopedia of DNA Elements (ENCODE) Consortium. Because there is no clearly relevant cell line in this dataset to study the biology of height, we decided to explore 24 epigenomic tracks available from the UCSC genome browser for human umbilical vein endothelial cells (HUVEC). We tested the overlap between the 180 height SNPs (and their linkage disequilibrium (LD) proxies) and features such as chromatin accessibility, DNA methylation, histone modification and transcription factor binding sites. To assess statistical significance, we repeated the analysis with 1000 sets of 180 SNPs matched on allele frequency, gene proximity and LD. We observed a strong enrichment ($P<0.001$) for most epigenomic features, except for the histone H3 lysine 27 tri-methyl (H3K27me3) mark associated with transcriptional repression ($P=0.25$) and for the hematopoietic lineage-specific GATA2 transcription factor binding sites ($P=0.58$). These results are consistent with the previously reported enrichment of expression quantitative trait loci (eQTL) among the height loci.

CONCLUSION: We show that there is a strong enrichment of epigenomic features that overlap with adult height association signals. Our approach is applicable to other complex human phenotypes and should help fine-map causal variants identified by GWAS.

Bioinformatic Parallel Processing Tools Development for Mutation Identification from Whole Exome Data Following Homozygosity Mapping for Autosomal Recessive Disorders. *Y. Al-Sarraj[1], A. Abouzehry[1], H. ElShanti[1,2], M. Kambouris[1,3].* 1) Shafallah Medical Genetic Center, Doha, Qatar; 2) University of Iowa | Iowa, Pediatrics, Iowa City, IA, USA; 3) Yale University School of Medicine, Genetics, New Haven, CT, USA.

Eight consanguineous Arab families with novel autosomal recessive disorders were mapped with illumina OmniExpress 700K SNP genotyping & Homozygositymapper software. All relevant positional candidate genes were screened for pathogenic mutations. None were identified. Multiple homozygosity intervals were obtained for each family since no significant LOD scores were possible. Whole exome target enrichment sequencing was on ABI SOLiD4 for one affected individual from each family. Sequence mapping and annotation was on LifeScope software. Data validation was done manually for each linkage interval, by visual inspection of read depth and bead number coverage. On average 30,000 sequence variations were detected in each sample including novel variants, known polymorphisms & exome sequencing errors. For each chromosome with a linkage interval, data was isolated and filtered by exportation to Excel spreadsheets and visual inspection to exclude non-linkage interval data. The number of variants in the linkage intervals for each family was between 400 and 1300. Homozygous sequence variations within the linkage intervals were between 50 and 300 with 15–30 novel variants. Determination if a variant was homozygous or heterozygous, novel or annotated was done manually upon visual inspection of data on Excel spreadsheets. For each novel variant it was manually determined if it were exonic, splice site specific or intronic. For each annotated variation it was manually determined if it is associated to a disease phenotype relevant to the family disease. Minor genotype frequency ware investigated for annotated variants if they represent disease states. All novel exonic variants were tested in silico with PolyPhen and Sift Protein Modeling software to access the effect on protein function. All damaging variants (novel or annotated exonic, and splice site) were validated by Sanger sequencing and tested for co-segregation to disease. An identical approach is essential to access pathogenic effects of insertion/deletion variants within each linkage interval. This approach is tedious, involves a tremendous amount of manual work and is prone to oversight errors. Software tool development for automating next generation sequencing data analysis is essential to eliminate manual work and identify pathogenic mutations among the plethora of existing variants. Such automation is applicable in cases without linkage intervals to limit the number of variants under consideration.

Kailos BlueTM: A Complete Cloud-Based Bioinformatics Solution for Management and Analysis of Targeted Sequencing Across Next Generation Sequencing Platforms. *R.C. Bachmeyer[1], D.A. Kloske[1], B. Stone[1], K.E. Varley[1,2], D.T. Moore[1].* 1) Kailos Genetics Inc., Huntsville, AL; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL.

Next-generation sequencing (NGS) applications are developing at unprecedented speed, enabling the large-scale production of sequence data for whole genome, exome and targeted sequencing. This scale of data generation presents significant computational challenges for most laboratories in storage, retrieval, analyses, and equipment run cost management. There exist many differing software solutions designed and optimized to handle each individual step in the overall NGS workflow. However, these solutions often require a high degree of IT knowledge to implement, configure, support and operate. Additionally, connectivity and storage are generally limited to local systems that were not conceived of with NGS in mind. We developed Kailos Blue, a highly secure, easily accessible cloud environment, for investigators to manage their NGS workflow, analyze sequences post-target enrichment and actively utilize their stored data. In combining the Amazon cloud (secure & scalable), the industry leading alignment and genotyping systems (BWA & GATK), statistical resources and an intuitive user interface, investigators from any size lab can perform complex analysis of samples within a run and across multiple runs over time, independent of the sequencing equipment utilized.

Kailos Blue provides an end-to-end informatics solution for targeted next-generation sequencing. The system can be used to plan and organize flowcells and configure sequencing runs. This feature is especially important for targeted sequencing approaches, such as Kailos Genetics' Target Rich system, where dozens of samples are barcoded and pooled to efficiently and optimally utilize sequencer capacity. Raw data can be uploaded from sequencing instruments to the cloud for fast and secure alignment and analysis. Analysis, including variant identification, can be performed on DNA samples and compared against a reference sample (1000 Genomes, HapMap, User Defined) or across multiple samples run over any period of time, enabling entire studies to be compiled and analyzed in one system. Here we will present the overall design of the cloud-based bioinformatics solution and its performance in analyzing targeted sequencing data generated on the Illumina MiSeq, GAIIx and the Ion Torrent PGM.

Streamlined, accurate low level detection of variants in deep, next generation sequencing data from amplicons. *C. Boysen, M. Matvienko, N. Thomson, B. Turner, J. Bendtsen, H. Sandmann, J. Jakobsen, P. Nielsen, A. Joecker, A. Joecker.* CLC bio, Cambridge, MA.

Purpose: Next generation sequencing is being added to research, diagnostics, and clinical labs to identify disease linked DNA variants. However, NGS applications and platforms each have various issues that can confound accurate detection of variants. Here we address issues associated with amplicon-based deep re-sequencing data analysis for identification of low level variants as warranted in the detection of somatic mutations in potentially mixed cancer/normal tissue. Study and Results: Using CLC bio Genomics Workbench, we have made an efficient re-sequencing workflow for the end-to-end analysis of NGS data. This workflow has been optimized to accommodate the characteristics associated with short amplicon, deep sequencing. Particular mapping and variant calling algorithms have been deployed to handle known NGS platform dependent issues, such as homopolymer problems and other consistent sequencing errors. Variants can be ranked and filtered according to a number of criteria, incl. quality values, forward/reverse reads, comparisons to variant databases and known function or disease associations. To help ensure sufficient coverage of all amplicons and flag potential drop-outs, an extensive suite of quality control measurements have been incorporated, and provides the user with an easily interpreted overview of all samples in a given run. Results regarding sensitivity and specificity are presented as is discussion on frequently encountered issues and the provided solutions for best practices.

De novo Assembly by Positional Sequencing. *B. Bready, P. Goldstein, W.H. Heaton, P. Ianakiev, H-Y. Li, J.S. Oliver, J. Thompson.* Nabsys Inc, Providence, RI.

Because of the highly repetitive nature of human DNA and the relatively short length scales over which DNA sequencing platforms obtain information, assembling the data produced by these platforms is computationally intensive and results in contig lengths that are very short compared to the lengths of chromosomes. Complete genomes require significant additional finishing to unambiguously place repeated or difficult regions and to order scaffolds and contigs. In contrast, Positional Sequencing as developed by NABsys using nano-scale detectors and specific hybridization probes will provide information over hundreds of kilobases and even megabases of contiguous sequence. Specifically, the platform locates, with sub-diffraction-limit resolution, the positions of oligonucleotide probes that have bound to long DNA fragments. This information can be assembled into contigs whose lengths approach the lengths of chromosomes. M13 has been used as a model system for sequencing. Hybridization probes of 8 to 20 long were found effective in providing data that allowed resequencing of parts of the M13 genome in preparation for larger genomes. An error model based on this effort is used to determine the performance of the system on more complex genomes.

Translational research in newborn screening: development of informatics tools to support longitudinal research and accelerate transformations in clinical practice. *A. Brower[1], B. Bowdish[1], M. Porter[2], J. Pennington[2], S. Wrazien[2], J. Loutrel[2], P. White[2,3], M. Watson[1].* 1) Newborn Screening Translational Research Network, American College of Medical Genetics, Bethesda, MD, 20814, USA; 2) Center for Biomedical Informatics, The Children's Hospital of Philadelphia, Philadelphia, PA, 19104, USA; 3) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA, 19104, USA.

Background: The goal of newborn screening is the early identification, diagnosis and treatment of disease to improve health outcome for affected infants. Over the past decade innovations in analytical technology have enabled the rapid expansion of the number of conditions included in screening efforts, and a system of evidence review has led to further expansion. All states have implemented screening for a core panel of conditions, resulting in nearly 12,500 newborns diagnosed each year. While the majority of the conditions require life-long medical care and management, there is no nationwide system to collectively assess health outcomes and further scientific understanding of the conditions. Informatics tools that can be incorporated into clinical workflows in a variety of care settings are required. These tools will facilitate the translation new discoveries to clinical practice and improve scientific understanding. Methods: In 2008, the NICHD established the Newborn Screening Translational Research Network (NBSTRN) Coordinating Center to develop tools and infrastructure to support research in newborn screening. The NBSTRN established a broadly constituted workgroup comprised of content experts from laboratory-based specialties, clinical care teams and state-based newborn screening programs to identify the data from routine clinical care that would be important for research efforts. A data capture tool and management system is under development and leverages the Research Electronic Data Capture (REDCap) system to create user friendly clinical case report forms that incorporate national information standards to facilitate information sharing, data mining and data aggregation. Development of this informatics tool and an accompanying almanac of definitions and standards are focused initially on the forty-two metabolic disorders as well as conditions that have not been recommended for routine newborn screening. Results: A series of clinical case report forms that incorporate a consensus data set defined by an NBSTRN workgroup and a data management system are in development. Condition-specific clinical case report forms for currently screened and candidate conditions for newborn screening will be presented. Conclusions: The creation of informatics tools to support the longitudinal gathering, sharing and analysis of the health information of diagnosed individuals supports research and facilitates the translation of new discoveries to clinical practice.

3531F

Web-based tool for target sequence capture assay design. *J. Cai, B. Morrow.* Department of Genetics, Albert Einstein College of Medicine, Bronx, NY.

Re-sequencing of selected genes of interest within the human genome has become a popular strategy to discover variants associated with disease. Compared with whole exome sequencing, the customized target capture approach of known genes related with a certain phenotype/disease has the advantage that of achieving deeper coverage with less cost. It also will enable putative regulatory regions or alternatively spliced exons to be included that may not be present in generic exome capture kits. We developed a user friendly web-based tool that create sequence capture assay design from a gene list suited for clinicians or basic researchers, who are not experts in mining genomic data. The tool has two components. One of the components is named as P2G (from Phenotype to Genes). Given terms of disease name or phenotype, such as hearing loss, deafness, the program will generate a list of known genes related to the input biological terms. The known gene information regarding a phenotype term is based on both OMIM database and the Genetic Association Database. The other component is named G2L (from Genes to Locations). Given a list of official gene symbols (can be automatically generated from the P2G component), the program will generate a bed file with genomic location according to Ref_Gene Annotation from UCSC database. This component also provides flexibility in selection of different regulatory regions, such as UTR, up/down-stream regions.

wANNOVAR: annotating genetic variants for personal genomes via the Web. *X. Chang[1], K. Wang[1,2].* 1) Zilkha Neurogenetic Institute, Keck School of Medicine, University of Southern California, Los Angeles, USA; 2) Department of Psychiatry and Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, USA.

High-throughput DNA sequencing platforms have now become widely available. As a result, personal genomes are increasingly being sequenced in research and clinical settings. However, the resulting massive amounts of variants data pose significant challenges to average biologists and clinicians without bioinformatics skills. To fill the urgent demands, we built a web server called wANNOVAR to address the critical needs for functional annotation of genetic variants from personal genomes. The server was developed based on the ANNOVAR (ANNOtate VARiation) software. It provides simple and intuitive interface to help users determine the functional significance of variants without the burden of typing command lines and configuring database files. wANNOVAR has two major features including “annotating variants” and “filtering variants”. For the submitted variants list, wANNOVAR will first annotate single nucleotide variants (SNVs) and insertions/deletions for their effects on genes, report their conservation levels (such as PhyloP and GERP++ scores), calculate their predicted functional importance scores (such as SIFT and PolyPhen scores), retrieve allele frequencies in public databases (such as the 1000 Genomes Project and NHLBI-ESP 5400 exomes). Optionally, a “variants reduction” protocol will be applied on the variants list to identify a subset of potentially deleterious variants/genes. We provide several default pipelines for different disease models such as “rare recessive Mendelian disease” and “rare dominant Mendelian disease”, but users can also use “advanced options” to specify custom filtering strategy. We next illustrated the utility and functionality of wANNOVAR on an exome sequencing and a whole-genome sequencing data set on the “Example” page. We conclude that wANNOVAR will help biologists and clinicians take advantage of personal genome information to expedite scientific discoveries. The wANNOVAR server is available at http://wannovar.usc.edu, and will be continuously updated to reflect the latest annotation information.

3533F

Simultaneous analysis of common and rare variants in complex traits. *G. Chen[1], A. Yuan[2], A. Bentley[1], D. Shriner[1], A. Adeyemo[1], C. Rotimi[1].* 1) NHGRI/NIH, National Institutes of Health, Bethesda, MD; 2) National Human Genome Center, Howard University, Washington DC, USA.

Genome-wide association studies (GWAS) have facilitated the detection of common genetic variants underlying common traits and diseases. However, significant proportions of the underlying genetic variance for the traits investigated to date remain unexplained. Also, the predictive power of common variants identified by GWAS has not been encouraging. Given these observations along with the fact that the effects of rare variants are often unaccounted for by GWAS and the increasing availability of sequence data, we developed a new method that enables the simultaneous analysis of the association between individual common and rare variants while controlling for the potential confounding effects of covariates. We refer to this method as SCARVAsnp. SCARVAsnp is implemented in four stages: first, all common variants in a pre-specified region (e.g. gene) are evaluated individually; second, a union procedure is used to combine all rare variants (RVs) in the index region and the ratio of the log likelihood with one RV excluded to the log likelihood of a model with all the collapsed RVs is calculated. On the basis of simulation studies, a likelihood ratio ≥ 1.3 is considered statistically significant; third, the direction of the association of the removed RV is determined by evaluating the change in λ values with the inclusion and exclusion of that RV. Lastly, significant common and rare SNPs along with covariates are included in a final regression model to evaluate the association between the index trait and variants in a pre-specified genomic region. We use simulated and real data sets to show that the method is simple to use, computationally efficient and that it can accurately identify both common and rare risk variants. This method overcomes several limitations of existing methods; for example, SCARVAsnp limits loss of statistical power by not including rare variants that are not associated with the trait of interest in the final model. The combined analysis of rare and common variants may be important in explaining the missing heritability from GWAS analyses. Also, SCARVAsnp takes into consideration the direction of association by effectively modelling positively and negatively rare associated variants.

On Combining Reference Data to Improve Imputation Accuracy. *J. Chen[1], J.G. Zhang[1], J. Li[1], Y.F. Pei[1,2], H.W. Deng[1,2].* 1) Center for Bioinformatics and Genomics, Department of Biostatistics and Bioinformatics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA 70112, USA; 2) Center of System Biomedical Sciences, University of Shanghai for Science and Technology, Shanghai 200093, P. R. China.

Background: Genotype imputation is an important tool in human genetics studies, which uses reference sets with known genotypes and prior knowledge on linkage disequilibrium and recombination rates to infer un-typed alleles for human genetic variations at a low cost. The reference sets used by current imputation approaches are based on HapMap data, and/or based on recently available next-generation sequencing (NGS) data such as data generated by 1000 Genomes Project. However, with different coverage and call rates for different NGS data sets, how to integrate multiple NGS data sets along with previously available reference data as references in imputation is not an easy task and has not been systematically investigated. Results: In this study, we perform a comprehensive assessment of three strategies on using NGS data and previously available reference data in genotype imputation for both simulated data and empirical data, in order to obtain guidelines for optimal reference set construction. Briefly, we consider 3 strategies: strategy 1 uses one NGS data as a reference; strategy 2 imputes samples by using individual available data sets as independent references and then combines the imputed samples with samples based on high accuracy reference selected when overlapping occurs; and strategy 3 combines multiple available data sets as a single reference after imputing each other. Our results show that strategy 2 and strategy 3 has higher imputation accuracy than strategy 1, and strategy 2 is the best strategy across all the conditions that we have investigated. Especially, strategy 2 also could acquire the better accuracy of imputation for rare variant than the other two strategies. The one reason is more reference information used for both strategy 2 and strategy 3. Another reason is that strategy 2 avoided the noise brought about because of repeated imputation (strategy 3), and retain more reliable genotype information from high accuracy reference. Conclusion: We illustrate and compare different imputation strategies to integrate multiple references. Our study is helpful in guiding application of imputation methods in next generation association analyses.

Improved Filtering and Annotation of Next-Generation Sequencing Variants in Clinical Gene Panels. *H.K. Chong, S. Mexal, A.M. Elliott, H.M. Lu, H. Lu, X. Li.* Ambry Genetics, Aliso Viejo, CA.

Gene panels offer a cost-effective and targeted approach to investigating complex inherited disorders, allowing clinicians to test multiple genes in parallel by target capture followed by Next-Generation sequencing. Comprehensive gene panels can often offer a definitive molecular diagnosis and aid in making a differential diagnosis. A major limitation to gene panel testing is that data interpretation becomes more challenging as more genes are tested and hence an increasing number of variants detected. To reduce the number of variant calls for clinical interpretation, we evaluated the ability of a new in-house custom pipeline in filtering and annotating variant calls from two comprehensive diagnostic gene panels offered on our test menu; the Pan Cardio Panel, an inherited cardiovascular disease panel testing 79 genes (1573 number of amplicons), and the CancerNext panel, a 22 gene panel (477 number of amplicons) test spanning genes implicated in hereditary breast, ovarian, and colon cancers. The pipeline filters out variants based upon population frequency from several databases and annotates alterations using disease mutation databases and evolutionary conservation. The pipeline ultimately classifies variants into several different categories, including common polymorphisms, mutations, and unclassified variants that require further investigation. In a pilot study of eight wild-type and five previously characterized dilated cardiomyopathy (DCM) samples, the Pan Cardio Panel generated an average of 200 variants prior to filtering and an average of 28 variants after the alterations were run through the pipeline. Across wild-type and previously characterized cancer samples (8 total), the CancerNext Panel generated an average of 57 variants prior to filtering and an average of 16 variants after the alterations were generated through the pipeline. Among the variants left in both the Pan Cardio and CancerNext samples, the pipeline successfully identified all the previously characterized mutations in the DCM and cancer patients as either deleterious based upon HGMD entries or evolutionary conservation. These data illustrate that our custom Next-Gen panel pipeline can successfully filter out non-causative variations resulting in a decrease in the number of variants that need to be verified by side assays, saving significant time and money.

Laumen[1,2,3].* 1) EKFZ, Chair for Nutritional Medicine, Technical University Muenchen, Freising-Weihenstephan, Germany; 2) ZIEL, Research Center for Nutrition and Food Sciences, Technical University Muenchen, Freising-Weihenstephan, Germany; 3) Clinical Cooperation Group Nutrigenomics and Type 2 Diabetes, Technical University Muenchen, Freising-Weihenstephan, and Helmholtz Zentrum Muenchen, Muenchen-Neuherberg, Germany; 4) Hebrew SeniorLife Institute for Aging Research and Harvard Medical School, Boston, MA, USA; 5) Research Unit of Molecular Epidemiology, Helmholtz Zentrum Muenchen, Muenchen-Neuherberg, Germany; 6) Institute of Medicine, University of Bergen, N-5021 Bergen, Norway; 7) Hormone Laboratory, Haukeland University Hospital, N-5021 Bergen, Norway; 8) Research Unit Protein Science, Helmholtz Zentrum München, Muenchen-Neuherberg, Germany; 9) Hanover Unified Biobank, Hanover Medical School, Hannover, Germany; 10) EKFZ, Chair for Molecular Nutritional Medicine, Technical University Muenchen, Freising-Weihenstephan, Germany; 11) Genomatix Software GmbH, Muenchen, Germany.

Genome-wide association studies (GWASs) have revealed numerous risk loci associated with a diverse range of diseases. However, identifying the disease-causing variants remains a major challenge in medical genetics. We used phylogenetic module complexity analysis (PMCA), a novel bioinformatic approach for delineating cis-regulatory variants hidden in GWAS loci. PMCA combines sequence conservation with functional conservation by considering the organisation of transcription factor binding sites in complex cis-regulatory modules. We have cross-validated our predictions for type 2 diabetes (T2D) susceptibility loci. For the PPARG risk locus we found genotype-dependent regulation of endogenous PPARγ2 mRNA expression. We identified the homeodomain transcription factor PRRX1, binding to the PMCA identified variant rs4684847, as an isoform-specific transcriptional repressor of PPARγ2 mRNA expression in adipose patient samples of risk allele carriers. Though the PPARγ2 Pro12Ala variant of the T2D susceptibility locus was reproducibly associated with improved insulin sensitivity, the Ala12 allele results in reduced PPARγ2 protein transcriptional activity. This contradictory finding might be explained by the identified cis-regulatory variant rs4684847. Thus, PMCA may contribute to translate genetic association signals to the mechanism underlying the biology of complex diseases.

3537F

dbGENO: A web based complex disease curation pipeline. *D. Cook, J. Dagle, K. Ryckman, J. Murray.* University of Iowa, Iowa City, IA.

Despite improving genetic technologies, there remain significant challenges for investigators trying to understand the genetic etiology of complex diseases. Disease/trait specific databases aim to further our understanding by indexing publications by genetic loci found to be associated (forming a comprehensive list of known genetic associations). Investigators and clinicians can browse and retrieve data for incorporation in the design of a study, for replication purposes, to further understand a complex disease, or for other data related purposes. While such databases have wide applicability, they are time consuming and challenging to assemble and deploy. We have developed a web-based pipeline of tools for the curation of disease/trait specific databases that aims to improve collaboration and efficiency of the development process. Additionally, our tool works to reduce error and increase the thoroughness of literature searches. Finally, our tool works to automate the process of finding and identifying new publications which may be candidates for inclusion. The pipeline begins with a utility for importing publications, by performing PubMed searches directly or via a custom list of publications relevant to a disease or trait of interest. From these imports, a variety of features are extracted such as SNPs, genes, diseases, and mutations. These extracted features are used as a basis for indexing and later searching and sub setting data for retrieval. Following feature extraction, users examine these features to ensure they are correct and appropriate and to add additional publication details if necessary. Finally, a web-based interface allows anyone to browse and export information from the database. The pipeline is written in PHP and uses MySQL for data storage. NCBI's EFetch tools are used heavily for data retrieval of publication, SNP, and gene records. A combination of regular expressions and rule-based algorithms are used to extract and filter features for indexing. We are performing diagnostics and continually improving feature extraction algorithms by testing against manual curation. Initially, we plan to assemble a database on the basis of the complications of prematurity. As our understanding of the human genome continues to grow, the need for database tools accessible to clinicians and researchers alike grows concomitantly. dbGENO aims to fulfill this need.

EVA: Exome Variation Analyzer, a tool for filtering strategies in medical genomics. *S. Coutant[1,2], C. Cabot[2], A. Lefebvre[2], M. Léonard[2], E. Prieur-Gaston[2], D. Campion[1], T. Lecroq[2], T. Frebourg[1,3], H. Dauchel[2].* 1) Inserm U1079, Institute for Research and Innovation in Biomedicine, (IRIB), University of Rouen, Normandy, France; 2) LITIS EA 4108 Computer science, Information processing and systems laboratory, IRIB, University of Rouen, Normandy, France; 3) Department of Genetics, University Hospital, Rouen, Normandy, France.

Exome-scale sequencing is a revolution in medical genetics, impacting both fundamental research and diagnostic. However, the challenge remains in efficient filtering strategies to find causing disease variant(s) among ~20,000 per individual exome. For this purpose, analytical procedures with various filtering strategies are required. With this aim, in parternship with and for medical geneticists, we developed EVA (Exome Variation Analyzer) a user-friendly web interfaced sofware dedicated to filtering strategies for medical projects. EVA allows managing data through different modules. Among them, the first is an offline Variation Integration module. It takes as input standard Variant Calling Format files and annotates the variations thanks to ANNOVAR and the Variation Effect Predictor Ensembl API. Annotated variations are then stored in a database. On the web interface, the Variation Statistics module displays basic count of SNV and indel for all the variations corresponding to a project or a selection of individuals, chromosomes, regions or genes. The filtering module proposes to combine multiple filters to drastically narrow down the variations number. It compares data to international catalogues of variations (dbSNP, 1000 genomes, ESP Cohort) and sorts out variations depending on their: a) functional categories (synonymous, missense, nonsense, frameshift...) b) genic region (UTR, exons, introns, splice sites) and c) quality. Finally, the major strength of EVA is the implementation of inheritance filters that considers intersection or differential exome strategies: a) recurrence strategy for dominant or recessive non-familial cases; b) intra-familial strategy with filters for homozygous or heterozygous composite; c) differential exomes strategy for de novo sporadic cases (trio). EVA offers export files and cross-links to external relevant databases and softwares for further inspection of the small subset of sorted candidate variations and genes. EVA is developed to be a user-friendly, versatile, and efficient-filtering assisting software. Thereby, it provides a response to new needs at the expanding era of medical genomics for both fundamental research and clinical diagnostics. EVA will be soon available for free downloads.

Random Design Tool for Additional MIDs for Roche Sequencing Platforms. *S.H. Eck, B. Grumbt, I. Nieberle, C. Marschall, K. Hirv, H-G. Klein.* Center for Human Genetics and Laboratory Medicine, Dr. Klein, Dr. Rost and Colleagues, Martinsried, Germany.

In order to achieve a higher grade of multiplexing we implemented a Perl tool to design additional MIDs for the Roche sequencing platforms. MIDs are designed following a simple two step procedure. In the first step randomized sequences of the desired length are generated. In the second step the sequences are checked against a set of rules to ensure compatibility with the Roche sequencing systems in general and existing barcodes in particular. These rules include a minimum number of mismatches to existing MIDs (default 4), defined number of flows to sequence (existing barcodes range from 4–6 flows, default 5) and limited homopolymer length within the barcode (default 1 = no subsequent identical nucleotides). Existing MIDs are loaded for comparison, if a new designed MID passes the rule check it is automatically added to the list of known MIDs to enable comparison with further designed MIDs. We validated designed primers by sequencing 96 barcoded samples (8 amplicons of mean length 570) on a quarter of a Roche FLX slide. 48 MIDs were taken from the Roche extended MID set, 48 MIDs were random designed by the tool. In total we generated 133,780 passed filter reads on this part of the slide. Mean number of reads per MID were 1237 (max 1826, min 784) and 1122 (max 1644, min 15) for the random designed and Roche extended MID set, respectively. Standard deviation was 299 and 336 for the two sets. We also included a negative control which counted 12 reads. In total only 1492 reads (~1.1%) could not be assigned to any MID. The tool is flexible and can be used to design arbitrary numbers of additional MIDs for the Roche platforms. MID parameters like length, minimum differences to existing MIDs and target flow count can be defined by the user depending on the particular experimental reads. The tool is designed to generate Roche compatible MIDs but can be easily extended to generate barcodes for every sequencing platform.

3540W

A functional gene-based test for association in Tourette's syndrome and obsessive-compulsive disorder. *P. Evans, TSA Consortium for Genetics, The International OCD Foundation Genetics Collaborative.* Dept of Med., Univ Chicago, Chicago, IL.

Tourette's syndrome (TS) is a developmental disorder characterized by motor and phonic tics that is present in 0.03–0.08 of the population, though more prevalent in males than females. Family members of probands with TS are significantly more likely than members of the general population to be diagnosed with obsessive compulsive disorder (OCD), and vice versa. Twin and family studies support a high heritability for both disorders, yet very little is known about the genetics of either disorder. In order to better understand the underlying genetics of TS and OCD we used a gene-based method to look for genes that may be playing a role in the genetic epidemiology of these disorders. One of the disadvantages to traditional genome-wide association tests is the large penalty paid for multiple testing correction for the one million plus SNPs that are commonly interrogated in these studies. This makes detection of the functional units contributing to disease difficult, as effect sizes are expected to be small for most loci contributing to complex. One alternative to this type of test is to use genes rather than SNPs as the unit of analysis, greatly reducing the number of tests performed. We have chosen to use this method by combining SNPs for a given gene based on function. This is accomplished by annotating each gene with nonsynonymous and nonsense mutations within a given gene, as well as any known cis or trans eQTLs for a given gene. The p-values from a traditional genome-wide association analysis are combined for all SNPs annotated to a given gene using an application of Fisher's method. Gene-based p-values are then obtained by permuting the data and seeing how often a similar score is achieved using the same number of minor allele frequency matched SNPs. We performed a function-based genome-wide association study on results from two studies on TS and OCD using eQTL data from lymphoblastoid cell lines. For TS, the gene CCDC102B was genome-wide significant given the total number of genes examined (p=0.00004). For OCD, the genes FZD5 and KCTD17 were genome-wide significant with p-values of 0.00009 and 0.00002 respectively. These results may provide some insight into the underlying mechanisms contributing to these disorders as no SNPs achieved genome-wide significance in the traditional SNP-based analysis. We are now conducting similar analysis using eQTLs identified in transcriptome studies on brain, which will be presented at the meeting.

Statistical considerations for decisions on applying globin RNA reduction in blood samples for gene expression experiments. *S. Feng[1], J. Dungan[2], S. Gregory[2], C. Haynes[2], W. Kraus[2].* 1) Biostatistics & Bioinformatics, Duke Univ, Durham, NC; 2) Center for Human Genetics, Duke Uniersity, Durham, NC.

The technique of globin RNA reduction (GR) aims to remove unwanted globin mRNA from whole blood total RNA. Some studies have suggested that GR can improve the quality of gene expression data. However, the evidences supporting those claims have not been absolutely convincing. In this study, we wished to address two questions: (1) the significant benefit (increment in data quality) gained by applying GR; and more important, (2) if a benefit does exist, how useful it is, i.e., how much additional statistical power will be gained for the complicated multi-step microarray data analysis? We conducted a pilot experiment to measure the differences and similarities between the pre- and post- GR gene expression profiles, as well as the standard summary statistics. A straightforward statistical simulation study was also designed to investigate the impact of GR on the statistical powers under various scenarios. The results confirmed others' observations, i.e., if the technical procedure is successfully performed, the overall sample variations are likely to be reduced. However, the overall benefit is clouded by significant sample and RNA loss (~16%) due to the additional experimental steps; the inconsistent results among samples and the new and untraceable variations generated by the procedure. The simulation study also suggested that improvements in data quality do improve statistical power, but is only relevant under certain conditions. Based on those observations, we conclude that the overall benefits of applying GR are much less certain than expected. Thus the decision of whether to apply GR should be specific to different experiment designs and conditions, as revealed by the simulation study.

Biofilter 2.0 for Advanced Predictive Model Development, Testing, and Hypothesis Generation using Expert Domain Knowledge Resources. *A. Frase[1], J. Wallace[1], C. Moore[1,2], N. Katiyar[1], S.A. Pendergrass[1], M.D. Ritchie[1].* 1) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA; 2) Center for Human Genetics Research, Vanderbilt University.

Leveraging the incredible diversity and wealth of biological information collected from the genome, transcriptome, proteome, and other -omic sources, is key for advanced and directed predictive model for the dissection of complex disease. We developed Biofilter for using biological information from public databases to direct complex risk model generation. The first application of Biofilter (Bush, et al., *Pacific Symposium on Biocomputing*, 2009) used 7 sources of domain knowledge: the National Center for Biotechnology (NCBI) dbSNP and gene Entrez database information, Kyoto Encyclopedia of Genes and Genomes (KEGG), Reactome, Gene Ontology (GO), Protein families database (Pfam), and NetPath - signal transduction pathways. Originally Biofilter was for use with gene or single-nucleotide polymorphism (SNP) based data, such as filtering genome wide association (GWA) genotypic data for biologically directed model generation. For example, through directing the search space using Biofilter with GWA data, pairwise SNP-SNP interaction models were developed, replicating across datasets (Turner et al.*PLoS One*, 2010). We expanded and updated Biofilter to version 2.0 in several important ways. First, we migrated the domain knowledge used by Biofilter into a separate database called the Library of Knowledge Integration (LOKI) and incorporated 4 additional data sources: Molecular INTeraction database (MINT), Biological General Repository for Interaction Datasets (BioGrid), Pharmacogenomics Knowledge Base (PharmGKB), Open Regulatory Annotation (ORegAnno), and the database of Evolutionary Conserved Regions (ECRBase). The independence of LOKI from Biofilter 2.0 facilitates easy update of the data sources contained within LOKI, reflecting the update of public LOKI data sources. Biofilter 2.0 now accepts a greater range of data types, including SNP, rare variant, copy-number variation (CNV), and evolutionary conserved region (ECR) data. Future directions include development of Biofilter for use with RNA-Seq based data. Biofilter 2.0 allows more user customization of filtering and annotation, and easier use of custom data sources, providing a flexible framework for the integration and user-driven combination of multiple data types, providing a way to use the ever-expanding expert biological knowledge that exists to direct complex predictive models for elucidating the etiology of complex phenotypic outcomes. The software is available for use at http://ritchielab.psu.edu/.

Iterated Correction of a Diploid Parental Reference Sequence and its use during Exome Alignments for Disease Gene Discovery. *T.R. Gall[1], D.R. Adams[1,2,3], C.F. Boerkoel[1], K. Fuentes-Fajardo[1], W.A. Gahl[1,2,3], P. Cherukuri[1], M. Sincan[1], C. Toro[1], C.J. Tifft[1,3], T.C. Markello[1,2,3].* 1) NIH Undiagnosed Diseases Program, NIH, Bethesda, MD; 2) Medical Genetics Branch, NHGRI, NIH; 3) Office of the Clinical Director, NHGRI, NIH.

A major remaining problem in using next-generation sequencing is the substantial number of mismapped and misaligned sequences that lead to false-positive and false-negative errors when using alignment to a reference genome sequence as the method to reconstruct a patient's genome from short read sequences. This is due to the fact that the degree of difference between any one individual and the reference genome is no less than the difference between any one gene and an evolutionary homologue resulting from duplication and divergence that occurred within a family of genes. This is equivalent to low complexity since these closely related sequences require a longer read length to uniquely identify different locations, when compared to what is expected by a random sequence data. One way to address this is to use information, obtained independently and not from the short-read sequencing data, to improve the reference genome. The purpose of this modification is to more closely match the reference to the exome sequence being reconstructed. SNP chip data, haplotype data from the inheritance state of a nuclear family, and parental sequence data are all readily available sources of independent information that can be applied to resolve low-complexity region mapping and alignment ambiguities. We have established and tested a bioinformatic pipeline that takes SNP and parental sequence data from trios and finds the most likely alleles for the 4 independent haplotypes, generates a set of alignments, and then iterates these results for 3 cycles to improve the reference sequence used to generate the final alignment output for the patient. In addition simultaneous multiple sequence genotype calling, together with inheritance state-aware genotype calling, is used to produce the final variant list. This pipeline has produced measurable improvements from a simulated data set and for two trio data sets from a quartet sequenced in the Undiagnosed Diseases Program.

Kinship index variations among populations and thresholds for familial searching. *J. Ge, B. Budowle.* Dept Forensics and Investigative Genetics, Univ of North Texas Health Science Center, Fort Worth, TX.

Current familial searching strategies are developed primarily based on autosomal STR loci, since most of the offender profiles in the forensic DNA databases do not contain Y-STR or mitochondrial DNA data. There are generally two familial searching methods, Identity-by-State (IBS) based methods or kinship index (KI) based methods. The KI based method is an analytically superior method because the allele frequency information is considered as opposed to solely allele counting. However, multiple KIs should be calculated if the unknown forensic profile may be attributed to multiple possible relevant populations. An important practical issue is the KI threshold to select for limiting the list of candidates from a search. There are generally three strategies of setting the KI threshold for familial searching: (1) SWGDAM recommendation 6; (2) minimum KI $\geq$ KI threshold; and (3) maximum KI $\leq$ KI threshold. These strategies were evaluated and compared by using both simulation data and empirical data. The minimum KI will tend to be closer to the KI appropriate for the population of which the forensic profile belongs. The minimum KI $\geq$ KI threshold performs better than the maximum KI $\leq$ KI threshold. The SWGDAM strategy may be too stringent for familial searching with large databases (e.g., 1 million or more profiles), because its KI thresholds depend on the database size and the KI thresholds of large databases have a higher probability to exclude true relatives than smaller databases. Minimum KI $\geq$ KI threshold strategy is a better option, as it provides the flexibility to adjust the KI threshold according to a predetermined number of candidates or false positive/negative rates. Joint use of both IBS and KI does not significantly reduce the chance of including true relatives in a candidate list, but does provide a higher efficiency of familial searching.

Transparent, accessible, and robust functional analysis of SNPs. *B. Giardine, R. Burhans, C. Riemer, A. Ratan, R. Harris, G. Von Kuster, R.C. Hardison, Y. Zhang, W. Miller, Galaxy Development Team.* Center for Comparative Genomics and Bioinformatics, Pennsylvania State Univ, University Park, PA.

Human genetic variants, both common polymorphisms and rare mutations, are being discovered at an unprecedented rate. Genetic studies find associations between some of these variants and certain phenotypes, both simple and complex. However, interpretation of each variant, and especially finding a direct connection to a function in the phenotype of interest, is still difficult. A large number of computational tools have been developed to aid in SNP interpretation. Many of these are deployed within a powerful computational framework, called Galaxy, that facilitates analysis by any user and provides a transparent setting for sharing both results and the methods used to obtain them. We also provide resources, derived from ENCODE data, that are helpful in predicting functions of variants in non-coding regions.

Galaxy is a free computational service that allows users to run a wide variety of tools on their data. We have added tools to Galaxy for working with SNP data. These tools can be used for tasks such as finding phenotype-associated SNPs in a single genome, and comparing SNPs from case-control studies. To illustrate the power of these tools for SNP interpretation, suppose we begin with a well-known example of a SNP responsible (at least in part) for light skin color in humans of European ancestry (SLC24A5 A111T). This was originally mapped by genetic association in a case-control study {PMID 16357253}. We want to determine how many other variants, including rare and non-coding variants, have similar allele and haplotype distributions to this one. How close can we come to finding a strongly phenotype-associated allele without doing a full genome-wide association study? Using the genotype results from low-coverage 1000 Genomes data, we found approximately 4,000 variants that are fixed in Caucasians of European ancestry and for which the other allele is at very high frequency in Yorubans from West Africa. A set of over 2,500 showed clustering, consistent with regions of diminished variation indicative of a selective sweep. Of these, ~25 were in coding regions, including SLC24A5 A111T. Most of the clustered SNPs were non-coding, and many fell in DNA segments associated with gene regulation via ENCODE data (DNase hypersensitive sites and transcription-factor occupied sites). These are additional candidates for regions that could be involved in skin color. URL: usegalaxy.org.

ParseCNV Integrative CNV Association Software with Quality Tracking. *J. Glessner[1,2], H. Hakonarson[1,2].* 1) The Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA.

A number of copy number variation (CNV) calling algorithms exist but comprehensive software tools for CNV association studies are lacking. We describe ParseCNV, software which takes CNV calls generated by any algorithm based on SNP array, array CGH, or sequencing and creates probe based statistics for CNV occurrence in cases and controls or family based studies with de novo and inheritance events. Case enriched significant probes are then separated from control enriched significant probes. Probe-based Fisher's exact test statistic output is then merged into CNVRs based on proximity and similar significance of neighboring probes. CNVRs are defined in a dynamic manner to allow complex CNV overlap and narrow association. The entire genome-wide dataset can be run at once without a static CNVR definition or repetitive SNP based statistics. Using this approach, we avoid failure to converge and non-monotonic curve fitting weaknesses of CNVtools (likelihood ratio trend test) and CNVassoc (latent class model). Plink (permutation-based test) only provides combined CNV state probe based statistics, not state specific CNVRs which are captured by ParseCNV statistics to increase power. In addition to p-value and odds ratio for each CNVR for all combined CNV state definitions, contributing samples, CN states, genomic features, and average number of probes of CNV calls are provided for confidence and biological interpretation. Contributing calls to each association, UCSC custom tracks, genotype and intensity values, and Plink .ped files are created for additional association review and characterization. In addition to up-front quality filtering, confidence scoring of significantly associated loci is done automatically based on genomic context, significance range, CNV overlap profile, number of probes underlying CNVs, external controls and inflated samples. 785 autism cases and 1,110 controls were assessed with 561,308 probes and resulted in 7 deletion and 12 duplication significantly associated CNVRs to demonstrate utility of the software. ParseCNV use has resulted in PCR validation rate of >80%, an often problematic stage due to inadequate significant association review. ParseCNV is freely available at http://parsecnv.sourceforge.net.

Web-based Interactive Visual Analysis of NGS Data using Galaxy. *J. Goecks[1], A. Nekrutenko[2], J. Taylor[1], The Galaxy Team.* 1) Biology and Math & Computer Science, Emory University, Atlanta, GA; 2) Center for Comparative Genomics and Bioinformatics, Penn State University.

Visualization is an essential scientific tool, making it possible to view large amounts of data simultaneously, identify patterns and outliers within data, and communicate findings to others. Using the Galaxy platform (http://galaxyproject.org), we have developed a Web-based visualization framework that addresses two challenges in visualizing next-generation sequencing (NGS) data: usability and integrated visual analysis. The Galaxy Visualization Framework (GVF) includes three visualizations: (1) Trackster, a genome browser; (2) Circster, a Circos-style genome-wide visualization; and (3) ParamaMonster, a visualization for exploring different parameter settings of an analysis tool. All visualization functionality is available using only a Web browser; no downloads/plugins are required. Composing visualizations is done using a graphical user interface, and even complex visualizations with many datasets can be created without any programming experience. Once created, visualizations can be shared with colleagues or published on the Web and included in publications' online supplementary materials. All shared and published visualizations are fully functional and can be accessed via a simple URL. By making it easy to create and share Web-based genomic visualizations, GVF makes genomic visualization more accessible and useful to investigators. Together, Trackster and ParamaMonster form a visual analysis environment that couples visualization and NGS analysis tools to enable interactive, user-friendly experimentation on NGS data. Trackster provides a fully-featured, Web-based genome browser that can be used to visualize most major genomic dataset formats. Any compatible Galaxy tool can be used in Trackster to analyze and visualize data in real time. Using Trackster, a tool's parameters can be set, the tool run, and the tool output visualized in a single, integrated interface. ParamaMonster enables visual exploration of a tool's complete parameter space, making it simple to visually compare outputs from many different combinations of parameter settings. We have used GVF to investigate interactions between structural variation and gene expression in pancreatic cancer. Trackster and ParamaMonster have been used for interactive RNA-seq analysis to find good parameter settings for assembling transcripts and to choose filters that remove assembly artifacts. Circster visualizations reveal regions where structural variation impacts gene and isoform expression.

Computational and informational challenges in providing clinically-relevant genome interpretation from high-throughput sequencing data. *R.K. Hart, Locus Development, Inc.* Locus Development, Inc., San Francisco, CA.

High-throughput genome and exome sequencing herald new opportunities to understand the genetic etiology of clinically-relevant conditions on an unprecedented scale. As the acquisition of sequencing data becomes cheaper and more routine, there is an increasing awareness that significant gaps remain in our ability to turn these data into meaningful clinical interpretations.

Locus Development provides sequencing and interpretation services to physicians from patient blood samples. Our value is based on three key assets: a high-quality database of associations of variants and conditions, custom sequencing assays, and computational analysis. Our panel is comprised of over 150 conditions in 250 genes and 10000 variants, curated by in-house geneticists and subjected to careful selection criteria. We use custom sequencing assays to target only these regions of interest and minimize costs. The entire process is substantially automated; we are currently targeting two weeks from the arrival of blood to the delivery of a clinical report.

In this presentation, we will describe the computational tools and pipeline that support our curation and interpretation efforts. We have integrated a complex assortment of external and in-house tools to provide a best-of-breed system that automates the analysis of reads, variant and haplotype calling, VUS analysis, clinical condition interpretation, and report generation. We will also discuss the suitability of publicly available data and tools.

Capture-Recapture Models for Evaluation of Algorithms Estimating Functionality of Missense Mutations. *S. Hicks[1], S.E. Plon[2], M. Kimmel[1].* 1) Department of Statistics, Rice University, Houston, TX; 2) Departments of Pediatrics and Human Molecular Genetics, Baylor College of Medicine, Houston, TX.

Whole genome and whole exome sequencing projects yield thousands of missense mutations with unknown effects on protein structure and function. Direct estimation of the sensitivity and specificity of bioinformatic algorithms such as SIFT or PolyPhen-2 which predict the impact of missense mutations on protein function requires a “gold standard” or a set of mutations with known functionality. In the absence of a “gold standard”, indirect statistical methods are needed to estimate the accuracy of these algorithms. Informative predictions depend on the algorithm and sequence alignment and in general the algorithms disagree as to which mutations are predicted to be deleterious or neutral. To investigate the level of agreement, we define disjoint categories of mutations depending on which algorithms predict which mutations to be deleterious or neutral. We develop two statistical models called Bernoulli Mixture (BM) and Augmented Bernoulli Mixture (ABM) based on the capture-recapture technique which use these disjoint categories. Application of these models allows to jointly estimate the sensitivities and specificities of each algorithm considered without the use of a gold standard and to estimate the proportion of deleterious mutations in a given set of mutations. When considering n algorithms, there are 2^n disjoint categories employed by the ABM model which includes $2n + 3$ parameters and the BM model is a special case of the ABM model which includes $2n + 1$ parameters. To estimate the parameters of the models, we use the Expectation-Maximization (EM) algorithm. We test the models using simulated and data-based predictions when a gold standard is available (Hicks et al. 2011). We perform simulation studies to evaluate convergence of the EM algorithm and to estimate bias and mean squared error (MSE) estimates which are reported as a function of sample size. Confidence intervals and confidence regions of the sensitivity and specificity estimates for each algorithm are reported. As an application, we estimate the sensitivity and specificity of the algorithms using mutations obtained from whole exome sequencing. We used 4 exome datasets sequenced at the Human Genome Sequencing Center at Baylor College of Medicine to identify cancer susceptibility genes for acute lymphocytic leukemia and lymphoma in children. Supported by CPRIT grant R83940, NCI grant CA155767 and NCI T32 training grant CA096520.

The Unified Sample Identifier - A universal sample coding system to manage large numbers of biological samples. *P. Hoffmann[1,2], J.E. Bolz[2], A. Reinscheidt[2], T.F. Wienker[4,5], S. Cichon[1,2,3], S. Herms[2].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 3) Institute of Neuroscience and Medicine (INM-1), Structural and Functional Organization of the Brain, Genomic Imaging, Research Center Juelich, Juelich, Germany; 4) Institute of Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany; 5) Gene Mapping Center, Max-Delbrueck-Center, Berlin, Germany.

Since the introduction of high-throughput DNA genotyping and sequencing technologies, the number of DNA samples analyzed for genetically complex phenotypes has tremendously increased. Furthermore it has become very important to combine samples from different sites to further increase statistical power to detect small genetic effects. This has led to serious challenges concerning the individual sample coding. Often encountered problems which hamper the unambiguous identification of individual samples include samples having the same identifier by chance as well as spelling errors in the sample identifier. To address these problems we have developed a universal sample coding system the Unified Sample Identifier (USI) over the last years. The USI is based on the ISO certified IBAN system which is used in the international banking system since more than 30 years. The USI includes a checksum making it very resistant to spelling errors and data about project, study, sample type and aliquot, but does not include any information on the affection status, diagnosis, gender and ethnicity. Here we present data on the implementation of the USI in our database system, the use of automatically generated barcodes and the evaluation of the checksum system. We especially analyzed the probable risk of collisions - different lab codes sharing the same check sum - in the normal lab context. We checked for random one letter changes first and focused on common human letter recognition issues in a second analysis. Based on these results we are further optimizing the algorithms for automatic correction of coding errors.

3551F

Systematic Evaluations of Sequencing Errors in Next-Generation Sequencing Data. *Y. Hu[1], Y. Liu[2], J. Ferguson[3], I. Silverman[4], B. Gregory[4], M. Reilly[3], M. Li[2].* 1) Department of Mathematics, University of Pennsylvania, Philadelphia, PA; 2) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA; 3) Cardiovascular Institute, University of Pennsylvania, Philadelphia, PA; 4) Department of Biology, University of Pennsylvania, Philadelphia, PA.

The emergence of next-generation sequencing technologies has revolutionized biological research. Next-generation sequencing involves the parallel sequencing of millions of DNA fragments simultaneously. Generally, these fragments are sequenced one base at a time in which the base is determined through fluorescent detection. Incorrect base calls can have a deleterious impact in sequence alignment, variant calling, and RNA editing detection. Although several studies have shown that base-call errors are not randomly distributed in sequenced reads, the error distributions and the impact of errors have not been thoroughly evaluated. By utilizing paired-end RNA sequencing data on three individuals sequenced using Illumina's HiSeq 2000 (4 RNA-Seq samples per individual), we performed a detailed characterization of sequencing errors. We generated 28M to 69M 101 bp paired-end data with 57% to 74% mapped uniquely to the reference genome. Our analysis was based on the observation that sequencing errors will leave a footprint in the base calls at overlapping sites of a mate pair. Specifically, a sequencing error was declared if one of the calls at a site agreed with the reference genome, but the other in the mate-pair read did not. Since the same individuals were sequenced multiple times, we can also identify systematic errors, which manifest as individual base-call errors from sequencing reads generated from independent RNA-Seq experiment occurring at the same genomic position. On average, each RNA-Seq sample had 29,287,719 sites covered by at least one base-call pair, among which 457,933 had errors, yielding an error rate of 0.43%. The most frequent error type is A->C (20%), followed by T->G (14%) and T->C (11%). We noticed that many of the error bases had low quality. If restricting analysis to bases with quality score ≥30, then only 10,698 error sites remained, yielding an error rate of 0.011%. Since variant detection and RNA editing analysis typically consider high-quality bases, we focused our systematic error detection on those bases only. On average, we identified 450 sites showing systematic errors with A->C (41%) being the most common, followed by T->G (13%) and A->G (12%). The error sites did not overlap with RNA editing sites identified using the same data (unpublished). Our analysis suggests that systematic sequencing errors are unlikely to confound with RNA editing sites if the editing sites were identified using a carefully designed pipeline.

EGprofile: a tool for rapid profiling analysis of epigenetic marks with ChIP-seq data. *W. Huang, L. li.* NIEHS, NIH, Research Triangle Park, NC.

Epigenetic environment or epigenome plays critical roles in chromatin remodeling and gene transcription regulation. Changes in epigenome (e.g., histone acetylation and methylation) can be detected by changes in enrichment level of a variety of epigenetic marks of histone modifications. Genome-wide survey of changes of epigenetic marks with high-throughput next-generation sequencing has now been widely used for gene regulation control studies, e.g., the ENCODE project. To facilitate such studies, we developed an efficient tool EGprofile that can be used to perform rapid profiling analysis of epigenetic marks using ChIP-seq data. Our tool can generate the empirical distribution of an epigenetic mark for a group of genomic regions/sites with a common genomic feature (e.g., TSS, TFBS), or a read coverage plot of any single genomic region. It can also automatically normalize data to enable cross-comparison of epigenetic mark profiles of different genomic regions/features. In addition, our tool can determine optimized region size for easy visualization when epigenetic marks having a single-mode distribution. Furthermore, EGprofile supports all popular read align file formats including SAM, BAM, MAQ, and UCSC BED files, and it is efficient with the typical running time less than 10 minutes for a single-lane Illumina ChIP-seq data. The core part of EGprofile was implemented with C++, and it will be available as an independent R package.

SOAPfuse detects gene fusions from paired-end RNA-Seq data with single base resolution. *W. Jia[1,2], K. Qiu[1], M. He[1], P. Song[1], Q. Zhou[1,2,3], F. Zhou[1,2,4], X. Hu[1], Y. Li[1], G. Guo[1,2].* 1) BGI-Shenzhen, Shenzhen, China; 2) BGI-Americas, Cambridge, USA; 3) School of Life Science and Technology, University of Electronic Science and Technology of China, Chengdu, China; 4) School of Bioscience and Bioengineering, South China University of Technology, Guangzhou, China.

We developed an open-source software tool, SOAPfuse, which detects gene fusions with single-base resolution from paired-end RNA sequencing (RNA-Seq) data. SOAPfuse applies several pioneering algorithms to overcome deficiencies of other widely-used fusion-detecting software tools. The most important component in our method for detecting fusions is SOAPfuse's local exhaustion algorithm, which is used for the highly efficient construction of a putative junction library. Moreover, by combining an iteratively trimming-realigning procedure with several strong filtrations, SOAPfuse achieves good detectability and high accuracy. We compared SOAPfuse with other tools, including chimerascan, deFuse, FusionHunter and TopHat-Fusion, based on both actual and simulated datasets. Actual data are from two published studies, which have several validated fusions. Compared with other tools, SOAPfuse consumed the least amount of computing resources (CPU-time and memory) to redetect the most validated fusions. We simulated 150 fusions, and generated RNA-Seq data at nine depth levels (5–200X) using MAQ. SOAPfuse showed the lowest false negative and false positive rates at all depths. We also applied SOAPfuse to RNA-Seq data from two bladder cancer cell lines, and identified 16 fusions, in which 15 (93%) are validated successfully. We reanalyzed this dataset using deFuse, which detected only nine out of the 15 validated fusions. We also found six pairs of recurrent fusions, some of which show strong signals, therefore inferring their structure variation sources. HADHB-RBKS is formed by genes from different strands, indicating an inversion. CIRH1A-TMCO7, PSMD8-SIPA1L3 and TIAM1-ATP5O are formed by intrachromosomal same-strand genes in their reversed genomic orientations, showing potential translocations. Interestingly, these recurrent fusions are not reported by previous studies on bladder cancer. To our knowledge, SOAPfuse is the only tool that uses a local exhaustion algorithm. SOAPfuse runs quickly and saves computing resources, making it suitable for analyzing vast samples in parallel. SOAPfuse not only identifies genuine fusions effectively at single-base resolution, but also provides a practical means to explore the potential structural variations that transcript to fusions. Our work offers a novel and efficient fusion detection tool for research on credible fusions. SOAPfuse is freely available from http://soap.genomics.org.cn/soapfuse.html.

Personalized genomics: personalized pathway mapping. *P. Jia[1], Z. Zhao[1,2].* 1) Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Department of Cancer Biology, Vanderbilt University, Nashville, TN.

The rapid application of next generation sequencing (NGS) in biomedical research revolutionized personalized medicine, but numerous challenges exist. Currently, the application of traditional pathway enrichment methods to next-generation sequencing data is prone to several potential biases including (1) genomic/genetic factors (e.g., the particular disease and gene length) and (2) environmental factors (e.g., personal life-style and frequency and dosage of exposure to mutagens). Therefore, new methods are urgently needed for these new data types, especially for individual-specific genome data. We proposed a novel method for the pathway analysis of NGS mutation data by explicitly taking into account the gene-wise mutation rate. We estimated the gene-wise mutation rate based on the individual-specific background mutation and the gene sequences. Taking the mutation rate as a weight for each gene, our method implements the weighted resampling strategy and builds the null distribution for each pathway while matching the gene-wise mutation patterns. The empirical P value obtained then provides an adjusted statistical evaluation. We demonstrated our method in a lung adenocarcinomas dataset and a glioblastoma dataset, and compared it to other widely applied methods. Our method could effectively reject many marginally significant pathways detected by standard methods, including several long gene based, cancer unrelated pathways. We further demonstrated that by reducing such biases, pathway crosstalk for each individual and pathway co-mutation map across multiple individuals can be objectively explored and evaluated. This method performs pathway analysis in a sample-specific fashion, and provides an alternative way for accurate analysis of personalized cancer genomes. We further extended this approach to network based analysis in personalized genomics and found promising results as well.

Correcting for expression heterogeneity while identifying regulatory hotspots. *J. JOO[1], J. Sul[2], B. Han[2], E. Eskin[2].* 1) Bioinformatics IDP, UCLA, Los Angeles, CA; 2) Computer Science, UCLA, Los Angeles, CA.

Expression quantitative trait loci (eQTL) mapping is a powerful tool that can systematically identify genetic variations affecting gene expression. From eQTL mapping studies, it has been known that thousands of genes are trans-regulated by eQTLs referred as ``regulatory hotspots". However, recent studies have shown that various confounding effects such as a batch effect induce heterogeneity in expression data and may cause spurious associations including spurious regulatory hotposts. Several computational methods have been developed to correct for the expression heterogeneity. However, the challenge in previous methods is that in an attempt to eliminate confounding effects, the genetic effects are also eliminated. Here, we introduce a novel method, that attempts to eliminate spurious regulatory hotspots while retaining hotspots caused by genetic effects on a new statistical framework. Our method is based on a rationale that confounding factors affect most of the genes while genetic factors affect fewer genes. Our method leverages a recently developed statistic to detect genes that do not have genetic effects but only confoundinf effects. Using those genes, we are able to remove confounding effets but preserve genetic effects. Applying to both simulation and real data, we showed that our method successfully corrects for expression heterogeneity while identifying regulatory hotspots.

GeneTalk: an expert exchange platform for assessing rare sequence variants. *T. Kamphans[1], P.M. Krawitz[2].* 1) Smart Algos, Berlin, Germany; 2) Charité, Berlin, Germany.

Next-generation sequencing (NGS) has become a powerful tool in personalized healthcare and is now starting to transform our society. The 1000 $ genome is within range and the really challenging question is: What is going to happen if Joe Consumer starts analyzing his own genome? GeneTalk is the first professional social network website for genome analysis and is currently growing faster than facebook. Right now, it is a networking tool used by about 10% of Europe's geneticists for expert based interpretation of family specific human sequence variants. This professional user base contributed mainly scientifically proven annotations about rare genetic disorders to GeneTalk's wiki-like knowledge base. Starting this year the first laymen joined the portal and showed a completely different user behavior. A first evaluation of the crowdsourced annotations from users searching and commenting their personal genomes illustrates that sequence variants associated with food intolerance, obesity and metabolism of recreational drugs were frequently searched. The genetic counseling of the years to come will certainly have to address questions that arise by private genome analysis.

UCSC Genome Browser 2012: distributed data, enhanced interactivity, variant annotation integrator. *W.J. Kent, A. Hinrichs, D. Karolchick, A. Zweig, B. Raney, H. Clawson, M. Cline, L. Guruvadoo, K. Learned, R. Kuhn, B. Rhead, T. Dreszer, L. Meyers, C. Li, M. Diekhans, G. Roe, P. Fujita, D. Haussler.* Dept Biomolecular Engineering, Univ California, Santa Cruz, CA.

The UCSC Genome Browser and database has improved in several ways over the past year. Here we will describe three new features - track hubs for distributed annotations, Javascript-based improvements to make the browser more interactive, and the development of a new tool aimed at human geneticists - the Varian Annotation Integrator. Our new Track Data Hub systems allows users to develop large scale annotation sets that can be viewed in context of other annotations on the browser. These hubs consist of files in standard distributed file formats such as BAM, BigWig, BigBed, and VCF placed in a directory on the users own web site, along with simple text formatted files that say how to label, color, and arrange the tracks in the hub. The data from hubs is fetched as needed in parallel, and cached at UCSC, with the result that the track hubs perform nearly as well as built in tracks, and allow for more permanence and flexibility than the existing custom track mechanism. We've used the JQuery library and local JavaScript development to increase the interactivity of the browser in several ways. It's now possible to rearrange the order of tracks, and of subtracks within tracks, by drag and drop. Drag scrolling is also now possible, and drag-zoom has been enhanced. Right click (control click on the Mac) now brings up a menu with context sensitive options depending on where you click. We've also worked to enhance the speed of the site. We are developing a new tool, the Variant Annotation Integrator. This tool lets you intersect variants in VCF and other formats with the gene and other annotation tracks at UCSC. This allows the user to see which sequence variants disrupt genes, regulatory features, or are just SNPs seen commonly across the human population.

Curating genomic epidemiology data in The PAGE Study. *G. Kumaraguruparan[1], G. Mehta[1], A.Q. Nato[2], J.L. Ambite[1], S. Buyske[3], R. Mayani[1], C. Cai[1], J.S. Vockler[1], E. Deelman[1], T.C. Matise[2].* 1) Information Sciences Institute, University of Southern California, Marina del Rey, CA 90292; 2) Department of Genetics, Rutgers University, Piscataway, NJ 08854; 3) Department of Statistics and Biostatistics, Rutgers University, Piscataway, NJ 08854.

The “Population Architecture using Genomics and Epidemiology” (PAGE) study investigates the epidemiologic architecture of genetic variants associated with complex diseases in large, ethnically diverse population-based studies. PAGE is genotyping 200–200,000 genetic variants/year in tens of thousands of European American (EA), African American, American Indian, Hispanic/Mexican American, and Asian/Pacific Islander participants. PAGE is addressing generalization of associations and variability of effects in diverse populations; identifying genetic and environmental modifiers; and investigating associations with novel phenotypes. The PAGE Coordinating Center (CC) warehouses and disseminates the results of the PAGE Consortium. Using predefined templates, studies submit SNP, phenotype, and association results files to the CC for data quality control and submission to dbGAP. A challenge of working with multiple institutions is the differences in which similar data are recorded, such as gender being either `Male' or `M,' or reporting proportions vs. percentages. To automatically review the PAGE results data, we provide a web-based Quality Control (QC) and Standardization system that checks whether the submitted data adhere to the prescribed templates and data formats, standardizes the various fields to the prescribed formats, and uploads them to a database backend for advanced quality checks and submission to dbGaP. The backend models the QC steps as a workflow deployed by the Pegasus Workflow Management System (WMS) and supported by a relational database to store and process data. Over 25 QC steps rigorously check the data to ensure that it is complete and semantically correct. In addition, QC ensures that data are reported according to a common strand orientation, which facilitates meta-analyses. Pegasus WMS can manage and execute PAGE workflows on local and distributed resources such as campus clusters or clouds. The system can run several QC workflows simultaneously allowing several studies to submit large amounts of data to be curated in a short time. Pegasus publishes the results of QC to a web GUI that displays the status of the QC steps that are running and reports errors at various stages with appropriate logs and messages so that the submitting scientists can correct and re-upload their data as needed. The PAGE QC workflow provides an efficient approach to data cleaning for a multicenter study using common data templates.

Predicting causal variants in exome sequencing of Mendelian disorders. *J. Kwan[1,2], M.X. Li[2,3,4], P.C. Sham[2,3,4].* 1) Department of Medicine, University of Hong Kong, Hong Kong, China; 2) Department of Psychiatry, University of Hong Kong, Hong Kong, China; 3) Centre for Reproduction, Development and Growth, University of Hong Kong, Hong Kong, China; 4) Genome Research Centre, University of Hong Kong, Hong Kong, China.

A major challenge of exome sequencing of Mendelian disorders is to pull out the causal variant(s) from a list of candidate mutations. Because the most common cause of Mendelian disease is a non-synonymous single-nucleotide variant (nsSNV) that results in a single amino acid change in the protein encoded by that gene, current strategy mainly relies on removing variants conflicting with the disease inheritance mode and/or catalogued in SNP databases, and then predicting the functional consequences of the nsSNVs left on disease. Here, we examine the actual performance of pathogenicity prediction in the analysis of exome sequencing data and propose a combined model tailored for predicting Mendelian disease-causing nsSNVs in exome sequencing based on the scores from multiple prediction algorithms. When used to distinguish Mendelian disease-causing mutations from other rare variations, our full combined model (based on the scores from five different algorithms, including SIFT and Polyphen version 2) outperforms the five individual algorithms and another well-known combined model, Condel (which is being used in Ensembl's Variant Effect Predictor). In addition, our reduced model (based on a subset of the scores from the five algorithms) has an even better predictive performance than our full model. However, no method is able to distinguish autosomal dominant disease mutations from autosomal recessive disease mutations. Since we estimate that human genomes typically contain ~100–200 genuine Mendelian disease-causing nsSNVs in heterozygous state, a method to classify Mendelian disease-causing mutations as autosomal dominant or autosomal recessive will be useful for exome sequencing studies.

Analysis of Ewing Sarcoma NGS transcriptome data highlights mechanisms of cancer progression. *M. Laurance, J. Billaud, C. Bullitt.* Ingenuity Systems, Redwood City, CA.

The Ewing Sarcoma family of tumors is a category of cancers that mostly affects teenagers of age 10 to 20. To understand the molecular mechanisms of tumorigenesis and metastatic processes in Ewing Sarcoma (ES), gene expression profiling of samples from Ewing Sarcomas patients was performed using Next-Generation-Sequencing (NGS) technology. In this study we present the results of combined bioinformatics and biological analyses that demonstrate the differences between samples from primary and metastatic tissues from one representative patient with ES. Initial statistical analysis of the RNA-Seq data was performed with SeqSolve software from Integromics. Ingenuity iReport was then used to analyze and understand the functional implications of the RNA-Seq data and identify molecular mechanisms participating in the development of ES. Using iReport we identified differentially expressed isoforms and highlighted their potential roles in tumor progression and/or metastatic processes. We also characterized and identified signalling and metabolic pathways (such as glucose and fatty acid metabolism) and biological processes (such as resistance to anoikis) that may be involved in the progression of ES. Subsequent transcription factor analysis of the RNA-Seq data using Ingenuity's IPA program enabled prediction of the activity state of several transcription factors (such as SREBF1, PPARGC1B, IRF3 and IRF7) that may contribute to the pathological context observed in this patient. IPA transcription factor networks were used to visualize potentially induced transcriptional programs in the metastatic process. Using complementary analysis capabilities in iReport and IPA we were able to highlight important biological processes and underestimated contributors to tumorigenesis (such as metabolic pathways) and identify key isoforms and molecular players in ES tumor progression (enzymes, transcription factors). The data presented here is from one patient, therefore similar studies are needed to understand if these insights are supported by data from other Ewing Sarcoma's patients and also to extend these insights by identifying miRNAs with roles in progression and mechanisms of metastasis in ES.

Low concordance of variant calling algorithms in exome sequencing. *G. Lyon[1,7], T. Jiang[2], G. Sun[2], W. Wang[3], J. Hu[2], P. Bodily[4], L. Tian[5], B. Moore[6], H. Hakonarson[5], J. Wang[2], M. Yandell[6], E. Johnson[4], Z. Wei[3], K. Wang[8].* 1) Stanley Institute for Cognitive Genomics, Cold Spring Harbor Laboratory, NY; 2) BGI-Shenzhen, China; 3) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ; 4) Department of Medicine, Boston University School of Medicine, Boston MA; 5)) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 6) Eccles Institute of Human Genetics, University of Utah, Salt Lake City, UT; 7) Utah Foundation for Biomedical Research, Salt Lake City, UT; 8) Zilkha Neurogenetic Institute, Department of Psychiatry and Preventive Medicine, University of Southern California, Los Angeles, CA.

There is a growing gap between the generation of massively parallel sequencing output and the ability to process, analyze and interpret the resulting data. New users to the sequencing era are left to navigate a bewildering maze of base calling, alignment, assembly and analysis tools. For the implementation of genomic analysis in the clinic, it will be critically important to optimize and standardize one overall pipeline with high sensitivity and specificity for variant calling. One must first have sufficient depth of sequencing coverage as well as high quality of sequencing data to tackle this problem. We optimized our depth of coverage in a pilot set of exomes to a depth of at least 20 reads per base pair in greater than 80% of the target region, captured using Agilent SureSelect v.2 and subsequently sequenced on the Illumina platform. We demonstrate that there is poor concordance (~60–70%) even for single nucleotide variants (SNVs) among the five variant calling algorithms used (SOAP, GATK, SNVer, GNUMAP, and SAMtools) under default parameters; concordance for indels is even worse, typically between ~25–50% for SOAPindel, SAMtools and GATK. Furthermore, concordance for novel variants is significant lower than common variants. While some researchers have suggested sequencing the same sample on two separate sequencing platforms (e.g. Illumina and Complete Genomics) and using only shared variants as determined by one variant calling platform (GATK), this may be impractical due to storage and economic considerations. As an alternative, we recommend using variants called by two or more variant calling approaches on one set of sequencing data. Additionally, we discuss the different expectations and tolerance to false positives in a research setting versus in a clinical setting, and the need to apply different filtering strategies in different settings. Finally, on a biological level, these 15 exomes are carefully selected from four large families with many symptoms of Tourette Syndrome, attention deficit hyperactivity disorder, and obsessive compulsive disorder. We are using various tools such as ANNOVAR and VAAST to prioritize variants from the families for follow-up in case-control and biological studies.

DIVERGENOMEnrich: Expanding information on a Genetic Variation database through automatic online data retrieval. *W. Magalhaes[1], G. Souza[1], G. Kingman[2], E. Tarazona[1], M. Rodrigues[1], Epigen-Brazil.* 1) Department of General Biology, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; 2) Departamento de Ciência da Computação, Pontifícia Universidade Católica de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil.

Large-scale genomics initiatives such as the HapMap project and the 1000-genomes rely on powerful bioinformatics support to assist data production and analysis. Contrastingly, few bioinformatics platforms oriented to smaller research groups exist to store, handle, share, and integrate data from different sources, enrich genetic diversity analyses, as well as to assist these scientists to perform their analyses efficiently. We developed such a bioinformatics platform, DIVERGENOME, to assist population genetics and genetic epidemiology studies performed by small- to medium-sized research groups. The platform is composed of two integrated components, a relational database (DIVERGENOMEdb), and a set of tools to convert data formats as required by popular software in population genetics and genetic epidemiology (DIVERGENOMEtools). In DIVERGENOMEdb, information on genotypes, polymorphism, laboratory protocols, individuals, populations, and phenotypes is organized in projects. Here we present a new component, DIVERGENOMEnrich, which allows users to achieve relevant genetic and biomedical knowledge, enriching variants with other types of biological data, such as biochemical pathways, pharmacogenetics, and genome wide association studies even though these data are fragmented in different databases.. To implement this feature we propose an Agent-based enrichment system that integrates different sources of biologically relevant data in order to improve the genetic diversity analysis of native and Latin-American populations in particular. In our system, agents are autonomous programs that perform a specific task and communicate with each other in order to combine information from different sources. We believe that an agent-based approach is suited to implement such enrichment system given the heterogeneity of different types of genetic and biological data and their distribution over distinct sources over the Web.

Fast and accurate local ancestry inference on whole genome-scale data using conditional random fields. *B. Maples, F. Zakharia, S. Gravel, E. Kenny, C. Bustamante.* Genetics, Stanford University, Stanford, CA.

Humans show assortative mating based on a diversity of geographic, linguistic, cultural, and biological traits. As a result, most humans trace their origins to two or more statistically distinct groups. Using genome-wide data, it is often possible to infer not only the populations from which an individual derives, but also the population from which individual loci along her genome originate. From a medical genomics perspective, such local ancestry information enables phenotype-to-genotype associations through admixture mapping for traits that correlate with ancestry. In population genetics, local ancestry tracts can shed light on the natural history of both the ancestral populations and the admixture process. The increasing availability of whole genome data provides unbiased ancestry informative markers and haplotypes to enable the inference of local ancestry at a sub-continental scale. However, most local ancestry inference methods are highly computationally intensive, making them difficult to apply to the number of markers and reference individuals needed to perform accurate genome-scale inference. In light of these limitations, we propose a fast, accurate statistical method using conditional random fields parameterized by random forests to classify genomic diversity and perform local ancestry inference. We compared an implementation of this method, called RFMix, to local ancestry inference results performed by different groups using recent data from the 1000 Genomes project and a diversity of widely-used inference methods, including HapMix, LAMP-LD and MULTIMIX. Accuracy of the method was 99.4% when inferring ancestry tracts on simulated African American samples, and 96.6% when applied to simulated Mexican individuals. Additionally, RFMix is similarly accurate but 10 times faster than the next fastest method, LAMP-LD (with S=10) . This new approach can be readily parallelized for multi-processor machines and enables fast and accurate inference for large-scale studies.

Exome Sequencing of Mayo Clinic Biobank samples for evaluation of quality and quantity of data. *S. Middha, SK. McDonnell, ZC. Fogarty, MS. DeRycke, KJ. Johnson, NM. Lindor, DJ. Schaid, JE. Olson, JR. Cerhan, SN. Thibodeau.* Mayo Clinic, Rochester, MN.

BACKGROUND: Whole exome sequencing (WES) is a powerful next generation sequencing technology that is mainly used in the research setting, but is rapidly moving towards the clinic. In order to better understand quality and reporting metrics, we conducted a study of 39 exomes from deceased participants in the Mayo Clinic Biobank. METHODS: The Mayo Clinic Biobank is a research resource that has enrolled over 20,000 Mayo Clinic patient volunteers since 2009. Participants are enrolled regardless of their health history, and provide biologic specimens, complete a health history, and allow access to their medical record. For this study, we selected participants who had died after enrollment, did not have blood cancer, and had a detailed medical history at Mayo. We used the Agilent 50Mb capture kit and sequenced on the Illumina HiSEQ 2000 using 100bp paired-end reads on one lane per sample. An in house analysis and annotation workflow (TREAT) was used to generate variant reports. Variants were called Tier I if they were nonsense, loss of stop or splice site variants; and Tier II if they were missense variants. Samples were also genotyped using the Illumina 5M SNP chip in order to verify data quality. RESULTS: A total of 202,064 SNVs (21,477 genes) and 19,832 indels were identified using SNVMix and GATK respectively. This includes 48,528 novel SNVs in 15,205 genes not already reported in dbSNP or 1000 Genome Project and 743 unique nonsense variants in 674 genes. In aggregate, there were 1,260 Tier I SNVs, 1,774 Tier I indels, and 43,529 Tier II SNVs. On a per subject basis, there were a mean of 271 Tier I SNVs, 388 Tier I indels, and 10,792 Tier II total variants (including known and novel variants). All samples had excellent concordance (more than 99 percent) between WES and the Illumina 5M SNP chip. The average depth of sequencing coverage was excellent across the entire exome (more than 80 percent of targeted region at 20x), but was quite variable at the gene level. CONCLUSIONS: Whole exome sequencing results conducted on blood of 39 deceased participants of the Mayo Biobank are described in detail. WES shows very high concordance with SNP genotyping. Establishing the frequency and types of variants likely to be found in our target clinical population facilitates preparation for more wide-spread clinical use of this technology. Correlation of molecular findings with clinical information may help interpret some of the vast number of variants detected.

Genome wide association study on the world fastest supercomputer, k computer. *K. Misawa[1], A. Hasegawa[1], T. Tsunoda[1,2].* 1) Research Program for Computational Science, Riken; 2) Center for Genomic Medicine, Riken.

More than a million single-nucleotide polymorphisms (SNPs) are analyzed in any given genome-wide association study (GWAS), therefore performing multiple comparisons can be problematic. One attempt to cope with multiple-comparison problems in GWAS was the development of haplotype-based algorithms to correct for multiple comparisons at multiple SNP loci in linkage disequilibrium (Misawa et al. 2008, J. Hum. Genet 53: 789-). In addition, permutation tests were found to also control problems inherent in multiple testing (Kimmel and Shamir 2006, Am. J. Hum. Genet. 79: 481-). However, both the calculation of exact probability and the execution of permutation tests are time-consuming and faster methods are required. To this end, we developed a suite of computer programs, ParaHaplo 4.0. ParaHaplo 4.0 can conduct parallel computation of accurate P-values in haplotype-based GWAS through use both Misawa et al.'s (2008) algorithm and Kimmel and Shamir (2006) algorithm. Our program is intended for workstation clusters and supercomputers using the Intel Message Passing Interface (MPI). GWAS requires a huge amount of data, such that file input/output can become a bottleneck in analysis. Thus, we implemented distributed file input/output in ParaHaplo 4.0. We compared the performance of ParaHaplo 4.0 on the HapMap dataset for Japanese in Tokyo, Japan and Han Chinese in Beijing, and Chinese. Computation was conducted on k computer, which is the world fastest computer as of November 2011. The parallel version of ParaHaplo 4.0 conducts genotype imputation much faster than the non-parallel version of ParaHaplo. ParaHaplo executable binaries and source code are available at http://en.sourceforge.jp/projects/parallelgwas/releases/.

A bioinformatics approach for the identification of developmental QTL candidate genes. *A.Q. Nato[1], B. Li[2], F. Chen[1,3], J.H. Millonig[1,2,4], T.C. Matise[1].* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Center for Advanced Biotechnology and Medicine, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ; 3) MedStar Health Research Institute, Washington, DC; 4) Department of Neuroscience and Cell Biology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ.

Neural tube defects (NTDs) occur in ~1/1,000 live births in the United States and are considered one of the most common birth defects. Approximately 20.5 million Americans over age 40 have cataract in either eye. We have formerly established a spontaneous mouse mutant, *vacuolated lens* (*vl*), as a multigenic model for cataract and NTDs. *Vl* arose on the C3H/HeSnJ background and exhibits cataract and NTDs with 100% penetrance. A mutation in an orphan G protein coupled receptor, *Gpr161*, which is expressed in the developing neural tube and lens, causes these disorders. However, the severity and incidence of the *vl* phenotypes are modified when the mutation is crossed to C57BL6/J, CAST/Ei, or MOLF/Ei backgrounds indicating that unlinked loci can bypass the effect of the *Gpr161* mutation. Quantitative trait locus (QTL) analysis mapped the position of five modifier loci (Modifiers of vacuolated lens: *Modvl1–5*). Several resources are available for the identification of candidate genes for adult QTL but not for developmental QTL. For this study, we developed a bioinformatics pipeline specifically designed for the identification of developmental QTL candidate genes. In-house computer scripts were created to mine the NCBI Entrez Gene, expressed sequenced tag (EST), and Gene Expression Omnibus (GEO) databases, and to identify genes within the *Modvl* 95% confidence intervals expressed at particular developmental stages. We utilized the dataBase for Gene Expression Evolution (Bgee) to determine which of these developmentally expressed genes are localized to the developing CNS and eye. dbSNP data, resequencing, and bioinformatics analysis were then employed to identify coding polymorphisms in these CNS- and eye-restricted transcripts and determine whether they are predicted to be functional. Finally, we identified pathways that are most significantly associated with these developmentally restricted transcripts and may therefore be relevant to neural tube closure and lens development. We have successfully identified candidate genes for each *Modvl* locus through our new bioinformatics pipeline that allows EST, microarray data, spatial/temporal expression, and dbSNP data to be searched successively. This pipeline (http://compgen.rutgers.edu/devQTL) may be utilized by other investigators to identify candidate genes for developmental QTL.

Multivariate profiling approach to inference on differential expression in RNA-Seq data with small sample size. *S. Oh[1], M. Kim[2], S. Song[3].* 1) Division of Human Genetics, Department of Pediatrics, Cincinnati Children's Hospital Medical Center Research Foundation, Cincinnati, OH; 2) Division of Epidemiology and Biostatistics, Department of Pediatrics, Cincinnati Children's Hospital Medical Center Research Foundation, Cincinnati, OH; 3) Department of Mathematical Sciences, McMicken college of Arts and Sciences, University of Cincinnati, Cincinnati, OH, 45221.

Identifying differential expression is one of the most widely used downstream statistical analyses of genomic data. We propose a multivariate profiling approach to the identification of differential expression in RNA-Seq data with small sample size. RNA-Seq is a powerful approach to transcriptome profiling that uses deep-sequencing technologies and is fast replacing microarray with superior sensitivity and precision, dynamic resolution, and isoform level quantification. Contrary to its gaining popularity, cost to sequencing is still expensive and often only a small number of samples for biological replications are included in individual experiments. The proposed fully bayesian multivariate approach will overcome limitations rising from the small sample size issue by pooling information and correlation structure across genes and samples. This idea of multivariate profiling is well justified by well-known facts that genes work collaboratively in a biological system as a network module and the functional connections are manifested as correlated structure of transcriptional regulation in gene expression among genes and among relevant tissue samples. Many multivariate approaches have successfully proposed for the analysis of microarray data. We will adopt them by addressing the discrete nature of the RNA-Seq data. The proposed approach will allow both identification and ordering of differential expressions. We will compare the proposed multivariate approach with gene-by-gene univariate approaches both in real data analysis and Monte Carlo simulation study. Keywords: RNA-Seq, differential expression, univariate/multivariate profiling approach, and Monte Carlo simulation study.

Challenges and approaches to computational candidate gene prioritization using gene networks. *P. Pavlidis[1], E. Mercier[1], J. Gillis[1,2].* 1) Department of Psychiatry and Centre for High-Throughput Biology, University of British Columbia, Vancouver, Canada; 2) Cold Spring Harbor Laboratory, NY.

It has long been hoped that computational methods will assist human genetics studies with sophisticated variants of “guilt by association” (GBA), based on the exploitation of information from gene networks. In principle such methods have wide application. Genome wide analyses of human genetic traits and disorders are often faced with the challenge of prioritization of findings for follow-up. For example, analysis of copy number variation results would be simplified by being able to choose which of the genes covered by the variant are most important to the phenotype. In addition, researchers planning focused studies could use computational methods to prioritize targets. In previous work, we found limitations of GBA methods to give specific results (Qiao Y et al., Hum Genet. 2010 128:179) and showed that such methods are affected by severe biases induced by genes which are highly “multifunctional” (Gillis J and Pavlidis P, PLoS Comput. Biol. 2012 8(3):e1002444 and PLoS One. 2011 6(2):e17258). We predict methods that do not account for multifunctionality will tend to prioritize genes which are either already highly annotated, or which have specific associations with highly-annotated genes. The result is that the same genes will tend to be prioritized for numerous phenotypes, simply due to biases in the underlying gene networks and annotations. Here we show that the non-specificity reported by Qiao et al. (2010) can indeed be accounted for by multifunctionality effects. We also present a novel approach for prioritization called Favourite Gene-Favourite Function analysis (FGFF) that considers not just the association of a gene with the phenotype or function of interest, but also the degree to which that phenotype is the one most specifically predicted to be associated with the gene. Thus each gene “votes” for its “favourite function”, and only if that function is the one of interest to the investigator is that gene considered a strong candidate. We describe several beneficial features of the approach based on analysis of large human protein interaction networks. FGFF dramatically reduces the degree to which the same gene is predicted for multiple functions, and it reduces the impact of highly annotated “hub” genes. Extensions of the approach to tissue-specific gene coexpression networks and other data types are under way and will be discussed. Our methods provide a way to increase the utility of computational gene prioritization for genetics research.

BlueSNP: An R Package for High-Scalability Genome-Wide Association Studies on Compute Clusters. *R.J. Prill[1], H. Huang[2,3], S. Tata[1].* 1) Healthcare Informatics, IBM Almaden Research Center, San Jose, CA; 2) Department of Biomedical Engineering, Johns Hopkins University, Baltimore, MD; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge MA.

Depending on the study design and statistical methodology, a genome-wide association study (GWAS) can sometimes require substantial computational resources. An example of a particularly demanding task is estimating empirical p-values via data permutation when a test statistic does not follow its parametric distribution or when a novel test statistic simply has no parametric distribution. Another example is the analysis of expression quantitative trait loci (eQTL) study designs with tens of thousands of gene expression phenotypes.

We introduce the BlueSNP R package, which distributes GWAS computations over a compute cluster configured with the MapReduce framework, making processor and memory intensive analyses feasible for large datasets. MapReduce is a parallel programming methodology for splitting a large problem into sub-parts (the map step), computing partial solutions on subparts independently, then assembling the partial solutions into the overall solution (the reduce step). BlueSNP removes the complexity of interacting with a compute cluster enabling the researcher to focus on advanced analytics using the R programming environment, primarily through the high-level gwas() function. Researchers can utilize the association tests provided with BlueSNP (e.g., case/control, regression, etc.) or supply a novel association test as a user-defined R function.

To assess performance, we simulated datasets with up to 4M SNPs, 100K individuals, and 100 traits using PLINK. We simulated 10 causal SNPs each contributing 1% of variance explained to a quantitative phenotype. We introduced 1% missing values to simulate genotyping failures. In most cases the time to complete an analysis was halved by doubling the number of compute nodes indicating near-optimal scaling. On our 40-node cluster configured with 200 map cores and 80 reduce cores it took 34 minutes to test 1M SNPs against 100 phenotypes in 100K individuals. Estimation of empirical p-values to a precision of $p \leq 10\text{-}8$ on the same dataset took 7.6 hours for one phenotype. The running-time of the adaptive permutation tests is largely determined by the number of highly significant SNPs (10 in this case).

Fast and Accurate Identification of Novel Sequences in *de novo* Human Genome Assemblies using NSIT. *B. Pupacdi[1], A. Javed[2], M.J. Zaki[3], M. Ruchirawat[1].* 1) Chulabhorn Research Institute, 54 Kamphaeng Phet 6, Laksi, Bangkok Thailand 10210; 2) Genome Institute of Singapore, A*STAR 60 Biopolis Street, Genome, #02-01 Singapore 138672; 3) Department of Computer Science Rensselaer Polytechnic Institute Troy, New York USA 12180-3590.

Novel sequences comprise a relatively new class of DNA sequence variations, and they are defined as non-repeating sequences present in a person's genome that are absent in the reference genome. A recent study showed that these sequences are consistent with the known migration paths and are potentially functionally important. Novel sequences can be detected both via sequence reads and via a *de novo* genome assembly. 2–5 Mbps of novel sequences have been reported per individual via both schools of methods. Our contribution is in the latter. The rapidly declining cost of sequencing contributes to the rising availability of *de novo* genome assemblies; hence there is a need for fast, accurate, and memory-efficient software to locate novel sequences. Using our software, NSIT (Novel Sequence Identification Tool), we identified 2.6Mbps, 2.5Mbps, and 2.3Mbps of novel sequences in the YH (Asian), NA18507 (African), and NA12878 (European) *de novo* genome sequences, respectively. NSIT was run on a 32-bit commodity desktop in 1.5 hours, on average, using less than 2GB of memory. Blastn and RepeatMasker were applied as post-processing steps, which took 30 minutes on average. The YH and NA18507 genomes were earlier reported to contain 5.1Mbps and 4.8Mbps of novel sequences, via aligning their *de novo* assemblies to the reference sequence using BLAT, LASTZ, Blastn, and RepeatMasker. The size discrepancies above are largely because the earlier work aligned to Build 36 only, while we also included Build 37. Moreover, the RepBase database in RepeatMasker used in our study was obviously more up-to-date. We adjusted their results accordingly and reduced the number of novel bases to 2.3Mbps and 2.2Mbps, respectively, and compared our results to them. Our identified novel sequences yielded 99% sensitivity and 85% precision. In addition, to the best of our knowledge, the novel sequences of NA12878 have never been reported elsewhere. Preliminary investigation revealed that about 8–15% of the novel sequences found by NSIT can be aligned to the haplotype chromosomes and unplaced contigs of the human genome. In addition, 70–75% of them can be aligned to the HuRef sequence. We also found that each pair of the three novel sequence sets overlap by 80–90%. Lastly, we compared NSIT with other aligners that have been used for this task, i.e. BLAT, LASTZ, and QueryLookupTable, and found that NSIT is several times faster.

NGS for the Masses: Empowering Biologists to Improve Bioinformatic Productivity. *K. Qaadri.* Biomatters, Inc., Newark, NJ.

Numerous enterprise-scale organizations spanning academic institutions, government facilities and commercial companies rely on a mixture of custom, open-source and proprietary commercial software for their NGS bioinformatics workflows. Dedicated bioinformaticians have been crucial to developing the tools, infrastructure and automated workflows available today, but are increasingly swamped by having to perform fairly routine bioinformatic tasks that could be done by biologists. To successfully engage biologists in mainstream NGS analysis requires a simplification of the software landscape with a data delivery platform and an interface that empowers biologists to access powerful hardware and software. This talk will focus on use cases that demonstrate how to build a flexible infrastructure for sequence-based research that combines commercial, open source and custom tools to improve ROI and accelerate discovery.

3572W

Evaluation and visualization of functional perturbations of pathways based on whole genome variations. *H. QIN, Y.Y. Shugart.* National Institute of Mental Health (NIMH)/NIH, Bethesda, MD.

While whole genome sequencing has opened a new era for personalized medicine for human complex diseases such as cancer, the complexity of genomic data presents challenge to the bioinformaticians. We have long anticipated that the involvement of multiple genes in pathways, and genetic heterogeneity of cancer cells determine drug response to treatment. Therefore, evaluating the contributions for the genetic variations to the functional change of pathways in cancer patients could be of high significance for personalized medicine. In this study, we aim to develop a new tool focusing on illustration the functional perturbations introduced by genetic variations in a whole genome scale. This tool is featured by: 1).Supporting multiple data sources for analysis, including data generated by many commercial services, such as Illumina and Complete Genomics. 2) Systematically integrating multiple pathway databases, including NCI-Nature Curated pathway, BioGrid, KEGG and Reactome; 3) Modeling functional changes of pathways by integrated functional evaluation algorithms and statistical methods. 4) Using new algorithms to compute the similarity of pathway models across samples and model-specific visualization. The features of the software include not only the robustness of integration of data by system biology methods, but also the ones used to evaluate the functional perturbations of pathways by comparing the similarity of matrixes. We applied this software to normal- cancer pair whole genome sequence data from the Complete Genomics in the initial stage and identified a tumor suppressor gene regulation pathway from 147 NCI-Nature curated pathways (including 29,626 nodes and 33,976 edges) as one of the most important pathways contributing to the cancer development. Currently, it takes 125.8 minites to finish all the processes. More features will be added gradually. We will also employ machine learning strategies for pathway ranking in simulation data and real data with larger sample size. This software will lead to the improved efficiency of the identification of the “shared” pathways and the pathways which may be “private” to the patients that are affected with complex diseases.

3573F

Use of an ad-hoc information system to support data search at a genomics center. *H. Qiu, F. Mentch, E. Frackelton, C. Kim, L. Hermannsson, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

In the setting of a large genomics research center, data integration and presentation to end users greatly impact efficiency in utilization of available phenotype and genotype information residing in disparate data sources which includes both open source and commercial relational databases. We develop a two-component information system to support up-to-date integrated data view and complex analytical queries. First, we develop a distributed real-time query system that, through web interface, allows users to search all production databases at the center: the phenotype database which includes electronic medical records, survey conducted at enrollment of a study and extra information from collaborators, patient families and disease related registries; biological sample laboratory information management system (LIMS); and genotyping and sequencing production LIMS. We support real time query functionality in keyword search, patient/project status lookup and information validation, data query up to a combination of a limited number of modalities, search limited within an uploaded list of predefined patient IDs. The real-time query system does not scale well in case of really complex queries which require joining data from multiple modalities as they consume significant computing resources. Next, we deploy an i2b2 (Informatics for Integrating Biology and the Bedside) based framework for user friendly complex query composition and ontology-driven cohort selection. From the first step, based on user activity logs and interactive discussions with end users, we are able to continuously identify most frequently used data fields and types of popular queries. The subset of data fields are extracted and transformed into the i2b2 data model and loaded into a separate i2b2 data warehouse. The i2b2 based system is highly optimized for query speed and response time for complex queries, which makes it effective in support of research cohort selection, hypothesis generation and advanced analytics. In conclusion, the use of the ad-hoc information system with two complementary components (real time distributed query tool and data warehouse based i2b2 tool) provides an efficient and user friendly way to facilitate phenotype and genotype information search and knowledge discovery at our center.

Using biosignatures to stratify clinical response: Evaluation of classification methods using simulated gene expression signatures and real patient cohorts. *P. Ravindran, C. Ooi, L. Kai, H. Zhong, A. Belousov, H. Bitter.* Hoffmann-La Roche Inc, Nutley, NJ.

The need for personalized health care is evident in the heterogeneity of patient treatment outcomes. Identifying biomarkers predictive of patient responses will improve clinical efficacy and reduce the sample size and cost, and improve the safety of clinical trials. While single biomarkers have been used to stratify patient treatment responses, panels of biomarkers or biosignatures, e.g. gene expression and protein analytes, have not been used widely in the clinic for several reasons. For example, some progress has been made in identifying gene expression biosignatures predictive of treatment response, but no systematic study for translating the identified biosignature to clinical usage has been conducted.

In this study, we performed simulations to investigate the relationship between clinical response, gene expression biosignatures, and classification methods with the goal of understanding which methods are preferred in different contexts. One important characteristic of gene expression datasets is the correlation structure among transcripts. To preserve this correlation structure, we compared the methods using biosignatures derived from real gene expression datasets from oncology and immunology. We simulated different levels of correlation between clinical response and biosignature to mimic various scenarios ranging from weak to strong prediction power from a biosignature. We then performed a systematic and comprehensive evaluation of several major classification and regression methods to classify patients into their response subgroups. The methods studied include classical machine learning algorithms and gene expression specific algorithms like Gene Set Variation Analysis, BinReg, and Connectivity Score. We defined several metrics, including sensitivity, specificity, and association estimate to quantify the strength of a biosignature, and used them to evaluate the performance of the classification methods. We discovered that most algorithms performed similarly in the presence of strong correlation between biosignatures and clinical responses. However, the algorithms' performance varied substantially when correlation is weak to moderate, and the variation depends on the correlation structure of the genes in signature panel. This study provides guidelines on how these classification methods can be optimally used to translate a gene expression biosignature predictive of treatment response to use in clinical trials.

Mitre; A tool for bulk updates of SNP identifiers. *N.W. Rayner[1, 2], N. Robertson[1, 2], M.I. McCarthy[1, 2, 3].* 1) WTCHG, Univ Oxford, Oxford, United Kingdom; 2) OCDEM, University of Oxford, Oxford, United Kingdom; 3) Oxford NIHR Biomedical Research Centre, Churchill Hospital, Oxford, UK.

With the increasing use of sequencing technologies there is a need to ensure the novel SNPs discovered can easily be updated to rs numbers with each new release of dbSNP. This coupled with the large quantity of GWAS data generated on previous genome builds means there is a requirement to easily assign rs identifiers to various SNP listings which may comprise multiple identifier types. To solve this we have developed Mitre a simple to use web based Java application with an H2 embedded database deployed in a Jetty HTTP Server that allows users to upload a list of SNPs with their current chromosome and position from any genome build and receive a set of summary files based on any other genome build. The output comprises several files, including a list of SNPs with their newly assigned rs number, SNPs without a current rs number and those where the identifier is different from that uploaded. The system is designed to cope with multiple SNP identifiers, including Affymetrix and Illumina SNP chip ids. To test the system we considered three likely use cases. 1) Sequence data comprising SNPs with chromosome and position (chr:pos) identifiers, 2) conversion of existing GWAS SNP ids from previous genome builds and 3) assigning up to date rs identifiers to common SNP genotyping chips. To test the bulk SNP assignment for sequencing we took 17,571,460 chr:pos identifiers from a sequencing experiment and compared them to dbSNP builds 132, 134 and 135 which comprise 30.4, 41.3 and 52.2 million SNPs respectively, from this we obtained 53%, 63% and 70% of SNPs with rs identifiers respectively. For the GWAS update we selected a data set imputed on NCBI genome build 36 using HapMap2 comprising 2,614,446 SNPs with various identifiers, this we remapped to NCBI genome build 37 dbSNP 135. Using rs identifiers (2,610,944 SNPs) 2,606,702 (99.84%) do not change, 4212 (0.16 %) are merged with another rs identifier and 30 (0.001%) lose their rs identifier. Using the positions 2,613,635 (99.97%) can be assigned an rs number, 811 (0.03%) are unassigned. Many genotyping chips contain non rs identifiers, the Human Exome chip from Illumina comprises non rs identifiers for all 247,867 SNPs on the chip, using Mitre and dbSNP 135 we were able to assign rs numbers to 187,968 (75.8%) SNPs. Mitre is an easy and convenient way to update many varied SNP based data sets and with dbSNP gathering new SNPs quickly Mitre is capable of being run repeatedly with each new dbSNP release.

Genomic Analysis from Sequencer to Bedside: An Integrated Analysis Pipeline for Research and Clinical Sequencing. *J.G. Reid[1], M.N. Bainbridge[1], F. Yu[1], M. Dahdouli[1], D. Challis[1], P. Pham[1], D. Sexton[1], E. Boerwinkle[1,2], R.A. Gibbs[1].* 1) Human Genome Sequencing Ctr, Baylor College Med, Houston, TX; 2) University of Texas Health Science Center, School of Public Health, Houston, TX.

As sequencing technology has grown ubiquitous it has naturally matured to the point where many groups are now offering whole exomes and genomes to clinicians. Bringing sequencing to the clinic requires a significant effort to monitor processes, perform validations, provide security, and ensure repeatability, all on top of the analysis challenges already inherent in sequencing. As bioinformatic genomic analyses are integral to sequence production and the generation of clinically useful results, we have developed an integrated, CAP/CLIA-approved analysis pipeline to meet the needs of clinical sequencing at the BCM Whole Genome Laboratory. A flexible and clinically validated genomic analysis software pipeline is somewhat of a paradox, as the flexibility required for best-in-class genome sequencing can run counter to the strict regulatory requirements for change control. However, by maintaining a set of strict validations along with the code (workflows with test data), we are committed to maintaining a current, validated clinical analysis pipeline.

Our analysis pipeline (“Mercury”) consists primarily of a Master Control Program (MCP) for handling data flow and communication. The MCP starts by initiating vendor primary analysis software for generation of raw reads using CASAVA, and then moves the resulting reads through a BWA-based mapping pipeline. After mapping, the resulting BAM files go through a BAM finishing process including GATK recalibration and realignment, and into Atlas-SNP and Atlas-indel for variant calling, producing a VCF file after applying minimal filtering to called variants. At this point the SNPs and indels are annotated using a variety of data sources, and a final annotated report is delivered. Throughout the pipeline QC metrics are generated, and input/output hooks are available to bring the pipeline together with LIMS and other metadata tracking resources. Currently this analysis framework is in place in the Human Genome Sequencing Center's main production pipeline and handles roughly 20 terabases of sequence data each month, including a variety interesting Mendelian disease pedigrees. A clinically validated version is in place at the BCM Whole Genome Laboratory where it has been used to process over a hundred clinical cases, and 11 validation samples resequenced and reprocessed multiple times.

Human genome pattern mining framework for complex diseases. *M. Riemenschneider, M. Stoll.* Leibniz Institute for Arteriosclerosis Research, Muenster, Germany.

Recent advances in genomic research have significantly improved our understanding of the genetic architecture underlying common complex diseases. However, a large proportion of the genetic variance leading to common diseases remains elusive. Apart from genetic variants, epigenetic regulation is thought to play an important role in disease pathogenesis. Recently, we reported regions of conserved gene clusters in the human genome enriched for disease variants, which are subject to selection pressure. We demonstrated the evolutionary spread of disease variants and the conservation of disease associated genes in the vertebrate lineage. Interestingly, these regions also exhibited patterns of co-expression on the transcriptome level, leading to the assumption that epigenetic mechanisms may contribute another layer of genetic information to the complex genomic architecture underlying common diseases. However, due to the partial knowledge on the interaction of epigenetic factors and other genomic elements further investigations are required. We are developing a comprehensive bioinformatics approach, which combines data on genetic variants (SNPs, SNVs, structural variants), methylation patterns and transcriptome data involving chronic inflammation. As a backbone, publicly available data from HAPMAP, the 1000 Genomes Project, the UCSC Genome Project and the Encyclopedia of DNA elements (ENCODE) are used to establish the data framework for our analyses. Upon completion of the basic framework, data on two different complex diseases comprising whole genome SNP data, methylation patterns as well as the corresponding transcriptome data generated on our Illumina HiScanSQ platform will be used to annotate our previous in silico observation with actual data, targeting the genetic architecture underlying inflammatory disease phenotypes on multiple levels. We will present our computational approach as well as the current status of our work, which likely contributes to the understanding of disease pathogenesis.

A Tool for selecting endogenous control for qRT-PCR using high throughput expression data. *C.S. Rocha, C.V. Maurer-Morelli, I. Lopes-Cendes, F.M. Artiguenave.* Department of Medical Genetics, Unicamp - FCM, Campinas, São Paulo, Brazil.

Objective: Quantitative real-time PCR has become a standard for quantitative gene expression, and for validation of genes detected as differentially expressed in high throughput experiments, but the reliability of gene expression studies by mRNA quantification is highly dependent upon several experimental procedures, especially the choice of reference genes used for data normalization. qRT-PCR gene expression results are generally normalized using endogenous control genes, these reference genes should be expressed at a constant level across all sample groups in a study, and should not be influenced by study treatments or conditions. The normalization usually is made with one or more endogenous control genes, which must have its expression stable within the samples to be compared, regardless of experimental conditions, treatments or tissue differences. With that in mind we developed a tool to select genes that have the most stable behavior throughout the experiment. **Methods:** This tool was written using R software environment for the statistical calculation and data filtering, and receives as input a file with the expression intensity values. Soon a web interface will be deve loped and the tool will be freely available. **Discussion:** In statistics, the relative standard deviation (RSD or %RSD) is the absolute value of the coefficient of variation. It is useful for comparing the uncertainty between different measurements. So, using high throughput expression experiments data, once we have all intensities values, the tool calculates the RSD for each gene or probeset for the whole experiment, and selects the data with the lowers values (a default cut of 5% is set, but the user can change it), creating a list with the better candidates to endogenous control. This list is divided in three parts: Genes with high expression, medium expression and low expression.**Conclusion:** Genes used as endogenous controls in qRT-PCR experiments are often chosen arbitrarily from a pool of commonly used endogenous control genes such as GAPDH, and actinβ without verifying their variation over the experiment. Selecting an endogenous control gene to normalize gene expression data is one of the most important phases in the experimental design. That is why we believe that this tool will be very useful for selecting the best endogenous control for qRT-PCR.

Golden Helix GenomeBrowse: Cloud-enabled visual analytics of DNA and RNA-Seq NGS data. *G. Rudy, S. Gardner, M. Thiesen.* Golden Helix, Bozeman, MT.

High-throughput sequencing (HTS) has recently provided price competitive alternatives to microarrays for both RNA expression profiling with the RNA-seq protocol and DNA genotyping with whole genome and whole exome sequencing. Although the bioinformatics tools have matured for secondary analysis of sequence data, including alignment, variant calling and gene and transcript level quantification, the outputs of these tools often require inspecting the "raw read alignments" for putative variants and genes with interesting expression profiles. Because the BAM files containing these reads are both very large and computationally expensive to create, it is ideal to host them in a cloud environment and only access them "on demand".

We introduce Golden Helix GenomeBrowse, a free visualization tool for DNA and RNA sequence alignment along with annotations tracks from a rich catalog of pre-curated public data. GenomeBrowse is built from the ground up with the guiding principles of (1) working seamlessly with cloud-hosted data as fluidly and quickly as local files, (2) being intuitive to use for non-bioinformaticans to utilize in their research, and (3) having a multi-threaded architecture to make big-data visualization and analysis accessible to anybody capable of navigating Google Earth. By including integration with a rich repository of public data, users have no barriers to the process of interpreting their sequencing results. In particular, we demonstrate the ability of GenomeBrowse to stream RNA-seq samples sequenced to the depth of 25 million reads from the Amazon Cloud at the whole genome down to the gene level with annotation tracks ranging from 1000 genomes, dbSNP, genes and miRNAs. With a set of public breast cancer cell lines, we show how GenomeBrowse can highlight Single Nucleotide Variants and small Insertion/Deletions that may explain differentially expressed genes between cell types.

Informatics challenges on utilizing next-generation sequencing to advance disease understanding. *S. Saisanit, J. Hakenberg, Y. Li.* Pharma Research & Early Development Informatics, Roche Pharmaceuticals, Nutley, NJ.

Next generation sequencing provides new avenue to deepen our understanding of disease processes. The increasing availability of data from large international consortiums such as TCGA/ICGC, 1000 Genomes as well as from our own sequencing projects poses a full spectrum of challenges in informatics including data management, data retention, data analysis, and integration. This presentation describes our approach to manage these challenges. Together with many other informatics colleagues across our organization, we contribute to building a foundation platform named Understanding Disease Informatics System (UDIS). The aim is to integrate NGS data with other kinds of omics and next gen data with comprehensive sample annotations. The ultimate goal is to support better target and biomarker selection, validation and profiling for Roche Pharma R&D.

3581F

Integrated genome-phenome analysis. *M.M. Segal[1], M.S. Williams[2], J.G. Gleeson[3].* 1) SimulConsult, Chestnut Hill, MA; 2) Geisinger Health System, Danville, PA; 3) UCSD, La Jolla, CA.

The cost of sequencing the human genome has fallen low enough that the main concern about using whole genome information is now the cost of interpretation. We have addressed this concern by integrating genome sequencing with automated comparison to known phenotypes of diseases using a diagnostic decision support tool, SimulConsult, already in clinical use. The integrated genome-phenome analysis is done by importing the variant table consisting of HGNC gene names, variant severity scores and zygosity information into the diagnostic decision support tool to match it up with the patient's findings. Variant severity scores are derived from available protein structure and mutation data, with high severity scores deemed highly unlikely to occur incidentally, and thus have a powerful effect on diagnosis. Zygosity information is used to match variants with known data about whether a gene abnormality in each known disease is autosomal dominant, X-linked, etc. Compound heterozygotes are analyzed using a worst-case scenario in which the two most severe variants are considered to be on opposite chromosomes, and the abnormality is flagged to allow the clinician to evaluate the clinical plausibility of the disease and decide whether to do traditional sequencing to test for compound heterozygosity. The diagnostic tool uses its detailed database of clinical and laboratory abnormality in thousands of diseases to present the genome information in the context of the clinical presentation (pertinent positive and negative findings, including clinical signs and symptoms, laboratory test results and imaging information). The output includes a display of likely diagnoses ranked by probability, including not only genetic diseases detectable on next generation sequencing, but also genetic diseases not well detected (e.g., trinucleotide repeats and large copy number variants), and nongenetic diseases. For each disease, the tool takes into account the incidence, treatability, and family history, and for each finding in each disease it takes into account the frequency, age of onset and age of disappearance. The output also includes a display of findings, including genes, ranked by pertinence (measured by the ability of a finding to modify the differential diagnosis). The output is not just a one-time report. As the clinical query changes, laboratory studies become available, or the phenome database is updated, an updated analysis and report can be generated.

Variation data services at NCBI: archives, tools, and curation for research and medicine. *S. Sherry, K. Addess, V. Ananiev, C. Chen, D. Church, M. Feolo, J. Garner, T. Heffron, D. Hoffman, M. Kholodov, A. Kitts, J. Lee, J. Lopez, D. Maglott, R. Maiti, L. Phan, G. Riley, W. Rubinstein, D. Rudnev, Y. Shao, E. Shekhtman, K. Sirotkin, D. Slotta, R. Tully, R. Villamarin-Salomon, Q. Wang, M.H. Ward, H. Zhang.* National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD.

NCBI operates several archives for sequence variation data that are increasingly relevant for medical research. These archives contain general variation data in the public domain and high density surveys of genetic diversity in medical study populations. Small scale variations are accessioned and distributed through dbSNP at http://www.ncbi.nlm.nih.gov/snp/ and larger structural variations (>50bp) are accessioned and distributed through dbVar at http://www.ncbi.nlm.nih.gov/dbvar/. Research participant genotypes, participant phenotypes and analysis results are distributed through the dbGaP controlled access system http://www.ncbi.nlm.nih.gov/dbgap/. Assertions of clinical significance for variants and alleles are accessioned and distributed through ClinVar at http://www.ncbi.nlm.nih.gov/clinvar/.

Tools for exploring and visualizing variation data include the 1000 genomes browser http://www.ncbi.nlm.nih.gov/variation/tools/1000genomes/, the 1000 genomes data slicer http://trace.ncbi.nlm.nih.gov/Traces/1kg_slicer/ and the phenotype-genotype data integrator http://www.ncbi.nlm.nih.gov/gap/PheGenI. The clinical remap tool at http://www.ncbi.nlm.nih.gov/genome/tools/remap#tab=rsg will provide sequence coordinates for variations on a clinical RefSeqGene record, and the variation reporter service at http://www.ncbi.nlm.nih.gov/variation/tools/reporter will provide a list of known variants and the functional consequences for a region of interest in BED format or set of variants in HGVS or GVS format.

The presentation will also report the results of NCBI's participation with the GET-RM consortium to establish standardized sequence data for next generation sequencing in clinical laboratories and to identify lists of variants with clinical phenotypes, and lists of common variants not known to be medically important. The latter are frequently used to filter normal variation from next generation sequencing results.

snpActs: A versatile webinterface for annotating and prioritizing SNV data sets. *B. Stade, D. Ellinghaus, B. Petersen, M. Forster, A. Franke.* Institute of Clinical Molecular Biology, University Hospital Schleswig-Holstein, Kiel, Germany.

The rapidly decreasing prices for sequencing entire human exomes and genomes resulted in large amounts of variation data. To cope with this variation data we developed snpActs, a database-driven toolset that allows scientists to annotate single nucleotide variants (SNVs) and to categorize them comprehensively. snpActs scans different gene annotations and identifies SNVs in functional elements. Additionally, snpActs utilizes the results of several established mutation effect prediction algorithms, such as SNAP, SIFT, and Polyphen2, to distinguish between deleterious and functionally neutral amino acid changes caused by SNVs. For this, it also checks the Human Gene Mutation Database (HGMD). In comparison to other annotation-programs snpActs can filter SNVs lists can be filtered using special rules (e.g. coding SNVs), special masks (e.g. cancer regions) or based upon other SNV lists (e.g. presence in relatives). snpActs further implements a classical and precise linkage analysis to examine regions that are identity-by-descent in data sets from complex pedigrees. Via these functionalities it is possible to identify potential disease causing genes in examined individuals.

3584W

Games for gene annotation and phenotype classification. *A.I. Su, S. Loguercio, C. Wu, B.M. Good.* Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA.

The Empire State Building was built with 7 million hours of human effort. The Panama Canal took 20 million hours to complete. By comparison, it is estimated that up to 150 billion hours are spent playing games every year (9 billion on Solitaire alone). Obviously people play games because they are enjoyable and fun. But aside from that enjoyment, games largely result in no tangible benefit, neither to the individual nor to society at large.

Recently, several groups have built “games with a purpose”, a class of games that focuses on collaboratively harnessing gamers for productive ends. In biology, games have been built to fold proteins and RNAs, and to perform multiple sequence alignment. Here, we present our efforts to apply games to two critical challenges in genetics.

First, we have built games focused on organizing and structuring gene annotations. With the increasing popularity of genome-scale science, many analysis strategies (including gene set enrichment, pathway analysis, and cross-species comparisons) depend on comprehensive and accurate gene annotations. These structured annotations are mostly the result of centralized manual curation efforts, but these initiatives do not scale well with the explosive growth of the biomedical literature. We describe several games that target working biologists to extract their expert domain knowledge in computable form. We present actual preliminary game play data, and demonstrate how mined annotations systematically improve gene set enrichment analysis.

Second, we describe a game for predicting human phenotypes from molecular descriptors. Researchers can now relatively easily characterize any biological sample according to a number of features, including genotype, gene expression, and epigenetics. A key challenge in the field is identifying exactly which of those molecular features can be used to predict a clinical phenotype like disease susceptibility or adverse drug events. While statistical classifiers have been applied to this challenge, they typically do not incorporate human expert knowledge, and they often fail to replicate in external test populations. Here, we describe a new classification strategy called “Human Guided Forests”. Based on the random forest algorithm, this hybrid classification approach incorporates crowdsourced human input through an online strategy game.

Prototypes of these and other games for genetics research are available at http://genegames.org.

3585F

HMM-Fisher: a hidden Markov Model based method for identifying differential methylation. *S. Sun[1, 2], X. Yu[2].* 1) Case Cancer Center, Case Western Reserve Univ, Cleveland, OH; 2) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH.

DNA methylation (the addition of a methyl group to a cytosine) is one of the most common molecular changes in cancer cells and plays a key regulatory role. Therefore, it is important to study cancer DNA methylation, especially differential methylation patterns between two groups of samples. With next generation sequencing (NGS) technologies, it is now possible to identify differential methylation patterns by considering methylation at all CG sites in an entire genome. However, it is challenging to analyze large and complex NGS data. In order to address this difficult question, we have developed a new statistical method using a hidden Markov model and the Fisher Exact test to identify differentially methylated regions. In particular, we first use a hidden Markov chain to model the methylation signals to infer the methylation state as Not methylated (N), Partly methylated (P), and Fully methylated (F) for each individual sample. We then use the Fisher Exact test to identify differentially methylated CG sites. The advantage of our method is that it can incorporate neighboring CG site methylation information and reduce the impact of sequencing errors. In this presentation, we show our HMM-Fisher method and compare it with a linear model based statistical method and a different HMM-based method (HMM-DM) that has been developed by our group using a publicly available data set.

Automated HGVS-recommended sequence variant description. *P. Taschner, J.F. Laros, M. Vermaat, J.T. den Dunnen.* Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands.

Errors in and consequent confusion from sequence variant reporting in relation to genetic disease is highly undesired. Although the recommendations for variant description of the Human Genome Variation Society (HGVS)[1] have been been largely accepted world-wide as the standard nomenclature, errors in reporting remain. To promote error-free reporting we have developed the Mutalyzer sequence variation nomenclature checker[2]. Construction of variant descriptions accepted by Mutalyzer requires basic knowledge of the standard nomenclature and comparison of the reference sequence and the variant sequence.

The chance of finding a complex variant increases with the advert of sophisticated variant callers (e.g., Pindel) and the rise of long read sequencers (e.g., PacBio). We have developed a new tool called Description Extractor[3] to help users describe complex variants. The algorithm used closely follows the human sequence comparison approach to describe a variant. It will first find the “area of change”. Then it finds the largest overlap between the original area and the area in the observed sequence. This process is repeated until the smallest description is found. The tool ensures that the same description will be generated every time researchers observe the variant. A significant advantage of the tool is that knowledge of the HGVS nomenclature is not required to generate correct descriptions. This not only helps clinicians to generate correct descriptions, but its implementation also allows automation of the description process.

Funded in part by the European Community's Seventh Framework Programme (FP7/2007–2013) under grant agreement No. 200754 - the GEN2PHEN project.

RNAseq Analysis using the Pipeline Graphical Workflow Environment in Neuropsychiatric disorders. *F. Torri[1,2], I.D. Dinov[2,3], A. Zamanyan[3], S. Hobel[3], P. Petrosyan[3], Z. Liu[3], P. Eggert[3,4], I. Guella[1], J. Pierce[3], A.P. Clark[5], J.A. Knowles[5], J. Ames[2], C. Kesselman[2], A.W. Toga[2,3], S. Potkin[1], M.P. Vawter[1], F. Macciardi[1,2].* 1) Department of Psychiatry and Human Behavior, University of California, Irvine, Irvine, CA 92617; 2) Biomedical Informatics Research Network (BIRN), Information Sciences Institute, University of Southern California, Los Angeles, CA 90292; 3) Laboratory of Neuro Imaging (LONI), University of California, Los Angeles, Los Angeles, CA 90095; 4) Department of Computer Science, University of California, Los Angeles, Los Angeles, CA 90095; 5) Zilkha Neurogenetic Institute, USC Keck School of Medicine, Los Angeles, CA 90033.

RNAseq is increasingly becoming the method of choice for investigating the transcriptional landscape of cells. This includes not only transcript abundance (i.e. differential expression), but also transcript diversity due to alternative splicing events, different promoter or transcription start sites or differential base pair editing of mRNA. An increasingly large number of workflows are available today to manage high-throughput genomics sequencing data, from basic data processing to high-quality visualization of results. Graphical workflow environments are emerging as useful tools for constructing, modifying, interconnecting and executing computational genomics protocols using data processing workflows, such as pipelines. We have developed the Graphical Pipeline for Computational Genomics and Visual Informatics for RNAseq (GPCGR) with a flexible graphical infrastructure for efficient RNA-seq analysis computing and distributed informatics research within the framework of a joint collaboration between LONI (Laboratory of Neuro Imaging) at UCLA and BIRN (Biomedical Informatics Research Network) at UCI, ISI and USC. We use this pipeline to analyze RNAseq data from 10 controls, 9 subjects with Bipolar Disorder (BD), and 8 Schizophrenics (SZ). Using our developed set of pipelines we performed, reference genome alignment and assembly of the reads into transcripts, estimation relative transcript abundance, identification of differentially expressed and spliced genes. We will report the possible diagnosis dependent differential expression and splicing of genes in pathways relevant to BD and SZ compared to controls. This study demonstrates the utility of collaboratively developed graphical pipelines to improve the efficiency of high-throughput RNAseq data analysis in investigations of the underlying pathophysiology of neuropsychiatric disorders.

ENViz: a Cytoscape plugin for integrative statistical analysis and visualization of multiple sample matched data sets. *A. Tsalenko[1], A. Kuchinsky[1], R. Navon[2], M.L. Creech[3], I. Steinfeld[4], Z. Yakhini[2].* 1) Agilent Laboratories, Santa Clara, CA; 2) Agilent Laboratories, Petah Tikva, Israel; 3) Blue Oak Software, Los Altos, CA; 4) Dept of Computer Science, Technion, Israel.

Modern genomic, metabolomics and proteomic assays produce high quality multiplexed measurements, often obtained from the same set of samples. These measurements characterize the molecular composition and activity of biological samples from complimentary points of view. Integrative analysis of such measurements still remains a challenge to researchers and practitioners in the field. Here we present ENViz - a plugin to the Cytoscape network biology software platform, that implements an enrichment networks approach to the joint analysis of two types of sample matched datasets. ENViz facilitates the extraction of biological insights from multiple types of highly multiplexed measurements via integrated statistical analysis of these measurements and by using available systematic annotations. ENViz analyses a primary data set (e.g. gene expression) with respect to a pivot data set (e.g. miRNA expression, metabolomics or proteomics measurements) and primary data annotation (e.g. pathway or gene ontology) in the following way. For each pivot entry, we rank elements of the primary data based on the correlation (or anti-correlation, or absolute value of correlation) to the pivot data across all samples, and compute the statistical enrichment of annotation elements (gene sets) in the top of this ranked list based on an mHG model (minimum hypergeometric statistics - Eden et al, PLoS CB 2007). Significant results are represented in Cytoscape as an enrichment network - a bipartite graph with nodes corresponding to pivot and annotation elements, and edges corresponding to pivot-annotation entry pairs with enrichments scores better than the user defined threshold. In addition, for analysis of enrichment in biological pathways, correlations of primary data and corresponding pivot data are visually overlaid on biological pathways for each significant pivot-annotation pair, using the WikiPathways (Kelder et al, NAR 2012) resource. Enrichments of GO categories are overlaid on top of the Gene Ontology DAG. Edges of the enrichment network, representing significant associations, may point to functionally relevant mechanisms. In Enerly et al. 2010 an association between miR-19a and the cell-cycle module was substantiated as an association to proliferation, further validated using high-throughput transfection assays where transfection of miR-19a to MCF7 cell lines resulted in increased proliferation.

Determining probability of rare variants: Design implications for family-based sequencing studies. *W. Wang, G. Peng.* Bioinformatics & Comp Biology, Univ Texas MD Anderson Cancer Ctr, Houston, TX.

It is still challenging to find rare variants in order to better understand the genetic basis of human disease. Family-based sequencing studies have been performed, in search for functionally important genes. A high false discovery rate in calling rare variants precludes comprehensive downstream functional analyses. To improve accuracy, recent studies have used linkage information among relatives. Ongoing sequencing studies include data on extended family members. We developed FamSeqPro, which evaluates the probability of variants in family-based sequencing data, given raw measurements from all family members, at a single base level. Using FamSeqPro, we performed simulation studies to identify cost-effective designs for finding inherited genetic mutations in families with diseases of interest. We illustrate the utility of FamSeqPro in real data: whole-genome sequencing of extended family pedigrees.

3590W

Harvest: A Web-Based Biomedical Data Discovery and Reporting Application Development Platform. *P.S. White[1,2,3], B. Ruth[1], M.J. Italia[1], J. Miller[1], J.W. Pennington[1].* 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Oncology, The Children's Hospital of Philadelphia, Philadelphia, PA, 19104, USA; 3) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA 19104, USA.

Biomedical researchers share a common challenge of making complex data understandable and accessible. This need is increasingly acute as investigators seek opportunities for discovery amidst an exponential growth in the volume and complexity of sequence data derived both from advances in experimental technology and the availability of large patient-oriented data stores relevant to genomic research. We sought to address this need by constructing novel tools to more effectively enable data discovery workflows that effectively integrate subject observational data with molecular data derived from patient samples. We developed Harvest, an open-source framework that provides a set of modular components to aid the rapid development and deployment of custom data discovery software applications. Harvest incorporates visual representations of multidimensional data types in an intuitive, web-based interface that promotes a rapid, iterative approach to exploring complex clinical and experimental data. These visualizations present data in contexts and formats immediately familiar to researchers without exposing them to underlying physical data models, which facilitates data exploration for hypothesis generation and pre-defined queries. The Harvest architecture capitalizes on standards-based, open-source technologies (e.g., HTML5, django, python, jQuery) to address multiple functional needs critical to a research and development environment, including domain-specific data modeling, abstraction of complex data models, and a modular, customizable web client. Harvest provides a large library of data visualization modalities, the ability to instantly identify subject cohorts based on user selection of both phenotypic and molecular attributes, an intuitive ETL tool, REST APIs to facilitate data exchange, and the ability to save, recall, and export user-defined data sets. Interfaces for novel disease investigations with well-structured data can be generated in days or weeks. We have demonstrated the utility of Harvest by developing and deploying multiple applications across several research domains, including hearing impairment, cardiology, and mitochondrial disorders. Examples include the NIDCD Audiological and Genetic Database (audgendb.chop.edu), the NHLBI Pediatric Cardiac Genetics Consortium (pcgc.research.chop.edu), and the NHGRI CSER Program, each of which support national-scale collaborative research. Harvest is available at http://harvest.research.chop.edu.

Pinpoint: A new algorithm to detect gene-gene interactions in large-scale genome-wide association studies. *D. Wong[1], S. Szymczak[2], J.E. Bailey-Wilson[2].* 1) Pinpoint Analytics, San Francisco, CA; 2) Statistical Genetics Section, Inherited Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, MD.

Genome-wide association studies (GWAS) have identified more than one thousand single-nucleotide polymorphisms (SNPs) that are reproducibly associated with hundreds of phenotypes. However, these variants explain only a small proportion of the overall heritability. The standard approach in GWAS is to analyze each SNP separately and is therefore not designed to identify genetic variants having a joint effect on the phenotype. Different statistical methods exist to identify gene-gene interactions, e.g. multifactor dimensionality reduction (MDR) or logic regression. However, most of these approaches do not scale well for testing all interactions in GWAS data, making these analyses computationally challenging. We evaluated a new computationally efficient algorithm, Pinpoint, that extracts multiple combinations of SNPs out of the data without restricting the search to a specific degree of interactions. We compared Pinpoint with logistic regression and random forests, a machine learning approach that jointly analyzes all SNPs. Genotypes for 100K independent SNPs in 10,000 samples were simulated with twenty-one SNPs having an effect on disease status by two-, three-, four-, five- and six-way interactions. In this model, the genetic main effects and interactions completely accounted for the risk of disease in the population. In this simple simulated model, all methods identified only causal SNPs, indicating good control of false positive findings. However differences were found in the ability to extract causal SNPs, the ability to interpret the extracted model, and the amount of computing resources required. In terms of the faintest signal successfully extracted by the algorithm, random forest was about two times more powerful than logistic regression, and Pinpoint was about five times more powerful. In terms of interpretability of the extracted model, Pinpoint provides explicit modeling of gene-gene interactions, whereas logistic regression and random forest only identify individual SNPs. In terms of required computing resources, Pinpoint requires several orders of magnitude less runtime than both logistic regression and random forest, and can be run on a PC. We plan to extend our simulation by simulating SNPs with realistic local linkage disequilibrium patterns and by simulating more realistic disease models with smaller effect sizes on risk of the disease. We will also present comparisons with other algorithms for analyzing large-scale datasets such as MDR.

3592W

A Unified Analysis Framework for Detecting Genetic Variations from Next-Generation Sequencing Data. *C. Xiao, S. Sherry.* NIH/NLM/NCBI, bethesda, md.

The per-base cost of whole genome sequencing has dropped significantly due to recent advancement of next generation sequencing (NGS) technologies, and a number of large-scale re-sequencing projects, e.g. 1000 Genomes, ICGC, TCGA, GO-ESP, and CGCI etc., have been initiated to extend our knowledge of single nucleotide polymorphisms (SNPs), short insertions/deletions (INDELs) and structural variations (SVs), and relate these variants to human diseases. However, data generation and analysis in a timely fashion present numerous challenges to researchers. In order to facilitate NGS data analysis in biomedical research, NCBI develops an integrated analysis framework (VPIPE) to profile genetic mutations from next-generation sequencing data in a uniform manner. This pipeline manages parallel-computing resources, aligns short reads to the reference genome sequences, refines the mapping of placed reads, calls SNPs, INDELs, and SVs, and performs de novo assembly and functional annotation according to data availability and project-specific policies. A centrally implemented pipeline streamlines the data processing workflow for the data generated by next-generation sequencing technologies.

HMM-DM: identifying differential methylation patterns using a Hidden Markov Model. *X. Yu[1], S. Sun[1,2].* 1) Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Case Cancer Center, Case Western Reserve University, Cleveland, OH.

DNA methylation is essential in both normal organism development and cellular differentiation. It is important to study the differential methylation patterns between two groups of biological conditions, especially for cancer diagnosis, prognosis, and therapeutics. With the rapid development of next-generation sequencing (NGS) technologies, it becomes possible to detect and analyze methylation patterns in single-base resolution for a large genome. However, it is challenging to process the enormous amount of complex methylation data generated by NGS technologies. Therefore, an accurate and effective NGS-based statistical method is in great need. To fulfill this demand, we have developed a Hidden Markov Model based method (called HMM-DM) to identify differential methylation between two groups. In particular, a Hidden Markov chain is used to infer the methylation of each CG site as Hypermethylated, Equally methylated, or Hypomethylated between two groups. Differentially methylated regions are then summarized based on the inferred hidden states, number of sites, and the distance between neighboring CG sites. We've compared our HMM-DM method to a CpG island-based linear model using a public available data set and shown that our method has the advantage of identifying local methylation patterns, and it can easily identify any differentially methylated regions in a genome. In addition, we have also compared this HMM-DM method with another HMM-based method (HMM-Fisher) that has been developed by our group.

Genotype calling for next-generation sequencing data from multiple populations. *K. Zhang, D. Zhi.* Dept Biostatistics, Univ Alabama at Birmingham, Birmingham, AL.

Genotype calling for next-generation sequencing (NGS) data from larger samples typically achieves higher accuracy than that from smaller samples. This is because current LD-based genotype calling methods, the best performing ones, leverage sharing of chromosomal segments among individuals, and there is a higher chance of chromosomal sharing in larger samples. As NGS data for multiple populations are becoming available, it is desired to combine the samples from multiple populations to achieve a large sample size. However, current LD-based methods typically assume a flat population structure, and thus may not work well with non-homogeneous samples. We developed a LD-based method that incorporates population structure into the commonly used chromosome segment sharing Hidden Markov models. Using simulated and real data, we show that our new models improve the accuracy of genotype calling and haplotype inference for samples from multiple related populations.

3595F

Detecting structural variants in cancer from whole genome and exome sequencing. *J. Zhang[1], Y. Shi[1], W. Foulkes[1,2], J. Majewski[1].* 1) Department of Human Genetics, McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 2) Program in Cancer Genetics, Departments of Oncology and Human Genetics, McGill University, Montreal, Quebec, Canada.

Next generation high-throughput sequencing technologies have been applied to investigate genetic disorders and gene expression changes on a large scale. Structural variants represent important types of genetic alternations that can lead to abnormal cell growth and proliferation, and therefore contribute to the development and progression of cancer. Various computational algorithms have been developed to identify and characterize structural variants from genome sequencing data. These approaches can be divided into four categories: read-pair, read-depth, split-read and assembly. However, most of these computational methods are not integrated, and their abilities to detect structural variants from cancer samples are not clear. Here we describe and evaluate three software: BreakDancer, CNAseg and Pindel, which are based on read-pair, read-depth and split-read algorithms, respectively. We performed the analysis using two cancer genomes from familial Wilms' tumor patients, and compared the three software based on their sensitivity and accuracy. Approaches for structural variant detection in exome sequencing data are more limited because of the discrete nature of the data as well as the presence of systematic biases that result in non-uniform distribution of read-depth. As a consequence, most current methods for copy number variation detection rely on pair-wise comparison of normalized read-depth; split-read and paired-end methods are inapplicable. Presently, we evaluate two software (Seqgene and CONTRA) and introduce our own modified implementation (fishing CNV), all of which are based on read-depth. Preliminary analysis of exomes from Neonatal opsoclonus and ovarian cancer patients using these software show highly comparable results, and suggest that read-depth approaches are capable of detecting copy number alterations at the resolution of the exon, as well as identifying large scale genomic alterations in cancer.

Causal inference of gene regulation based on sub-network assembly. *W. Hsieh[1], C. Peng[2], A. Dai[1], S. Peng[4], T. Yen[3,4].* 1) Inst Statistics, National Tsing Hua Univ, Hsin-Chu, Taiwan; 2) Resource Center for Clinical Research, Chang Gung Memorial Hospital, Taoyuan, Taiwan; 3) Head and Neck Oncology Group, Chang Gung Memorial Hospital and Chang Gung University, Taoyuan, Taiwan; 4) Department of Nuclear Medicine and Molecular Imaging Center, Chang Gung Memorial Hospital and Chang Gung University, Taoyuan, Taiwan.

Identifying disease-causing genes requires studying the nature of genes in the context of regulatory systems. We develop a four-step strategy to integrate both gene expression and SNP variation to make causal inference on a gene regulatory network. The first step towards our goal is to select gene modules on an interaction map that includes the protein-protein interaction, gene-gene interaction and well recognized pathways. Those modules are overlapping to each other and they individually are highly connected according to the gene expression profiles. The modules are also selected according to their discriminative power of distinguishing patients' disease status. The second step is to select the sequence variation underlying each of the modules. A multivariate modeling strategy is adopted to select SNPs that are strongly associated with the expression. It is close to the expression QTLs while the response we concern now is the joint variation of the whole module. The third step is to build directed sub-networks with each module and its associated SNPs. The sub-networks are then assembled with a ranking strategy that transfers the local information into global information. The proposed procedure was applied on a cohort of oral squamous cell carcinoma patients that were profiled with both exon expression and SNP variation. The modules were selected according to their association with lymph node metastasis. The causal network of our inference shows a change of regulation direction among a few key genes in the PPAR signaling pathway.

Identification of candidate variants in population based whole exome sequencing data through integration of functional prediction with bayesian penalized regression. *J. Lu[1,2], A. Sabo[1], J. Reid[1], D. Muzny[1], E. Boerwinkle[1,4], R. Gibbs[1,3], ARRA Autism Sequencing Consortium.* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Structural and Computational Biology and Molecular Biophysics, Baylor College of Medicine, Houston, TX; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA; 4) Institute of Molecular Medicine, University of Texas Health Science Center, Houston, Texas, USA.

Despite their success in identifying variants associated with complex disease, current SNP by SNP methods used in genome-wide association studies (GWAS) are inadequate for use with population case -control with whole exome sequencing data. Rare variants inherent in exome data (minor allele frequency < 5%) challenge traditional frequentist approaches. Further, joint modeling of rare and common SNPs and INDELs while computationally challenging, provides more accurate analysis of genetic structure. For example, any statistical model for exome data should accommodate models where multiple rare variants throughout the population may affect genes and pathways at different nucleotide positions but still produce the same disease phenotypes.

We are implementing two concurrent solutions to identify the significant variants in case-control whole exome sequencing data. We employ both a Bayesian Probit and Logistic penalized (LASSO) regression. Through the appropriate use of priors, these models are able to engage in variable selection. Parameters in these models are estimated using Markov Chain Monte Carlo or with variational methods, respectively.

We model our data in several ways: we first employ both additive and dominant genetic models. We then include in step wise fashion functional, conservation, and gene based annotation data from ANNOVAR and dbNSFP. Lastly we aggregate the variant level data into our hierarchical regression as gene and pathway level effects. To test our methods we apply them to the ARRA Autism Sequencing project, a multi-institutional collaboration focused on identifying heritable variation in Autism Spectrum Disorders via whole exome sequencing of 1000 cases and 1000 matched controls. These methods are generating candidate variants and genes for further functional testing.

Joint association of multiple correlated phenotypes using matrix-variate linear mixed-models. *N. Furlotte, E. Eskin.* University of California, Los Angeles 3532-J Boelter Hall Los Angeles, CA 90095-1596.

Genome-wide association study (GWAS) methods have become a favorite tool among those available to researchers attempting to dissect complex traits. However, most GWAS methods are designed to interrogate individual phenotypes, while ignoring the availability of multiple correlated phenotypes. Multi-trait mapping approaches, exploiting the utility of correlated phenotypes in the mapping procedure, have been proposed in the context of linkage analysis and a small number of works have proposed similarly motivated methods for GWAS. Unfortunately, the complex dependency structures present in many current GWAS datasets, often caused by population structure or cryptic relatedness, make it difficult to translate linkage-based approaches to the GWAS context and limit the applicability of the proposed multi-trait GWAS approaches. Linear mixed-models (LLMs) are a widely accepted approach to avoid the pitfalls of population structure in single trait association analysis and LMM-based methods for performing artificial selection in agricultural and livestock communities using multiple correlated traits have a rich history in the literature. Such LMM-based multi-trait models may be adapted for use to map multiple correlated traits in GWAS. However, such approaches become computationally intractable, when considering multiple correlated phenotypes across large GWAS cohorts. In this paper, we introduce a genome-wide association study methodology for use with multiple correlated phenotypes, which we call the matrix-variate linear mixed-model (mvLMM). Our mvLMM method has a significantly lower computational cost when compared with a standard LMM-based formulation. We first show that this method results in increased power over single trait mapping. Next, we show how when using the mvLMM framework, it is possible to isolate the fraction of the total phenotypic correlation that is attributable to genetics from that which is attributable to environment. Finally, we apply our method to map traits in the 1966 Northern Finnish Birth Cohort and evaluate the ability of the proposed method to identify known associations with increased significance and to identify novel associations that were not uncovered in single trait analysis.

The Human Gene Connectome: A Map of Short Cuts for Morbid Allele Discovery. *Y. Itan[1], S.Y. Zhang[1], G. Vogt[1], A. Abhyankar[1], L. Quintana-Murci[3], L. Abel[2], J.L. Casanova[1,2].* 1) The Rockefeller University, New York, NY; 2) INSERM, Paris, France; 3) Pasteur Institute, Paris, France.

High-throughput genomic data reveal thousands of gene variants per patient and it is often difficult to decipher which of these variants underlie disease in individuals. At the population level however, there can be some level of phenotypic homogeneity, with alterations of specific physiological pathway underlying the pathogenesis of a particular disease. Here we describe the human gene connectome (HGC) as a new approach facilitating the interpretation of abundant genetic data, guiding subsequent experimental investigations. We identify the set of degrees of separation, shortest plausible biological distances and routes between all pairs of human genes, by applying a shortest distance algorithm to the full human gene network. We demonstrate a hypothesis-driven application of the HGC in which we generate a TLR3-specific connectome, which may be useful for the genetic dissection of herpes simplex virus encephalitis of childhood. We also developed the functional genomic alignment (FGA) approach from the HGC. In FGA, the genes are clustered according to their biological proximity (rather than the traditional evolutionary genetic distance), as estimated from the HGC. We discuss HGC application for discovering the comprehensive set of disease causing alleles in full cohorts of patients and for complex diseases and traits. The HGC and FGA should facilitate the genome-wide discovery and experimental validation of disease-causing alleles.

Transcriptome sequencing of nPOD type 1 diabetes pancreatic samples for viral sequence identification. *S. Morfopoulou[1], G. Zhao[2], R. Ferreira[3], A. Pugliese[4], J. Petrosino[5], L. Thackray[2], V. Plagnol[1], nPOD-Virus group.* 1) University College London (UCL) Genetics Institute, United Kingdom; 2) Division of Immunobiology, Washington University, St Louis; 3) WT/JDRF Diabetes and inflammation laboratory, University of Cambridge, Cambridge, UK; 4) Diabetes Research Institute, Miller School of Medicine, University of Miami; 5) Department of Molecular Virology and Microbiology, Baylor College of Medicine, Houston.

A growing body of genetic and epidemiological evidence suggests a link between viral infections and type 1 diabetes (T1D). Viruses may act as a trigger for T1D onset and the identification of viral agents that are present in young onset cases may provide new clues into T1D pathogenesis. Transcriptome sequencing, or RNA-Seq, is a powerful technology to detect active viral infections in human tissue. To identify viruses relevant to T1D etiology, we undertook as part of the network of pancreatic donors virus group (nPOD-V) initiative a RNA-Seq experiment for a set of post-mortem pancreatic samples from young onset T1D cases and controls. We sequenced total RNA from n = 7 pancreatic samples using a combination of Illumina short sequencing reads and longer 454 reads. We used a metagenomic analysis to detect pathogens present in these samples. To maximize the power of this study, we developed a novel Bayesian statistical approach to detect organisms expressed at very low levels in metagenomic mixtures. Our results highlight the difficulties and opportunities provided by deep short read sequencing to generate insights into the contribution of viral infections to T1D.

VARITAS: Variant Analysis with Rapid Incorporation of Annotation Sources. *B. Powell.* Medicial Genetics, Baylor College Med, Houston, TX.

The analysis of genome-scale data for purposes of diagnosis or gene discovery begins with automated analysis but typically involves manual evaluation of variants of possible significance by comparison with a number of databases that are undergoing frequent upgrades. This manual step can be facilitated by presentation of a broad class of existing annotations to the expert annotator. VARITAS is a software package that allows for incorporation of information from internally-developed or external annotation sources such as the 1000 Genomes Project, NIEHS Environmental Genome Project, NHLBI Exome Sequencing Project, dbSNP, etc. This software was designed for a particular balance of performance with ease of installation and use. The tabix indexing scheme is used, obviating the need for maintenance of a generalized database program. Reference datasets are stored in a compressed format, minimizing disk utilization and read-time when used in network file storage. The standard VCF (variant call format) is used for both input and output, allowing VARITAS to be easily included in other data analysis pipelines. Configuration may be performed at the command-line or with a script-like configuration file; addition of new data sources does not require recompilation. Variants are processed in a streaming fashion, so runtime memory usage is less than 1GB. Processing time varies with the number of data sources incorporated, but annotation of variants from a typical exome can be performed in less than 20 minutes on a personal computer. VARITAS runs using the Java virtual machine, so it can be used on all major computing platforms. This work is supported through 5R01CA138836 and 5T32GM007526.

Clinical Diagnostic Tools for Family Genome and Exome Data. *A. Russell, F. De La Vega, J. Rule, M. Reese.* Omicia Inc, Emeryville, CA.

Continuing declines sequencing costs combined with successes in the elucidation and diagnosis of Mendelian diseases through NGS whole-genome and exome sequencing is creating enthusiasm for using these technologies in the clinic. These analyses are much more powerful when unaffected or affected family members are analyzed together with the patient, resulting in higher diagnosis rates. However, the analysis pipelines described to date are either custom workflows or tailored for expert researchers and are complex to use or install, lack secure access and project management capabilities, or use terminology unfamiliar in a clinical setting. Here we present the family analysis capabilities of the Omicia Opal system, a secure online service which enables analyses of whole-genome, exome or gene panel data provided in commonly used formats such as VCF and Complete Genomics (CGI). When supplied family pedigrees, it verifies that family relationships are correctly labeled to rule out relationship misspecification, and employs the VAAST algorithm to rank genes with regard to the likelihood that they are disease-causing. The user is presented a filterable table of candidate disease-genes and their variants, along with their genotypes in each family member,,classified following the guidelines from the American College of Medical Geneticists (ACMG). Information is presented on any protein impact the variant might cause, allele frequency information, and disease information associated with the either the genes or variants from publically-available and licensed databases, or from the user's own gene and variant databases, as well as sequencing metrics such as quality values and read depth. Users can annotate relevant variants, flag non-disease causing variants or variants of unknown significance (VUS) where appropriate, share their findings with colleagues and generate reports in PDF format suitable for consumption by clinicians. We present results for several simulated cases, constructed by spiking two trios of Puerto Rican and Yoruban origin sequenced by CGI, with disease variants for several recently elucidated Mendelian diseases. These cases are analyzed with Opal's variant mining interface and VAAST report showcasing how the tool could be used in clinical research and eventually diagnostics. The Opal system addresses deficiencies in current analysis software and provides capabilities that enable interpretation of NGS genome and exome data in a clinical setting.

3603F

ASAP: an easy to use pipeline for sequencing data processing. *E. Torstenson[1], C. Li[1,2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Biostatistics, Vanderbilt University, Nashville, TN.

Modern sequencing technologies have given researchers access to deep sequencing data on a large scale and in a timely fashion. However, data of this size presents many new challenges, including lengthy processing times and increased probability of human error when processed manually. We have developed a new program, Advanced Sequence Automated Pipeline (ASAP), as a way to simplify the process of translating fastq sequence data into annotated variant calls by typing as few as three commands; all without the need for administrative rights or dedicated hardware. ASAP works both on computer clusters and on standalone machines with minimal human involvement and maintains high data integrity, while allowing complete control over the configuration of its component applications. It is highly configurable and allows users to align fastq data, realign reads around insertions and deletions, recalibrate quality scores, perform variant calls and annotation in any combination while offering flexible sample grouping schemes to suit various needs and resources. It also provides tools for dividing jobs into small pieces for maximum throughput on the local cluster and offers an easy to use interface for submitting and tracking jobs and identifying job failures. ASAP also allows basic quality checking such as transition-transversion and het:hom ratios so that researchers can immediately spot problems before committing resources toward analysis. The program allows users to incorporate configuration settings from other researchers to allow shared, “Best Practice” methodologies, assist groups in using common resource paths as well as providing a simple mechanism for reproducibility. ASAP is designed to minimize user involvement and maximize flexibility for use and future development. We used ASAP to process 5 exome and 2 whole genome paired end sequencing data with >30x coverage which completed without any further user intervention. Steps performed include alignment, local realignment, recalibration and SNP calling. Each step was broken down into a number of jobs which were run in parallel. For the 5 exomes, a total of 287 jobs were executed with average runtimes of 43.6, 29, 7 and 1.6 minutes respectively at each step. For the 2 whole genome sequence data, a total of 192 jobs were created with average runtimes of 277.5, 181.7, 109.3 and 9.8 minutes respectively at each step.

Identifying biological pathways and human diseases in high-throughput human genetic studies. *C. Xie[1], X. Mao[2], J. Huang[1], Y. Ding[1], J. Wu[3], S. Dong[1], L. Kong[1], G. Gao[1], C. Li[4], L. Wei[1].* 1) Center for Bioinformatics, State Key Laboratory of Protein and Plant Gene Research, College of Life Sciences, Peking University, Beijing, China; 2) Computational Systems Biology Lab, Department of Biochemistry and Molecular Biology, Institute of Bioinformatics, University of Georgia, USA; 3) Cancer Research Program, Garvan Institute of Medical Research, 384 Victoria Street, Darlinghurst, NSW, Australia; 4) Laboratory of Bioinformatics and Genomic Medicine, Institute of Molecular Medicine, Peking University, Beijing, China.

Genome-wide high-throughput technologies give the opportunity to study polygenic effects existed in complex diseases. These high-throughput human genetic studies often identify dozens to hundreds of relevant genes. From these genes, geneticists want to understand which biological pathways may be involved in and which other human diseases may be related with. Here, we report a method to deal with this problem. We retrieved and integrated data from five pathway databases (KEGG PATHWAY, PID, BioCyc, Reactome and Panther) and five human disease databases (OMIM, KEGG DISEASE, FunDO, GAD and NHGRI GWAS Catalog) as our background knowledge base. For an input set of genes, our method annotates them with putative pathways and disease relationships based on mapping to genes with known annotations. Then it performs hypothesis tests and FDR corrections to identify statistically significantly enriched pathways and diseases. Our method can be accessed at http://kobas.cbi.pku.edu.cn. We further optimized our statistical method, and incorporated knowledge from Gene Ontology, which improved the results in our researches of complex diseases.

3605F

GenAMap: An Visual Analytics Software Platform for eQTL and GWAS Analysis. *E. Xing[1,3], R. Curtis[2,3], S. Lee[1], S. Shringarpure[1], J. Yin[3].* 1) School of Computer Science, Carnegie Mellon University, Pittsburgh, PA; 2) Joint Carnegie Mellon-University of Pittsburgh PhD Program in Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 3) Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA.

Structured association mapping has been shown to be a powerful approach to find disease associated genetic polymorphisms. However, these algorithms are often difficult to use as it requires expertise and effort to customize. Because of the difficulty required to use these state-of-the-art techniques, simpler and less powerful methods are more popular. To make algorithms easily accessible to users, we developed a software platform called GenAMap. It integrates computational methods for association mapping and population genetics with novel visualizations and graphical user interface. GenAMap uses an automatic processing system called Auto-SAM, which enables biologists to automatically perform structured association mapping using various algorithms. Auto-SAM includes algorithms to discover gene-networks and find population structure. It can also run popular association mapping algorithms. For efficient execution of these algorithms, Auto-SAM makes use of parallelization. Auto-SAM is available through GenAMap. GenAMap and AutoSAM are implemented in JAVA; GenAMap is available through http://sailing.cs.cmu.edu/genamap.

3606W

PHV: A high accuracy SNP and INDEL variant caller based on the Profile Hidden Markov Model. *M. Zhao, W. Lee, G. Marth.* Biology Dept., Boston College, Chestnut Hill, MA., USA.

Accurately calling single nucleotide polymorphisms (SNPs), and insertion and deletion (INDELs) polymorphisms is crucial to medical and population genetics. A variety of algorithms have been developed to detect such variations using next-generation sequencing (NGS) data and have been successfully applied to large-scale re-sequencing projects (for example the 1000 genomes project), but INDEL detection still presents significant problems. Moreover, most of the existing algorithms are designed for high-quality short-read data with a low INDEL sequencing error rate whereas upcoming technologies such as Oxford Nanopore single molecule sequencing technique produce long reads at the cost of an increased sequencing error rate. This leads to more challenging variation detection, and is beyond the scope of present variant detection algorithms. We have developed a tool based on Profile Hidden Markov Model (PHMM) for accurately calling SNPs and INDELs from data with varying quality. In particular, it focuses on jointly modeling sequencing and alignment uncertainties, which are overlooked or not properly modeled by most existing variant calling algorithms. While this tool is developed for use with long read technologies, it also demonstrates an improvement in variation detection when deployed on currently available short read technology data. A single sample (NA12878 from the 1000 genomes project) with deep sequenced whole genome data (Illumina and LS454) has been used to test the algorithm. Comparisons with variants called using the popular Samtools and Freebayes software, PHV (the PHMM supported Variation detector) showed higher sensitivity and specificity for INDEL detection and higher specificity for SNP detection, especially in the genomic regions with poorly aligned reads. We plan to use banded PHMM in a sliding window along the whole genome to achieve comparable processing speeds to other variation callers and test the performance of this tool on PacBio and Ion Torrent sequenced E.coli data at the next step.

3607F

Developing copy number variation based case-control association analysis tool and its application for disease analysis. *Y. Chung[1], J.H. Kim[1], H.J. Hu[1], S.H. Yim[1], J.S. Bae[2], S.Y. Kim[3].* 1) Integrated Res Ctr Genome Polymorphism, Catholic Univ Korea,Sch Medicine, Seoul, South Korea; 2) Laboratory of Genomic Diversity, Sogang University, Seoul, Korea; 3) Medical Genomics Research Center, KRIBB, Daejeon, Korea.

Copy number variation (CNV) is one of the major components of human genetic variations and it is thought to contribute to inter-individual differences in diverse phenotypes. Although there are several tools for CNV association studies, most of them do not provide appropriate definitions of CNV regions (CNVRs), which are essential for CNV-association studies. We previously develop a user-friendly program called CNVRuler for CNV-association studies (Bioinformatics 2012 doi: 10.1093/bioinformatics/bts239). Outputs from the ten most common CNV defining algorithms can be directly used as input files for determining the three different definitions of CNVRs. CNVRuler supports chi-squared and Fisher's exact tests in addition to logistic and linear regression analyses using defined CNVRs and clinical information. Clinical information can be easily coded into a simple tab-delimited text file format. Both the false discovery rate and Bonferroni correction can be used for multiple testing with this software. CNVRuler supports the likelihood ratio test (LRT), which can be used to assess the goodness-of-fit of logistic regression models. For population stratification, CNVRuler uses principal component analysis. It calculates eigenvectors and uses 0 to 3 principal components as covariates of regression. In order to validate the performance of CNVRuler, we applied the data of 4,574 CNVs identified by Bae et al. in 500 cases of subarachnoid aneu-rysmal hemorrhage (J Hum Genet. 55, 726). The three different CNVR-defining algorithms identified different numbers of CNVRs: 1,843 CNVRs, 2,211 ROs and 2,797 fragments. We compared the lists of our CNVRs with their significant CNVs. Two significant CNVs identified by Bae et al. were detected by all three algorithms of CNVRuler. In association analyses, the two CNVRs were consistently significant in univariate models regardless of the CNVR-defining algorithm. After validation, we adopt CNVRuler to analyze the genome-wide lupus-CNV association and got two significant results. Here we present our CNV-disease association result using CNVRuler.

DWAC-seq - Dynamic Window Approach for CNV detection using next-generation targeted and full genome sequencing tag density. *V. Koval[1], J. van Rooij[1], K. Estrada[1], P. Arp[1], M. Jhamai[1], R. Kraaij[1], A. Uitterlinden[1], E. Cuppen[2,3], V. Guryev[2].* 1) Genetic Laboratory, Department of Internal Medicine, Erasmus MC, Rotterdam, Netherlands; 2) Hubrecht Institute KNAW, Utrecht, Netherlands; 3) Department of Medical Genetics, UMCU, Utrecht, Netherlands.

We present a novel method for the detection of relative copy number variants (CNVs) between a set of genomes based on next-generation sequencing (NGS) tag density. It is suitable for both targeted (e.g., exome) and full genome sequencing. The distinctive dynamic window approach allows for efficient CNV detection independent of sequenceability and mappability of genomic regions. The accurate breakpoints estimation is rigid to the sequencing noise and the presence of off-target reads. We demonstrate the sensitivity and high dynamic range of DWAC-seq by analyzing a family trio with full exome NGS data, full genome NGS data of the Genome of The Netherlands (GoNL) project, and SNP array (Illumina 550K, 610K, 2.5M, 5M) results of the Rotterdam Study (RS), a deeply phenotyped population-based cohort study of ~15,000 Dutch Caucasian elderly subjects. The tool opens wide possibilities for GWAS studies based on sequencing CNV data. DWAC-seq will be applied to full exome NGS data of 3,000 RS subjects in the CNV analysis of diseases and phenotypic traits.

3609F

Fast detection of de-novo copy number variants from case-parent SNP arrays identifies a deletion on chromosome 7p14.1 associated with non-syndromic isolated cleft lip/palate. *I. Ruczinski[1], R.B. Scharpf[1], S. Younkin[1], H. Schwender[2], M. Marazita[3], A.F. Scott[1], T.H. Beaty[1].* 1) Johns Hopkins Univ, Baltimore, MD; 2) University of Dortmund, Germany; 3) University of Pittsburgh, Pittsburgh, PA.

We define a statistic called “minimum distance” to capture differences in copy numbers between offspring and parents using genome wide SNP array data. Following segmentation of the minimum distance by circular binary segmentation, final inference regarding de novo copy number events is based on a posterior calling step. We apply both the MinimumDistance and PennCNV algorithms to simulated data, and to a study of oral clefts, validate several de novo regions by qRT-PCR, and assess the overall concordance of these two algorithms. We conclude that MinimumDistance is an effective approach for reducing technical and experimental sources of noise which can generate false positives in experimental datasets. Coupled with smoothing by segmentation and posterior probabilities to incorporate information regarding allelic frequencies, this MinimumDistance algorithm compares favorably with PennCNV, and it is much faster. Using trios not selected for phenotype as controls, we identify a region on chromosome 7p14.1 with a (genome-wide) significantly higher number of de-novo deletions in the case-parent trios ascertained through an oral cleft.

VarioML Framework for Comprehensive Variation Data Representation and Exchange. *M. Byrne[1], I.A.C. Fokkema[2], O. Lancaster[3], T. Adamusiak[10], A. Ahonen-Bishopp[9], D. Atlan[7], C. Beroud[11], M. Cornell[8], R. Dalgeish[3], A. Devereau[8], G.P. Patrinos[6], M.A. Swertz[5], P.E.M. Taschner[2], G.A. Thorisson[3], M. Vihinen[4], A.J. Brookes[3], J. Muilu[1].* 1) Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland, Helsinki, Uusima, Finland; 2) Department of Human Genetics, Leiden University Medical Center, Netherlands; 3) Department of Genetics, University of Leicester, Leicester, UK; 4) Department of Experimental Medical Science, Lund University, Lund, Sweden; 5) Genomics Coordination Center, Department of Genetics, University Medical Center Groningen and Groningen Bioinformatics Center, University of Groningen, Netherlands; 6) University of Patras, School of Health Sciences, Department of Pharmacy, Patras, Greece; 7) Phenosystems Inc., Belgium; 8) National Genetics Reference Laboratory, Manchester, UK; 9) Biocomputing Platforms, Ltd., Espoo, Finland; 10) European Molecular Biology Institute, Hinxton, UK; 11) Inserm, Paris, France.

Sharing of data about variation and the associated phenotypes is a critical need, yet variant information can be arbitrarily complex, making a single standard vocabulary elusive and re-formatting difficult. Complex standards have proven too time-consuming to implement.

The GEN2PHEN project addressed these difficulties by developing a comprehensive data model for capturing biomedical observations, Observ-OM, and building the VarioML format around it. VarioML pairs a simplified open specification for describing variants, with a toolkit for adapting the specification into one's own research workflow. Straightforward variant data can be captured, federated, and exchanged with no overhead; more complex data can be described, without loss of compatibility. The open specification enables push-button submission to gene variant databases (LSDB's) e.g., the Leiden Open Variation Database, using the Cafe Variome data publishing service, while VarioML bidirectionally transforms data between XML and web-application code formats, opening up new possibilities for open source web applications building on shared data. A JAVA implementation toolkit makes VarioML easily integrated into biomedical applications. VarioML is designed primarily for LSDB data submission and transfer scenarios, but can also be used as a standard variation data format for JSON and XML document databases and user interface components.

VarioML is a set of tools and practices improving the availability, quality, and comprehensibility of human variation information. It enables researchers, diagnostic laboratories, and clinics to share that information with ease, clarity, and without ambiguity.

Gene-centered viewing, storing and sharing of exome/genome variant and phenotype data. *J.T. Den Dunnen, I.F. Fokkema, I.C. Lugtenburg, J. Hoogenboom, Z. Tatum, G.C.P. Schaafsma, M. Vermaat, J.F.J. Laros, P.E.M. Taschner.* Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands.

The favourite view of sequence variant data in DNA diagnostic centers is gene-centered. We have developed a new version of the LOVD platform (Leiden Open-source Variation Database, http://www.LOVD.nl) facilitating the analysis of exome and genome sequence data. During installation, web services retrieve gene and transcript information on the fly. Imported variant data are stored using chromosomal nucleotide positions as a reference. Data can be stored and displayed in several ways: variant-by-variant or all connected to one individual. Using the existing LOVD functionality, users have the option to perform query per gene or individual, to link to other resources of interest, to get genome browser views of the data and to using web services to access variants stored in other gene variant databases. LOVD 3 has the unique option to independently store both the phenotypes screened and the variants detected. This gives submitters the chance to share inconclusive results, allowing collaborators with matching data to join the gene identification project and crack the case together. In addition, LOVD3 has a new access level, designated “collaborator”, allowing submitters to share otherwise non-public data with other submitters, e.g., to share detailed phenotype information with other diagnostic labs only.

Funded by the European Community's Seventh Framework Programme (FP7/2007–2013) under grant agreement n° 200754 - the GEN2PHEN project.

Leveraging metadata for experimental discovery at the ENCODE Portal. *E.L. Hong[1], C. Sloan[2], V. Malladi[2], K. Rosenbloom[2], G. Barber[2], G. Binkley[1], E.T. Chan[1], R. Fang[2], B.C. Hitz[1], D. Karolchik[2], V. Kirkup[2], K. Learned[2], J. Long[2], M. Maddren[2], M. Wong[2], A. Zweig[2], D. Haussler[2,3], J. Kent[2], J.M. Cherry[1].* 1) Dept of Genetics, Stanford University, Stanford, CA, 94305; 2) Center for Biomolecular Science and Engineering, University of California, Santa Cruz, CA, 95064; 3) Howard Hughes Medical Institute, University of California, Santa Cruz, CA, 95064.

The Encyclopedia of DNA Elements (ENCODE) Project is a collaborative project to create a comprehensive catalog of functional elements in the human and mouse genomes. To date, the ENCODE project has generated 3000+ experiments, using over 30 different experimental techniques and 300+ cell lines and tissue types, in order to investigate the binding sites of over 200 DNA-binding proteins, refine the annotation of protein-coding genes and non-coding RNAs, and examine the chromatin structure. As the ENCODE project enters its 6th production year, the data volume is expected to increase, covering more DNA-binding proteins, chromatin structure, and transcription in more cell lines and tissue types. All data generated by the ENCODE project are submitted to the Data Coordination Center (DCC) for validation, tracking, storage, and distribution to community resources and the scientific community. The number of data sets and the complexity of the methods used makes identification of experiments that match the interests of a researcher challenging. To accommodate the complex and diverse needs of researchers a new facility is being created. The ability to identify and download the appropriate data is being enhanced with the expansion of metadata that will be used to describe an experiment, the development of tools that will facilitate searching based on these metadata, and summaries of the experimental data. Data from the ENCODE project can be accessed via the ENCODE portal (http://www.encodeproject.org) and the UCSC Genome Browser (http://genome.ucsc.edu/cgi-bin/hgGateway).

3613F

A Bayesian hierarchical generalized linear model for identifying multiple interacting genes in family-based case-control studies. *J. Li, N. Yi.* Biostatistics, University of Alabama at Birmingham, Birmingham, AL.

Genetic interactions and rare variants are hypothesized to be two important putative explanations for the missing heritability of complex human diseases. Jointly analyzing interactions and rare variants could remarkably improve our understanding of the genetic architecture of most complex human diseases. We recently proposed a hierarchical generalized linear model (GLM) approach that can simultaneously analyze numerous common and rare variants as well as gene-gene and gene-environment interactions for population-based genetic association studies. In this article, we extend our previous method to family-based case-control genetic association studies. We develop a hierarchical Poisson GLM that is statistically equivalent to the standard conditional logistic models for family-based case-control genetic association studies but is more computationally feasible. We employ the Multinomial-Poisson transformation technique to simplify maximization of multinomial likelihood in model fit. To facilitate the process of model fit in presence of high dimensionality and rare variants, we create a fast and stable algorithm by incorporating an expectation-maximization (EM) algorithm into the usual iteratively weighted least squares as implemented in the R package glm. Extensive simulations based on real data show that the proposed method outperforms the existing approaches in terms of statistical power and parameter estimates, especially for interactions and rare variants. The new method has been implemented in our R package BhGLM which is available free to practitioners (http://www.ssg.uab.edu/bhglm/).

A national platform for clinical genetic analysis of high-throughput sequencing data in Norway. *M.C. Eike[1], H. Lærum[2], T. Hughes[1], S. Bremer[3], S. Bergan[4], G. Thomassen[5], M. Aanestad[6], T. GRünfeld[1], D.E. Undlien[1].* 1) Department of Medical Genetics, Oslo University Hospital, University of Oslo, Oslo, Norway; 2) IT Department, Oslo University Hospital, Oslo, Norway; 3) Department of Medical Biochemistry, Oslo University Hospital, Oslo, Norway; 4) Department of Pharmacology, Oslo University Hospital, Oslo, Norway; 5) University Center for Information Technology (UCIT), University of Oslo, Oslo, Norway; 6) Department of Informatics, University of Oslo, Oslo, Norway.

The introduction of high-throughput sequencing (HTS) into clinical practice poses great challenges in terms of analytic resources, integration and data security. The project *Norwegian clinical genetic Analysis Platform* (genAP) was initiated as a response to these challenges, aiming to establish a centralised infrastructure for secure storage and analysis of human sequencing data that allows for disseminated clinical use. GenAP is a collaborative project between Oslo University Hospital and the University of Oslo, with implementation of the system in an established high-performance computing environment. As part of this project, we are in the process of establishing pilot HTS pipelines for a set of clinical packages, each with a defined set of targeted genes. The pilots cover diagnostic, prognostic and pharmacogenetic areas, including cardiomyopathies, breast cancer and tacrolimus dosage, respectively. Initially, the pipelines involve targeted capture and resequencing, but the system will be scalable to exome and genome data for a large number of patients. To reduce the workload associated with manual analysis, we have sought to achieve a high degree of automation, including variant annotation and quality control, filtering based on public resources, identification of previously classified variants, and standardization of report information structure for integration with existing patient journal systems. The pilot phase includes comparing the performance of HTS to conventional methods, building a database of genetic variants adapted to our patient populations and real-world testing using collaborating clinicians. The experiences gained will be used to expand to other clinical packages, and the ultimate goal is to introduce the pipelines for widespread use in the clinic. Complementing the genetic, bioinformatic and clinical issues, the project also addresses legal, ethical and organizational issues encountered when HTS is deployed in large scale clinical decision making.

This presentation will demonstrate the overall architecture of our system and present initial experiences with the pilot systems.

3615F

Haplotyping human genomes using whole-genome sequence data. *V. Bansal.* Scripps Translational Science Institute, La Jolla, CA.

Rapid advances in high-throughput sequencing technologies have enabled the sequencing of the genomes for hundreds of individuals. However, virtually all individual genomes sequenced using next-generation sequencing technologies are incomplete with respect to haplotype information. Humans are diploid and haplotype information is essential for the complete understanding of genomic variation both at the individual and population level. Sequence reads that span multiple heterozygous variants in a diploid genome are informative about the phase between neighboring variant sites. Computational tools for assembling these reads into longer haplotype segments and integrating these haplotypes with alternate sources of haplotype phase information are needed. We describe a computational framework for leveraging the haplotype information present in sequence reads generated using next generation sequencing technologies for phasing individual genomes. Although the relative short read lengths of current high-throughput sequencing technologies combined with the short inserts used to sequence individual genomes limit the length of haplotypes that can be assembled using this approach, we have found that that (a) haplotype information can be used to improve the accuracy of variant calling, (b) long haplotypes can be assembled for highly polymorphic regions of the genome, e.g. HLA and (c) sequence-based haplotypes can complement family and population based methods for resolving haplotypes.

Comparing Protein Prediction Methods Using Disease-Causing Missense Variants. *P. Duggal[1], Y. Kim[2], M.K. Tilley[2], M.M. Parker[1], A. Maroo[1], A.P. Klein[1,3].* 1) Dept Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Inherited Disease Research Branch, NHGRI, NIH, Baltimore, MD; 3) Department of Oncology and Pathology, Johns Hopkins University, Baltimore, MD.

The success of next-generation sequencing studies to identify genetic variation associated with disease is dependent upon the ability distinguish between genetic variation that leads to a change in protein function and benign variation. Deciphering the role of these identified variants is often difficult because of low allele frequencies. Computational methods that classify the functionality of these variants are used to filter variants and to weight the relevance or importance of a given missense mutation in statistical analyses. We manually curated the Uniprot database, and the clinically associated variant list from the Human Genetic Mutation Database and identified 150 variants present in 1000 genomes data regardless of ethnicity. Using the OMIM database we identified 43 missense mutations from the 150 with published evidence of a functional role for the mutation, including differences in animal studies, clinical assays and binding affinities. We considered these 43 variants to be a “gold standard” since there were appreciable differences in function associated with each genetic change. Using 9 different prediction programs, we evaluated and compared the prediction performance. The programs used in this study were: SIFT, SNAP, PolyPhen-2, PMUT, VarioWatch, The Grantham Matrix Score, GERP++, SNPs&Go and MAPP. Depending on the algorithms and sources used in each protein prediction method, the prediction results were varied. Overall, the percent of variants predicted to be deleterious ranged from 51–77% using each program. Although for any given variant the percent of programs that predicted it to be deleterious ranged from 17–100%. These programs have been evaluated previously, but the use of a “gold standard” in which function was shown to be evident in the literature should provide the most informative comparison. The discrepancy in programs raises concerns about the use of an individual program to predict functionality in filtering or weighting analyses, since these may result in the exclusion of truly functional variants. This study suggests that multiple programs be considered when evaluating novel variants to limit the risk of false negatives, which will be especially important for complex diseases.

Considerations for the Processing and Direct-to-Consumer Return of Exome Sequences. *E.D. Harrington, C. McLean, A. Shmygelska, A. Chowdry, B. Naughton.* 23andMe Inc, Mountain View, CA.

In late 2011 23andMe announced our first publicly available sequencing product: the Exome Pilot Project. To return these data directly to consumers (DTC) we implemented a processing pipeline that would maximize the value to the consumer while maintaining data quality and security at each step. Enrollment in the pilot was limited to individuals who had been genotyped on the 23andMe platform. Samples were enriched using the Agilent SureSelect 50Mb platform and sequenced to at least 80X unaligned coverage using Illumina's HiSeq technology. Participants received their aligned raw data, variant calls, and a summary report describing relevant statistics and potential variants of interest based on a custom filtering process. We implemented a flexible and scalable pipeline for processing sequence data (exome and whole genome) using the Broad Institute's best practices. It employs a combination of standard tools (eg GATK) and custom software to automate the tracking of samples, data distribution to and collection from compute nodes, read mapping, variant calling, report generation, and validation against our existing genotype database. To quickly meet fluctuations in demand the pipeline can be deployed either locally or on a cloud platform. All variant calls were validated against existing genotype data when coverage on the 23andMe genotyping platform overlapped with the exome targets. For variant calls that passed our filters and had unambiguous stranding, we observed 99.6–99.9% concordance between chip and sequence data, consistent with the error rate of the chip. Lowering our stringency of filtering had a marked, though expected, effect on our concordance. Data security is integral to DTC data delivery. Data was encrypted with keys delivered via secure messaging on the 23andMe website. The encrypted raw data for each exome was on average 6GB, making bandwidth and data integrity another concern. We delivered data via Amazon S3 and the use of encryption made errors in transfer immediately obvious. Participant response to their exome data was varied but largely positive. Some participants had significant scientific background in genetics and interacted with others via the 23andMe community to provide guidance on their data. Some used their data to bootstrap research into rare diseases affecting family members, while others shared their results publicly via the Personal Genome Project. To date, no negative consequences of such data return have been observed.

3618W

Topological Mapping and Exploration of Genotyping Data using Iris. *J. Paquette, G. Singh, G. Carlsson, P.Y. Lum.* Ayasdi, Palo Alto, CA.

Genotyping samples from single-nucleotide polymorphism (SNP) arrays and next-generation sequencing (NGS) are large and complex. Furthermore, there is a systematic heterogeneity of samples due to sampling bias as well as natural patterns in the human population. These two issues, complexity and heterogeneity, confound the interpretation of genotyping samples via supervised detection of significant variants with respect to clinical status. A specific genomic variant might significantly confer sensitivity to a drug in one subgroup of a population whereas it may be less significant, or even have the opposite effect, in a different subgroup. Combining both subgroups in a supervised analysis of drug response will under-estimate the significance of the variant for the former subgroup and over-estimate the significance of the variant for the latter. Conventional methods for analysis and visualization of heterogeneity in a population of genotyping samples such as principal components analysis (PCA) often fail to indicate true patterns and similarities between samples. We make a case here for a novel approach to tackle the interpretation of large genotyping data sets, Topological Data Analysis (TDA), and present a software implementation, Iris, that leverages TDA to produce comprehensive network visualizations. TDA networks allow an investigator to visualize and understand complex patterns of heterogeneity in the overall population as well as local patterns of heterogeneity in select subgroups. The Iris software also contains tools for interactive supervised analysis via clinical data and exploration of significant variants in the chromosomal location and cellular pathway context. We present case studies applying TDA to the Wellcome Trust Consortium SNP array data set, the 1000 Genomes Project DNA-Seq data set, and a cancer genotyping data set. We contrast the differences between TDA and PCA, and highlight new variants discovered to significantly relate to disease incidence and drug response.

3619F

Development of 1920 Barcodes for Large-Scale Targeted Sequencing using the Access Array™ System. *X. Wang, F. Kaper, P. Chen, C. Friedlnader, G. Sun, A. May.* R&D, Fluidigm inc, South San Francisco, CA.

With the development and commercialization of high-throughput sequencing technologies, it has become possible to process hundreds or thousands of samples in parallel on a single sequencing run. In particular, targeted sequencing and genotyping of specific loci within the human genome can be enabled at high throughput with an appropriate barcoding strategy. Combining highly parallel barcoding with the Access Array™ System streamlines preparation of targeted sequencing libraries in large-scale genomic studies. We developed an algorithm to generate 1920 10-base barcodes (384×5) for use with any sequencing systems, including those from Roche, Illumina and Life technologies. 10-base barcodes were selected with different Hamming distances to enable accurate multiplexing of samples in the presence of single-base substitution errors. The barcodes have been further evaluated in the context of sequence tags required for multi-primer PCR amplification as implemented on the Access Array™ System. A number of sequence features were considered in barcode selection including potential homopolymers, hairpins or heteroduplex formation between tagging primers. Furthermore, the 1920 barcodes have been binned into different groups to incorporate different sequencing workflows. We will present data demonstrating successful amplification, sequencing and demultiplexing with 384 samples labeled with a subset of these barcodes. Sequence data are high quality, relative representation of samples, and amplicons within those samples have uniform coverage, and exhibit excellent technical reproducibility.

NGS Catalog: A database of next generation genome sequencing studies in humans. *J. Xia[1], Q. Wang[1], P. Jia[1], B. Wang[1], W. Pao[2,3], Z. Zhao[1,3,4].* 1) Department of Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, TN; 2) Department of Medicine/Division of Hematology-Oncology, Vanderbilt University School of Medicine, Nashville, TN; 3) Vanderbilt-Ingram Cancer Center, Vanderbilt University Medical Center, Nashville, TN; 4) Department of Psychiatry, Vanderbilt University School of Medicine, Nashville, TN.

Next generation sequencing (NGS), also known as massively parallel sequencing, is rapidly transforming biomedical and biological research from single gene to genome scale. Within only a few years of the advent of NGS technologies, it is now possible to allow researchers to apply whole exome sequencing (Exome-Seq), whole genome sequencing (WGS), whole transcriptome sequencing (RNA-Seq), or a combination of them to investigate individual genome(s), especially those related to disease. These rapidly emerging NGS studies provide us with an exceptional opportunity to examine the potential impact of genetic variants on diseases by systematically cataloging and summarizing key characteristics of the observed mutations. To provide the research community with a comprehensive NGS resource, we have developed the database Next Generation Sequencing Catalog (NGS Catalog, http://bioinfo.mc.vanderbilt.edu/NGS/index.html), a continually updated database that collects, curates and manages available human NGS data obtained from published literature. NGS Catalog deposits publication information of NGS studies and their mutation characteristics (SNVs, small insertions/deletions, copy number variations, and structural variants), as well as mutated genes and gene fusions detected by NGS. Other functions include user data upload, NGS general analysis pipelines, and NGS software. NGS Catalog is particularly useful for investigators who are new to NGS but would like to take advantage of these powerful technologies for their own research. Finally, based on the data deposited in NGS Catalog, we summarized features and findings from germline mutations and somatic mutations studies for human diseases/traits.

3621F

Genotype Imputation via Matrix Completion. *E.C. Chi[1], H. Zhou[2], G.K. Chen[3], D. Ortega Del Vecchyo[4], K. Lange[1,5].* 1) Human Genetics, University of California, Los Angeles, Los Angeles, CA; 2) Department of Statistics North Carolina State University Raleigh, NC; 3) Department of Preventive Medicine, USC, Los Angeles, CA; 4) Interdepartmental Program in Bioinformatics University of California Los Angeles, CA; 5) Departments of Biomathematics and Statistics University of California Los Angeles, CA.

Most current genotype imputation methods are model-based and computationally intensive, taking days to impute one chromosome pair on 1000 individuals. We describe an efficient genotype imputation method based on matrix completion. Matrix completion aims to recover an entire matrix when only a small portion of its entries are actually observed. Making an appeal to Occam's razor, it seeks the simplest matrix consistent with the observed entries. Often this statement formally translates to searching for a low rank matrix with a small squared error difference over the observed entries. Genotypes can be coded as 0, 1, or 2's by counting reference alleles and entering the counts into a matrix whose rows are labeled by individuals and whose columns are labeled by SNPs. Despite matrix completion's purely empirical nature, it seemed natural to us to investigate its application to a central problem in modern genetics research. Specifically, we apply a matrix completion strategy for the problems of imputation in a traditional GWAS and of genotype calling in low coverage sequencing. We consider simulated data based on haplotypes from HapMap and 1000 Genomes. Compared to the gold standard MACH program, matrix completion as embodied in our program Mendel-Impute achieves similar or better imputation accuracy while reducing run time by orders of magnitude.

Phenome-wide association study of common PXDN variants demonstrates association with aortic aneurysms. *J. Denny[1], L. Bastarache[1], G. Bhave[1], S. McCall[1], M. Sample[1], R. Carroll[1], P. Peissig[2], A. Kho[3], C. McCarty[4], M. Brilliant[2], J. Cowan[1], R. Chisholm[3], E. Larson[5], G. Jarvik[6], C. Chute[7], I. Kullo[7], D. Roden[1], B. Hudson[1].* 1) Vanderbilt University, Nashville, TN, 37232; 2) Marshfield Clinic, Marshfield, WI; 3) Northwestern University, Chicago, IL; 4) Essentia Institute of Rural Health, Duluth, MN; 5) Group Health Research Institute, Seattle, WA; 6) University of Washington, Seattle, WA; 7) Mayo Clinic, Rochester, MN.

Peroxidasin (PXDN) is an extracellular matrix heme peroxidase that forms reinforcing sulfilimine bonds within collagen IV protein networks. The enhanced expression of PXDN within endothelial and vascular smooth muscle basement membranes along with its cross-linking function suggested a potential role in vascular integrity and disease. To test this hypothesis in an unbiased fashion, we conducted an electronic medical record (EMR)-based phenome-wide association study of 29 SNPs located in or near PXDN available within existing genome-wide SNP data performed for other phenotypes selected by the electronic MEdical Records and GEnomic (eMERGE) network. The study was performed in 13,582 participants of European ancestry. Logistic regression for each of the 1547 algorithmically-defined phenotypes was performed for each SNP using an additive genetic model adjusted for age and sex. The top associations were with rs12714332, an intronic SNP in PXDN, and abdominal aortic aneurysms (AAA) (odds ratio [OR]= 1.55, 95% confidence interval [95%CI]=1.27–1.88, $P=1.2\times10^{-5}$) and any aortic aneurysms (OR= 1.41, 95%CI=1.19–1.68, $P=8.0\times10^{-5}$). The threshold for phenome-wide significance is 3.2×10^{-5}. Post-hoc evaluation of the accuracy of the PheWAS algorithm for predicting AAA cases was 86%. We then sought to replicate the association in a cohort of ~3800 patients with genome-wide SNP data. All patients with a billing code for AAA were manually reviewed by clinicians with full access to the EMR to confirm the presence of AAA. The set identified 46 cases with AAA. Comparing to 2860 controls without any aneurysms, the p-value trended toward significance, P=0.07, OR=1.9. These data suggest that PXDN may be associated with AAA and other aneurysms in humans. The PheWAS method, applied to large populations with extant genotype data, may enable rapid discovery of potential clinical implications of genes of unknown significance.

3623F

Rare Variant Association Testing under Low-Coverage and Pooling. *E. Halperin[1], J.H. Sul[2], O. Navon[1], B. Han[2], L. Conde[3], P. Bracci[4], J. Riby[3], C. Skibola[3], E. Eskin[2].* 1) School of Computer Science, Tel-Aviv University, Tel-Aviv, Israel; 2) Computer Science Department, University of California, Los Angeles, California 90095, USA; 3) Division of Environmental Health Sciences, School of Public Health, University of California, Berkeley, California 94720, USA; 4) Department of Epidemiology and Biostatistics, University of California, San Francisco 94107, California, USA.

Deep sequencing technologies allow us to study rare variants involved in disease. To increase the statistical power to detect effects of rare variants, several methods have been developed that group variants in genes and test for association between a disease and the set of variants. However, detecting subtle associations requires studies of hundreds or thousands of individuals, which is prohibitively costly. Low coverage sequencing and DNA pooling, where a pool of DNA samples from multiple individuals is sequenced in one experiment, are strategies that can help reduce the cost associated with current sequencing technologies. However, current disease association methods cannot be applied directly to such data as they require individual genotypes, which are lost in pooling, and are susceptible to errors in low coverage sequencing. In this work, we propose two novel methods for the analysis of rare SNPs from low coverage, error-prone sequencing with or without DNA pooling. We show by simulations that our methods outperform previous methods under low and high coverage sequencing, with and without pooling. By analyzing real pooled sequencing data from a study of non-Hodgkin's lymphoma, we estimate the sequencing error rate and the accuracy of pooling by comparing sequencing data to previously obtained GWAS data on the same samples. We simulate different study designs based on the parameters from the real data, and show that for a given budget, it is desirable to include all available individuals in sequencing pools in order to maximize power.

BioBin: A Bioinformatics Tool for Biologically Inspired Collapsing of Rare Variants. *C.B. Moore[1,2], J.R. Wallace[2], A.T. Frase[2], S.A. Pendergrass[2], M.D. Ritchie[2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) 1Center for Systems Genomics, Department of Biochemistry and Molecular Biology, The Huck Institutes of the Life Sciences, The Pennsylvania State University, University Park, PA.

There has been increasing interest in rare variants (RVs) and methods to detect their association to disease. We propose a flexible collapsing method inspired by biological knowledge. We have built a database, Library of Knowledge Integration (LOKI), which contains resources such as: the National Center for Biotechnology (NCBI) dbSNP and gene Entrez database information, Kyoto Encyclopedia of Genes and Genomes (KEGG), Reactome, Gene Ontology (GO), Protein families database (Pfam), NetPath - signal transduction pathways, Molecular INTeraction database (MINT), Biological General Repository for Interaction Datasets (BioGrid), Pharmacogenomics Knowledge Base (PharmGKB), the database of Evolutionary Conserved Regions (ECRBase), and the Open Regulatory Annotation Database (ORegAnno). BioBin can apply multiple levels of burden testing, including: functional regions, evolutionary conserved regions, genes, and/or pathways. BioBin has been tested using resequenced data with simulated variants, NHLBI GO Exome Sequencing Project Kabuki dataset, and low coverage data from the 1000 Genomes Project. BioBin was able to reliably detect causative variants in resequenced data with high sensitivity in a variety of simulated models and effect sizes. We successfully demonstrated the use of BioBin on NHLBI GO Sequencing data (Ng et al. Nature Genetics 2010). Lastly, we conducted a pairwise comparison of rare variant burden differences (MAF < 0.03) between ancestry groups (15 populations) of the 1000 Genomes Project and found marked differences. For example, between Yoruba (YRI) and European descent (CEU) individuals, we found that 56.8% of gene bins, 78.9% of intergenic bins, and 83.5% of pathway bins have significant differences in RV burden. Comparing two related populations, YRI and ASW (African ancestry in Southwest USA), we identified 0.39% gene bins, 0.60% of intergenic bins, and 0.98% of pathway bins had significant differences in RV burden. Ongoing efforts are examining regional characteristics using BioBin (evolutionarily conserved and/or regulatory). We are also exploring ancestry correction, the magnitude of potential stratification in RVs is large and inadequate correction could have large implications for sequence data analysis. BioBin is a useful, powerful, and flexible tool in analyzing sequence data and will be successful at uncovering novel associations with complex disease.

NCBI's ClinVar: data archive and tools for human variation of medical interest. *D. Maglott, S. Chitipiralla, D. Church, M. Feolo, J. Garner, W. Jang, J. Lee, R. Maiti, J. Ostell, L. Phan, G. Riley, W.S. Rubinstein, D. Shao, S. Sherry, K. Sirotkin, R. Tully, R. Villamarin, M. Ward.* Natl Ctr Biotech Info, NIH/NLM, Bethesda, MD.

The discovery of human sequence variation is outpacing development of resources and tools to maintain information about clinical significance. Clinical and experimental evidence on which interpretations are based have frequently been captured in local databases, as unstructured data or without standardized usage. Thus the primary use cases for maintaining these data—namely (1) identification of variation known to be disease-related, (2) identification of variation not thought to be disease-related and (3) automatable re-evaluation—are difficult. The National Center for Biotechnology Information (NCBI) established ClinVar (http://www.ncbi.nlm.nih.gov/clinvar/) to solve these problems by centralizing management of these data. ClinVar is a versioned archive of submissions reporting genotype, phenotype, clinical interpretation and supporting evidence, including observations in affected or unaffected individuals, animal models, in vitro assays, and in silico predictions. Once data are accumulated in standardized structures, they can be reviewed by experts. ClinVar provides infrastructure for such deliberations, and captures decisions attributed to the group contributing the intellectual effort. In other words, ClinVar accepts both submitted reviews of clinical interpretation by authoritative groups and primary data. To identify genes and variations about which some assessment of pathogenicity has been made, ClinVar integrates data from OMIM®, GeneReviews, the Genetic Testing Registry, locus-specific databases, as well as multiple testing laboratories. Common variation without such assessments are also reported. Users can interrogate ClinVar starting at different points—by genomic location, by phenotype, by gene, by associated citation—to name a few. The user can retrieve data interactively, or download reports after submitting large sets of variation calls, such as from high-throughput sequencing. Data are also accessible by interactive browsing, ftp, and NCBI E-utilities. These modes are intended to facilitate integration of ClinVar into clinical interpretation analysis workflows. ClinVar welcomes data sharing with resources maintaining information on human variation. For example, ClinVar is the data repository for the proposed U.S. node of the Human Variome Project (HVP).

This presentation will review data submission, data access, and current status of ClinVar.

Estimation of haplotype frequencies from pooled sequence data. *D.E. Kessner[1], J. Novembre[1,2].* 1) Bioinformatics, UCLA, Los Angeles, CA; 2) Ecology and Evolutionary Biology, UCLA, Los Angeles, CA.

DNA samples are often pooled, either by experimental design, or because the sample itself is a mixture. For example, when population allele frequencies are of primary interest, individual samples may be pooled together to lower the cost of sequencing. Alternatively, the sample itself may be a mixture of multiple species or strains (e.g. bacterial species comprising a microbiome, or pathogen strains in a blood sample). We present an expectation-maximization (EM) algorithm for estimating haplotype frequencies in a pooled sample directly from mapped sequence reads, in the case where the possible haplotypes are known. Our algorithm performs best when the SNP density of the strains under investigation is sufficiently high so that haplotype information can be extracted from individual reads. This condition is satisfied in, for example, inbred lines of Drosophila, and we anticipate that this method will be useful in other model organisms as advances in sequencing technology continue to increase sequence read lengths.

3627F

Leveraging the haplotype information in long reads for variant calling. *A.P. Singh, Y. Shen.* Center for Computational Biology and Bioinformatics, Columbia University, New York, NY.

Nanopore sequencing technologies are ushering the era of very long read sequences that can be used for alignment or variant calling. However, the high error rates of the reads are a matter of concern. Long reads (or jumping reads) are likely to harbor multiple polymorphic sites. Each read represents a haplotype. When the number of haplotypes is smaller than the number of reads, we can jointly infer the haplotypes of the reads and the genotypes of the putative polymorphic loci (PPL). Yun Li first used haplotype information to perform genotype calling in their package, Thunder. Zhi et. al extended the concept to use haplotype information from jumping reads for genotype calling from population data, in their HapSeq package. Their method is optimized for low depth coverage sequencing but can look at only two neighboring PPLs due to complexity of the HMM. We simplified their model and optimized it for the scenario where there are only two haplotypes, but can also take advantage of the haplotype information from three or more neighboring PPLs in the jumping reads. We assign the probability of a read belonging to either haplotype using a dynamic programming procedure based on sharing of known and novel candidate variants between two overlapping reads. We use an HMM to compute the genotype likelihood of the overlapping candidate variants in the reads. The emission in the HMM is based on the assumption that reads from the same haplotype are likely to produce the same variants at each loci. The candidate variants are obtained using bwasw by altering the mismatch and gap open penalties while allowing for large band widths in the alignment. We use the genotype likelihoods obtained from the shared set of known and novel snps as priors in calculating the posterior likelihoods of the genotypes. The priors for novel snps are downweighted compared to those of the known snps. We performed simulations to measure the accuracy of our method in inferring the haplotypes and determining the genotype likelihoods. Simulated reads were generated on chromosome 21 of the human reference genome at medium depth coverage (~10X) which included a set of phased snps and simulated mismatches and indels. We obtained an accuracy of more than 95% in determining the haplotype of the reads. We also obtained the new improved genotype likelihood values for snps that account for the haplotype information in this EM-like procedure.

A Model of binding on DNA microarrays: Understanding the combined effect of probe synthesis failure, cross-hybridization, DNA fragmentation and other experimental details of affymetrix arrays. *Y. A. Jakubek, D. J. Cutler.* Human Genetics, Emory University, Atlanta, GA.

DNA microarrays are used both for research and diagnostics. Affymetrix arrays are commonly used for genome wide association studies, resequencing, and gene expression analysis. Microarrays are often analyzed using statistical methods that ignore many of the details of the experimental protocol and the manufacturing process. The aim of this study was to develop a comprehensive model for hybridization on microarrays that incorporates these details and consequently predicts probe intensities for Affymetrix arrays more accurately. The model begins by assuming that hybridization kinetics on a chip are fundamentally similar to binding in solution (i.e. follow a Langmuir isotherm), but that differences between chip and solution binding largely arise from details of the experiment not usually considered. These details include target fragmentation, wash stringency, scanner settings, probe synthesis efficiency, and target concentration. All the parameters used in the model have well-established physical origins. For the 302 chips that were analyzed the mean correlation between expected and observed probe intensities was 0.701 with a range of 0.88 to 0.55. All available chips were included in the analysis regardless of the data quality. Our results show that batch effects arise from differences in probe synthesis, scanner settings, wash strength, and target fragmentation. We also show that probe synthesis efficiencies for different nucleotides are not uniform. To date this is the most complete model for binding on microarrays. This is the first model that includes both probe synthesis efficiency and hybridization kinetics/cross-hybridization. These two factors are sequence dependent and have a large impact on probe intensity. The algorithms developed in this work provide useful tools for the analysis of cross-hybridization, probe synthesis efficiency, fragmentation, wash stringency, temperature, and salt concentration on microarray intensities. The next step is to apply this model to SNP arrays in order to achieve better call rates and to call variants within CNVs.

3629F

A recursively partitioned mixture model for clustering time- course gene expression data. *D.C. Koestler[1], C.J. Marsit[1], B.C. Christensen[1], K.T. Kelsey[2], E.A. Houseman[3].* 1) Community and Family Medicine, Geisel School of Medicine at Dartmouth College, Lebanon, NH; 2) Department of Epidemiology, Brown University, Providence, R!; 3) Department of Public Health, Oregon State University, Corvallis, OR.

Longitudinally collected gene expression data provides an opportunity to investigate the dynamic behavior of gene expression and is crucial for establishing causal links between changes on a molecular level and disease development and progression. Clustering of subjects based on time-course expression data may lead to a more comprehensive understanding of temporal expression patterns that result in disease phenotypes. Although there are numerous existing methods for clustering subjects using gene expression data, most are not suitable when expression measurements are repeatedly collected over a time-course. We present a modifi ed version of the recursively partitioned mixture model (RPMM) for clustering subjects based on longitudinally collected gene expression data. In the proposed time-course RPMM (TC-RPMM), subjects are clustered on the basis of their temporal profi les of gene expression using a mixture of mixed effects models framework. This framework captures changes in gene expression over time and models the autocorrelation between repeated gene expression measurements for the same subject. We assess the performance of TC-RPMM using both simulation studies and a dataset from a multi-center research study of inflammation and response to injury (www.gluegrant.org), which consists of time-course gene expression data for 140 subjects. Methods for clustering subjects based on temporal gene expression pro files is a high priority for molecular biology and bioinformatics research. Simulation studies demonstrated the ability of TC-RPMM to correctly classify subjects on the basis of their temporal gene expression pro le. When applied to real epidemiologic data with repeated-measures, longitudinal gene expression measurements, TC-RPMM identi ed clusters that had strong biological and clinical signifi cance. Hence, TC-RPMM represents a promising new approach for analyzing time-course gene expression data.

Probing altered gene expression profiles and pathways that affect mitochondrial metabolism in cancer cells and neurodegenerative diseases through network biology approach. *A.Devi. Yadavalli[1], Naresh.B Sepuri[2].* 1) Dept of Bioinformatics, Karunya University, Coimbatore, India; 2) Department of Biochemistry, School of Life Sciences, University of Hyderabad.

Mitochondria are implicated in several metabolic pathways including cell respiratory processes, apoptosis, and free radical production. Mitochondrial dysfunction has been associated with neurological disorders, cell signaling and different kinds of cancers. Increasing evidence suggest that altered mitochondrial metabolism may play a significant role in onset or progression of these diseases. Little is known about the common genes or pathways, if any, that are connected to mitochondrial metabolism and disease status. To detect altered gene expression profiles and pathways that affect mitochondrial metabolism in cancer cells and neurodegenerative diseases, the public domain microarray data has been used. The differentially expressed genes are utilized to build the biological networks for each disease state. Computation of topological parameters for these networks showed the scale-free pattern and hierarchical organization. From the large network involving 1000's of genes, we synthesized sub-networks and annotated them with highly enriched biological processes. A careful dissection of the functional modules, important nodes, and their connections identified the common networks that are altered in neurological and cancer diseases. Further categorization of the identified genes may yield valuable mechanistic clues to understand the common metabolic pathways which may be of interest for developing therapeutic drug targets.

Drug repositioning through data integration and advanced classification tools. *D. Greco[1], Y. Zhao[2], F. Napolitano[3], R. Tagliaferri[3], M. D'Amato[1], J. Kere[1].* 1) Karolinska Institutet, Sweden; 2) University of Heksinki, Finland; 3) University of Salerno, Italy.

High-throughput technologies have allowed the production of an unprecedented amount of genomic data in the last decade. However, it has been very difficult to translate this information into clinical practice, and the impact on therapeutic intervention strategies is still negligible. De novo drug development is time consuming, expensive and laborious. Integrating several layers of information on drugs already in use (e.g. FDA approved), including data on their chemical and physical properties, their mode of action and their clinical effects, may help to highlight new therapeutic indications for translational medicine. In this study, we have re-analyzed a large collection of genome-wide gene expression data from human cell lines treated with several hundred drugs. We have found that previously published preprocessing of this data set is heavily biased, and does not allow precise estimation of the mode of action of the drugs. Conversely, our novel approach allows the identification of gene expression signatures that better reflect similarity between drugs. Further, we have assessed the relatedness of drugs from multiple layers of information concerning their chemical structures, intracellular molecular targets and known clinical effects. We show that, only when different similarity matrices are combined, highly successful prediction of therapeutic indication can be achieved. We systematically explore this possibility by building a computational classification system based on cutting edge machine learning algorithms. Finally, we use this classification tool also for guiding the selection of genes whose expression patterns best describe the activity of the drugs as well as their chemical, physical and clinical properties. Altogether, our results are valuable both in academic and industrial environments as they are useful for inferring the behavior of new drugs as well as for reliably operating drug repositioning.

Gemini: a flexible, scalable analysis framework for medical and population genomics. *U.D. Paila[1], A.R. Quinlan[1,2].* 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) Department of Public Health Sciences, University of Virginia, Charlottesville, VA.

Motivation. Genetics researchers have a wealth of affordable sequencing technologies for the discovery of genetic variation on a population scale. However, existing data analysis tools struggle to scale to the size and complexity of modern datasets and limit discovery because they are unable to integrate the wealth of informative genome annotations (e.g., ENCODE, OMIM, dbSNP).

Results. We have developed GEMINI, a novel framework for mining large, complex genomics datasets involving thousands of samples, as well as a suite of data analysis, exploration, and visualization tools. Our framework integrates and annotates population-scale genomic variation data in the VCF format with a growing collection of genome annotations from resources such as dbSNP, OMIM, KEGG, and the 1000 Genomes Project. The integrated data are stored in an efficient database framework facilitating intricate SQL queries and an intuitive interface to the data. Our database stores variation and annotations on a genome scale, and, uniquely, provides access to genotypes for thousands of individuals. We provide users with built-in analyses for quality control, standard population genetics metrics (e.g., HWE, Pi) as well as common data analysis tasks. Users can interact with our database through ad hoc SQL queries and importantly, researchers can easily integrate their own annotations into the GEMINI framework. Using this framework, we are able to quickly develop tools for medical genetics using various disease models and can easily integrate new analysis techniques such as “collapsing” methods. While most existing analysis tools are restricted to SNP variants, GEMINI represents SNPs, INDELs and structural variants, allowing researchers to explore all forms of genetic variation in the context of their disease phenotype or population analysis. To illustrate the power and flexibility of this framework, we demonstrate genome-scale analyses on genome-wide datasets from the 1000 Genomes Project. **Conclusion.** GEMINI is a scalable and easy to use analysis resource for medical and population genomics research. Its novel analysis and data integration features facilitate data exploration and discovery by enabling innovative analyses of genome variation.

3633F

NOCALLER - a tool to account for missing genotypes. *Z. Kronenberg[1], C.D. Huff[2], M. Yandell[1].* 1) Human Genetics, Eccles Institute of Human Genetics, Salt Lake City, UT; 2) Department of Epidemiology, The University of Texas M.D. Anderson Cancer Center, Houston, TX.

Next-generation sequencing data are now commonly used to identify disease-causing alleles, to infer population structure, and to identify genomic regions under selection. These analyses often do not account for missing data (no-calls). No-calls are placeholders for regions of the genome where sequence quality and/or depth of coverage preclude genotype inference. These regions are often ignored and treated as homozygous reference; this introduces systemic errors into downstream analyses, often with disastrous consequences. NOCALLER has been created to solve this problem by adding no-calls to files in Genome Variation Format (GVF). NOCALLER relies on depth-of-coverage and sequence quality data together with probabilistic modeling to identify no-call regions in exomes, whole genomes, and pooled sequencing data. NOCALLER's GVF-compliant output can be directly used in the VAAST suite of tools. Using simulations and 1000 genomes data we show that no-calling results in more accurate estimates of the minor allele frequencies and improves the accuracy of disease-gene searches.

A novel model to predict splicing consequences of intronic nucleotide substitutions in the human genome. *A. Shibata.* Nagoya University Graduate School of Medicine, Nagoya, Japan.

The next generation sequencers disclose a large amount of single nucleotide variations (SNVs) in the human genome. Tools to analyze effects of SNVs on the protein functions have been recently published PolyPhen-2 and SIFT. Effects of SNVs on pre-mRNA splicing, however, remain mostly nebulous. Here we developed a novel algorithm, the Aberrant Splicing Finder (ASF), to predict aberrant splicing events. We first extracted splicing cis-elements from the annotation database, ENSEMBL 62, that is based on the human reference sequence, GRCh37/hg19. Using the neural network modeling, we generated an algorithm to predict alternative splicing events from primary sequences of splicing cis-elements. The splicing cis-elements included the branch point sequence, the polypyrimidine tract, a nucleotide at intron -3, exonic length, and the 5' splice site. Our algorithm efficiently predicted alternative splicing events and yielded a correlation coefficient of 0.686 on the validation dataset. We also calculated ASF scores of benign SNPs in the dbSNP134 database, as well as of pathogenic mutations in HGMD, and found that benign SNPs reduce the scores by -0.00122 on average, whereas mutations reduce them by -0.0282 ($p < 0.001$). Our algorithm also disclosed that G at intron -3 has a prominent negative regulatory effect on pre-mRNA splicing.

Prioritizing disease-linked variants, genes, and pathways with an interactive whole genome analysis pipeline for the MedSeq project. *S. Kong[1], K. Lee[2], K.B. Hwang[3], J.M. Bohn[1], R.C. Green[4], I.S. Kohane[1,2].* 1) Informatics Program, Boston Children's Hospital, Boston, MA; 2) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 3) Soongsil University, Seoul, South Korea; 4) Genetics, Brigham and Women's Hospital, Boston, MA.

The increased availability and maturation of whole genome sequencing technology has shifted the researcher's burden from genetic variant identification to the interpretation of large numbers of variants per individual, and has fueled the development of a multiplicity of bioinformatics pipelines for whole-genome and exome analysis. Many of these focus on processing raw sequence data to detect highly confident genomic variants without providing any downstream annotation or filtering measures. Where such measures do exist, they are generally limited to few annotation options, static filtering, and lack of multiple-genome comparison. We have considered what combinations of annotations and statistical analyses would meet the growing needs of investigators using Whole Exome Sequencing/Whole Genome Sequencing in medical research and eventually in medical care settings such as the MedSeq project (HG006500). These considerations have led to the design and implementation of gNOME, a freely available interactive downstream analysis pipeline that combines diverse genomic annotation sources with statistical analysis methods in a scalable framework. gNOME consists of 3 core components: a knowledge database, a search engine, and an interactive web-based user interface. The pipeline's modular architecture allows further variant annotations, such as MutationTaster score, to be easily added to the database if desired. A user can interactively drill down to a small number of disease/phenotype linked variants by using dynamic reports that enable the investigation of personal genomes at three different levels simultaneously: variant-level, gene-level and gene set-level. Additionally, gNOME can apply non-parametric statistical tests to variant- and gene-level counts of filtered variants between two groups, and supports gene set enrichment analyses for biological pathways and known disease-linked genes. Sets of publicly available exomes and genomes such as the 1000 Genomes Project are prepared as comparison groups to reduce false positive incidental findings as well, and unlike most existing tools, our pipeline is easily scalable to accommodate thousands of genomes. We hope that, in combining these strengths, gNOME will be of use to the biomedical research community.

3636W

The 1000 Genomes Project, data availability and accessibilty. *L. Clarke, H. Zheng Bradley, R. Smith, I. Streeter, E. Kulesha, I. Toneva, B. Vaughan, P. Flicek, 1000 Genomes Project Consortium.* EBI, The Wellcome Trust Genome Campus, Hinxton, CB10 1SD, Cambridge, United Kingdom.

The 1000 genomes data sets continue to represent one of the largest public variation resources available to the community. Providing coherent and useful resources based on this data continues to be a key goal for the project Data Coordination Center (DCC). We present here a selection of the tools built on top of the 1000 genomes data to make it as useful as possible to the wider community. Finding data sets on the 1000 genomes FTP site can be a challenge with a 279 Tbyte data set spread over more than 260,000 files. We provide both an index in the current.tree file and a search based on this index in the form of http://www.1000genomes.org/ftpsearch to give all levels of users easy access to the complete set of files we have available. Our variant sets are all provided in VCF format, which represent a very data rich format. We have developed several tools to allow users to query theses files in a meaningful way. Many users are interested in a specific region of the genome rather that genome wide data. All our BAM and VCF files are indexed to allow retrival of slices of this data. We also provide a data slicing tool that provides users with subsections of bam and vcf files and also allow vcf files to be subset on the basis of individual or population. We have developed a variation pattern finding tool that organizes variants with functional consequences according to which individuals share particular genotypes. This allows uses to query which individuals an inheritance pattern for a given set of variation. Many users want to be able to view the linkage disequalibrium patterns for the 1000 genomes variant sets using tools like haploview. We now provide a tool that will convert our vcf files into the pedigree and locus information files that these visualization tools need. All of our BAM and VCF files are now available in the Amazon Cloud in a public s3 bucket. We also provide a simple Amazon Machine Image for interacting with this data. We also ensure users can keep up with new data releases with through several means including an email list (1000announce@1000genomes.org), rss and twitter (@1000genomes.org).

Bioinformatics optimization for the detection of low-level heteroplasmy in the mitochondrial genome in myelodysplastic syndrome. *S. Dames[1,2], E. Duncavage[1], J. Thompson[1], P. Shami[4], K. Eilbeck[2], M. Salama[1,3], R. Mao[1,3].* 1) Res & Development Sequencing, ARUP Lab, Salt Lake City, UT; 2) Department of Biomedical Informatics, University of Utah School of Medicine, Salt Lake City, UT, USA; 3) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT, USA; 4) Department of Hematology, University of Utah School of Medicine, Salt Lake City, UT, USA.

Background: Next generation sequencing (NGS) allows for the detection of low-level heteroplasmy in the mitochondrial genome (mtDNA). ARUP offers an mtDNA assay and reports heteroplasmy levels >10%. Different alignment and variant call strategies generally produce concordant results, but not always. These differences are often seen with heteroplasmy levels <10%. In an effort to accurately detect variants with heteroplasmy levels <10%, we compared different alignment and variant calling strategies using isolated stem cell DNA obtained from individuals with Myeloid Dysplasia myelodysplastic syndrome (MDS). For each patient, samples are flow-sorted using markers CD3+ (early T-cell), CD33+ (myeloid), and CD34+ (hematopoietic progenitor) to look for differences in the mtDNA sequence. **Methods**: mtDNA is enriched by long range PCR and sequenced on an Illumina HiSeq 2000. Sequences are aligned using BWA or CLCBio using different quality metrics and seed length parameters. Alignments to hg19, hg19 with chrM removed and replaced with NC_012920 (mtDNA refseq), and NC_012920 itself are compared. Refining of alignments and variant calls is performed using Samtools, Picard, GATK, and CLCBio. Different metrics for each step were compared including PCR duplicate removal and subtraction of baseline error rates, among others. **Results**: Results suggest the human genome should not be included in alignment due to areas of high homology that may skew heteroplasmy percentages and limit mtDNA coverage. PCR duplicate removal, varying seed lengths and different base and alignment quality metrics all alter low-level heteroplasmy levels, but to varying degrees. At base and alignment quality scores are >30, coverage of >200 is sufficient for the detection of >10% heteroplasmy, but should be >1,000 for <10%. When stringent quality metrics are applied, excessive coverage does not improve heteroplasmy accuracy. **Conclusions**: The initial phase of this project is complete, but further sequencing and analysis for reproducibility is underway. Results show the average background at a given base for the HiSeq is 1.4–1.6%, making it difficult to detect heteroplasmy in the 2–3% range. Furthermore, secondary verification of heteroplasmy levels <5% is difficult. We hope hypothesize that optimized alignment and variant call metrics will not only improve low-level heteroplasmy detection in mtDNA, but may also be extrapolated to potentially detect variants in mixed cell populations.

Rare Variant Discovery in Illumina Next Generation Sequencing Data: Prediction Method to Differentiate True variants from False positives. *J. Durtschi[1], R.L. Margraf[1], K.V. Voelkerding[1,2].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT.

Variant discovery for rare genetic diseases using Illumina genome or exome sequencing involves screening of up to millions of variants to find only the one or few likely causative variants. Sequencing or alignment errors create “false positive” variants. These false variants are often retained in the screening process, since they are not usually in databases used to filter out common variants. Methods to remove false variants consider parameters such as base or mapping quality or alignment biases. While somewhat effective, these methods can miss many false variants. As part of a rare variant discovery pipeline, we prioritize variants into 4 bins based on a false variant likelihood prediction. Our presented method uses the Genome Analysis Toolkit (GATK) variant calling software to calculate the variant-to-wildtype genotype likelihood ratio at each position. The Phred-scaled ratio is divided by read depth (to minimize the strong, linear effect of depth). This likelihood-by-depth (LBD) is calculated for a proband of interest as well as for approximately 40 exome and whole genome samples (proband's family or unrelated) all run on the Illumina HiSeq at our facility. At variant sites with no apparent sequencing error or alignment biases, wildtype calls cluster near -3 LBD and variant calls typically cluster above 10 LBD. Sites with systematic variant call problems (e.g., low coverage, sequencing error, or alignment error, as evident by GATK quality values and biases as well as displayed on the iGV viewer) show broadening and merging of these clusters, indicating lowered variant call accuracy. Depending on the separation of the proband's variant LBD value from the cluster of wildtype calls from other samples, the variant is put into one of the four bins of false variant likelihood with bin 1 most likely true and bin 4 most likely false. A comparison of two sets of variants from one genome sample that were either mostly true (20,000 chromosome 1 variants seen at between 10 and 20 % allele frequency in the 1000 genomes data) or mostly false (154 novel proband variants, not within the proband's family or in the 1000 genomes). The likely true variant set resulted in 85, 14, 0, and 1 % in bins 1, 2, 3, and 4, respectively. The likely false variant set resulted in 5, 27, 33, and 36 % similarly ordered. This indicates correspondence between real variants and bins 1 and 2, leading to more accurate prioritization of variants for subsequent analyses.

3639F

Memory Efficient Assembly of Mammalian Size Genome. *F. Hormozdiari, E. Eskin.* Computer Science, UCLA, Los Angeles, CA.

The ability to detect the genetic variations between two individuals is an essential component for genetic studies, where obtaining the genome sequence of both individuals is the first step towards variation detection problem. The emerge of high-throughput sequencing (HTS) technology has made the DNA sequencing practical, and is widely used by diagnostician to increase their knowledge about the causing factor for diseases. As HTS advances more data are generated every day than the amount that scientists can process. Genome assembly is one existing method to tackle the variation detection problem. The de bruijn graph formulation of the assembly problem is widely used in the field; furthermore, it is the only method which can assemble any genome in linear time. However, it requires an enormous amount of memory in order to assemble any mammalian size genome. The high demands of sequencing more individuals and the urge to assemble them are the driving force for a memory efficient assembler. In this work we propose a hybrid method which builds the de bruijn graph while consuming lower memory. Moreover, our proposed method can reduce the memory usage by 37%; compared to the existing methods. In addition we used a real data set (chromosome 17 of A/J strain) to illustrate the performance of our method.

Target capture-assisted sequence assembly for accurate genotyping of insertions and deletions. *C.J. Kennedy, N. Chennagiri, MA. Umbarger, GJ. Porreca, PC. Saunders, V. Greger.* Good Start Genetics, Cambridge, MA.

Alignment of short DNA sequences to a reference genome is the standard first step for next-generation sequencing (NGS) data analysis. While providing global genomic coordinates and variant information to individual reads, alignment often fails to detect insertions and deletions (indels) of significant size relative to the read length. De novo sequence assembly, by contrast, generates contiguous sample sequence (contigs) and generally improves indel detection; however, assembly is computationally intractable for very high volume data, depends critically on the extent of read overlap, and may disregard important read-based information such as coverage depth or base qualities. Here we describe a hybrid approach that uses target capture design to rapidly map individual reads to their constituent exons. Reads are assembled into contigs, which are then aligned to the reference with improved accuracy due to enlarged sequence context. The coordinate and variant information from this assembly is then transitively associated with the corresponding raw reads to enable coverage- and base quality- enabled genotyping. We sequenced exons of 14 genes associated with monogenic disorders from 150 samples chosen for their ethnic diversity or clinical significance. Sample-exons were sequenced to an average depth of 1500x with 85bp single-end (Illumina) reads and compared to corresponding bi-directional Sanger sequence. Assembly-derived genotypes were concordant for all 137 Sanger-identified insertions (up to 12bp) and deletions (up to 18bp) with no false positives. Alignment alone failed to detect 6 of 26 unique indels (23%) including compound heterozygous alleles within the highly polymorphic signal peptide sequence of SMPD1 (Niemann-Pick disease) as well as c.2207_2212delinsTAGATTC, which is the most common disease-causing mutation in BLM (Bloom syndrome) for individuals of Ashkenazi Jewish heritage. To test the robustness of our approach, we simulated data for rare pathogenic variants for which no sample data were available. All simulated variants, including 31 that were clinically relevant but undetectable by alignment alone, were correctly genotyped using our hybrid assembly algorithm. Clinical NGS applications apply new rigor and acceptability criteria to variant detection. We present an integrated analysis method that uses target capture-assisted assembly for accurate, robust, and scalable genotyping of indels.

CLC bio's integrated framework for identification and comparison of genomic variants in mendelian diseases. *M. Matvienko[1], A. Joecker[2], C. Boysen[1], U. Appelt[2], A. Fejes[2], L. Kahns[2], S. Mønsted[2], J. Grydholt[2], B. Knudsen[2], M. Bundgaard[2], J. Buur Sinding[2], H. Handberg[2], A.-M. Hein[2], M. Nygaard Ravn[2], A. Joecker[2], M. Værum[2], R. Forsberg[2].* 1) CLC bio, Cambridge, MA; 2) CLC bio, Aarhus, Denmark.

The use of personal genomics for predictive medicine is becoming increasingly popular in clinical settings due to its potential for identifying optimal drug treatments for particular individuals based on their genetic background. However, the bioinformatics analysis underlying the foundation of personal genomics, including the identification of “disease relevant” genomic variants, is still a bottleneck. CLC bio's Workbench and Server solution has been extended to an integrated framework for comparison and functional analysis of genomic variants with the purpose of supporting clinicians and scientists in the identification of clinically relevant variations. In this work, we show how the analysis of a publicly available data set from 11 patients with inherited hearing loss can be performed using the CLC Workbench. We will show the complete re-sequencing workflow, from mapping of the sequencing reads to the reference sequence, through to the identification of genomic variants. Furthermore, we demonstrate a process for the annotation, filtering and comparison of identified genomic variants to emphasize clinically relevant variants and interesting new findings.

Sensitivity and Resolution of Whole Chromosome Mapping for Detection and Characterization of Structural Variations in Human Genomes. *R. Moore.* OpGen, Gaithersburg, MD.

Structural changes in human genomes such as copy number variations, insertions, deletions, inversions, and translocations have been associated with a wide variety of clinical conditions including developmental delay, degenerative disorders, and cancer. Classically, chromosomal structural variations have been investigated with cytogenetic techniques such as Fluorescent In Situ Hybridization (FISH) but these techniques have limited resolution, typically > 2 Mbp. More recently, techniques such as Next Generation Sequencing (NGS) and array Comparative Genomic Hybridization (CGH) have been used to investigate genomic structural variants. However, NGS cannot detect variants larger than a few kilobase pairs without the use of costly and inefficient techniques such as fosmid or BAC libraries. Array CGH detects only unbalanced events such as copy number variation and does not provide information on the location of additional copies.

Here we investigate the performance characteristics of Whole Genome Mapping (WGM) as applied to the detection of structural variations in human chromosomes. WGM uses restriction maps from long individual DNA molecules to construct high resolution maps of human chromosomes. These maps can be compared between samples or to maps derived from sequence to detect structural variants. In this study human genomes previously characterized with FISH, array CGH, and NGS were analyzed with WGM to benchmark the performance of WGM for structural variant detection. Results demonstrate that WGM detects > 95% of homozygous structural variations larger than 2kbp. This was true for all types of structural variations including both balanced and unbalanced events.

This study suggests that WGM is an excellent compliment to NGS for complete evaluation of human genomes. NGS provides detection of single nucleotide polymorphisms and small structural variants. WGM detects structural variants larger than a few kbp and could eliminate the need for array CGH and FISH. We expect the WGM will be a powerful tool for the investigation of the role of structural variation in human disease.

Comparison of next-generation sequencing alignment programs using 215 whole genomes from the Cache County Study on Memory Health and Aging. *P.G. Ridge Jr[1,2], J.D. Durtschi[2], C.D. Corcoran[3,4], R.G. Munger[4,5], Q.O. Snell[6], M.J. Clement[6], K.V. Voelkerding[2,7], J.S.K. Kauwe[2].* 1) Department of Biology, Brigham Young University, Provo, UT; 2) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 3) Department of Mathematics and Statistics, Utah State University, Logan, UT; 4) Center for Epidemiologic Studies, Utah State University, Logan, UT; 5) Department of Nutrition, Dietetics, and Food Sciences, Utah State University, Logan, UT; 6) Computer Science Department, Brigham Young University, Provo, UT; 7) Department of Pathology, University of Utah School of Medicine, University of Utah, Salt Lake City, UT.

Introduction: For many years the primary barrier impeding the analysis of full genome sequences was the cost and time required for sequencing. With the advent of next generation sequencers the challenge has shifted to downstream processing of the millions of short reads generated by sequencers: alignment, variant detection, and variant interpretation. There are many programs available for each step, but the question remains: which of the programs, or combination of programs is most accurate? Comparisons of new algorithms against existing programs have done little to resolve the issue since reported results are inconsistent. Here we provide an unbiased comparison of four of the most frequently used alignment programs: BWA, Bowtie2, Novoalign, and SOAP. For our comparison we will use 215 complete genomes. The accuracy of each alignment is measured by comparing concordance rates of detected variants against genotyped data (arrays and Sanger sequenced variants).

Methods: Genomes were sequenced by Illumina on the HiSeq2000. Using the BAM files provided by Illumina, we used bam2fastq to regenerate fastq files. Parameters for each alignment program were selected based on the recommendations by the developers of each program for Illumina paired end, 100 bp reads. Variants were called using SamTools. All data processing was performed on Brigham Young University's supercomputer, Marylou (Marylou.byu.edu).

Results: The 215 genomes were sequenced to an average depth of 37. Based on our preliminary data, Bowtie2 was the fastest program requiring approximately 13 hours to perform an alignment, followed by SOAP (~28 hours), BWA (~52 hours), and Novoalign (~56 hours). As expected, identified variants were different for each program. Novoalign resulted in the highest number of unique variants (141854) and SOAP the fewest (23964). Collectively, all four programs detected 3329437 variants. We will validate observed common variants using genotypes obtained from Illumina 2.5M arrays. A set of rare variants will be selected for validation using Sanger sequencing to investigate the accuracy of the SNP calls obtained from each alignment method.

Continuously Evolving Informatics at a Medium-Scale Genomics Center. *L. Watkins, M. Barnhart, J. Goldstein, S. Griffith, E. Hsu, K. Roberts, D. Snyder, B. Craig, K. Hetrick, K. Doheny, Center for Inherited Disease Research.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-gen sequencing (NGS), genotyping, and statistical genetics consultation to investigators working to discover genes that contribute to disease. Rapidly advancing technologies for interrogating genomes and the concomitant explosion of data create a formidable challenge for sustaining throughput of 80–100,000 samples per year on a demanding schedule while maintaining the utmost data quality. CIDR began in 1996 with human STRP 400-marker linkage panels, switched to SNP genotyping in 2004, and now runs arrays up to 5 million SNPs. With the addition of a next-gen sequencing service in 2011 and establishment of the joint Baylor-Hopkins Center for Mendelian Genomics, CIDR now releases data for about 5 studies per month varying from a few to over 35,000 samples each. Our present (May 2012) capacity for GWAS or epigenetic genotyping is 145,000 samples/year; for custom genotyping, 138,000 samples/year. Our sequencing workflow can process a 4,000 sample project targeting a custom 3Mb region, 150 whole exomes, or 15 whole genomes in 16 weeks, with multiple projects in progress simultaneously. A typical sequencing project now totals around 14TB of data per run; combined with many TB of genotyping data per week, this yields a genomic data deluge. We continuously evolve our informatics to meet these challenges by paying close attention to every step of the process and optimizing each one via improvements at every level of operation, from speeding up data movement (e.g., moving to 10 gigabit Ethernet), to writing better and smarter software (e.g., our own sample de-multiplexer is several times faster than the program it replaced), to rigorous data triage and compression. Our sequence analysis pipeline, CIDRSeqSuite, now takes 60% less time to process 5 times as much data per run as it did in 2010. We also leverage the best commercial products as well as our own software: we wrote a genotyping LIMS to maximize flexibility and productivity, adapted and extended a commercial LIMS for sequencing, and we're completely rewriting our entire sample- and problem-handling system to accommodate current and future demands. Current work emphasizes better and faster analysis tools, improved approaches to parallelism (e.g., GPU and hybrid-core compute platforms), sophisticated data staging, improved storage I/O using solid-state disks, and advanced hardware- and reference-based compression for data reduction.

3645F

Genotype Concordance Between Low-Coverage Whole Genome and High-Coverage Exome Sequencing: Results from the UK10K Study. *H. Zheng on behalf of the UK10K Consortium Cohorts Group.* Department of Medicine, Human Genetics, Epidemiology & Statistic, Lady Davis Institute, Montreal, Quebec, Canada.

Background: Given the high cost of large, next-generation sequencing studies there is considerable debate as to the optimal study design to accurately capture rare variants. While low-coverage whole genome sequence provides an accessible survey of genotypes across the entire genome, including regulatory regions, it is unclear if low-coverage studies yield sufficient genotypic accuracy to justify their utility. Aim: To compare the genotype concordance rates of low coverage sequencing and high depth sequencing in the same individuals. Methods: Low-coverage whole genome sequence (WGS) data, generated from the UK10K project (median depth per variant=6), and high-coverage whole exome sequence (WES) (median depth per variant =65.6) were compared for genotypic accuracy for 157 samples from TwinsUK. Variant calls from 22 autosomes were compared using VCFtools for variants called in both WGS and WES. Results: The 157 samples had 178,112 sites in common between WGS and WES. 190 sites had missing genotypes. The overall genotype concordance rate was 99.41%. 177,635 reference alleles had concordant genotypes, and 287 reference alleles displayed discordant genotypes. The concordance rate for reference allele homozygote, heterozygote and non-reference allele homozygote were 99.6%, 98.33% and 98.86%, respectively. The non-reference concordance rate was 96.8%. Concordance rates increased with the allele depth and allele frequency, yet remained high even for alleles of low frequency (99.1% for variants with a non-reference allele frequency between singletons and 1%). Discordance rates were also observed to be higher at specific genomic locations. Conclusion: The concordance rate between low coverage sequencing and high depth sequencing is high. These findings have important implications for sequencing study design and suggest that low coverage sequencing is able to accurately call genotypes.

Genotype calling and haplotype inference for next-generation sequencing data incorporating haplotype information in sequencing reads. *D. Zhi, K. Zhang.* Dept Biostatistics, Univ Alabama, Birmingham, Birmingham, AL.

A critical, but often overlooked advantage of sequencing over array-based genotyping is that sequencing provides a sequential readout of nucleotides along a single chromosome, and thus providing direct haplotype information. However, most existing genotype calling and haplotype inference methods only use read nucleotide and quality information at individual sites, and thus bypass such useful information. We recently developed a LD-based method that integrates haplotype information in reads into the commonly used chromosome segment sharing hidden Markov models [1]. While achieve improved accuracy to MACH/Thunder [2], our method only used read joint allele counts across two consecutive sites. In this work we developed the notion of haplotype likelihood, which is parallel to the commonly used genotype likelihood, but capturing haplotype information across multiple variant sites. Using simulation and real data, we show that our method achieve superior genotype calling accuracy than competing methods. 1. Zhi, D., et al., Genotype calling from next-generation sequencing data using haplotype information of reads. Bioinformatics, 2012. 28(7): p. 938–46. 2. Li, Y., et al., MaCH: using sequence and genotype data to estimate haplotypes and unobserved genotypes. Genetic epidemiology, 2010. 34(8): p. 816–34.

Exploring why whole genome sequencing methods result in different variant calls by comparing and integrating multiple datasets. *J.M. Zook, D. Samarov, M. Salit.*Biochemical Science Division, National Institute of Standards and Technology, Gaithersburg, MD.

As it is becoming possible to sequence even large whole genomes deeply, systematic errors and biases become very important. Integrating data from multiple platforms and algorithms can improve variant call accuracy and allow interrogation of the reasons behind method-specific errors and biases. To generate well-characterized human genome reference materials that help assess and improve performance of sequencing methods, we are comparing and integrating the large diversity of data from multiple versions of Illumina, Complete Genomics, SOLiD, and 454 on the CEU sample NA12878. Hundreds of thousands of differences exist between whole genome variant calls on this sample from the variety of sequencing platforms, mapping algorithms, and variant calling pipelines. Recent publications have demonstrated these differences when comparing just two different platforms, but have not explored the reasons for these differences or developed methods to increase sensitivity and specificity of variant calls by integrating multiple data sets. To arbitrate between variant calls that are discordant among datasets, we first find the distributions of various characteristics (e.g., strand bias, coverage, base quality score bias, mapping quality, and allele balance) for high-confidence variants for each dataset. Then, for discordant calls, we only use calls from each individual dataset that fall within the typical distribution of each characteristic. These integrated consensus variant calls have higher accuracy than any individual dataset, when compared to fosmids finished by Sanger sequencing or OMNI array data for NA12878. Therefore, we use our consensus calls to assess the accuracy of whole genome sequencing methods, and show that using microarrays to assess accuracy underestimates genome-wide false positive and false negative rates. In addition, we determine characteristics of false positive and negative calls to show strengths and weaknesses of platforms and algorithms and how they could be improved. By integrating the large amount of current and future data for NA12878, we will develop an increasingly sensitive and specific set of variant calls for this individual. DNA from this individual and others will be developed into NIST Reference Materials, which can be used by research, commercial, and clinical laboratories to assess and improve performance of sample preparation, sequencing, and bioinformatic methods.

Next Generation Biomarker Screening: Using Roche's 454 Sequencing Platform to Identify Somatic Biomarkers. *C. Lasyone, X. Tan, A. Pond, L. Szkotnicki, V. Venegas, K.B. Thomas, M. Berry, F. Lu.* SeqWright, Inc., Houston, TX.

It took half a century and three billion dollars to sequence the first human genome. Now, next generation sequencing technology makes it possible to screen entire genomes or specific genetic loci for mutations, producing actionable data for personalized, targeted treatment and patient screening. In addition, deep sequencing can identify biomarkers below the level of detection for most diagnostic tests. The ability to detect somatic mutations present in low percentages of the test sample holds enormous implications for the diagnosis and treatment of diseases such as cancer, and the confident validation of somatic biomarkers is critical to the development of new companion diagnostics for screening such diseases. Sanger sequencing is a widely established, validated sequencing method accepted by the Food and Drug Administration (FDA). Although accurate and reproducible, Sanger sequencing has a limit of detection of 20%, a sensitivity level insufficient to identify some clinically relevant somatic mutations. At SeqWright, we overcome these challenges by designing customized biomarker validation assays using next-generation sequencing on Roche's 454® GS-FLX platform which provides several thousand-fold depth of coverage, and therefore has the sensitivity to identify sequence variants present in much lower percentages. Using a subcloned region of human chromosome 7 with a known single nucleotide polymorphism (SNP), we created a limiting dilution series of SNP containing plasmid DNA spiked into wild type plasmid sample. Using this reference sample set, we then are able to demonstrate the accuracy, repeatability, and limit of detection of our 454 amplicon sequencing protocol. With a coverage depth ranging from 7,587 to 30,790, we demonstrate the accuracy of the platform to exceed 99%, capable of reproducibly detecting a SNP present in only 1% of the total DNA target population. Once validated, the assay can be used for the detection of the biomarker within biological samples within this range. Using Roche's 454® GS FLX sequencing platform, SeqWright provides a highly sensitive method for the detection of low percentage mutations, currently below the limit of detection of current sequencing technologies. Validated next-generation sequencing assays are critical to the development and marketability of companion diagnostics for low abundance mutations.

***De Novo* Assembly of extremely long single-molecule genome maps imaged in Irys nanoChannel arrays.** *M. Requa, M. Austin, H. Dai, P. Deshpande, O. Hampton, H. Sadowski, M. Saghbini, M. Xiao, H. Cao.* BioNano Genomics, San Diego, CA.

Despite significant advances in shotgun sequencing technology, *de novo* genome assemblies using only short read data are generally incomplete due to the complexity found in large genomes. This complexity, consisting mainly of large duplications and repetitive regions, hinders sequence assembly and subsequent comparative analysis. We present a single molecule genome analysis system based on a nanochannel array technology that resolves these sequence ambiguities. This technology provides high throughput sequence motif maps of single molecule fragments hundreds of kilobases in size. Capitalizing on the information encoded in the extremely long single molecule maps, assembly algorithms unique to this format deliver high-resolution whole-genome sequence motif maps. Parallel assembly by shotgun sequencing and sequence motif mapping offers a multi-scale pathway for whole genome *de novo* assembly solving many of the ambiguities inherent in using short read assembly alone. Here we detail the BioNano genome assemblies of select prokaryotic and eukaryotic organisms demonstrating applicability of this technology to genome sizes spanning three-orders of magnitude and to a diversity of organisms. In the cases where a high-quality genome draft exists, the BioNano assembly is compared to the reference highlighting the utility of parallel multi-scale genome assembly. With these demonstrations, *de novo* assembly of the human genome using BioNano technology is within reach.

Defining best practice guidelines for the use of NGS applications in genome diagnostics. A national collaborative study of Dutch genome diagnostic laboratories (LOD). *N. van der Stoep[1], M.M. Weiss[2], Q. Waisfisz[2], C. Ruivenkamp[1], M. Nelen[3], J.D.H. Jongbloed[4], H. BRüggenwirth[5], M. van Slegtenhorst[5], R. Lekanne dit Deprez[6], O. Mook[6], A. Van den Wijngaard[7], M. Vogel[8], B. Van der Zwaag[8], M.M.A.M. Mannens[6], Dutch National Board for DNA-diagnostics (LOD) http://www.dnadiagnostiek.nl/).* 1) Dept Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Dept. Clinical Genetics, VU University Medical Center, Amsterdam, Netherlands; 3) Dept Genetics-Genome Diagnostics, St Radboud University Medical Center, Nijmegen, Netherlands; 4) Dept. Genome Diagnostics, University Medical Center Groningen, Groningen, Netherlands; 5) Dept. Clinical Genetics, Erasmus Medical Center, Rotterdam, Netherlands; 6) Dept. of Clinical Genetics, Academic Medical Center, Amsterdam, Netherlands; 7) Dept. of Clinical Genetics, University Medical Center Maastricht, Maastricht, Netherlands; 8) Dept. of Medical Genetics, University Medical Center Utrecht, Utrecht, Netherlands.

Next-generation sequencing (NGS) has developed over the past few years into a valuable tool for research applications in genomic research. There have been remarkable advances in NGS technologies which resulted in a considerable reduction in sequencing costs and a significant increase in throughput. Mean while in genome diagnostics the total number of genes tested has increased as well. Therefore the implementation of NGS applications in diagnostics is becoming an inevitable step. However the validation of this technique according to diagnostic standards must be established first and is quite a challenge for individual diagnostic laboratories. In the Netherlands all accredited diagnostic laboratories are joint and represented in a coordinating body named the `DutchNational Board for DNA-diagnostics' (LOD). The primary goal of this organization is to ensure the availability of a growing number of high quality diagnostic tests for hereditary and congenital disorders. This study was initiated by the LOD organization through recruiting representatives from all diagnostic laboratories in order to exchange their ongoing validation processes and experiences in NGS applications. Different applications of NGS are addressed including whole exome sequencing and analysis but also targeted analysis of specific gene sets. All stages of the process are evaluated including aspects as DNA preparation, various quality checks at different stages of the process, analysis pipelines, disclaimers and reports. From this study we define a first set of critical criteria and best practice guidelines for validating and implementing NGS applications in genome diagnostics according to accredited diagnostic standards. In addition all Dutch diagnostic laboratories are currently collaborating in a national NGS research study named “project CARDIO” which is initiated by the joint research group, `the Centre for Genome Diagnostics' that is also presenting data at this meeting. Results from this study will provide additional details on critical aspects to consider when using NGS in routine diagnostics.

Genome phantasmagoria: naming genes in alternative loci. *E. Bruford, R. Seal, M. Wright.* HGNC, EMBL-EBI, Hinxton, United Kingdom.

The HUGO Gene Nomenclature Committee (HGNC) has assigned unique approved gene symbols and names to over 33,000 human loci to date. Over 19,000 of these are protein coding genes, but we also name pseudogenes, non-coding RNAs, phenotypic loci and genomic features. Our website, genenames.org, is a searchable repository of human gene nomenclature and associated resources, including links to genomic, proteomic and phenotypic information, our curated gene family pages and the HGNC Comparison of Orthology Predictions (HCOP) tool. The HGNC assigns nomenclature to genes that are present on the current human genome, which is a combined reference assembly based on only a small number of anonymous donors. Now that the majority of protein coding genes on the reference assembly have been annotated and named, it has become clear that a single tiling path cannot adequately represent regions of complex human variation. The Genome Reference Consortium (GRC) aims to improve the human genome by correcting errors, closing sequence gaps and providing alternative assemblies for some of the hypervariable regions. The GRC generates patches, small regions of genomic sequence that are released independently from the major genome assembly releases, which can either be a fix patch correcting an error or a novel patch containing additional alternate loci. Fix patches are incorporated into the next full assembly release, while novel patches will be represented as alternate reference loci. The HGNC is currently working directly with the GRC to provide gene symbols for genes in novel patches when requested. We will provide some examples of nomenclature for alternate loci and will discuss the issues that we face as complex variation is increasingly represented.

Rapid Preparation of Targeted Resequencing Libraries from DNA Samples Using the Access Array™ System. *C. Friedlander, X. Wang, R. Ramakrishnan.* R&D, Fluidigm Incorp., South San Francisco, CA.

The dramatic drop in cost and decreased turnaround time associated with next-generation sequencing (NGS) platforms has created a demand for methods that permit rapid library preparation, targeting multiple genomic regions, in large cohorts. The Access Array System is a microfluidic integrated fluidic circuit (IFC) platform capable of simultaneously amplifying 48 samples with 48 primer sets per run. Each reaction contains a target-specific primer pair and a sample-specific barcode primer pair resulting in 2,304 unique amplicons in a single-step reaction and takes four hours to complete. Coverage and throughput can be further increased by a factor of ten by using multiplexed reactions generating 23,040 PCR reactions per run, thereby further reducing the cost. As little as 50ng of DNA sample is enough to generate products which can be used for sequencing on all commercialized next-generation sequencing platforms, including Roche 454, Illumina, and Ion Torrent sequencers. To demonstrate the performance of libraries generated on the Access Array System, we have carried out multiplexed amplifications of about 2,500 genomic regions that map into genes with relevant roles in cancer development. Both normal DNA from cell lines and human liver tissue were used to interrogate these regions. These samples were amplified for the target regions on the IFC, followed by the addition of sample specific barcodes in a subsequent reaction, in a two-step library preparation. On average, 80–98% of the NGS data produced across all platforms map to the human genome and, of these, over 95% map to the target regions. Over 80% of all assays produced reads within five-fold from the average number of total reads. The results obtained from our experiments demonstrate the ability of the Access Array System to generate high-throughput libraries for 454, Illumina, and Ion Torrent NGS platforms in just a few hours, decreasing hands-on time and overall cost per sample.

3653F

MitoExome: A Custom Whole Exome Kit for Mitochondrial Disease Research and Diagnosis that Captures All MitoCarta Genes and the Mitochondrial Genome. *X. Gai[1], E.A. Pierce[2], M. Consugar[2], M. Lvova[3], D.C. Wallace[3], E. LeProust[4], M.J. Falk[5].* 1) Center for Biomedical Informatics, Loyola University Stritch School of Medicine, Maywood, IL; 2) Ocular Genomics Institute and Berman-Gund Laboratory for the Study of Retinal Degenerations, Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA; 3) Center for Mitochondrial and Epigenomic Medicine, Department of Pathology, The Children's Hospital of Philadelphia, and University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 4) Agilent Research and Development, CA; 5) Divisions of Human Genetics, and Rehabilitation and Metabolic Disease, Department of Pediatrics, The Children's Hospital of Philadelphia, and University of Pennsylvania Perelman School of Medicine, Philadelphia, PA.

Discovering mitochondrial disease variants and genes requires simultaneous interrogation of both the mitochondrial genome and the nuclear genome, which encodes at least 1100 mitochondria-targeted proteins whose exact composition varies between tissues. Currently available whole exome capture kits do not capture the mitochondrial genome and provide insufficient capture for some MitoCarta-catalogued nuclear mitochondrial genes. METHODS: To improve upon this, we formulated a custom SureSelect library by blending RNA “baits” from three separate designs: (A) Agilent Technologies (Santa Clara, CA) SureSelectXT 50 Mb All Exon PLUS Targeted Enrichment Kit, (B) a panel of 16 nuclear-encoded mitochondrial genes that target sequences not included in the All-Exon design, and (C) sequences targeting the entire mitochondrial DNA genome. Designs B and C were created in eArray by standard 1X tiling across the target hg19 mitochondrial loci or 2X tiling across nuclear genes. The final custom formulations consisted of a 1:1 ratio of Design A/All-Exon to Design B baits. Design C/mitochondrial baits were subsequently blended in either at equal molar ratio or reduced concentrations by 10, 50, 100, 200, 500, or 1000 fold less than the nuclear baits. Patient sample capture libraries were 2 × 101 bp paired-end sequenced on an Illumina (SanDiego, CA) HiSeq 2000 Next-Generation Sequencing system using v3.0 SBS chemistry. RESULTS: As expected, the mitochondrial genome coverage varied depending on the mitochondrial:nuclear blend ratio, with 1:100 and 1:200 ratios providing the optimal coverage for both genomes. 1X, 10X, or 20X coverage was achieved for over 99%, 97%, and 95% of all targeted nuclear exons. 1X, 10X, 100X, and 1000X coverage was obtained on average for 100%, 99.99%, 99.9%, and 99% of the mitochondrial genome. Low-level heteroplasmy was sensitively detected. Analysis of nuclear-encoded mitochondrial transcripts is ongoing. CONCLUSIONS: This custom mito-plus whole exome capture kit allows simultaneous detection of both nuclear and mitochondrial DNA genomes, including sensitive detection of low-level heteroplasmy mtDNA variants that commonly cause mitochondrial disease. It represents an ideal experimental platform for both research and clinical-based diagnostic investigations of suspected mitochondrial diseases.

High Throughput Solution For Illumina Fragment Library Sample Preparations. *A. Jackson, S. Verrow, M. Blair.* Beckman Coulter, Inc., Brea, CA.

Beckman Coulter has released SPRIworks chemistry for low-throughput using the SPRI-TE Nucleic Acid Extractor and has now released chemistry for high-throughput (HT) automation using Biomek® liquid handlers for Illumina compatible Next Generation Sequencing (NGS) library sample preparation. The SPRIworks HT automation solution turns a tedious process that can require fragment size selection through agarose gel separation into a simple process. The HT solution can produce up to 96 libraries in a 96-well format with minimum hands on time. The automation friendly kit uses Solid Phase Reversible Immobilization (SPRI) paramagnetic beads to offer various fragment sizes selection (150–350 bp, 250–450 bp, 350–550 bp, and 150 bp up) with high accuracy as shown by bioanalyzer data. SPRIworks HT has also been utilized to produce libraries for additional applications such as RNA sequencing and Target Capture. Downstream processes, including PCR cleanup, qPCR setup, and normalization and pooling, have been automated to create a suite of methods. This suite of automation methods has a single user interface (UI) to allow for easy selection of options.

3655F

Comparison of two next-generation sequencing technologies on the genomes of a trio family. *E. Jorgenson[1,2], R. Kazma[3].* 1) Department of Neurology, Ernest Gallo Clinic and Research Center, University of California San Francisco, San Francisco, CA, USA; 2) Division of Research, Kaiser Permanente, Oakland, CA, USA; 3) Department of Epidemiology and Biostatistics and Institute for Human Genetics, University of California San Francisco, San Francisco, CA, USA.

Next-generation sequencing provides a new level of scrutiny on the human genome, and its rapidly decreasing cost is making the investigation of the effect of rare genomic variants on complex diseases and traits increasingly affordable. Yet, our knowledge of the relative quality of the various competing technologies is scarce, and only one comparison of a single individual has been published to date (Lam et al., Nature Biotech 2012;30:78–82). Here, for the first time, we compare the two most widely used sequencing technologies, Illumina and Complete Genomics using the genomes of a trio family. We sequenced the genomes of two parents and one male child from Costa Rica using two technology pipelines: Complete Genomics version 1.10.0.28 and Illumina version 1.3.0.0 (MARS). Both pipelines were also used to call single nucleotide variants and small insertion/deletions using the reference genome (NCBI build 37) for alignment. Additionally, the Complete Genomics pipeline called copy number variants and larger structural variants, and provided gene annotations. The average read depth was about 55× for Complete Genomics and 50× for Illumina. Furthermore, the three genomes were genotyped on two Illumina chips: HumanHap650y and HumanOmni 2.5, providing another level of comparison. The use of a trio family for this comparison allowed for crosschecking calls and better estimation than a single genome of the coverage, concordance, and false positives of both pipelines.

Single-Molecule, Electronic, Solid-State Sequencing of M13 DNA. *J.S. Oliver, B. Bready, D. Dederich, J. Freitas, H. Geiser, Y. He, D. Hevroni, M. Jouzi, H-Y. Lee, P. Mukhatira, M. Nadel, J. Sariadaridis, J. Thompson.* Nabsys Inc, 60 Clifford Street, Providence, RI.

Nabsys' positional sequencing technology is a single-molecule approach that utilizes solid-state nanodetectors. The platform locates, with sub-diffraction-limit resolution, the positions of oligonucleotide probes that have bound to long DNA fragments. The platform does not require amplification of samples. As a result, the method is capable of providing very long reads (in excess of 100 kb) with unbiased, quantitative information. Positional sequencing does not attempt to discriminate individual nucleotide bases passing through an electrical detector. Instead, the Nabsys approach hybridizes short oligonucleotide probes to very long DNA templates, passage of probe-bound templates through solid-state nanodetectors, and electronic detection of the locations of the hybridized probes. By combining information on the positions of probes, it is possible to create detailed genomic maps with sparse probe coverage, or true de novo sequences of large genomes with dense probe coverage. We demonstrate the utility of the method by showing resequencing and map data for M13 using single molecule detection of events in solid-state detectors.

Efficient Genotyping of Individuals using Overlapping Pool Sequencing and Imputation. *Z. Wang[1], F. Hormozdiari[1], W. Yang[1,2], E. Eskin[1].* 1) Computer Science, Univ California, Los Angeles, Los Angeles, CA; 2) Interdepartmental Program in Bioinformatics, Univ California, Los Angeles, Los Angeles, CA.

Next generation sequencing technologies are rapidly decreasing the cost of obtaining genetic information. The cost for utilizing one of these technologies consists of a sample preparation step and a sequencing step of the prepared sample. The dramatic increase in the efficiency of the sequencing technology makes the costs of the sequencing step negligible for small target regions. Thus the main remaining cost is the sample preparation step. Using overlapping sequencing pools where samples are mixed together into pools which are prepared and sequenced together has been shown to reduce the cost significantly for collecting information on genetic variants which only occur in a few of the samples. These methods utilize ideas from compressed sensing. In this paper, we extend this approach to utilize additional information from reference genetic variation datasets which provide the correlation structure between genetic variants. Utilizing this information, we can significantly increase the efficiency of overlapping pool sequencing.

Whole-genome sequencing analysis of SNPs and structural variants in DNA from blood vs. EBV-transformed lymphoblasts from the same subject. *X. Zhu[1], C. Laurent[2], M. Haney[1], AE. Urban[1,3], DF. Levinson[1].* 1) Department of Psychiatry and Behavioral Sciences, Stanford university, Palo alto, CA; 2) Department of Child and Adolescent Psychiatry, UPMC, Paris, France; 3) Department of Genetics, Stanford, Palo alto, CA.

Lymphoblastoid cell lines (LCLs) created by in vitro infection of human B-lymphocytes with the Epstein-Barr Virus have been widely used in genetic and genomic studies due to their wide accessibility in repositories. There are concerns about the effect of EBV-induced artifacts on sequencing studies, but the degree and nature of these changes is still unclear. Several direct comparisons of paired blood and LCL specimens based on SNP and CGH arrays suggested that there might be characteristic copy number changes in several chromosomal regions. But in a study using Sanger sequencing of exons of 401 candidate genes, 13 of 28 presumed de novo mutations (observed in LCL from a single proband but not in the parents) were not observed in DNA from the proband's blood, and thus were considered LCL artifacts (PMID: 20797689). We carried out a systematic comparison of SNPs and structural variants in two DNA specimens from the same individual (one extracted from LCL and one from peripheral blood mononuclear cells), using both whole-genome deep sequencing (Illumina HiSeq2000, 30x) and a SNP array (Illumina Omni1-Quad). The discordancy rate for ~700,000 SNP array genotypes (~0.01%) was less than the established error rate for the method. A much greater discordancy rate (~ 0.18%) was observed for the ~4,500,000 SNPs called with adequate confidence from sequencing data, likely due to the higher error rate of this method. Similar proportions of SNPs were called only in the LCL or the blood specimen, and there was no clustering of discordant calls in the genome. Detailed analysis of structural variants is in progress, along with experimental investigation of a subset of the discordant SNP and CNV calls. The very low proportion of discordant SNP array genotypes suggests that very few SNP artifacts are introduced by EBV transformation. However, such artifacts would be problematic for studies focusing on de novo mutations. Validation experiments will permit us to estimate the full extent of SNP and structural variation introduced by EBV transformation in these specimens. This information may be of value to investigators considering or undertaking sequencing-based studies with LCL specimens.

Genomic capture combined with long read and short read high-throughput sequencing for assembly of the MHC region. *R.J. Bloom[1], A.L. Collins[1], A.E. Byrnes[2], Q. Langdon[1], S. Happe[3], J. Barboza[3], O. Hardy[3], G. Yuan[4], S. Ranade[4], P. Mieczkowski[1], P.F. Sullivan[1,5].* 1) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Agilent Technologies, Santa Clara, CA; 4) Pacific Biosciences, Menlo Park, CA; 5) Department of Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, NC.

The major histocompatibility complex (MHC) region has emerged as important for many human diseases, including multiple autoimmune diseases and infectious disease. An extended region (chr6:25–34 Mb) has emerged as significantly and replicably associated in schizophrenia, but the complexities of this region have made narrowing of the region intractable. Given the large variability between different individuals, we designed a study to re-sequence and assemble this region in multiple individuals homozygous across the region, with the goal of creating a new reference sequence for each of the most common MHC haplotypes. As proof of principle, we have started with DNA from cell lines with known sequence across the MHC: PGF, SSTO, and DBB. We used a novel variation of Agilent's SureSelect technology to enrich for DNA from this region. We designed baits across the targeted region (25–34Mb on chromosome 6, including the 7 alternative builds in UCSC; including SSTO and DBB). This protocol generates large fragment sizes and allowed us to prepare DNA from the same capture for sequencing with Pacific Bioscience's SMRT technology and Illumina's HiSeq2000. Alignment of the PacBio reads to hg19 confirms that we have enriched for the region (~75% enrichment for each of the cell lines) and that we obtained average insert sizes of up to 1400bp. Mean target coverage for PacBio reads is approximately 10X. Illumina reads have been generated using 100bp paired end sequencing. We will use both sets of reads for hybrid assembly, which combines the advantages of long reads with the accuracy of short reads to allow us to assemble the region from each of the cell lines, independently of the reference sequence. These assemblies will be compared to the existing build from each cell line to verify the method. We therefore have a technique for capturing long fragments from a single Agilent SureSelect enrichment that allows both PacBio and Illumina sequencing from the same capture. These experiments will determine whether the combination of these techniques can allow individual level assembly of complex regions of the human genome, elucidating regions intractable to genetic study in the past.

Automated pipeline for whole exome/genome sequencing analysis on Mendelian diseases. *Y. Guo, K. Wang.* University of Southern California, Los Angeles, CA.

The development of high-throughput sequencing technologies has dramatically changed the landscape of human genetics research on Mendelian diseases. Currently, there are approximately 1,772 known Mendelian diseases whose genetic basis remain elusive, based on the Online Mendelian Inheritance in Man (OMIM) database. Identifying causal genes and variants for these diseases will greatly improve disease diagnosis and facilitate the development of therapeutic strategies. Compared to complex diseases with complex inheritance patterns and multiple causal genes with incomplete penetrance, Mendelian diseases may be easier to interrogate by sequencing a few cases and family members. Here we present a computational pipeline that performs a series of automated steps to help biologists and clinicians with limited bioinformatics skills identify candidate causal genes for Mendelian diseases. This pipeline perform QC assessments of raw sequencing reads, map single-end or paired-end reads to user-specified reference genome, remove duplicates where necessary, perform local realignments and base quality recalibration, generate SNPs and indels calls by multiple popular algorithms, then compile a set of consensus calls to improve calling accuracy while maintaining high sensitivity. Subsequently, we use a set of filtering and annotation procedures implemented in the ANNOVAR package, including variant function, gene function, allele frequency, conservation scores, functional prediction scores, family information, combined information on multiple unrelated cases, gene-gene networks, phenotype similarity to known Mendelian diseases, to reduce the search space to a small ranked list of candidate genes. We tested the pipeline on whole-exome and whole-genome sequencing data sets on several Mendelian diseases or Mendelian forms of complex diseases. We demonstrated the efficiency of the analysis pipeline to generate candidate genes with minimum human intervention, and discussed the practical challenges in finding causal genes for Mendelian diseases.

Computational Analysis of Exome-seq for Disease Gene Identification with eDIVA. *S. Ossowski, R. Rahman, O. Drechsel.* Genomic and Epigenomic Variation in Disease Group, Centre for Genomic Regulation (CRG) and UPF, Barcelona, Spain.

Novel or inherited genetic variations can lead to drastic phenotypes including rare and common diseases. Human exome analysis using next generation sequencing (Exome-seq) has recently been established as a key approach to identify genetic variations in protein coding genes. We have developed computational methods for the identification and functional analysis of causal and disease associated mutations in Exome-seq studies of rare and common, mendelian and complex diseases. To facilitate the routine application of Exome-seq for the identification of disease associated genetic variants and somatic mutations, diagnosis and improved personalized treatment we have implemented eDIVA. This pipeline performs read alignment, SNP, indel and CNV prediction, functional annotation of variants and estimation of damaging potential for coding SNPs. To improve variant annotation, data accessibility and comparison between studies we integrated a BioMart based database and disease variant annotation tool. eDIVA-DB incorporates predicted variants together with relevant functional data as well as known variants in the population. It supports rich annotation of variants by adding OMICs information from e.g. dbSNP, 1000genomes, EVS, KEGG, BioGRID and OMIM. Furthermore it supports gene and pathway based mutation enrichment studies for the analysis of complex diseases. We further integrated a rank product based algorithm to prioritize candidate SNPs and indels using all integrated information. The prioritization algorithm has been validated on Exome-seq data from a study on Familial Hyperkalemic Hypertension (FHHt) by successfully identifying the causal variant KLHL3, previously shown to be causal for FHHt in this family. eDIVA allows for automated analysis of large-scale Exome-seq studies and we currently analyze various types of diseases including cardio-vascular (early onset varicose veins), neurological (congenital myopathies and ataxia) and rheumatologic diseases (fibromyalgia) as well as cancer (chronic lymphocytic leukemia).

The Biologist's Tool for Finding a Needle in a Haystack: CLC bio's Platform to Identify Interesting de novo and Accumulative Variants in the Whole Genome Sequence of Family Trios. *N. Thomson[1], A. Joecker[2], C. Boysen[1], M. Matvienko[1], U. Appelt[2], A. Fejes[2], L. Kahns[2], S. Mønsted[2], J. Grydholt[2], B. Knudsen[2], M. Bungaard[2], J. Buur Sinding[2], H. Handberg[2], A. Hiene[2], M. Nygaard Ravn[2], A. Joecker[2], M. Værum[2], R. Forsberg[2].* 1) CLC bio, Cambridge, MA; 2) CLC bio, Finlandsgade 10–12, Katrinebjerg, 8200 Aarhus N, Denmark.

The debate over the value of Whole Genome Sequencing (WGS) vs Whole Exome Sequencing (WES) revolves around the expense of data generation, the challenge of analysis, and the ability to interpret results. However there are ever increasing reasons to suggest that phenotypic variation may be the result of genotypic variation outside of the exome. Over 90% of variants reported in dbSNP lie outside of the annotated coding regions. Additionally, while less than 2% of the human genome is translated into protein, much larger percentages are conserved, transcribed and assigned functionality. Advances in DNA Sequencing technology eliminate the expense of data generation as one obstacle in pursuing WGS. Mapping sequencing reads to the human genome, a task that previously consumed weeks and huge compute resources, can now be done in a reasonable time on a single compute node with CLC bio's mapping algorithms. The integration of advanced algorithms, access to public resources, and a friendly user interface within the Genomics Workbench create an environment in which biologists can fully leverage WGS data. In this work we will analyze a European family trio from the 1000 genome project, using CLC bio's Genomics Workbench. We will show all steps, from mapping sequencing reads to the human genome, to the identification of potential disease relevant variants. Specifically we will emphasize the method for discovering de novo (only present in the child) and accumulated (heterozygote in the parents, homozygous in the child) variants. This process could reveal candidate variants for disease, when a child is ill, for instance, and the parents are not. Furthermore, we will show how a prioritization of these variants, through annotation of potential functional consequences, will facilitate the identification of variants of interest.

3663F

Ultra-fast clinical sequencing and annotation of human genomes on the Illumina HiSeq 2500 platform. *S. Humphray, J. Weir, Z. Kingsbury, T. James, R. Grocock, P. Saffrey, E. Margulies, K. Hall, D. Bentley, G. Smith, J. Betley, C. Raczy.* Illumina UK, Saffron Walden, Essex, United Kingdom.

We demonstrate an easy to use whole genome sequencing workflow from DNA to annotated variants. In many clinical settings, such as Neonatal, Paediatric and Medical Intensive Care Units, time to answer is critical for patient care. We describe the system advances that have been made in the areas of library preparation, sequencer performance and alignment/annotation software. We illustrate the application of this rapid workflow, and the ability to use low amounts of DNA including FFPE samples, to a real-world clinical environment with a time to answer of less than 48 hours. Whole genome sequencing (WGS) is being increasingly adopted in both research and clinical settings. We are able to use low input amounts of DNA (100ng). Optionally using a PCR-free sample preparation protocol improves uniformity of coverage. The improvements also allow the user to go from genomic DNA to clustering in less than 4 hours. The HiSeq 2500 enables very rapid production of whole genome data with the time from introducing the prepared library to completed paired end 2×100 cycle runs being reduced to less than 27 hours. A new suite of software enables very fast analysis and annotation of genomes for clinical interpretation and reporting. Features include a new fast sequence aligner that, combined with variant calling and generation of genomic VCF (gVCF) files, provides information of quality and depth of coverage of all genomic positions including variant calls. Annotation with Variant Effect Predictor (Ensembl) output and data from 1K Genomes, Encode and other public sources produces a compressed annotated gVCF file (of approximately 1Gbyte) that is highly portable in local and remote (e.g. Cloud) environments for maximum accessibility in clinical and research environments.

Managing Computing Resources in Large Sequencing Studies: Strategies and Lessons from Sequencing 2,120 Sardinian Genomes. *A. Kwong[1], C. Sidore[1,2,3], S. Sanna[3], H.M. Kang[1], G. Jun[1], M. Trost[1], P. Anderson[1], T. Gliedt[1], R. Cusano[3], M. Pitzalis[3], M. Zoledziewska[3], A. Maschio[1,3], F. Busonero[3], M. Lobina[3], M. Balloi[3], B. Tarrier[4], C. Brennan[4], C. Jones[5], F. Cucca[2,3], G. Abecasis[1], SardiNIA project.* 1) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy; 3) Istituto di Ricerca Genetica e Biomedica, CNR, Monserrato, Cagliari, Italy; 4) DNA Sequencing Core, University of Michigan, Ann Arbor, MI, USA; 5) CRS4, Advanced Genomic Computing Technology, Pula, Italy.

Though the cost of sequencing has decreased drastically in the last few years, the computing resources required for processing the data, which includes read mapping, alignment refinement, variant calling, and genotype refinement, remain substantial. Here, we briefly summarize our current results, and describe our strategy for managing, scheduling, and optimizing the computing resources required to conveniently process these data and update results as new samples are sequenced. We have low-pass sequenced the genomes of 2,120 Sardinian individuals (at ~3.5x coverage) to study the genetics of lipid levels and other aging-related traits. From our current dataset of >50 Tb of raw sequence data, an average of 3.4 million SNP variants were called per individual; ~17 million SNP variants were called across all individuals. We discovered 151k coding variants in our samples, and rediscovered 88% of the European variants found in 1000 Genomes with an overall allele frequency > 0.01. Our strategy starts with the design of physical computing resources, with a mixture of large networked file systems that serve as the central repository for project data, and small local file systems for managing intermediate results in each compute node. Jobs are scheduled to maximize the use of local storage for intermediate results and to minimize costly swapping of memory to disk and transfer to network file systems. Samples are aligned in parallel, with one to three samples assigned to each physical computing node. Initial read mapping and alignment refinement requires ~50 CPU-hours per sample (corresponding to >130 CPU-months for all 2,000 samples). After alignment, we performed variant calling and genotype refinement across all 2000 samples together to increase the power to detect rare variants, using parallel jobs that each handle a small chromosomal region (typically 5M bases). Variant calling, a high I/O job, typically requires ~6 CPU-hours per region (corresponding to ~5 CPU-months for all regions), and is run on the cluster with the fastest data access, while genotype refinement, a CPU-intensive job, typically requires ~2 CPU-days per 10,000 SNPs (corresponding to ~100 CPU-months for all regions), and is run on the cluster with the most computational power. The strategies described are instrumental in our large sequencing project, and serve as a useful guideline for sequencing projects of all sizes.

Clinical implementation of targeted next generation sequencing in a mid-sized diagnostic laboratory. *H. Racher[1], L. Dimnik[1], P. Gordon[2], M.I. Innes[1], F. Bernier[1], J.S. Parboosingh[1].* 1) Medical Genetics, Alberta Children's Hospital/University of Calgary, Calgary, AB, Canada; 2) Genomics & Bioinformatics Facility, University of Calgary, Calgary, AB, Canada.

Sequencing of the entire human exome by next generation sequencing (NGS) is a powerful tool for disease variant detection. This is a useful starting point for translation into the clinical setting as the coding sequence and flanking splice sites harbour ~85% of all human disease-causing mutations (Choi et al., 2009). However, translation of whole exome NGS into the clinic is problematic due to: (1) interpretation and handling of large data sets, (2) incidental findings, (3) inconsistent and/or incomplete coverage, and (4) system accuracy, sensitivity and precision. Using the Life Technologies SOLiD 5500 platform to perform whole exome NGS we determined system performance through orthogonal validation on six exomes with Agilent SNP microarrays. Accuracy was determined to be 98.6%, while sensitivity and specificity were 99.1% and 99.7%, respectively. We explored the variability in sequence coverage between two exon capture kits, Agilent SureSelect v3 kit and Life Technologies TargetSeq kit. The kits, by design, cover 99% ad 98.4% of the 32.9 Mbps of total refGene human coding sequence in addition to varying amounts of flanking intronic/non-coding sequence. ≥20X coverage of coding regions was observed in 85.6% of the SureSelect reads and 91% of the TargetSeq reads. In order to address some of the other challenges, we explored customizing enrichment kits by restricting analysis of the exome data to targets associated with known diseases. We used 31 genes associated with hypertrophic cardiomyopathy (HCM), a common disorder with a prevalence of 1/500, to evaluate the utility of this approach. A coverage level of ≥20X was observed for 99.6% of the regions using SureSelect and 99.8% with TargetSeq. The regions with low coverage varied, however, ~30% of the low coverage reads occurred within exon 1 sequence, a commonly underrepresented region due to GC rich sequence. Our next step in this analysis will be to run a customized kit, specific to the HCM panel of genes, using the SOLiD 5500 platform and compare this data to our whole exome NGS data. Our ultimate goal will be to move to benchtop sequencers, which will improve our turn-around-time by requiring fewer samples per run.

3666W

High-fidelity sequencing for detection of low-frequency single nucleotide variants. *K.M. Squire, Z. Chen, S.F. Nelson.* Human Genetics, UCLA, Los Angeles, CA.

It is often useful to identify very low frequency variants present in a DNA sample, for example, when attempting to identify variants from an unlabeled pool of many unidentifiable individuals, or when attempting to identify mutations that might confer resistance to a subset of cancer cells. Here we propose a method to identify single nucleotide variants (SNVs) present at a very low frequencies within a sample. Previously sequenced ecoli DNA was prepared according to standard Illumina library preparation protocols, with the exception that the DNA was sheared and size selected on a gel so that the insert size was 80±10bp. The DNA was sequenced using 100+100 paired end sequencing on a HiSeq 2000. Because the average insert size was less than 100bp, in almost all cases the same fragment was read twice. We aligned both ends of each read pair against one another, trimmed adapter sequence, and used the overlapping portion of the reads to form a single high-fidelity output read. Bases which were not identical in both reads were covered to Ns. These high-fidelity reads were aligned against a standard ecoli reference, and simple pileup and counting was used to identify variants. The list of variants was compared against previously identified variants from the same DNA pool. Newly identified variants were either low-level variants or sequencing errors, and allowed us to put an upper limit on the sequence error rate of 0.01%, compared with a sequence error rate of 0.1% for the original sequence. This suggests that the proposed method can be used to identify single nucleotide variants present above this rate.

3667F

Species identification by polymorphisms of mitochondrial 12S rRNA and 16S rRNA genes. *R. Li[1], L. Yang[2].* 1) Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH; 2) Dept. of Molecullar & Cellular Physiology, College of Medicine, University of Cincinnati. Cincinnati, OH.

There are two genetic systems in cells of all animals - the nuclear and mitochondrial genomes. The unique properties of mitochondrial DNA (mtDNA), including maternal inheritance, multiple copy numbers, high mutation rate and polymorphism, have made mtDNA a good choice to study biological evolution and species identification. Interspecific and intra-specific variations (polymorphism) of mtDNA have been found by bioinformatic analyses of the mitochondrial genomic sequences of thirteen of species, including Xenopus laevis, Plecoglossus altivelis, Mus musculus, Bos Taurus, Pan Paniscus, Pan troglodytes,Gorilla gorilla, Papio hamadryas, Lemur catta, Cebus albifrons, Tarsius bancanus, Hylobates lar, and Homo sapiens. Some conserved regions have been identified in mitochondrial 12S rRNA and 16S rRNA genes from these thirteen species. Therefore, the universal primers designed in the conserved regions of 12S rRNA and 16S rRNA genes will be capable of amplification mtDNA fragments of 12S rRNA and 16S rRNA genes most animal mtDNA. Using these primers, spanning 1068 to 1076 (forward) and 1341 to 1360 (reverse) for mitochondrial 12S rRNA gene, from 2582 to 2591(forward) and 3044 to 3063(reverse) for the mitochondrial 16S rRNA gene (NCBI: NC_012920.1), to amply DNA samples from culture cells of human and mouse as well as commercial tissues of shrimp, pork, beef and chicken, we successfully obtained ~300 bp (298 bp in human) and ~480 bp (482 bp in human) of PCR products. Sequencing these PCR products, then blast searches at (http://blast.ncbi.nlm.nih.gov/Blast.cgi?-PROGRAM=blastn&BLAST_PROGRAMS=megaBlast&PAGE_TYPE=BlastSearch&SHOW_DEFAULTS=on&LINK_LOC=blasthome#), identified their species origins and similar sequences in NCBI database by their nucleotide variations in these two mitochondrial rRNA genes. This molecular technique combined with bioinformatics provides a reliable method for identification of the maternal origin of animal tissues. It can be used for the study of phylogenetic relationship, species evolution, forensic biology, food industry, protection of extinct animals and classification of novel species.

Rapid and Efficient Methods for Preparing Globin- and rRNA-Depleted Directional RNA-Seq Libraries. *C. Kinross, J. Hitchen, N. Caruccio, R. Sooknanan.* Epicentre, an Illumina Company, Madison, WI.

Massively parallel sequencing of cDNA libraries (RNA-Seq) is the preferred method for profiling and analysis of novel transcripts, isoforms, alternative splice sites, rare transcripts and cSNPs. However, a persistent challenge is that ribosomal RNA (rRNA) represent >95% of total RNA content and its removal is essential for increased sensitivity and coverage of transcripts when preparing next-generation sequencing (NGS) libraries. Additionally, for whole blood RNA samples, reticulocyte globin transcripts can constitute up to 76% of total mRNA and, unless removed along with the ribosomal RNA transcripts, the detection of low-abundance mRNA transcripts is further compromised. Here, we present an efficient “single-pass” method (GlobinZero™ Gold Kit) for the concomitant removal of rRNA and globin mRNA from intact and fragmented blood total RNA samples (human, mouse and rat), and an improved, more user-friendly version of the ScriptSeq™ RNA-Seq library preparation method. Globin-Zero-treated samples contain <2% of rRNA and globin sequences, while maintaining representation of coding and noncoding transcripts independent of polyadenylation. This reduction in rRNA and globin sequence reads improves sequence depth and coverage of mRNA, and increases the percentage of uniquely mapped reads.

Sequencing performance of FFPE DNA in the SureSelect^{XT2} Target Enrichment System. *J. Barboza[1], M. Ramirez[2], A. Giuffre[1], J. Ong[1], H. Ravi[1], M. Guadalupe[1], S. Joshi[1], M. Visitacion[2], C. Pabón-Peña[2], S. Hunt[2], B. Novak[2], D. Roberts[2], S. Happe[1], E. LeProust[2].* 1) Genomics Division, Agilent Technologies, Cedar Creek, TX; 2) Genomics Division, Agilent Technologies, Santa Clara, CA.

Massively parallel sequencing technologies have enabled scientists to discover rare mutations, structural variants, and novel transcripts at an unprecedented rate. Agilent Technologies has developed the SureSelect platform to enable fast, inexpensive and accurate genome analysis. Recently developed, the SureSelect^{XT2} kit has a more streamlined sample preparation protocol as well as the capacity for multiplexed sequencing, greatly reducing sequencing cost per sample. To extend the capabilities of the SureSelect^{XT2} system we probed the limits of gDNA input amounts. Our data shows that reducing the input amount of starting material from 1µg to 0.5µg and 0.25µg did not affect the sequencing quality of the libraries produced. We expanded our studies by analyzing a set of human tumor DNA samples extracted from paraffin-embedded (FFPE) blocks. In agreement with our initial experiments, FFPE samples with varying starting amounts produced sequencing results that were comparable to control samples. In addition, we tested two commercially available FFPE DNA extraction kits. While the two preparations produced DNA that differed in total yield and quality, sequencing results were comparable between FFPE DNA prepared from both kits. Our studies highlight the robustness of the SureSelect^{XT2} Target Enrichment System, and its utility in analyzing DNA from valuable archived material that may be in low abundance and susceptible to damaging modifications.

Torrent Variant Caller: Enabling Next Levelel of Genomic Analysis. *D. Brinza, Z. Zhang, E. Tsung, A. Joyner, C. Scafe, G. Del-Mistro, F. Hyland, E. Beasley, S. Utiramerur.* Life Technologies, Foster City, CA.

Ion Torrent PGM and Proton sequencing platforms have a very quick turnaround time and produce longer high accuracy reads. These create a computational challenge of making an extremely fast and accurate variant caller that can take advantage of unique error model, and enable detection of longer indels. Here we introduce a Torrent Variant Caller software suite designed to address these challenges. One approach to variant calling is first to align reads to reference genome, then call variants based on pile-up formed by alignments. With longer reads, the challenge is to extend alignments beyond long indels. We address this by first mapping reads to the reference and then de novo assembling non-aligned read portions in regions with evidence for novel sequences. We then quickly traverse all alignments and predict candidate variants based on a very fast heuristic algorithm. The framework models around flow-space alignments of each candidate variant and accurately estimates the length, position, and the score of the variants. The method fast and accurately predicts SNPs, long and short INDELs.

3671F

A Next-Gen Sequencing Software Workflow for Cancer Genomics on a Desktop Computer. *M. Keyser[1], K. Maxfield[1], T. Schwei[1], T. Durfee[1], A. Pollack-Berti[1], D. Nash[1], J. Stieren[1], S. Baldwin[1], R. Nelson[1], K. Dullea[1], J. Schroeder[1], P. Pinnkas[1], G. Plunkett III[1,2], F. Blattner[1,2,3].* 1) DNASTAR, Inc., Madison, WI; 2) University of Wisconsin, Department of Genetics, Madison, WI; 3) Scarab Genomics LLC, Madison, WI.

DNASTAR offers an integrated suite of software for assembling and analyzing sequence data from all major next-generation sequencing platforms supporting key workflows on a desktop computer, including. The cancer genomics workflow that integrates some of the most powerful functionality in the software includes assembling and analyzing multiple samples using one reference template; probabilistic identification of SNPs, small indels and genotype calls with known variants correlated to their dbSNP and COSMIC IDs and GERP reference data; review and filtering of SNPs from multiple samples within a single project; identification of structural variations; and, for large multi-sample projects with hundreds of individual data sets, tools for SNP quantitation, filtering, set comparison, clustering and indication of the gene disruption impact from called SNPs. Interactive views within the software facilitate fast, comprehensive analysis, helping scientists move quickly from raw next-gen sequencing data to genetic and genomic impact, including gene ontology. By using innovative algorithms within the software, scientists can have all of the assembly and analysis capabilities available to them on their desktop computer, supporting large data sets generated by any or all of the next-gen sequencing instruments and platforms.

3672W

Strategy for identification, prediction, and prioritization of non-coding variants of uncertain significance in heritable breast cancer. *P.K. Rogan[1,3], E.J. Mucaki[1], A. Stuart[2], N. Bryans[3], E. Dovigi[1], B. Shirley[3], J.H. Knoll[2], P. Ainsworth[2].* 1) Biochemistry; 2) Pathology; 3) Computer Science, Western University, London ON Canada.

High-throughput sequencing (HTS) of both healthy and disease singletons yields many novel and low frequency variants of uncertain significance (VUS), most of which are likely to be benign. Current approaches to predict pathogeneticity generally do not focus on non-coding variants even though they contribute to Mendelian disorders and contain many VUS. Using cleavable solution microarrays, we are capturing and enriching for variants in a set of genes known to harbor mutations that increase breast cancer risk. Oligo baits covering *ATM, BRCA1, BRCA2, CDH1, CHEK2, PALB2* and *TP53* were synthesized for solution hybridization with a custom cleavable microarray spanning the complete coding and intergenic regions 10 kb upstream and downstream of each gene. Non-exonic sequences are densely populated with repetitive sequences that can affect short read assembly. A novel probe design method was used to capture both repeat-free and divergent repeat sequences that are effectively single copy. Sequencing of multiple samples captured 86.1% of bait sequences with minimal off-target coverage and an error rate of 2.5×10^{-5}/bp. Information theory-based sequence analysis was used to prioritize non-coding variants which occurred within sequence elements recognized by proteins or protein complexes. The novel VUS identified are being investigated for effects on transcription factor-binding site (TFBS) and mRNA splicing mutations. We have developed and apply bipartite information theory based models for exon recognition which predict the relative abundance of natural, cryptic, and mutant splice isoforms resulting from predicted mutations using the combined donor and acceptor site strengths of each mRNA species. We have applied a similar approach to detect mutations in the promoters of *BRCA1* and *BRCA2* that alter strengths of TFBS. Information weight matrices were automatically computed by entropy minimization of c-Jun, FOSL2, GRP20, HSF1, IRF4, NF-κB, PU.1, RAD21, RXRα, TCF12, and YY1 TFBS from the global set of ENCODE ChiP-seq regions embedded within DNAaseI hypersensitive domains. These models are then used to evaluate novel variants discovered by sequence analysis of breast cancer patients for alteration the TFBS binding strengths. This strategy more comprehensively covers non-coding regions in breast cancer genes, and introduces a unified framework for systematic interpretation of VUS that may affect expression.

Genomic approach for environmental stress assessment in coral, *Scleronephthya gracillimum*. *S. Woo[1], S. J. Hwang[2], S. Yum[1], J. I. Song[2].* 1) South Sea Research Department, Korea Ocean Research and Development Institute, Geoje, Gyungsangnam-do, South Korea; 2) Division of EcoScience, Ewha Womans University, 120–750 Republic of Korea.

Coral ecosystem is the most magnificent and diverse marine ecosystems on Earth. They have had a crucial role in shaping the ecosystems that have dominated tropical oceans over the past 200 million years. Coral ecosystem is the home for fish, millions of invertebrates, algae, and microbes. However, environmental stresses such as climate change, ocean acidification and anthropogenic effects have been recognized as the major destructive impacts on coral ecosystems. Motivated by the precarious state of coral ecosystem, there is currently a keen interest in coral transcriptomics. By investigating changes in coral gene expression that are triggered by particular environmental stressors, we can begin to characterize coral stress responses at the molecular level, which should lead to the development of more powerful diagnostic tools for evaluating the health of corals in the field. Toward this end, we performed NGS (next generation sequencing) of the soft coral, Scleronephthya gracillimum, a geographically spread through the Kuroshio current species and developed oligo microarray using approximately 34,000 clones. Total 33,401 reads were input to analyze KOG categorization and 32.42% of reads were successfully categorized, 2.14%, uncharacterized and 67.58% were not hit in the known information using BLASTx algorithm. For the microarray experiment, We collected specimens from 2 sites in Jeju island, Republic of Korea which are geographically separated and isolated RNA from colonies exposed to heat stress (26°C, 28°C and 30°C) or control condition (24°C) at 6h, 12h, 24h and 48h post-exposure, respectively. Among the genes showing significant changes (2-fold) we selected 18,523 genes which were shared in heat stress groups and investigated their expressions. The clusters of genes showed the similar pattern of transcriptional changes such as upregulation or down regulation between 26 and 28°C groups but over 35% of genes revealed totally opposite pattern of expression in 30°C group. The identified differentially expressed genes have a potential to identify specific stressors in environmental changes and could act as molecular biomarkers for biological responses against external environmental stimuli. And this transcriptomic approaches can be used to develop a diagnostic tool for coral health assessment.

RNA-seq uncovers the influence of structural variants on transcriptome diversity. *E. Ait Yahya Graison, A. Reymond.* CIG, Univ Lausanne, Lausanne, Switzerland.

Structural variants (SV) of DNA segments have been identified as a major source of genetic diversity, but a comprehensive understanding of the phenotypic effect of these variants is only beginning to emerge. Our group and others established extensive maps of SV in mouse strains, covering ~11 percent of their autosomal genome. In this study, we used the RNA-seq technology to unravel the effects of SV on expression at the nucleotide resolution and simultaneously on alternative splicing. We generated extensive RNA-Seq data from liver and brain (>450 millions single-end reads) from brain and liver of three mouse inbred strains (129S2, DBA/2J and C57BL/6J) using the Illumina Genome Analyzer IIx. We mapped reads on the mouse genome using TopHat, assembled and estimated the abundance of the different isoforms using Cufflinks. To evaluate expression changes for transcripts mapping within and outside SVs, we took advantage of the sequencing of the genome of 17 key mouse strains with high-throughput technologies. We intersected the coordinates of the identified SVs with the transcriptome data we generated to define different categories of expressed features according to their degree of overlap with a rearrangement. Generally, for both brain and liver, gene expression seems impacted for all genes, which are at least partially overlapping with a SV. At transcript level, transcripts lying in large SVs show constant overexpression compared to those outside SV. This is consistent with the fact that larger SVs encompassing whole coding regions of genes in our dataset are mainly copy number gains. We also assessed the impact of SV on alternative splicing by evaluating for each SV category the number of isoforms per gene we could detect in brain and liver for both 129S2 and DBA/2J strains. We observed that genes including exons which contain small SV and genes affected by SV in their upstream or downstream regions display significantly more isoforms per gene than genes not affected by SV. To conclude, our findings suggest that SV affecting the whole gene region have a more direct impact on their expression, whereas SV occurring in regulatory regions (e.g. inside exons or overlapping non-coding regions upstream/downstream of genes) are more likely to influence alternative splicing leading to higher number of isoforms of these genes. This study provides a unique opportunity to extensively gauge the influence of SV on the transcriptome complexity and regulation.

Detection of Local Signals in Genomics. *D. Siegmund[1], B. Yakir[2], N. Zhang[3].* 1) Dept Statistics, Stanford Univ, Stanford, CA; 2) Dept Statistics, Hebrew University of Jerusalem; 3) Department of Statistics, University of Pennsylvania.

A large class of problems of genomic analysis involve detection of local genomic signals. Examples are (i) linkage and/or association analysis, (ii) detection of intervals of copy number variation based on SNP arrays, (iii) detection of DNA structural variations from paired end reads, (iv) detection of protein-DNA interactions by ChIP-Seq. Theoretical approaches to some of these problems based on change-point methods are described, with particular attention to the problems of multiple comparisons. The theoretical results are illustrated on simulated and on real data.

Gene Expression Profiling of Prokaryotic samples using LIQA WT kit. *N. Guha.* Genomics, Agilent Technologies, Bangalore, Karnataka, India.

Agilent's Low Input Quick Amp Labeling WT Kit provides a reliable method to amplify and label whole transcripts for the robust generation of cRNA upstream of microarray hybridization. We describe a method to perform microarray analysis of two key prokaryotic organisms, Mycobacterium tuberculosis (MTB), a high GC-rich organism and Escherichia coli (E.coli) using the LIQA WT kit. This kit is also used for analysis of Agilent human, mouse and rat SurePrint G3 Exon Microrrays, catalog and custom arrays. The study demonstrates that the LIQA WT kit can be successfully used to label these prokaryotic transcripts and yield high quality microarray data. The data shows strong correlation (R2>0.95–0.99) between the replicates of the microarrays for both 1- and 2-color. Excellent sensitivity and signal linearity (>5 logs) were demonstrated using spike-in controls. Differential gene expression analysis of E. coli whole transcripts upon treatment with paraquat, a potent inducer of oxidative stress, revealed several key genes to be significantly regulated. The key genes included superoxide dismutase and fumarase C that are known to be strongly induced by paraquat. Overall the data demonstrates that using the LIQA WT Labeling kit along with Agilent's catalog E. coli and custom-designed MTB arrays one can generate high quality biologically relevant expression data.

In silico identification of microRNA-mRNA target pairs as potential biomarkers in Prostate Cancer. *J. Billaud, C. Tavano, D. Toburen.* Ingenuity Systems, Redwood City, CA.

This study will focus on identifying microRNA-mRNA target pairs as potential biomarkers for Prostate Cancer using in silico techniques. Prostate Cancer (PrCa) progresses in stages; from early stage primary tumors developing in the prostate to lethal metastatic forms in the bones. Two screening methods are used for the detection of tumors, namely their localization, and the presence of metastasis. However, conflicting studies suggest that in particular, PSA testing displays low specificity and inability to distinguish latent from aggressive cancer. In fact, a substantial number of men are over-diagnosed and over-treated for prostate cancer mainly due to the poor performance of the PSA test. Therefore, better biomarkers of diagnostic, predictive, prognostic values are urgently needed. Our in silico research combines the results of two studies that looked for i) a gene signature (158 mRNAs) that map to clinical conditions and ii) the potential use of microRNAs (miRNAs) as diagnostic and/or prognostic markers for prostate carcinoma. Studies have highlighted the role of miRNAs in normal and pathological situations, and as such they add an extra level of complexity to the regulation of gene expression. Indeed changes in their expression have been identified in inflammatory diseases, viral infection as well as human cancer. The miRNAs are a class of non-coding, short RNAs (an average of 22 nucleotides) that function as post-transcriptional regulators by binding to complementary sequences on target mRNAs and resulting either in translation repression or degradation of mRNA and gene silencing. A combination of capabilities within Ingenuity Pathway Analysis (IPA) will help dissect the role of these miRNAs in PrCa by highlighting which specific mRNAs are targeted, their involvement in important canonical pathways and networks as well as in biological processes that would explain tumor progression and/or metastasis. This in silico research will finally suggest hypothetical biomarkers that combine units of microRNA-mRNA pairs as potential biomarkers of disease progression in PrCa. In conclusion, it will be shown that IPA is an important tool for exploration of the molecular signature of cancer, for understanding consequences of miRNA expression changes in cancer by combining different aspects of biology, and exploring the clinical aspects related to biomarker identification.

3678W

Active Learning for Phenotype Mapping. *C. Hsu[1], J.L. Ambite[1], Y. Arens[1], L. Lange[2], S. Sharma[1], S. Voinea[1].* 1) USC/Information Sciences Inst, Marina del Rey, CA; 2) Department of Genetics, University of North Carolina, Chapel Hill, NC.

Many genetic epidemiologic studies of cardiovascular disease have multiple variables related to any given phenotype, resulting from different definitions and multiple measurements or subsets of data. A researcher searching such databases for the availability of phenotype and genotype combinations is confronted with a veritable mountain of variables to sift through. This often requires visiting multiple websites to gain additional information about variables that are listed on databases, and examination of data distributions to assess similarities across cohorts. While the naming strategy for genetic variants is largely standardized across studies (e.g. “rs” numbers for single nucleotide polymorphisms or SNPs), this is often not the case for phenotype variables. For a given study, there are often numerous versions of phenotypic variables. Manually mapping and harmonizing these phenotypes is a time-consuming process that may still miss the most appropriate variables. Previously, we have developed a supervised learning algorithm that learns to determine whether a pair of phenotypes is in the same class. Though this algorithm accomplished satisfying F-scores, the need to manually label training examples becomes a bottleneck to improve its coverage. Herein we present a novel active learning solution to solve this challenging phenotype-mapping problem. Active learning queries users for labels of unlabeled phenotypes that may improve the mapping the most and therefore will reduce the need of labeling efforts. Active learning will make phenotype mapping more efficient and improve its accuracy, along with intuitive phenotype query tools, would provide a major resource for researchers utilizing these databases. Our active learning method explores the connectivity of related phenotype variables to infer a set of sure matches and pairs of phenotypes variables that confuse the program the most, and query users for labels for these variables. We tested our method to a set of 1700 annotated variables from 7 large cohort studies. We show that by applying our active learning method, we can improve the F-scores of mapping from 61% to 66% by adding forty more annotated variables, a huge improvement compared to annotating variables randomly. Remarkably, the set of sure matches are completely correct in our experiments.

FAVR (Filtering and Annotation of Variants that are Rare): methods to facilitate the analysis of rare germline genetic variants from massively parallel sequencing datasets. *D.J. Park[1], T. Nguyen-Dumont[1], F. Odefrey[1], A. Lonie[2], M.C. Southey[1], B.J. Pope[2].* 1) Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Melbourne, Victoria, Australia; 2) Victorian Life Sciences Computation Initiative, The University of Melbourne, Melbourne, Victoria, Australia.

Massively parallel sequencing (MPS) is a powerful tool to facilitate research on the genetic basis for observed phenotypes, including predisposition to and progression of human diseases. However, interpretation of MPS data is challenging. A typical single whole -human exome analysis outputs thousands of genetic variant signals. Only a fraction of these are real, the remainder being artefacts from the processes of sequencing and mapping to the reference genome. Many of these are not readily distinguishable from true variants on the basis of `quality metrics'. Of the authentic variants, only a very small proportion might be relevant to a given disease. Here, we present FAVR, a suite of new methods designed to assist the shortlisting of genetic variants under a rare variant-disease model. The methods are designed to work with commonly used MPS analysis pipelines. The FAVR methods use signatures in comparator sequence alignment files to facilitate the filtering of mapping artefacts and common genetic variants, and annotation of genetic variants based on evidence of co-occurrence in individuals. As relevant, FAVR methods can also be used to filter out artefacts derived from imbalanced paired-end sequencing. By applying FAVR methods to whole-exome sequencing datasets, we demonstrate a 3-fold reduced single nucleotide variant shortlist compared to a conventional analysis pipeline with no detected reduction in sensitivity. This analysis included Sanger sequencing of rare variant signals not evident in dbSNP131, assessment of known variant signal preservation, and comparison of observed and expected rare variant numbers across a range of first cousin pairs. The principles described herein were applied in our recent work identifying XRCC2 as a new breast cancer risk gene and have been made publically available as a suite of software tools. FAVR methods are platform-agnostic and significantly enhance the analysis of large volumes of sequencing data for the study of rare genetic variants and their influence on phenotypes.

Accurate, Efficient Next-Generation DNA Sequencing for Clinical Carrier Screening. *G.J. Porreca, M. Umbarger, C. Kennedy, P. Saunders, B. Breton, N. Chennagiri, J. Emhoff, V. Greger, D. Maganzini, C. Micale, M. Nizzari, C. Towne.* Good Start Genetics, Cambridge, MA.

Next-generation DNA sequencing (NGS) is poised to displace genotyping technology for clinical applications because it promises richer information at low cost. However, to date a number of considerations including sequence accuracy and completeness, as well as workflow scalability, have limited its adoption in the clinical laboratory. Here we describe a NGS-based platform designed for genetic carrier screening in a clinical setting. A set of 14 genes are isolated from genomic DNA by automated multiplex target capture, tagged with molecular barcodes, and pooled and sequenced on the Illumina Hiseq system. Reads from each sample are de-multiplexed, aligned to a reference, and integrated into accurate genotype calls which are then interrogated for pathogenic mutations. A total of 42,660 bp were targeted for capture by a set of molecular inversion probes designed to tile across the target such that each base was captured by at least three different probes. Across a set of 182 DNA samples derived from cell lines or blood, a median of 99.71% of bases were sequenced to sufficient depth and quality for inclusion in genotype calling. Replicate runs exhibited a high level of concordance, with 23 discordant single nucleotide variant (SNV) calls out of 5,684,154 across 148 samples. Concordance of genotype calls with bi-directional Sanger sequence of PCR amplicons derived from a set of 193 samples was 99.97% at SNV positions (1 out of 3,973 Sanger SNV calls discordant), and 99.9998% at non-variant positions (8 out of 5,166,654 Sanger non-variant calls discordant). We identified, in a set of 57 samples, a total of 94 mutations (out of 94) that have been previously reported to be causative of recessive Mendelian disease. We also determined that 10 previously uncharacterized samples contained mutations that were either known or expected to be pathogenic. Clinical carrier screening has traditionally been performed using genotyping technology, and demands high analytical accuracy. Our NGS platform achieves exceedingly high concordance with Sanger sequencing, long considered an accuracy gold standard. Furthermore, we made high-confidence genotype calls across the vast majority of basepairs within our target regions. Taken together, these results indicate that NGS, when paired with the appropriate sample preparation methodology, automation, and data analysis, can deliver the performance required for use in clinical carrier screening.

High-Throughput *CFTR* Full-Gene Analysis Using Illumina's MiSeq TruSeq Custom Amplicon Technology. *J. Radecki, S. Lee, H. Lu, S. Mexal, A. Elliott.* Ambry Genetics, Aliso Viejo, CA.

Cystic Fibrosis Transmembrane Conductance Regulator (*CFTR*) gene is responsible for the autosomal recessive genetic disorder Cystic Fibrosis (CF). CF is one of the most frequently diagnosed autosomal-recessive diseases in the Caucasian population. Using a genotyping technology that can rapidly identify disease-causing mutations is important for high-throughput general-population carrier screening, confirming clinical diagnosis, determining treatment options, and prenatal diagnosis. Here, we demonstrate Illumina's TruSeq Custom Amplicon (TSCA) technology on the MiSeq platform is capable of sequencing ~92% of known *CFTR* disease-causing mutations with an average coverage of 723X for targeted regions in 48 clinically validated samples. Importantly, using our custom bioinformatics pipeline for *CFTR* variant identification, TSCA reliably detects the IVS9 poly-T TG-repeat polymorphism, thus alleviating the need for low-throughput gel-electrophoresis genotyping. The current version of Illumina DesignStudio produces suboptimal probe design that causes coverage dropout in overlapping regions and is incapable of designing oligos to detect known gross deletions/insertions and complex rearrangements; therefore a secondary assay is needed to detect causative structural variations. Due to the high GC content of the 5'UTR and exon 1, these regions do not meet the minimum quality values 10 mapping and 20 Q-score, creating a need for another secondary assay. In conclusion, TSCA coupled with our custom bioinformatics pipeline provides a robust high-throughput alternative to conventional full gene Sanger sequencing for *CFTR* clinical diagnostics; however, the suboptimal amplicons generated for the 5'UTR and exon 1 regions along with the inability to detect known gross deletions/insertions and complex rearrangements results in additional side assays which increases testing cost and turn-around-time.

3682W

Sensitive detection of minor variants and viral haplotypes using Single-Molecule, Real-Time (SMRT®) sequencing. *A. Sethuraman[1], Y. Guo[1], M. Brown[1], J. Toma[2], A. Newton[2], W. Huang[2], M. Sugiyama[3], C. Petropoulos[2], M. Mizokami[3], E. Paxinos[1].* 1) Pacific Biosciences, Menlo Park, CA. USA; 2) Monogram Biosciences, South San Francisco, CA USA; 3) National Center for Global Health and Medicine, Tokyo, Japan.

Genotypic testing of chronic viral infections is an important part of patient therapy and requires assays capable of detecting the entire spectrum of viral mutations. Most genotypic assays are CE-based and offered as CLIA-validated Lab Developed Tests (LDTs). Single Molecule, Real-Time (SMRT®) sequencing offers several advantages to CE, including superior resolution of mixed populations and long read lengths capable of spanning entire viral protein coding regions. We examined detection sensitivity of SMRT sequencing using amplicon mixtures of various coding regions of both HCV and HBV. Initially, two mutations were introduced separately into a plasmid containing the NS3 coding region of HCV genotype 1b Con 1 by site-directed mutagenesis. Resulting SDMs were mixed at 20%, 10%, 5%, 2% and 1% frequencies of V36M in T54A before amplification of a 563 bp region of NS3. Additionally, larger fragments spanning NS3/4a (2,055 bp) and NS5a (1,341 bp) were amplified from plasmids containing either Con1 or the HCV genotype 1a strain H77. Amplicons were purified, concentrations normalized, and reciprocal mixtures made by serial dilution at the same minor variant frequencies. Finally, we examined detection sensitivity of SMRT sequencing to detect very low level mixtures of known resistance-associated mutations in the Polymerase Gene (P) of HBV. Three mutations were introduced into HBV plasmids by site-directed mutagenesis. Two amplicons (575 bp and 1,389 bp) were generated for both wildtype and mutant plasmids, which were purified, normalized, and mixed by serial dilution at 20%, 10%, 5%, 2.5%, 1.25%, 0.62%, 0.31%, 0.16%, and 0.08% frequencies. SMRTbell™ libraries were constructed and sequenced using standard Pacific Biosciences® C2 chemistry and protocols. We used both a reference-based approach and de novo approaches for variant detection and haplotyping. Average read lengths were 3,500 bp across samples, with 5% of reads longer than 9,000 bp. From a single SMRT ® Cell, minor variants were accurately and reliably detected down to 0.1% with simple analyses. The random error profile and long read lengths make it possible to call variants from as few as 10 molecules, while sequencing individual molecules allows phasing of mutations hundreds of bases apart. SMRT® sequencing can identify species comprising a mixed viral population, with granularity and low cost of consumables allowing for smaller multiplexing of samples and first-in-first-out processing.

High Throughput Amplicon Sequencing using the Personal Genome Machine. *J. Boland, D. Roberson, M. Cullen, M. Yeager, K. Jacobs, S. Chanock, V. Lonsberry*. Cancer Genomics Research Laboratory, NCI Frederick, Gaithersburg, MD 20855.

Since January 2011, when the first Personal Genome Machine (PGM) from Life Technologies arrived at our facility, we have been in the process of developing an amplicon sequencing pipeline that would be able process 1000s of samples across multiple amplicons, exons or regions of the human genome. Over the past year and a half, we had successfully installed a high throughput amplicon sequencing pipeline that can accommodate project sizes from single samples up to 1500 samples. Through development of barcodes, protocol improvements and the acquisition of several PGMs, we have now accomplished our goal of sequencing upwards of 1500 samples per day. The variant follow-up pipeline currently involves automated primer design (either in-house or outsourced), sample prep processes including but not limited to, Fluidigm Access Array and Life's Ampliseq products, PGM sequencing protocols and variant calling software using the latest Torrent Browser software. This presentation will highlight the developmental milestones that were achieved in the laboratory with regards to increased barcoding ability, improved protocols and reagents and, most importantly, back-end bioinformatic support that has been crucial for the laboratory success. This pipeline has primarily served as our variant validation pipeline from exome data generated from our familial exome sequencing program. In addition, the pipeline has also processed several projects outside of our exome program. These projects included regional studies and studies investigating variants across large population groups. The presentation will highlight two of these >1000 sample studies that were completed by the laboratory using this pipeline. The results will show consistent high quality results across all samples, regardless of plate position, technician or day. This project has been funded in whole or in part with federal funds from the National Cancer Institute, National Institutes of Health, under contract number HHSN261200800001E. The content of this publication does not necessarily reflect the views or policies of the Department of Health and Human Services, nor does mention of trade names, commercial products, or organizations imply endorsement by the U.S. Government.

3684W

A simple method for improving the limit of detection for capillary electrophoresis DNA sequencing: A comparison of methodologies for *KRAS* variant detection. *C. Davidson[1], E. Zeringer[2], K. J. Champion[4], M.-P. Gauthier[1], F. Wang[1], J. Boonyaratanakornkit[3], J. R. Jones[4], E. Schreiber[1].* 1) Life Technologies, Foster City, CA; 2) Ambion, Austin, TX, USA; 3) AcroMetrix, Benicia, CA; 4) Greenwood Genetic Center, Greenwood, SC.

Fluorescent dye terminator Sanger sequencing (FTSS), with detection by automated capillary electrophoresis (CE), has long been regarded as the gold standard for variant detection. However, software analysis and base-calling algorithms used to detect mutations were largely optimized for resequencing applications in which different alleles were expected at heterozygous mixtures of 50%. Increasingly, the requirements for variant detection are an analytic sensitivity for minor alleles of <20%, in particular, when assessing the mutational status of heterogeneous tumor samples. Here we describe a simple modification to the FTSS workflow that improves the limit of detection of cell-line gDNA mixtures from 50–20% to 5% for G>A transitions and from 50–5% to 5% for G>C and G>T transversions. In addition, we use two different sample types to compare the limit of detection of sequence variants in codons 12 and 13 of the *KRAS* gene between Sanger sequencing and other methodologies including shifted termination assay (STA) detection, single-base extension (SBE), pyrosequencing (PS), high resolution melt (HRM), and real-time PCR (qPCR).

3685F

HaloPlex target enrichment from FFPE tissues. *F. Roos, H. Johansson, M. Isaksson, P. Eriksson, L. Forsmark, F. Dahl.* Agilent Technologies, Uppsala, Sweden.

Formalin-fixed paraffin-embedded (FFPE) tissues compose an enormous archive of samples obtained from biopsies of various human cancers, in several institutions around the world. However, as DNA purified from FFPE tissue is highly degraded, damaged, and available only in small quantities, being able to perform molecular analysis of these samples is a common challenge. Extracting molecular information from FFPE samples has the potential to drastically improve our understanding of genetic components that underlie disease states.

The HaloPlex PCR method combines targeted enrichment and library preparation in a simple 6 hour protocol without the requirement of any dedicated instrumentation. The protocol associates all targeted fragments with a common primer motif which enables multiplex PCR using only one primer pair. The resulting complex pool of PCR products is ready for direct sequencing using any Illumina or Ion Torrent platforms.

A simple QC assay was developed with the aim to allow accurate prediction of individual samples' performance in a HaloPlex enrichment assay by assessing the level of fragmentation of the DNA sample. A set of rules was empirically derived to provide guidelines on how to make small alterations to the standard HaloPlex protocol based on the fragmentation state of the sample. By following these guidelines the chance of generating successful enrichment and correct sequence information was significantly increased even in highly fragmented samples.

We demonstrate HaloPlex enrichment data from matched FFPE / fresh-frozen (FF) samples of different quality states showing more than 95% sequencing coverage of the targeted region. Specificities above 90% were observed in all samples and the uniformity of sequenced reads across the target region was comparable between matched samples. The high coverage was shown to be attributed to the fact that several amplicons cover each base in a HaloPlex assay so that smaller amplicons can act as a backup for longer amplicons that are more likely to fail in fragmented FFPE samples.

3686W

Optimized sample and library preparation of FFPE tumor samples for targeted next-generation sequencing. *N. Udar, R. Haigis, E.B. Jaeger.* Illumina Inc, San Diego, CA.

The use of formalin-fixed paraffin-embedded (FFPE) tissues for DNA-based assays is limited by the quality of the DNA that can be obtained. In addition to introducing chemical contaminants that can inhibit molecular reactions, the fixation process leads to crosslinking, DNA fragmentation, and other damage to nucleotides. The extent of this damage can vary widely from sample to sample, but the end result is generally reduced performance of the DNA template. We have optimized performance by selecting an optimal DNA extraction process, ascertaining the amplifiability of the extracted material, maximizing the amount of assay template input, and modifying reagent formulation. This permitted the generation of high-quality data with 90% of FFPE samples screened to date. Four different solvents for the deparaffinization of FFPE samples were tested in combination with eight different FFPE DNA extraction kits from six different manufacturers on a variety of FFPE samples from multiple cancer tissue types. Extracted DNA was used as input for a quantitative PCR reaction, and the delta Cq for each sample was calculated relative to the Cq of the standard non-FFPE human reference gDNA from the Illumina® FFPE QC Kit. To maximize the volume of template added to the library prep assay, the hybridization buffer was modified to remove all dead volume, and reagents were added as powders rather than solutions where possible. Deparaffinization with the Qiagen DPS solution followed by DNA extraction with the Qiagen All-Prep DNA/RNA FFPE Kit yielded the most consistent high-quality sample preps for the TSCA assay. The amplifiability of these sample preps according to our qPCR measurements was completely concordant with sample performance in the library prep assay. Sample input volumes for the library prep assay were increased four-fold, and the sample success rate correspondingly improved from 75% to 90%, or 45 of 50 samples. We have optimized the performance of our library prep assay for use with FFPE tumor samples. We have also developed a qPCR assay that correctly identifies all samples that will provide interpretable sequence data. These samples yielded high quality data that enabled the identification of mutant alleles at frequencies as low as 1%, which were subsequently confirmed by allele-specific PCR. Given the large numbers of tissues preserved as FFPE material, the added robustness of the assay increases its value as a research tool for genetic analysis.

TargetRich™: Targeted Sub-Exome Sequencing. *I.A. Vasenkova[1], K. Jansen Spayd[1], T. Shvetsova[1], D.A. Kloske[1], R.C. Bachmeyer[1], D.T. Moore[1], K.E. Varley[1,2].* 1) Kailos Genetics Inc., Huntsville, AL; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL.

Next-generation sequencing (NGS) enables researchers to access large amounts of genetic information from a whole human genome or exome. Sequencing tumor and blood samples obtained from cancer patients reveals that a single tumor may contain as many as 150 mutations in the protein coding region of different genes. Some genes are found to be consistently mutated in various tumors and therefore are believed to be important for the onset or maintenance of oncogenic phenotype. The most frequent mutations in these genes have been cataloged and commercial cancer panels have been developed to amplify and deeply sequence these mutational “hotspots”. As these cancer enrichment panels cover selected portions of the gene's coding sequences, their use in clinical research and the discovery of lower frequency mutations associated with cancer is still limited. In genes such as tumor suppressors, sequence analysis of the entire coding region is especially important since any mutation in these genes could give rise to tumorigenesis.

We have developed TargetRich gene enrichment panels to enable the complete analysis of cancer associated genes. The sixty three gene TargetRich cancer research survey panel is the largest cancer gene panel available and includes oncogenes, tumor suppressor and drug metabolism genes, targeting nearly all exonic bases. TargetRich employs Nested PatchPCR™ technology, a limited-cycle PCR and targeted ligation reaction protocol allowing one to amplify hundreds of fragments together with remarkable specificity in single-tube in less than 9 hours. Platform-specific adapters incorporated during the nested ligation step allow for the high levels of multiplexing and direct sequencing of products on Illumina or Ion Torrent platforms without time-consuming library construction. Here we compare depth of coverage, uniformity and genetic variant detection achieved through whole exome sequencing using hybrid capture, TargetRich and “hot spot” sequencing approaches. We demonstrate utility of the TargetRich approach as a cost effective, scalable solution for development of high-resolution next generation sub-exome sequencing assays for clinical and discovery research.

3688W

A Functional Approach to Sequence Capture Analysis of Disease Pathways. *M. Wijdicks, D. Burgess, M. D'ascenzo, M. Brockman, J. Wendt, C. Skalitzky, D. Green, T. Richmond, L. Brown, R. Slezer.* Roche NimbleGen, 504 S. Rosa Rd., Madison WI 53719.

Enrichment sequencing has quickly become a standard technique for identifying inherited, de novo and somatic alleles responsible for genetic diseases. Whole exome sequencing is often selected for discovering candidate mutations in biochemical pathways that are still poorly understood, while disease specific gene capture panels, for example targeting oncology and neurology candidate loci, are a more efficient embodiment of the technology for high-throughput, focused analysis of better characterized disorders. To increase the efficiency and success of allele identification, we have developed a series of disease specific gene panels to probe the most relevant targets within the human genome for a fraction of the cost, time and data analysis requirements of whole exome and whole genome sequencing. We present two designs. The first is an oncology focused panel that targets 578 known or predicted cancer genes, including content from the MHC where applicable. The second design is a neurology focused panel that targets 256 candidate genes representing 87 different disease classes. We report on the application of these sequence capture panels for the discovery and validation of disease specific genetic variants.

Comparison of two NGS preparation methods for preimplantation and prenatal screening and diagnostics. *J.P. Langmore, E. Kamberov, M. Mastronardi, T. Tesmer.* Corporate, Rubicon Genomics, Inc., Ann Arbor, MI.

To improve ease of sequencing fetal cells and fetal cell-free DNA for prenatal diagnostics, as well as for sequencing single embryo cells for preimplantation diagnostics, two new methods for producing sequencing templates for NGS were compared. The PicoPLEX™-scD Prep and the ThruPLEX-FD Prep kits are capable of producing sequencing libraries of single cells and small plasma samples. Earlier versions of these technologies have been used extensively for preimplantation testing and prenatal and cancer testing using array and PCR assays. Each technology has been modified to attach adapters with Illumina sequencing and indexing sequences. We compared these two NGS prep kits for specific applications in prenatal diagnostics and preimplantation screening and diagnostics using workflows able to prepare 200 NGS samples per day. Results: ThruPLEX-FD Prep Kit is a 1-tube, 2-hour, 3-step ligation-based process to prepare fragmented DNA for NGS without intermediate purifications. Sequence representation was excellent from 15% to 85% GC in human samples from 20 pg to 100 ng of plasma DNA, yielding mean quality scores >35, <5% unmapped reads, <0.4% mismatch with hg19, and >95% intact PE reads. The high efficiency, low background, and simple workflow made it possible to test single cells and small plasma samples yielding more complex libraries than other prep methods. PicoPLEX-scD Prep Kit is a 1-tube, 3-hour, 4-step process to manually prepare hundreds of single cell or sorted chromosomes for targeted sequencing per day. Greater than 95% of sorted cancer cells or blastomeres were successfully prepared for sequencing. Typically >99% of reads were high quality, 98.5% mapped to human, and <0.6% did not match hg19. Indexed NGS was able to reproducibly detect human single-cell copy number changes less than 20 kb in size. The targeted NGS results produced by PicoPLEX-SC also can be used to prepare cell-free plasma DNA for very reproducible determination of abnormal chromosome numbers. ThruPLEX-FD and PicoPLEX-scD were used to sequence duplicate aliquots of plasma and single cells. Sequence coverage and accuracy was compared for these two types of samples for purposes of establishing the strengths of both for prenatal and preimplantation diagnostics. research and testing.

Droplet Digital PCR Enables Reliable Discrimination of Copy Number Variation. *J.R. Berman, N. Heredia, J. Regan, L. Montesclaros, S. Hodges, C. Troup, G. Karlin-Neumann.*Digital Biology Center, Bio-Rad Laboratories, Pleasanton, CA., USA.

The ability to quantify and discriminate copy number variation (CNV) at a given locus is increasingly critical to a diverse set of research and diagnostic applications. CNVs encompassing both deletion and duplication of wild-type and mutant alleles have been associated with cancers, neurological, autoimmune, and other diseases, adverse drug response, and other traits. Existing techniques, namely qPCR, are of limited utility for CNV determination due to imprecise discrimination at higher (>3) copy number states. Droplet digital PCR (ddPCR) enables accurate and reproducible copy number determination using a simple, cost-effective workflow amenable to high throughput. Using single-well ddPCR, consecutive copy number states can be distinguished between samples of 5 and 6 copy number at 95% confidence levels. We present use of the QX100 ddPCR system to assess CNV of multiple genes with low to high copy number states, including CYP2D6, MRGPRx1, and CCL3L1. We further demonstrate use of CNV analysis by ddPCR to interrogate loci implicated in cancer and other diseases. Strategies for assay optimization for CNV analysis by ddPCR will be highlighted.

Integrating high-quality DNA sequence capture with MiSeq for clinical sequencing. *P. Shen[1], W. Wang[2], A. Chi[1], R. Davis[1], C. Scharfe[1].* 1) Genome Technology Ctr, Stanford Univ, Palo Alto, CA; 2) Bioinformatics and Computational Biology Dept, Univ of Texas MD Anderson Cancer Ctr, Houston, TX.

The accurate and complete selection of candidate genomic regions from a DNA sample before sequencing is critical in molecular diagnostics. Several recently developed DNA sequence capture technologies await substantial improvements in performance, cost, and multiplex sample processing. Here we present the utility of long padlock probes (LPPs) for targeted exon capture followed by Illumina MiSeq sequencing. One LPP was sufficient to capture sequences from <100–500 bp in length, while LPPs were pooled together to target 5,471 exons from 524 disease candidate genes in a single-tube reaction. MiSeq sequencing identified a 99% exon coverage at >1x and 95% at >10x (mean coverage 276 reads). More than 98% of the QC-passed reads mapped to our target regions (specificity) and 91% of the targets were within 50 fold coverage uniformity. Our targeted sequencing methodology was highly reproducible and quick (48hrs) and detected DNA variants at a concordance of 98% on the basis of known sample genotypes and Sanger verification. From the same sequencing data we detected copy number variation (CNV) at exon-level resolution in a patient with ornithine transcarbamylase (OTC) deficiency and in another case with Trisomy 13. We also performed multiplex targeted sequencing of up to four samples per MiSeq run for SNP and CNV detection in the 524 candidate genes, making our method particularly interesting for molecular genetic and clinical applications.

Improved Performance of Solution Based Target Enrichment by Spike-in of Individually Synthesized Capture Probes. *G.R. Mehta, Locus Development, Inc.* Locus Development, San Francisco, CA.

While DNA sequencing costs have decreased and throughput increased at an incredible rate recently, the cost for sequencing a complete genome at high depth is still prohibitively expensive for clinical applications, and thus the vast majority of clinical sequencing-based tests still consist of decoding targeted portions of the genome (exome, cancer panels, etc.). Over the past few years, several commercial methods and technologies of targeted enrichment have emerged. One such example is solution hybrid capture (SHS), where specific biotinylated probes hybridize to genomic DNA targets and then are selectively enriched with the use of streptavidin beads and finally sequenced. There are many advantages to this process, namely the ability to capture precise targets efficiently and in an automatable manner, and recent commercial success of these companies is evident. Unfortunately, there are limitations and challenges to SHS—targets that are high GC, homologs and paralogs, and the inability to accurately assess quality of capture probes on a large scale. For clinical testing, it is imperative that all relevant regions of a gene are assayed in order to provide a high level of diagnostic completeness and accuracy. Here, we present a method to overcome some of these deficiencies by performing spike-ins of individually synthesized and quality controlled oligonucleotide capture probes into our existing SHS probe pools to complement them prior to sequencing. We validated our method by sequencing twelve HapMap samples on the Illumina miSeq platform and directly comparing a fill-in PCR approach of 800 155mer amplicons (our current method of overcoming the gaps left by our capture) to a spike-in strategy (~1200 120mer probes designed to the same regions as the PCR amplicons). Advantages are numerous: we have successfully seen greater on-target capture, reduced GC bias, more uniform coverage, whilst maintaining similar sensitivity and specificity. Furthermore, the spike-in method incorporates the ability to fine-tune our final captured product by the addition or removal of probes easily and is fully automatable / more scalable than PCR.

Accurate Multiplexing for Clinical Next Generation DNA Sequencing. *M.A. Umbarger, G.P. Porreca.* Good Start Genetics, Cambridge, MA.

Next generation sequencing (NGS) has begun to supplant a number of traditional technologies within the clinic. While the per-base cost of NGS is extremely low, the high capacity of NGS instruments necessitates that clinical labs employing such instruments divide the per-run fixed cost over multiple samples. Such sample multiplexing is frequently accomplished via the use of patient specific DNA barcodes that are covalently attached to patient molecules via ligation or the polymerase chain reaction. Since these barcodes uniquely tag each molecule, it is possible to map a given sequenced molecule to the appropriate patient by simply sequencing its associated barcode.

While the utilization of patient specific barcodes reduces per-sample sequencing costs, this approach is not without risk. For example, if a significant fraction of the molecules from a given patient are accidentally associated with the barcode for another patient, the genotypes of both patients may be incorrectly called. In fact, simulations indicate that at a sequencing depth of 20X, a misassociation rate of 1 in 1,000 yields a clinically non-negligible genotype error rate.

We have developed strategies for identifying and minimizing the contribution of three major sources of incorrect sample and barcode pairing. First, to identify any stock barcode oligonucleotides which are contaminated with other barcode oligos, we have instituted a sequencing-based barcode quality control procedure that allows us to detect contamination down to a level of 1 in 100,000. Second, to minimize the frequency at which sequencing errors lead to a given barcode incorrectly mapping to another barcode, we have developed a quality score-based filtering strategy. Finally, to identify and filter out cases in which recombination between homologous molecules from different patients has yielded chimeric molecules containing the genomic sequence from one patient and the barcode for another, we have developed a dual barcoding strategy in which barocodes are incorportated at each end of a patient DNA molecule. Together, our strategies minimize the rate of incorrect barcode-patient association and thereby render our barcode multiplexing strategy compatible with the high accuracy requirements of clinical settings.

Enhanced performance of the Illumina MiSeq® next-generation sequencing ecosystem. *K. Hall[1], C. Tregidgo[1], I. Rasolonjatovo[1], A. Breton[1], J. Bwanali[1], A. Jackson[1], E. Vermaas[2], D. Bond[2], M. Siu[2], C. Bruce[3], A. Powell[3], P. Tran[3], D. McBride[1], M. Ross[1].* 1) Illumina Cambridge Ltd., Saffron Walden, Essex, United Kingdom; 2) Illumina Hayward 25861 Industrial Blvd. Hayward, CA 94545 USA; 3) Illumina, Inc. 5200 Research Place San Diego, CA 92122 USA.

Recent improvements to the performance of the MiSeq personal sequencing system has enabled many key metrics to be improved. The yield of the system has increased to around 7 gigabases per run with the read length supported increased to 250 bases with paired end capability. The run time for a paired end 150 cycle run has been reduced to around 20 hours with an average quality score of greater than 75% of Q30 bases. The number of reads passing filters has also been increased to around 12–15 million clusters passing filters. The improvements are derived from a new modified SBS (sequencing by synthesis) chemistry and a hardware upgrade. The system maintains its features of being extremely easy to use with simple workflows, having on board cluster generation, paired end fluidics, plug and play reagents and RFID tracking. As such no further ancillary equipment is needed. Data for most applications is processed to variant calling and alignment is less than 2 hours on instrument with the option of using BaseSpace. These advances have enabled many more applications to be targeted. In this presentation we will demonstrate some of the uses of the advances, these will include the improved de novo assembly performance from the longer reads with a variety of genomes from bacterial and viral sources. Other examples will include resequencing and RNA-Seq applications. In particular we will demonstrate the use of highly multiplexed targeted resequencing of amplicons with the TruSeq Custom Amplicon workflow together with its application in human genomic studies.

Single-Day, Highly Multiplexed Amplicon Sequencing with MiSeq®. *A. Iyer, A. Tian, K. Chang, E. Guzman, E. Upsall, I. Lewis, M. Won, W. Chang, D. Pokholok, R. Haigis, S. Norberg, M. Ronaghi, K. Gunderson, R. Shen, C. Lin.* Illumina, Inc., San Diego, CA.

Targeted enrichment strategies enable cost-effective analysis of desired genomic regions with next-generation DNA sequencers. We introduce the TruSeq® Custom Amplicon Kits, a new sample preparation method developed and optimized for high-throughput amplicon sequencing on MiSeq, the personal sequencing system from Illumina. Up to 384 user-defined genomic regions can be enriched in a single tube with high specificity (>90% of reads on target) and high uniformity (>85% of targets represented at ≥0.2X mean coverage) in <8 hr (from purified genomic DNA to sequencing-ready library). By comparison, only a dozen or so targets can be amplified in a single tube with multiplex PCR, and hybridization-capture enrichment approaches require 3 days or more from DNA to library. In addition, we have developed a robust and highly scalable sample indexing strategy supporting 96 libraries to be sequenced simultaneously with MiSeq. We also will demonstrate a new library quantification and normalization approach that allows 96 libraries to be adjusted to sequencing-ready concentrations in <1 hr instead of current approaches relying on qPCR and subsequent sample dilution. These innovations streamline amplicon sequencing workflows, and provide unprecedented amplicon and sample multiplexing. Here we present data demonstrating high-accuracy detection of single-nucleotide polymorphisms (SNP) and structural variants, some of which are implicated in drug metabolism and cancer biology.

3696W

WildFire: A simple monoclonal colony generation technology without emulsion PCR. *Z. Ma, K. Lao, R. Lee, S. Goyal.* Life Technologies Inc., Foster City, CA.

We have developed a new massive parallel monoclonal template generation technology, called “WildFire”, where sequencing libraries are in-situ isothermal amplified directly on the surface of a 5500 flowchip. Sequencing libraries are added directly to the 5500-series Genetic Analyzer flowchip, whose surfaces have been coated with a special library-adaptor capture oligonucleotide. A DNA polymerase reaction mix is added, and in a single isothermal step for 30 minutes, single templates are amplified in-situ on the flowchip. The net density of sequencing-colonies created in this manner far exceeds anything currently utilized in next-generation sequencing, reaching 1.5 million colonies per mm2 per flowchip surface. During in-situ amplification, the capture oligonucleotide is “consumed”, and each individual nucleic-acid fragment “spreads” (like a WildFire) inside the flowchip until reaching an adjacent library fragment(s). When the individually-growing fragments “meet”, the amplification step terminates, because all of the surface-bound primer was consumed. These “self-assembled”, spatially resolved, monoclonal colonies, are then sequenced by SOLiDTM chemistry. The resulting colony-sequencing reads maintain the same high accuracy as our bead-based method. Full genomes (from bacterial to human), exomes (human), and transcriptomes (human) have now been sequenced using WildFire technology. WildFire technology greatly improves NGS workflow, increases throughput, and significantly decreases net cost-per-genome.

3697F

Nextera® Enrichment: A New Nextera Library Prep Protocol for Targeted Enrichment Supporting 12-plex Pre-enrichment Sample Pooling. *P. McInerney[1], S. Melnyk[1], M. Chen[1], M. Tsan[1], S. Cooper[1], H. Grunenwald[2], M. Lewis[1], R. Shen[1], J. Whitacre[1].* 1) Illumina, Inc., San Diego, CA; 2) Epicentre, Inc. (an Illumina Company), Madison, WI.

Targeted sequencing is a cost-effective method to sequence specific regions of the genome for large sample collections that require high coverage. Applications include discovery of rare variants in cancer and disease association studies. Currently available targeted sequencing workflows require at least 1ug of DNA as starting material. This requirement often precludes analysis of samples that are precious or limited in quantity, such as tumor biopsies and buccal swabs. We describe a new sample preparation method utilizing Nextera sample preparation technology to create up to 96 uniquely barcoded libraries from only 50ng of input DNA. The new protocol includes reagents for target enrichment, using probes for either exome or custom panels. This protocol generates libraries with optimal insert sizes and improved GC coverage relative to TruSeq libraries. This new low input, streamlined Nextera Enrichment protocol generates 96 enriched libraries in 2.5-days; making it attractive for users who require high-throughput sample processing and a fast time-to-answer. Furthermore, the protocol enables pre-enrichment sample pooling of up to 12 samples, the highest level of multiplexing currently available. We present data showing simultaneous, uniform enrichment of 12 different Nextera indexed samples in a single enrichment reaction using either Illumina's TruSeq® Exome or a panel with ~400 cancer genes. Specifically, we show that the Nextera Enrichment assay exhibits high specificity with >60% of reads on target and excellent coverage uniformity with >85% of targeted bases covered at 0.2X mean coverage.

3698W

Development of Ion Torrent's 400-base Sequencing Technology. *X. Peng, G. Luo, T. Lincecum, E. Tozer, D. Mazur, K. Aguinaldo, G. Lowman, M. Landes, B. Strohecker, T. Nikiforov, P. Vander Horn.* Ion Torrent, LIFE Technologies, Carlsbad, CA.

We have made substantial advancements on Ion Torrent's semiconductor chip-based sequencing system in a number of areas including on-beads library amplification, sequencing polymerase, and sequencing reaction condition. These innovations resulted in high quality and robust 400-base sequencing performance on Ion Torrent PGM platform. The improvement on the sequencing polymerase and reaction conditions is based on a new mutated enzyme that shows high accuracy and high processivity sequencing behaviors. Our efforts on optimizing 400bp insert library emulsion PCR conditions resulted in enhanced on-beads library amplification as demonstrated on PGM by the increased library key signals during sequencing run. We show here the optimal 400-base sequencing performance on an ion 316 chip by sequencing a 404bp insert E. coli dh10b library and compared it with the performance produced by using ion torrent's commercially available 200-base sequencing reagents and protocols. The peak in the AQ20 read length histogram shifts dramatically to the 400bp region using the improved reagents and protocols. The raw error rate @400bp position decreases dramatically to 0.857%, and the overall mean raw read accuracy increases to 99.5%. The %AQ30 base yield holds steadily between 76% and 64% of the total aligned bases during the entire 400bp sequencing run, which translates into 586M AQ20 bases throughput on a Ion 316 chip. The homopolymer accuracy also improved to 99.2% level for the 6-mer homopolymer stretch and the number of Indels per 100 bp also reduced to 0.41 by the new Ion Torrent's 400-base sequencing chemistry.

3699F

From tumor to genome sequence with nanogram quantities of DNA: ultralow target capture and DNA-Seq from FFPE samples. *M. Phelan, L. Pham, G. Miyada, S. Kain, T. Cormier.* NuGEN Technologies, Inc., San Carlos, CA.

With the rapidly increasing number of NGS samples, many laboratories face challenges in reproducibly and cost-effectively generating high-quality libraries for RNA-Seq, ChIP-Seq and DNA-Seq. To that end, NuGEN® Technologies, Inc., has partnered with Advanced Liquid Logic, Inc., (ALL) to develop and commercialize the Mondrian™ SP System - a digital microfluidics system that automates genomic sample preparation for NGS. Several NuGEN Library Systems are available for the Mondrian™ SP Workstation, including the Ovation® SP Ultralow and the Encore® SP Rapid Library Systems. The Ovation SP Ultralow Library System offers scientist the ability to generate NGS libraries from as little as 1ng of human dsDNA (making it well suited for very low input applications like ChIP-Seq, and DNA-Seq from FFPE samples). The Encore SP Rapid Library System is an amplification-free protocol for library preparation that is ideal for use with high-GC genomes and/or in conditions where scientists wish to avoid introducing amplification bias into the final library. In this poster we compare the results of using various human DNAs (including HapMap and FFPE samples) as template for both the Ovation SP Ultralow Library System and the manual Ovation Ultralow Library System. The resulting libraries were used in a target capture and enrichment protocol prior to sequencing on an Illumina® HiSeq™ 2000 instrument using Illumina TruSeq™ SBS Kit v3-HS. Additionally an Ovation SP Ultralow library (whole genome human) was sequenced directly on three lanes of the HiSeq 2000 (without performing target capture and enrichment prior to sequencing) to investigate the levels of coverage and duplication seen in a complex eukaryotic library prepared at nanoliter volumes via microfluidic manipulation.

GnuBIO Desktop Sequencer - Fully Integrated DNA Preparation Sequencing and Analysis. *T. Raz, A. Aslam, J. Boyce, N. Nerkizian, J. Emhoff, A. Esmall, J. Fanning, H. Ghandour, K. Moulton, P. Stokes, T. Hung, S. Kiani, P. Mary, J. Healy.* GnuBio Inc., Cambridge, MA.

DNA sequencing has become fundamental to biological research, and is poised to be a crucial tool in clinical medicine, once several technical challenges are answered. Sample preparation (enrichment and library creation) is expensive and labor-intensive. While throughput is high, separate samples must be accumulated, bar-coded, and comingled to keep cost from becoming prohibitive. In addition, some current instruments have lower accuracy than would be suited to diagnosis or treatment selection. Certain applications require longer read-lengths than are available from some platforms. Finally, interpretation of the raw output from today's equipment requires specialized personnel, hardware, and some considerable time. GnuBIO is developing an instrument that integrates the sequencing work flow, beginning from genomic DNA, and encompassing enrichment, PCR amplification, sequencing, and analysis, delivering long reads and variant-calls on completion. The user injects a sample into the instrument after which all steps are automated. Microfluidics permits the process to be automated and integrated. Independent patients' samples flow through the instrument serially, obviating the need to accumulate or intermix patients' samples. Hundreds of thousands of emulsion droplets each act as independent reaction vessels, following their way through the steps of enrichment and amplification. Each sample droplet is then sequenced. The data arrive incrementally and once a patient's last probed sample droplet has worked its way through to the last optical detection, analysis is virtually complete. The GnuBIO platform is an innovative synthesis of technologies that are separately well understood including emulsion-based microfluidics, a polymerase extension based assay, diffractive optics and commodity dyes. In prototype instruments, the platform so far shows a per-base error rate of 0.03%, which is independent of position along the read. Reads reach 600nt routinely, and variant calling, averaged against all positions comes in at more than Phred 70. The GnuBIO system will remedy many challenges faced by researchers today, such as obviating the requirement to prepare sequencing libraries and eliminating the need to optimize sample capture reagents. Due to the integration of sample capture, amplification, and sequencing within emulsions (without ever breaking the emulsion), the system will also provide uniform coverage across the target.

3701F

Utilizing next-generation sequencing for exome analysis. *K. Stangier, F. Ernst, Y. Kumar, T. Paprotka.* GATC Biotech AG, Konstanz, Germany.

Next generation sequencing has changed the possibilities for analyzing human exomes. Several commercial kits are available allowing exome enrichment with subsequent library preparation in a cost efficient way. These libraries can be directly analyzed on e.g. an Illumina HiSeq. Enrichment is performed by pull down of coding regions with baits, which differ in overall design depending on the manufacturer. The depth of analysis can be enhanced by increasing the number of reads by using higher sequencing coverage mapped on the genome or the targeted region. We used commercially available exome enrichment kits and designed a pipeline for data quality analysis, mapping and especially SNP detection. The mapping of reads was analyzed in detail to determine the efficiency of enrichment for the targeted exons. Variants were filtered according to several criteria like base quality, read quality, thresholds for coverage, and the overall mapping quality. In order to improve the overall quality of reads for data processing, a quality score which represents the probability of a particular base mismatch in the reference genome was established. This highly increased the probabilities of validating certain mismatches. In addition, FFPE samples were used for exome enrichment and the mapping and SNP detection compared to other starting material. Utilizing exome sequencing in clinical and genetic diagnosis and personalized disease risk profiling is expected in the near future. Optimizing the sensitivity and data analysis pipelines will help to integrate exome analysis into a common clinical setup.

3702W

Novel enrichment reagent for the study of the human microbiome. *F.J. Stewart, G.R. Feehery, E. Yigit, E.T. Dimalanta, B.W. Langhorst, L.M. Apone, P. Liu, D.B. Munafo, C.J. Sumner, J. Bybee, L.M. Mazzola, T.B. Davis, S. Pradhan.* New England Biolabs, Inc., Ipswich, MA.

Nucleic-acid based techniques such as hybridization, PCR, qPCR and Next-Generation Sequencing (NGS) offer a rapid and highly sensitive option for detecting pathogenic bacteria directly from specimens, when compared with culture-based techniques. The overwhelming amount of human DNA in many specimens consumes most of the sequencing capacity of high-throughput sequencers, limiting the detection and identification of pathogens. As a consequence, analyses of a metagenome or microbiome from clinical samples by NGS or PCR are expensive, difficult and time consuming. To address this problem, we have developed a unique method for the separation of large pieces (~15kb) of human DNA from similar sizes (~15kb) of bacterial DNA using Eukaryotic Binding Protein (EBP). As a demonstration of the efficacy of this methodology, DNA extracted from human saliva was added to the EBP beads and incubated for a period of time. A magnetic field was then used to separate the human DNA bound to beads from the supernatant containing bacterial DNA. The enriched bacterial DNA from the supernatant was sequenced on multiple NGS platforms and was found to have a dramatic increase (9 fold) in the number of reads matching bacterial genomes. Likewise, a substantial drop (50 fold) was seen in the number of reads matching the human genome. Bacterial diversity following the procedure remained intact. This simple methodology can be used to analyze entire microbiomes in a cost-effective manner utilizing established NGS platforms, as well as newer single molecule sequencing technologies.

Structural Variations Identified Using Solid-state Nanodetectors. *J. Thompson, B. Bready, D. Dederich, D. Hevroni, M. Jouzi, H-Y. Lee, D. Lloyd, P. Mukhatira, M. Nadel, J. Oliver, J. Saraidaridis.* Nabsys Inc, 60 Clifford St, Providence, RI.

Many human diseases are caused by insertions, deletions, or duplications of large segments of DNA. Understanding the nature of structural variants and how prevalent they are within a population of cells is sometimes critical for diagnosing and treating patients. However, many structural variants are difficult to detect using classical and next-gen sequencing techniques. Positional sequencing of DNA using nanodetectors can provide the relative locations of various sequences and thus a direct readout on structural rearrangements. Distances between probe-bound sites are determined electronically using solid-state nanodetectors. Long-range information is preserved in these single-molecule reads so structural rearrangements and duplications are easily identified and correctly assembled. Results for the detection of deletions and inversions of various sizes will be presented.

Automaton of whole exome and targeted sequencing workflows in a high throughput lab. *M. Zilka, B. Marosy, A. Robinson, J. Gearhart, B. Craig, J. Romm, K. Doheny.* Center for Inherited Disease Research (CIDR), IGM, JHU - SOM, Baltimore, MDCenter for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next gen-sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. CIDR began production level automated genotyping in 1996 with Human STRP linkage panels and has continued to automate its production workflows from Illumina GWAS arrays to CIDR's newest offerings, whole exome and targeted sequencing. CIDR requires the use of laboratory automation and informatics tools in order to process samples quickly and to reduce human error in a high-throughput environment. CIDR has created a workflow implementing a Beckman FX®, a Perkin Elmer Multiprobe®, a Covaris E210 and an Agilent© Bravo in its automation of library prep using Agilent SureSelect™ XT Library Prep reagents. Back up programs for the FX and Multiprobe were created on the Beckman Biomek® 2000. For the targeted enrichment phase, CIDR has added the use of a Perkin Elmer Multiprobe, a Beckman Biomek® 2000 and an Agilent Bravo. The Perkin Elmer Janus® is used to normalize and pool samples for clustering on the cBot followed by 76bp paired- end sequencing on the Illumina® HiSeq™ 2000. At several points in the library prep and target enrichment workflow, QC steps are performed to ensure that samples are being processed correctly and should continue in the workflow. CIDR uses a Beckman FX and an Agilent Bravo to make aliquots of the samples that are run on the Agilent BioAnalyzer or the Caliper LabChip®GX. Samples that require pooling before sequencing are pooled by a Perkin Elmer Janus and are then QC'd on the Illumina MiSeq. In addition, CIDR has also integrated the Exemplar LIMS and customized java plugins to help with validation, sample worklist generation and sample tracking. With each addition of automation to the workflow, QC measures were compared to manual processing to verify that the additions of the automated steps did not decrease the quality of the data that was being generated. From our pilot studies, 73 samples were processed with the automated sequencing workflow. The QC measures reviewed were percent target bases 8X, mean target coverage, mean Ti/Tv ratio, mean concordance to GWAS array calls, estimated library size, mean sensitivity and mean percent duplication. Over a period of two weeks, our current workflow can prepare ten 96 well plates for sequencing.

Automated Genomic DNA QC ensures High Quality Data from Downstream Workflows. *M. Gassmann[1], D. Rabiller[2], A. Padmanaban[3], D. McDade-Walker[2].* 1) Agilent Technologies, Waldbronn, Germany; 2) Agilent Technologies, Loanhead, UK; 3) Life Sciences Application Centre, Agilent Technologies, Bangalore, India.

Assessing the quality of experimental starting material is key to the success of any assay. Ensuring that genomic DNA (gDNA) is of sufficient quality to continue with the Next Generation Sequencing (NGS) or array Comparative Genomic Hybridization (aCGH) workflows saves precious time and money further downstream. The new Agilent Genomic DNA ScreenTape has been developed for the electrophoretic separation, sizing and quantification of genomic DNA. This new ready-to-use ScreenTape device, which runs on the Agilent 2200 TapeStation instrument, provides a reproducible QC method for analyzing the integrity of genomic DNA starting material combined with the convenience of an automated system. With minimal sample preparation, automated loading and a variable throughput system, digital results can be presented in a gel image, data table and electropherogram within approximately 1 minute per sample. In addition, the ability to overlap and compare electropherograms within the 2200 TapeStation software enables the discrimination of sample quality across different degradation states and sample types. We present data that shows the Genomic DNA ScreenTape can easily verify the integrity of gDNA starting material with sensitivity, precision and accuracy.

3706W

Optimization of a miRNA Expression Profiling Workflow for Ion Semiconductor Sequencing. *T. Guettouche[1,2], J. Clarke[3], A. Andersen[1], L. Navarro[2], Y. Cardentey[2], W. Hulme[1], G. Bademci[1], D. van Booven[1], D. Hedges[1], M. Pericak-Vance[1], J. Gilbert[1].* 1) Hussman Institute for Human Genomics, University of Miami, School of Medicine, Miami, Florida; 2) Sylvester Comprehensive Cancer Center, University of Miami, School of Medicine, Miami, Florida; 3) Department of Epidemiology and Public Health Division of Statistical Theory and Methods, University of Miami, School of Medicine, Miami, Florida.

MicroRNAs (miRNAs) are non coding RNA molecules with a size range of 18 to 24 nucleotides that have important functions in regulating numerous cellular processes. Several technologies such as microarrays, real-time PCR and second-generation deep sequencing have been used to profile miRNA expression and characterize variances in miRNA species. This study focuses on miRNA expression profiling using ion semiconductor sequencing with an improved workflow that utilizes multi-channel microfluidics to isolate miRNAs from total RNA. This microfluidics approach replaces urea polyacrylamide gel electrophoresis for size fractionation and enrichment of miRNAs commonly used in sequencing protocols. We compared miRNA expression profiles of commercially available preparations of lung and brain total RNA obtained by ion semiconductor sequencing, second-generation sequencing and real-time PCR array. Using the microfluidics approach and ion semiconductor sequencing we detected 434 and 238 unique known mature miRNAs (mirBase18) in total RNA from brain and lung respectively. Using the urea polyacrylamide gel electrophoresis approach to fractionate total RNA from brain and lung followed by ion semiconductor sequencing we detected 343 and 224 mature respectively. The urea polyacrylamide gel electrophoresis approach produced 60% and 94% of the total number of reads compared to the microfluidics approach for brain and lung respectively. Using a subset of miRNAs detected by sequencing and available on a real-time PCR miRNA array we validated detection of 88% and 79% of brain and lung miRNAs respectively. Our workflow streamlines and significantly improves the utilization of ion semiconductor sequencing for miRNA profiling both in a research and clinical environment.

Functionalized Nanoparticles For Effective DNA Purification. *A. Lai, A. Fu.* NVIGEN, Inc 265 Sobrante Way, Suite H Sunnyvale, CA 94086.

Multifunctional nanoparticles represent a dexterous platform that can be used to realize innovative solutions for translational research. We have developed a simple and convenient method for the isolation, purification and detection using functionalized nanoparticles. We show that DNA fragments were easily recovered and purified by our high-efficiency magnetic nanoparticles with comparable performance alongside current commercially-available magnetic beads. Purified DNA substrates can be incorporated into experimental workflows, such as for sequencing and detection. Our results serve a basic demonstration in integrating the chemico-physical versatility of biofunctional nanoparticles for biomedical applications.

POP-ONE™: A New Sieving Matrix for Capillary Electrophoresis That Supports a Wide Range of Applications With a Single Instrument Set-up. *J.A. Romero, B.F. Johnson, F. Mercer, J.A. Fisher, D. Rodriguez, S. Hung, M. Wenz, W. Liao, J. Lee.* Life Technologies, Foster City, CA.

The sieving polymer formulations, POP-4®, POP-6™, and POP-7™, manufactured by Life Technologies for capillary electrophoresis (CE) are designed to provide optimal performance for a variety of separation applications. A new sieving polymer formulation, POP-ONETM, has been designed to capture a broad spectrum of the electrophoretic properties of POP-4®, POP-6™, and POP-7™ so that a single POP formulation can now be used for multiple sequencing applications. For example, POP-ONETM provides better resolution for fragment analysis applications than POP-4®, while providing slightly faster run times. Use of POP-ONETM can provide substantially faster sequencing run times than experiments using POP-6™. Further, significantly better resolution of short sequencing fragments is obtained using POP-ONETM compared to the resolution obtained using POP-7™. For sequencing applications, using either a 36 cm or 50 cm capillary array, a set of three run modules were developed that provide (1) the longest possible basecalling read-length without consideration of run time, or (2) the best compromise between basecalling read-length and run time, or (3) the fastest run time but with a shorter read-length (> 500 bases). For fragment analysis applications, run modules have been developed to support a range of applications from very fast analysis of short fragments (e.g. single-base extension genotyping) to high-resolution analysis of long fragments up to 1kb long. We will compare the resolution performance of POP-ONETM to POP-4®, POP-6™, and POP-7™, and provide examples of sequencing and fragment separations with the different run modules.

Automation of the Agilent Target Enrichment Portfolio. *M.R. Visitacion[1], J. Karbowski[2], F. Roos[4], B. Arezi[5], B. Novak[1], M. Isaksson[4], A. Giuffre[3], S. Happe[3], D. Roberts[1], E. Leproust[1], F. Dahl[4].* 1) Genomics R&D, Agilent Technologies, Inc, Santa Clara, CA; 2) Agilent Automation Solutions, Agilent Technologies, Inc, Santa Clara, CA; 3) Genomics R&D, Agilent Technologies, Inc, Cedar Creek, TX; 4) Genomics R&D, Agilent Technologies, Inc, Uppsala Sweden; 5) Genomics R&D, Agilent Technologies, Inc, La Jolla, CA.

With the advent of desktop sequencers, turn-around time from sample to sequencing data has been dramatically reduced. As a result, the need to process more samples reproducibly and efficiently has increased. We have developed several options for target enrichment, including SureSelect XT, SureSelect XT2, and HaloPlex. These sample prep kits are designed to be compatible with multiple sequencing platforms, including Illumina HiSeq and MiSeq, SOLiD 5500, and Ion Torrent. We have also developed validated companion protocols for the Agilent Automation solutions NGS workstation. These include support for SureSelect XT for Illumina and SOLiD 5500, SureSelect XT2 (pre-capture pooling) for Illumina, and HaloPlex for Illumina and Ion Torrent. The Automation Solution enables the processing of 96 HaloPlex samples per day and up to 96 SureSelect XT or XT2 samples at one time. The addition of automation allows greatly increased throughput and reproducibility, while maintaining excellent performance. Herein we describe the instrumentation, processing workflow and performance data for the automation system and the respective target enrichment platforms. In Summary, we provide easy to use, automated solutions for target enrichment enabling analysis of discrete genomic regions with unprecedented depth, accuracy and throughput.

Sequencing of complete HLA haplotypes: resequencing and population studies. *M.S. Won[1], S. Norberg[1], T. Royce[1], T. Dunn[1], T. Mann[1], N. Nemat-Gorgani[2], L.A. Guethlein[2], L. Abi-Rached[2], L. Tian[2], K.L. Gunderson[1], P.J. Norman[2], M. Ronaghi[1], P. Parham[2].* 1) Illumina, Inc., San Diego, CA; 2) Stanford University School of Medicine, Stanford, CA.

The HLA and KIR regions are two of the most polymorphic and structurally complex regions in the human genome. Because of the high functional diversity they impart to the human immune system, HLA and KIR are associated with susceptibility to numerous infectious diseases, autoimmunities and some pregnancy syndromes. HLA matching is required for most forms of allotransplant, and HLA genotyping is becoming increasingly important for predicting adverse drug reactions. To provide in-depth understanding of the HLA and KIR regions, we developed methodology for determining complete haplotype sequences across large population cohorts. This approach includes paired-end library preparation from genomic DNA, a hybridization-capture enrichment assay, and a dedicated alignment/assembly informatics pipeline. The protocol currently achieves >97% coverage of the 4.7 Mb HLA and 200 kb KIR regions. We have completed sequences for eight disease-associated HLA haplotypes previously investigated in the MHC Haplotype Project. We will present data on an additional 96 HLA haplotypes, obtained from homozygous cell lines, which represent a significant proportion of worldwide HLA diversity. This methodology will be beneficial for discovering disease mechanisms and disease diagnostics.

3711F

DNA Sudoku: Hunting Rare Genetic Variations Using Combinatorial Pooling. *D. Esposito[1], D. Golan[2], B. Blumenstiel[3], Y. Erlich[1].* 1) Whitehead Institute for Biomedical Research, Cambridge, MA; 2) Tel Aviv University, Tel Aviv, Israel; 3) Broad Institute, Cambridge, MA.

In the past few years, we have experienced a paradigm shift in human genetics. Accumulating lines of evidence have highlighted the pivotal role of rare genetic variations in a significant number of traits and diseases. Studying rare variations is a needle in a haystack problem, as large cohorts have to be sequenced in order to trap the variations and gain statistical power. Sample preparation techniques have not scaled with the exponential growth in high throughput sequencing technology. Current methods rely on individual barcoding, which requires tedious preparation of large numbers of samples. We are developing a scalable solution, called DNA Sudoku, to reduce preparation time and increase throughput. We use a combinatorial pooling approach, in which we multiplex specimens and then barcode and enrich the pools. Our pipeline substantially increases the feasibility and reduces the costs of large-scale experiments since the pools, rather than the individual specimens, are sequenced. To reduce the possibility of specimen dropout, the DNA samples are first quantified and calibrated so that equal amounts can be pooled and sequenced. We then determine the pooling strategy that best balances the number of specimens and pools while maintaining robust decodability, or the ability to correctly link a sequencing result to its specimen. We have rigorously tested the pipeline by targeted resequencing of samples from the HapMap Project, which we successfully decoded using publicly available 1000 Genomes data. After several successful pilot studies, we plan to employ the DNA Sudoku pipeline to uncover rare human genetic variants with the intent of increasing throughput and significantly reducing sample preparation costs. Our next application of DNA Sudoku will be to take a genetic snapshot of risk alleles for diseases in the Jewish population. Our aim is to utilize our pooling strategy to genotype a cohort of ethnically matched individuals to create a more effective carrier screening diagnostic tool.

3712W

From sample collection to bacterial identification in a single day: 16s rRNA sequencing using novel primers on the Ion Torrent Personal Genome Machine. *G.S. Watts[1], M.M. Oshiro[1], B.W. Futscher[1], D.G. Armstrong[2].* 1) The University of Arizona Cancer Center, University of Arizona, Tucson, AZ; 2) Southern Arizona Limb Salvage Alliance, University of Arizona, Tucson, AZ.

Identification of the bacteria present in clinical infections is important for treatment decision making, including proper antibiotic selection. Culturing samples on agar plates and biochemical assays have historically been used to identify bacteria, but these methods are inherently biased and can take several days. The time required to culture bacteria for identification can be a serious drawback in the setting of a clinical infection. An alternative to culture is offered by 16s rRNA gene sequencing to identify bacteria within samples. Sequencing-based approaches to bacterial identification do not have the inherent bias that culture-based methods possess, and can be more comprehensive. After a sample is collected, polymerase chain reaction is used to amplify a portion of the 16s rRNA gene which is then sequenced. Sequence generated from the amplicon is compared to a reference library to identify the bacteria that were present in the sample. Despite its advantages, 16s sequencing still took several days whether performed using Sanger sequencing or pyrosequencing. The Ion Torrent Personal Genome Machine (PGM) is a new sequencing technology that can rapidly sequence short DNA fragments in a cost effective manner. Current commercially available methods for 16s sequencing utilize ~500 base portions of the 16s rRNA gene for bacterial identification. While next generation sequencing platforms such as the PGM are currently unable to sequence amplicons of this length, recent studies have indicated shorter amplicons can perform well in bacterial identification. To this end, we have developed novel PCR primers to amplify a short amplicon containing the V6 hypervariable region of the 16s rRNA gene. We describe a PCR method that allows amplicon library generation in a bar-coded format directly from bacterial samples without template DNA isolation. The combination of our PCR primers and method with the PGM sequencing platform offers same day bacterial identification from clinical samples. We will present proof of principle of our method on pure bacterial strains as well its application to clinical samples.

3713F

Very high resolution HLA genotyping with the 454 Life Sciences GS FLX system: Simplification of workflow using fusion primers or a four primer system. *B.N. Hoglund[1], C.L. Holcomb[1], T.C. Williams[2], D. Goodridge[3], H.A. Erlich[1].* 1) Roche Molecular Systems Pleasanton, CA; 2) Children's Hospital Oakland Research Institute Oakland, CA; 3) Conexio Genomics Perth, Australia.

Purpose: The HLA genes are the most polymorphic in the human genome, making HLA typing challenging. HLA typing is important for stem cell transplantation and for disease association and population genetics studies. Most current typing methods provide data consistent with many different genotypes ("ambiguity"). We have previously developed very high resolution (VHR) genotyping of HLA using the 454 GS FLX Sequencing System and Conexio Assign ATF 454 genotyping software. The VHR assay was designed to resolve the majority of the thousands of HLA alleles as well as rare expression variants, i.e. the "null" alleles. Amplicon library construction was performed using 22 PCR fusion primers, containing genome target specific sequence contiguous with 454 sequencing adaptors. The VHR assay provided reliable and very high resolution (limited ambiguity) genotyping but required extensive handling of individual amplicons. To simplify the workflow, we prepared the amplicon libraries by three alternative procedures. Methods: PCR amplicons were generated for HLA-A/B exons 1–5; HLA-C exons 1–7; DPA1, DPB1, DQA1 exon 2; DQB1, DRB exons 2 and 3 from 10 cell lines using three different workflows. Amplification required 22 pairs of fusion primers (14 primer pairs in the GS GType HLA primers plates from 454, plus 8 amplicons in a third plate) with 10 Multiplex Identifiers (MIDs), OR 22 primer pairs each containing, at the 5'end, a universal sequence which matched the 3' end of a set of primers that contained 10 MIDs and the 454 sequencing adaptors. Amplicons derived from fusion primers were purified, quantified, diluted to a standard concentration, then pooled OR pooled prior to the other operations. Amplicons generated by the four primer system on the Fluidigm Access Array™ were handled by the latter procedure. Pools of amplicons were sequenced on the GS FLX and genotyped with Conexio software. Results: All three procedures resulted in very high resolution genotyping. Pooling amplicons immediately following the genomic PCR gave a dramatic reduction in the number of pipetting steps necessary to produce an amplicon library; ~80 and 90 percent reduction in pipetting was achieved using fusion primers and the four primer system, respectively. Conclusion: This 22 primer genotyping assay provides very high resolution HLA class I and class II typing. Pooling amplicons early in the 454 library preparation greatly simplifies the workflow of the VHR HLA genotyping assay.

3714W

Highly Multiplexed Amplicon Preparation for Targeted Re-Sequencing of Sample Limited Specimens using the Ion AmpliSeq™ Technology and Semiconductor Sequencing. *C. Li, B. Kong, D. Joun, I. Casuga, M. Shannon, S. Chen, M. Andersen, D. Ruff, R. Bennett.* Molecular Biology, Life Technologies, South San Francisco, CA.

Genomic and exome sequencing has presented researchers a grand view of germ-line and somatic genetic variations that occur in cells. The de-novo identification of cancer mutations or mapping for inherited genetic disorders relies on interrogation of selected regions in the genome across well-annotated specimens. Target enrichment for coding regions of genomic DNA has been proven to be a cost effective way for genetic variation studies without the need of sequencing the entire genome. Typical hybridization-based exon enrichment has extensive sample preparation time and is challenged by applications that require analysis of scarce and highly degraded DNA materials from sources such as single cell, fine needle biopsy or archival FFPE sample. Researchers need a rapid and flexible targeted re-sequencing process that is compatible with small amount of highly degraded DNA derived from a limited tissue source. Ion AmpliSeq™ technology combines the specificity, sensitivity, and efficiency of PCR technology to enrich tens to thousands of genomic targets from less than 10ng of FFPE or gDNA in a reaction for next generation sequencing (NGS). The unique amplicon preparation workflow sharply reduces side-products in multiplex PCR and thereby enables this technology to venture into extremely high levels of multiplex PCR for NGS. The workflow consists of target amplification using primer pools designed by Ion AmpliSeq™ Designer software. The amplicons (150bp ~ 200bp) are subsequently ligated to sequencing adapters and purified. The resulting DNA libraries can typically be completed in 3.5 hours with as little as 30 minutes of hands-on-time using the Ion AmpliSeq™ Library Kit 2.0. Ion AmpliSeq™ Comprehensive Cancer Panel and Inherited Disease Panel have primer designs of up to 4,000 amplicons in a single tube that target defined coding regions in the genome. Sequencing results consistently achieve >98% of all reads on target at >99.5% per base accuracy and uniform coverage of >94% of bases covered ≥20X when normalized to 100X average coverage. By monitoring amplicon PCR efficiency and normalized amplicon uniformity from sequencing, an early demonstration of 18,500-plex single tube reaction suggests the multiplex limit of the AmpliSeq™ technology has yet to be reached. The scalability opens up the possibility of rapid targeted re-sequencing of exons from 25,000 genes in a few reactions with only sub-microgram quantities of DNA. Data will be presented.

3715F

A Fast Solution to NGS Library Preparation with Low Nanogram DNA Input. *P. Liu, G. Lohman, E. Cantor, B.W. Langhorst, E. Yigit, L.M. Apone, D.B. Munafo, C. Sumner, F.J. Stewart, T.C. Evans, E.T. Dimalanta, T.B. Davis.* New England Biolabs, Ipswich, MA.

Next Generation Sequencing (NGS) has significantly impacted human genetics, enabling a comprehensive characterization of human genome as well as better understandings of many genomic abnormalities. By delivering massive DNA sequences at unprecedented speed and cost, NGS promises to make personalized medicine a reality in the foreseeable future. To date, library construction with clinical samples has been a challenge, primarily due to the limited quantities of sample DNA available. To overcome this challenge, we have developed a fast library preparation method using novel NEBNext reagents and adaptors, including a new DNA polymerase that has been optimized to minimize GC bias. This method enables library construction from an amount of DNA as low as 5 ng, and can be used for both intact and fragmented DNA. Moreover, the workflow is compatible with multiple NGS platforms.

3716W

Pre-Capture Pooling for Targeted Enrichment of Libraries for Next Generation Sequencing. *B. Marosy, B. Craig, A. Robinson, M. Zilka, K. Hetrick, S. Griffith, H. Ling, J. Romm, K.F. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-generation sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. CIDR has developed a NGS lab using the Illumina® HiSeqTM2000 platform in conjunction with the Agilent© SureSelect TM XT library prep and target enrichment kits. Agilent has recently added improvements to their library prep/target enrichment (XT2 reagent kit) including pre-mixed reagents and indexed adapters for ligation to allow multiple samples to be pooled together in a single well for the enrichment step. CIDR has added optimizations (`with Bead' clean-up and `off Bead catch' as published by the Broad Institute) to the protocol to reduce DNA input while maintaining library complexity. Eight unrelated HapMap samples were used to test the updated process using 500ng DNA input into the library prep. Samples were hybridized using a combined total of 1.5ug of constructed library across 8 samples (187.5ng/sample) with the SureSelect Human AllExon v4 + UTRs (71Mb) for 24hrs. These 8 samples were then clustered for sequencing across two lanes of the HiSeq2000 using the Illumina cBOT TM Cluster Generation system. Seventy-five bp paired-end sequencing was performed on the HiSeq2000 which generated on average 5.7 Gb of data (unique passing filter aligned) per sample. Preliminary data analysis was performed on 6 out of 8 samples and yielded an estimated library size of 314 million with a duplication rate of 6.4%. Mean percent of on target and on bait bases covered to at least 8x was 95.4% and 94.6%, respectively. The mean transition/transversion ratio on exon for these samples was 3.11. Sensitivity and concordance to previous genotypes was 96.0% and 99.8% respectively.

Rapid and accurate semiconductor-based sequencing of human exomes: workflow and performance on a familial trio. *G. Meredith, G. Bee, L. Pickle, M. Dudas, G. Del Mistro, C. Scafe, M. Schorn, J. Miller, M. Minto, B. Reed, G. Fry, J. Gioia, J. Hildebrandt, P. Leong, M. Reddy, K. Atehortua-Khalsa, M. Sedova, S. McLaughlin, V. Sheth, M. Shah, D. Thomas, H. Breu, M. Rhodes, C. Adams, F. Hyland, R. Bennett.* Life Technologies Corp / Ion Torrent, 5791 Van Allen Way, Carlsbad, CA 92008.

Though it is now possible to sequence a human genome in a single day, the need for high sample throughput and reduction in informatics necessitates exome enrichment in many cases. We will discuss three key areas of the human exome workflow, design of the exome enrichment panel, rapid sequencing turnaround, and assessment of the results. We have designed and built a set of efficient hybridization probes that permit the enrichment of protein-coding exons from 6 major gene-model databases (GenCode, RefSeq, Ensembl, UCSC, VEGA, and CCDS), functional RNA genes from miRBase and UCSC databases, predicted micro-RNA binding sites, and COSMIC cancer variants. In total, this set of probes is optimized to enrich ~46 Mb of target regions with probe sequences that densely tile ~52 Mb of the human genome and the workflow yields an on-target read mapping rate of 80%. Following exome-enriched library preparation, templated particles are prepared using an automated device (OneTouch™) or manually and sequenced in one (Proton™) or five (PGM™) instrument runs, with each run taking ~4 hours. Such rapid exome sequencing in a single Ion Torrent Proton™ System run or 5 runs on Ion Torrent PGM™ Systems yielded >5 Gb of aligned base reads and provided an average depth over targets of >50x with >85% of target bases covered at a 20x depth or more. Rapid read mapping, determination of exome coverage metrics, and variant calling is done seamlessly using the Torrent Suite™ Software that is provided with these instrument systems. Annotation of variants was carried out using Ion Reporter™ Software. To validate the performance of this workflow, exome-enriched fragment libraries were sequenced from a familial trio (parents NA12891, NA12892, and child NA12878) from CEPH/Utah Pedigree 1463. Each individual exome dataset, yielded more than 30,000 SNP calls (>18,000 homo and >12,000 het) and more than 98% of all SNPs called exist in dbSNP135. Each exome dataset also permitted the calling of hundreds of indels. Comparison to whole-genome data from the 1000 Genomes project and Complete Genomics along with Mendelian inheritance analysis permitted estimation of the specificity, sensitivity and accuracy of variant calling. The combination of focused exome enrichment and Ion Torrent Systems-based sequencing and analysis provides an efficient, accurate, and rapid means to detect genetic variation in the well-annotated portion of the genome for state-of-the-art genetic disease research.

3718W

TotalScript: A versatile and robust tool for RNAseq applications. *F. Syed, S. Kuersten, A. Radek, R. Vaidyanathan.* Illumina, Madison, WI.

Deep sequencing can provide a digital readout of gene expression and can be used for a variety of distinct applications in human biology and genetics including allele-specific expression profiling, alternative splicing regulation and promoter usage in disease states, non-coding RNA analysis and many others. The diverse and complex world of RNAseq and the rapid development of sequencing technology require the development of simple, versatile tools that competently reflect RNA levels in the cell. We have developed a novel, transposome-based stranded RNAseq method capable of using variety of RNA sample types and a range of input levels to produce high quality RNAseq libraries for illumina-based sequencing. Samples made from this method produce libraries with high complexity, ~97–99 % stranded and low rRNA contamination. The method is scalable (automation) and robust, allowing input amounts down to ~100 pg of polyA+ RNA or ~5ng of total RNA. Furthermore, due to the nature of the technology, input RNA type is quite flexible; polyA+ selected, Ribo-Zero treated or Total RNA samples can be used and both random priming and oligo-dT priming of first strand cDNA synthesis are compatible. The method provides a simple, innovative and integrated solution to RNAseq applications.

3719F

Automating high-throughput creation of sequencing libraries. *J. Bishop, W. Zhang, D. Mandelman, M. Allen, A. Harris, R. Bennett.* Life Technologies, Carlsbad, CA.

Obtaining the best results from high throughput sequencing studies often depends on the ability to produce high quality sequencing libraries, yet creating these libraries is a repetitive, labor-intensive, error-prone process with often variable results. To achieve greater throughput and consistency, we have developed automated protocols for creating DNA and transcriptome libraries for use in semi-conductor sequencing. To create DNA fragment libraries, our protocols automate shearing, end-repair, adaptor ligation, and library size-selection from as little as 50 ng of input DNA. User-control options also allow customization of the insert-sizes produced during automated shearing and size selection. The resulting DNA libraries are of sufficient yield and quality to be used directly in downstream steps without requiring amplification or additional manual manipulation. To create strand-specific transcriptome libraries, our protocols automate adaptor ligation, reverse transcription, and library size selection from as little as 50 ng of fragmented RNA. Semiconductor sequencing demonstrates that both fragment and transcriptome libraries produced by these automated protocols are complete and unbiased relative to manually-constructed libraries. The technologies described here provide automation solutions for increasing the speed, throughput, consistency, and efficiency of semiconductor sequencing applications.

3720W

Highest sample quality for molecular analysis through ambient stabilization technologies. Improved genome, transcriptome and proteome analysis from saliva, blood and tissue samples. *R. Muller, V. Liberal, S. Wilkinson, A. Stassinopoulos, J. Muller-Cohn.* Biomatrica, San Diego, CA.

Biospecimen stabilization during collection and transport is of critical importance in the fields of biomedical research and molecular diagnostics. The emergence of personalized medicine has placed an even greater emphasis on the significance of protecting the quality and reliability of clinical samples. The results obtained during biomarker discovery is directly linked to potential disease diagnostics and therapeutic intervention. Current methods for blood and saliva collection depend heavily on cold-chain logistics. The reliance on cold and ultra-cold based sample preservation is fraught with potential complications to specimen integrity that can result in inconsistent result generation impacting the discovery of suitable and reliable biomarker and their transition to clinical applications. Chemical stabilization of biomolecules at ambient temperatures is far superior in preserving the sample quality and integrity over conventional low temperature based stabilization methods. In this report we describe the development of chemical stabilization technology that addresses the problem of sampling induced inconsistencies in human blood and saliva. The formulations described preserve nucleic acids in these biospecimens even under extreme environmental shipping conditions and remove the need for cold-chain logistics during sample collection, transport or storage. Here we show that the genomic DNA in blood collected in DNAgard Blood Tubes is stabilized during extreme temperature fluctuations ranging from -20°C to +45°C. Samples remain stable for up to 14 months at room temperature. The analogous DNA stabilization technology for saliva specimens, DNAgard Saliva, preserves sample integrity for over 12 months at ambient temperature. We also compare freezer storage with the room temperature stabilization formulation RNAgard Blood and other technologies for ambient temperature blood RNA and protein stabilization. The presented results are demonstrating that transcriptome and protein based analysis is vastly improved through ambient biostabilization. This data is relevant for large scale cohort studies as well as moving biomarkers to the clinic.

Increased sensitivity in whole-genome bisulfite sequencing (WGBS): A novel "post-bisulfite conversion" library construction method for sub-nanogram inputs. *R. Sooknanan[1], A. Adey[2], J. Hitchen[1], J. Shendure[2], N. Caruccio[1].* 1) Epicentre® (an Illumina® company), Madison, WI; 2) Department of Genome Sciences, University of Washington, Seattle, WA, USA.

Genome-wide analysis of 5-methylcytosines is possible with whole-genome bisulfite sequencing (WGBS), where unmethylated cytosine residues are converted to uracil. However, a major challenge in WGBS is the degradation of DNA that occurs during bisulfite conversion under conditions required for complete conversion. Typically, ~90% of input DNA is degraded and thus, is especially problematic with limited starting amounts of DNA. Additionally, regions that are rich in unmethylated cytosines are more sensitive to strand breaks. As a consequence, a majority of DNA fragments contained in di-tagged NGS DNA libraries treated with bisulfite "post-library construction" can be rendered inactive due to strand breaks in the DNA sequence flanked by the adapter sequences. These mono-tagged templates are then excluded during library enrichment resulting in incomplete coverage and bias when performing whole genome bisulfite sequencing. Here, we describe a novel "post-bisulfite conversion" library construction method for preparing NGS libraries from genomic DNA prior to the addition of one or both adapters. This "post-bisulfite conversion" library construction method uses the resulting untagged or mono-tagged single-stranded DNA as template for the subsequent addition of adapter sequences required for NGS. Thus, single-stranded DNA fragments independent of size and position of strand breaks remain as viable templates for library construction, eliminating the loss of fragments and the selection bias associated with a "post-library construction" bisulfite conversion strategy. This novel "post-bisulfite conversion" library construction method exhibits increased sensitivity and efficiency (500 picogram input), and improved coverage required for WGBS.

3722W

Highly efficient miRNA isolation method using Solid Phase Reverse Immobilization (SPRI) Technology and Biomek automation. *BN. Lee.* Beckman Coulter 250S Kramer Blvd., Brea, CA 92822.

miRNA is a short ribonucleic acid with the average size of 22 nucleotides and is found abundantly in many human cell types as well as in other organisms. Over 1000 unique miRNA have been identified in human genome and it is reported that miRNA may target and regulate over 60% of human genes in cellular responses. In human cells, miRNA complementary binds to the 3'UTR of mRNA and binding of the miRNA plays a role in gene silencing, transcriptional/translational regulation in cellular responses, developmental processes, signal transduction and cancer or disease control. In the past two years biomedical research has placed much importance on characterizing miRNA to further understand its biological function and how it can be used as a biomarker for cancer development, and be utilized as therapeutic targets for cancer treatment. Sample preparation for this process can be very challenging. It often requires isolation of high quality miRNA from FFPE samples, cell culture and tissues. Most commercial nucleic acid extraction kits and protocols are inefficient in recovering small molecules such as miRNA. We describe efficient and robust miRNA extraction methods using Agencourt SPRI* (Solid Phase Reverse Immobilization) technology and Biomek automation*. The two methodologies described are (1) miRNA extracted and purified from FFPE samples using the Agencourt FormaPure Kit* and (2) miRNA extracted and purified from cell culture using the Agencourt RNAdvance Cell v2 kit*. The TaqMan** qPCR expression of let-7c demonstrates successfully purified miRNA from FFPE and cell culture samples. * Biomek/AgencourtFormaPure/Agencourt RNAdvance Cell v2 kits are registered trademarks of Beckman Coulter, Inc. ** TaqMan qPCR is registered Trademark of Roche Molecular System, Inc.

3723F

MiRNA extraction from human plasma using high capacity miRNA Anti-Probe Magnetic beads. *A. Zampetaki[1], T. Xu[2], A.V. Vlassov[3], N. Bernard[4], M. Mayr[1].* 1) Cardiovascular Division, King's College London, LONDON, United Kingdom; 2) Life Technologies, 850 Lincoln Centre Drive Foster City, California, 94404, USA; 3) Life Technologies, 2130 Woodward st, Austin TX 78739, USA; 4) Life Technologies Europe B.V. - Belgisch bijkantoor Regus Gent Zuiderpoort Gaston Crommenlaan 4 bus 0501 9050 GENT Belgium.

Background: Circulating microRNAs (miRNAs) have emerged as promising biomarkers. Objective: In this study, we assessed the efficiency of the miRNA extraction using Anti-probe Magnetic Beads or the conventional extraction technology based on phenol/ guanidine sample lysis and glass-fiber binding purification of RNA. Methods and Results: MiRNA Anti-probe Magnetic Beads were used to capture the miRNA pool from 50ul of human plasma (n=10). Beads Panel A that targets a total of 377 human miRNAs that are based on the Megaplex Pool A and 6 non-human positive and negative controls. Following the initial sample lysis, anti-probe beads were hybridized to the specific miRNA targets. The extracted miRNA was reverse transcribed using the Taqman MicroRNA RT kit and the Megaplex Pool A with RT primers. In parallel, RNA was extracted using the conventional method of extraction using 100ul from the same human plasma samples. In both protocols, the exogenous cel-miR-39 was spiked-in during extraction and served as a normalization control. MiRNA expression was validated by QPCR using the Taqman miRNA assays. In all samples an extremely high association was detected between the two extraction protocols (r= 0.856), with several miRNA targets reaching almost perfect association (e.g. miR-92a, r=0.992). Conclusions: Our study demonstrates that the miRNA Anti-probe Magnetic beads can offer high sensitivity and reproducibility in miRNA extract using a short and simple workflow with minimal biological sample. These findings suggest that miRNA Anti-probe Beads could be used to establish an automated protocol to facilitate the screening of miRNAs in large cohorts.

3724W

Single Molecule Real-Time (SMRT®)Sequencing of genes implicated in autosomal recessive diseases. *Y. Guo[1], A. Bashir[2], E. Gould[2], R. Kornreich[2], L. Edelmann[2], T. Brandt[2], Y. Kasai[1], J. Chin[2], E. Paxinos[1], A. Kasarskis[2], E. Schadt[2].* 1) Pacific Biosciences, Menlo Park, CA., USA; 2) Mount Sinai School of Medicine, Dept. of Genetics and Genomic Sciences, New York, NY USA.

In today's clinical diagnostic laboratories, the detection of the disease causing mutations is either done through genotyping or Sanger sequencing. Whether done singly or in a multiplex assay, genotyping works only if the exact molecular change is known. Sanger sequencing is the gold standard method that captures both known and novel molecular changes in the disease gene of interest. Most clinical Sanger sequencing assays involve PCR-amplifying the coding sequences of the disease target gene followed by bi-directional sequencing of the amplified products. Therefore for every patient sample, one generates multiple amplicons singly and each amplicon leads to two separate sequencing reactions. Single Molecule, Real-Time (SMRT®) sequencing offers several advantages to Sanger sequencing including long read lengths, first-in-first-out processing, fast time to result, high-levels of multiplexing and substantially reduced costs. For our first proof-of-concept experiment, we queried 3 known disease-associated mutations in de-identified clinical samples. We started off with 3 autosomal recessive diseases found at an increased frequency in the Ashkenazi Jewish population: Tay Sachs disease, Niemann-Pick disease and Canavan disease. The mutated gene in Tays Sachs is HEXA, Niemann-Pick is SMPD1 and Canavan is ASPA. Coding exons were amplified in multiple (6–13) amplicons for each gene from both non-carrier and carriers. Amplicons were purified, concentrations normalized, and combined prior to SMRTbell™ Library prep. A single SMRTbell library was sequenced for each gene from each patient using standard Pacific Biosciences® C2 chemistry and protocols. Average read lengths of 4,000 bp across samples allowed for high-quality Circular Consensus Sequences (CCS) across all amplicons (all less than 1 kb). This high quality CCS data permitted the clean partitioning of reads from a patient in the presence of heterozygous events. Using non-carrier sequencing as a control, we were able to correctly identify the known events in carrier genes. This suggests the potential utility of SMRT sequencing in a clinical setting, enabling a cost-effective method of replacing targeted mutation detection with sequencing of the entire gene.

Detection of Rare Somatic Mutations Using a Simplified, Specific digital PCR Workflow with Zero Dead Volume. *M.C. Pallas, D. Keys, J. Wilde, J.C. Nurse.* qPCR R&D, Life Technologies, Foster City, CA.

The detection and enumeration of low frequency somatic mutations is important to continued advances in the understanding of cancer. Conventional PCR is limited in its sensitivity to the rare mutants due to large background of the wild type. Digital PCR utilizes PCR technology to precisely count the number of nucleic acid templates. Its basis is the dilution of the nucleic acid template to a point where each PCR reaction vessel contains a single copy or no copies. The single copies amplify while no amplification is detected in the vessel lacking DNA template. Using a large number of reaction vessels with the assumption of Poisson distribution of copies, the average number of copies per vessel can then be calculated. This results in a highly precise and specific method of detecting and quantifying DNA. We have developed a simple, three step, digital PCR workflow that allows for highly specific detection of rare somatic mutations with zero dead volume. It is difficult to achieve high sensitivity mutation detection with conventional qPCR because the high concentration of non-mutant template outcompetes the target for amplification reagents, masking the mutant signal. In dPCR, individual reaction vessels containing mutant DNA strands have no, or very low, numbers of non-mutant template. This allows the signal from the mutant to emerge, and the overall frequency to be precisely determined. Our digital PCR workflow consists of three steps, loading the sample, thermal cycling, and detection of the digital results. Operator interaction with the sample exists in only the first step, loading the sample. We demonstrate the utility of this method using well characterized cell lines containing six KRAS mutations. DNA from these lines was titrated with wild-type DNA to give mutant concentrations as low as 0.025%. dPCR runs on these samples, as well as mutant-free control samples, demonstrate high sensitivity, specificity, and precision of this simplified workflow.

Rapidly profiling thousands of large non-coding RNAs and mRNAs from nanogram amounts of total RNA using a single microarray design. *A. Bergstrom Lucas, K. Swaminathan, V. Kulkarni, E. LeProust, S. Fulmer-Smentek.* Genomics R&D, Agilent Technologies, Santa Clara, CA.

Large intergenic non-coding RNAs (lincRNAs) are emerging as key regulators of diverse cellular processes. As researchers face the challenge of investigating the function of lincRNAs, there is a need for tools that can accurately and rapidly measure the expression of both lincRNAs and mRNAs in the same assay. In 2011, a reference catalog of more than 8,000 human lincRNAs was annotated from 4 billion RNA-Seq reads across 24 tissues and cell types by scientists at the Broad Institute of MIT and Harvard. Using this new reference catalog of lincRNAs we have updated the content of the SurePrint G3 Human microarrays to enable systematic profiling and simultaneous detection of coding and non-coding gene expression from a single RNA sample. We used low nanogram amounts of total RNA from matched tumor and adjacent normal tissues to detect both large and subtle differences in gene expression profiles that were consistent with the current literature. GeneSpring GX software rapidly identified differentially expressed lincRNAs and protein-coding RNAs resulting in expression measurements from total RNA in less than two days. The SurePrint G3 Human Gene Expression v2 microarrays provided data that demonstrated good reproducibility, wide dynamic ranges and high sensitivity. The tumor versus normal ratios generated from the v2 microarrays showed high correlation with ratios generated from whole transcriptome sequencing from the same matched RNA samples. In this study we demonstrate that the new v2 microarrays can provide accurate differential expression measurements of both protein coding and non coding RNA from very low amounts of total RNA, rapidly providing biologically relevant gene expression measurements that are equivalent to whole transcriptome sequencing data.

Development of a system based on SMART technology for robust transcriptome library preparation from small quantities of degraded sample. *M. Bostick, C. Chang, A. Farmer.* Clontech Laboratories, Inc, Mountain View, CA., USA.

By providing sequence data on millions of short DNA fragments in parallel, Next Generation Sequencing has revolutionized biomedical research. In particular, the technique has enabled RNA expression analysis over the entire transcriptome with superlative sensitivity and dynamic range. With this has come a drive to utilize smaller and smaller sample inputs - with the ultimate goal of analyzing the transcriptome of a single cell. Achieving this requires highly sensitive and robust sample preparation methods. One powerful method for cDNA preparation is Clontech's proprietary SMART technology (Switch Mechanism At the 5' end of the RNA Template), which utilizes the template switching activity of reverse transcriptase to enable the direct addition of a PCR adaptor to the 3' end of the first-strand cDNA; thus avoiding inefficient ligation steps. The result is a single-tube protocol that greatly enhances library amplification efficiency as compared to traditional technologies, while minimizing the chance for contamination or degradation of the sample, making it ideal for library preparation from small amounts of starting material. Indeed, the currently available SMART kit allows researchers to readily obtain high quality data from as little as 100 pg of total RNA. Although the SMART system provides many benefits, one drawback of the current system is the inability to work with samples comprising degraded RNA, owing to the method's dependence on an oligo dT primer for first-strand synthesis. In many samples where input amount is low - e.g., FFPE specimens - the starting RNA is often degraded; limiting the applicability of such poly A based strategies. Accordingly, we have adapted the SMART protocol to work with degraded starting material - even with starting amounts as low as 1ng total RNA. Data will be presented out-lining various optimization steps, including the use of random primers of varying lengths, as well as methods for both purifying RNA from FFPE sections and depleting rRNA. In addition, the use of novel polymerase formulations to further enhance yield in the amplification step has also been investigated. These newer formulations are compared to other currently available enzymes with respect to total DNA yield, mutation rate and sample bias. Based on these modifications, we have developed a system that is capable of generating cDNA libraries for transcriptome profiling from FFPE samples starting with as little as 1 ng of total RNA.

Selective sequencing of mature transcripts in the human brain by cytoplasmic RNA-Seq. *A. Zaghlool, A. Ameur, J. Halvardson, L. Cavelier, L. Feuk.* Dept Immunology Genatic & Patholohy, Science for Life Laboratory Uppsala, Rudbeck Laboratory, Uppsala University, Uppsala, Sweden.

The recent data from total RNA and polyA RNA sequencing experiments have significantly increased our understanding of the human transcriptome and led to identification of previously unknown exons and splice isoforms. However, previous studies have also indicated that a large fraction of sequencing reads align to introns and intergenic regions, which may lead to a reduced efficiency of these methods to detect novel exons and new splice junctions. To provide deeper insight into the dynamics of the transcriptome, and to avoid the biases associated with polyA selection, we developed a technique to extract pure RNA populations from cytosolic and nuclear fractions and sequenced these separately. We show that our technique generates RNA populations with substantially lower cross contamination as compared to commercially available kits. We then sequenced cytosolic, nuclear, polyA selected and total RNA from human frontal cortex using SOLiD5500 to investigate the sequencing profiles of these fractions. The results show that cytoplasmic RNA is highly enriched for mature transcripts with low levels of intronic reads, as compared to polyA and total RNA-seq. The exonic/intronic ratio of the reads in the CytoRNA-Seq was 0.74, while the corresponding ratios were 0.20 and 0.27 for total RNA-Seq and polyARNA-Seq respectively. The NucRNA-seq data showed the lowest ratio of 0.13. Our results also show that CytoRNA-Seq yields substantially larger amounts of splice junction reads compared to the NucRNA-Seq. We propose that our CytoRNA-Seq offers a new and more accurate method to selectively sequence and measure the levels of mature transcripts compared to conventional RNA-seq approaches.

Targeted library preparation for Ion Torrent sequencing using HaloPlex PCR. *H. Johansson, E. Agne, K. Zettermann, M. Isaksson, P. Eriksson, B. Skarpås, F. Roos, F. Dahl.* LSG Genomics, Agilent, Uppsala, Sweden.

We have developed a method for multiplex target capture and library preparation of genomic regions. The protocol can target up to 250 Kbp regions, requires 200 ng of gDNA and produces ready-to-load PGM sequencing libraries in less than six hours. Benchtop sequencing instruments such as the Ion Torrent PGM sequencer is capable of generating several gigabases of sequence data in less than 24h. This capacity allows for comprehensive studies of genetic material to be carried out within a few days. However, since the entire human genome is too large to be sequenced on this platform, without spending an unreasonable amount of time and sequencing reagents, it is often advantageous to enrich for regions of interest prior to sequencing. Methods used for genetic research studies as well as for clinical applications need to meet a few important criteria. The coverage of targeted regions should be close 100 percent and capture efficiency of different regions should be uniform to preserve initial allele representation. High specificity is important to direct sequencing capacity to regions of interest without discriminating against novel variants. Furthermore it is also useful if the protocol is fast to make use of the short turnaround time of the PGM. The HaloPlex protocol consists of four main steps. In the first step the genomic DNA is fragmented using restriction enzymes followed by the second step where HaloPlex probes are hybridized to targeted fragments. During hybridization, both strands of the restriction fragment are targeted to achieve bidirectional sequencing and thereby improve coverage. The third step involves DNA ligation of a common primer motif to all targeted fragments which is then used in the final step for multiplex amplification all targeted fragments using one single primer pair. Samples are barcoded during ligation and can thereby be pooled to optimize use of the sequencing capacity on the sequencing chip. The protocol can be applied for enrichment of exonic or intronic regions that are either continuous or interspersed. To demonstrate the performance of the new protocol we have enriched three different target regions (25Kb, 60 Kb and 250 Kb) on genomic sample material and sequenced them on the PGM. More than 95% of targeted bases were covered for all designs and all samples were enriched with >80% specificity. Furthermore, over 90% of the targeted bases were covered at >10% of average depth.

SNP Genotyping using the Affymetrix® Axiom® 2.0 platform. *M. Shapero, M. Purdy, H. Dong, S. Hsiung, R. Kurapati, J. Law, H. Lee, H. Loi, D. Nguyen, P.H. Wang, A. Yan, C.S. Yu, M. Shirazi.* Affymetrix, Inc. Santa Clara, CA.

The use of high-density DNA microarrays for accurate, cost-effective genotyping of SNPs and in/dels continues to play an important role in the identification of the genetic basis of common and complex human diseases through genome-wide association studies (GWAS). As next-generation sequencing expands the catalog of both common and rare variants in multiple worldwide populations, microarrays are well positioned to capitalize on this evolving information content. Here an overview of recent advances related to the biochemistry and lab automation of the Axiom® 2.0 platform is presented.

The Axiom 2.0 platform had previously validated the use of multiple sources of human genomic DNA (gDNA) including blood, saliva, whole-genome amplified DNA, and DNA from cell lines. At an input mass of 100 ng to 200 ng per sample per array, performance consistently achieves an average sample call rate ≥99.0%, average sample concordance to independent DNA genotype information (HapMap) ≥99.5%; and intra- and inter-run reproducibility ≥99.8%. The Axiom® Assay performance profile has continued to be evaluated relative to several new human sample types including FFPE gDNA, mouthwash-derived gDNA, and ultra-low gDNA input mass. Additionally, a protocol is described in which amplified DNA target can be hybridized across multiple arrays.

The Axiom 2.0 platform enables complete automation of DNA target preparation, DNA amplification, and enzymatic fragmentation of post-amplification products on the Beckman Coulter Biomek® FX^P Target Prep Express platform. Here we describe an alternate liquid handling workstation as well as development of a new array format which offers the capability to dramatically increase the weekly throughput of samples while retaining full compatibility with the existing Axiom® Instrumentation platform and all downstream data analysis.

In summary, new Axiom 2.0 additions to sample compatibility, lab automation, and array formats further extend the platform's capabilities to genotype hundreds of thousands of SNPs in a single assay, offering a sample throughput coupled with minimal manual intervention that is consistent with the needs of both large-scale GWAS and targeted studies being conducted as part of the search for the underlying genetic basis of complex human disease.

Information Tracking Through the Use and Customization of the Exemplar LIMS in a Medium Scale Sequencing Laboratory. *B. Craig, D. Newcomer, S. Griffith, B. Marosy, A. Robinson, M. Zilka, KF. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-gen sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. The rapidly changing sequencing landscape brings the complicated task of how to quickly adapt existing methods of workflow information tracking. CIDR's in-house developed genotyping Laboratory Information Management System (LIMS) handles the tracking of detailed information for large numbers of samples going through the Illumina® genotyping assays. When changes to genotyping protocols are required, software developers implement them by modifying validation criteria, adding or removing elements for tracking or creation of a new LIMS module to accommodate new genotyping services. A sequencing LIMS was required that allowed for even faster development of modules for different sequencing protocols and technologies. For this challenge, CIDR evaluated the Exemplar LIMS© from Sapio Sciences. The Exemplar LIMS allows for the creation of user specific data types and incorporation of these elements into tasks and workflows. These workflows create sequential tasks that record information about reagent lot numbers, robotics used and timestamp task completion. Each of these tasks can be made to enforce predefined order to ensure that tasks are not skipped in the lab. Exemplar LIMS allows for some native validations and reporting elements but also has a robust Java application programming interface (API) that gives the ability to create custom plugins to extend CIDR specific validations and tasks. With the Exemplar LIMS, a workflow can be created to integrate with a new sequencing wet bench protocol in as little as one day. CIDR has created workflows to track NGS library and target capture preparation for Agilent© SureSelect™ XT and XT2 methods and clustering and sequencing preparation using the Illumina cBot™ and HiSeq™ 2000 systems. A framework using the API has been created to quickly add plugins to validate user input, update values in the Exemplar database, upload QC data in bulk for experiments and integrate with existing sample information databases. Current work focuses on creation of workflows for sequencing on the Illumina MiSeq™ and Ion Torrent© PGM™, preparation of libraries for whole genome sequencing and target capture preparation for Roche Nimblegen© SeqCap EZ.

Locus Reference Genomic sequences: reference sequences for the reporting of clinically relevant sequence variants. *J.A.L. MacArthur[1], A. Astashyn[2], E. Birney[1], R. Dalgleish[3], P. Flicek[1], L. Gil[1], P. Larsson[1], D.R. Maglott[2], W.M. McLaren[1], R.E. Tully[2], F. Cunningham[1].* 1) European Bioinformatics Institute, Cambridge, UK; 2) National Center for Biotechnology Information, Bethesda, MD, USA; 3) Department of Genetics, University of Leicester, Leicester, UK.

Locus reference genomic (LRG) sequences are internationally recognized reference-sequences designed specifically for the reporting of clinically relevant sequence variants. An LRG provides a stable genomic DNA sequence for a region of the human genome which will never be changed and so is not versioned. They are created by the NCBI (http://www.ncbi.nlm.nih.gov) and EBI (http://www.ebi.ac.uk/), as part of the GEN2PHEN (http://www.gen-2phen.org) and RefSeqGene (http://www.ncbi.nlm.nih.gov/refseq/rsg) projects, in collaboration with the community of diagnostic and research labs, locus specific database curators and mutation consortia. The LRG project aims to create an LRG reference sequence for every genomic locus with clinical implications. Currently over 350 LRGs have been created, with this number expected to increase significantly by the end of this year. LRGs have been created for a panel of genes involved in inherited cardiac disease, in collaboration with the British Heart Foundation. LRGs are also in preparation for genes involved in cancer predisposition, including BRCA1 and BRCA2. All information relating to an LRG is contained within a single XML file, which comprises separate sections for the fixed and updatable annotation. The fixed (stable) section contains the genomic sequence and annotation for exons and coding regions of transcripts used as reference standards. The updatable section contains chromosome and coordinate mapping information for the LRG sequence, as well as annotation of additional cDNAs, co-located genes, variation, database cross-references and alternative (legacy) exon and amino-acid numbering systems. The stable nature of these reference sequences enables unambiguous reporting of variants in LRG coordinates, as recommended by the Human Genome Variation Society (HGVS) and European Molecular Genetics Quality Network (EMQN). Variant reporting in accordance with HGVS conventions using the LRG as the reference standard is possible in genomic DNA (e.g. LRG_1:g.8463G>C), coding DNA (e.g. LRG_1t1:c.572G>C) or protein coordinates (e.g. LRG_1p1:p.Gly191Ala). LRGs can be viewed in the Ensembl and NCBI genome browsers, while tools such as Mutalyzer (https://mutalyzer.nl) also support LRGs. All LRG records are available on the LRG website (http://www.lrg-sequence.org), which also provides instructions on requesting LRGs and the complete LRG specification.

QC Measures for Whole Exome and Targeted Sequencing Library Prep and Enrichment in a High Throughput Lab. *A. Robinson, M. Zilka, B. Marosy, B. Craig, J. Romm, K. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-gen sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. CIDR uses Agilent© SureSelect™ XT library prep kits for whole exome sequencing and custom target enrichment. Quality control measures (QC) are evaluated after shearing (QC1), prior to hybridization (QC2), after post hyb amplification (QC3), and after pooling, prior to clustering (QC4) using the Agilent© Bioanalyzer™, the PerkinElmer LabChip®GX and the KAPA SYBR® FAST qPCR kits. CIDR utilizes separate lab spaces for the workflow to maintain pre/post PCR separation between the two amplifications. Since CIDR physically separates its lab space and enforces a strict flow of samples, separate sample aliquots and/or dilution plates must be made to utilize the BioAnalyzer and LabChip GX. The first QC is performed after sample shearing to ensure samples have been sheared to the necessary fragment size. QC2 evaluates adapter ligation and concentration and is used to normalize samples for hybridization. QC3 is done after capture to check size and molarity. Samples are then normalized using the PerkinElmer Janus® to 1–2nM and retested to confirm the concentration before pooling. Once the pools are created (between 3–96 samples), each pool is tested (QC4) to ensure the samples do not become over-clustered. Pool balance is important, such that one sample is not over-sequenced in comparison to the other pooled samples. A final QC is done on the Illumina® MiSeq™ to ensure the evenness of the pools and check optimal cluster density before finally being clustered on the Illumina® cBOT Cluster Generation System™ and set up on Illumina® HiSeq 2000™. While QC tasks can add time to the lab processing workflow, ensuring only high quality libraries are sequenced will save time and money in the long run. A LabChip GX chip can run up to 96 samples at a time which takes ~3 hours and costs about $125 per chip, or $1.30/sample. A Bioanalyzer chip can run up to 12 samples at a time which takes 45 minutes and costs $19–$32, or $1.58–$3/sample (depending on chip type). The Bioanalyzer is more cost and time effective for smaller sample sets. The MiSeq run takes another 12–24 hours and costs about $695 for each run. Overall, this can add 1–2 days to the lab process but can save up to 14 days and >$6K in sequencing time and reagents.

3734W

Additional annotation enhances biologically relevant sub classification of the Illumina HumanMethylation450 BeadChip array. *E. Price[1,2,3], A. Cotton[3], L. Lam[2,3,4], E. Emberly[5], C. Brown[3], W. Robinson[2,3], M. Kobor[2,3,4].* 1) Obstetrics & Gynaecology, University of British Columbia, Vancouver, British Columbia, Canada; 2) Child and Family Research Institute, Vancouver, British Columbia, Canada; 3) Medical Genetics, Vancouver, British Columbia, Canada; 4) Centre for Molecular Medicine and Therapeutics, Vancouver, British Columbia, Canada; 5) Department of Physics, Simon Fraser University, Burnaby, British Columbia, Canada.

Over the past six years, Illumina has been a leading source for DNA methylation (DNAm) microarrays. To facilitate biologically significant data interpretation, we set out to enhance probe annotation of the newest HumanMethylation450 array (with >450,000 probes covering 99% of RefGenes). Annotation that was expanded on includes a) CpG island and b) gene feature classification; while annotation that was added includes c) SNPs in target CpGs and d) cross-hybridizing probes. a) Probes were annotated into four CpG island groups based on Weber's 2007 definition: high density CpG islands (HC; n=142,474); intermediate density CpG islands (IC; n=110,225); IC shores (i.e. ICs adjacent to HCs; n=31,724) and non-islands (n=201,059). The majority of HC probes were in Illumina-annotated CpG islands, while only 18% of Illumina-annotated shores were in IC shores. Shores may be important regions for changes in DNAm and a comparison to Weber's islands may elucidate shores with differing biological roles. We assessed tissue differences in DNAm ($\Delta\beta$ >0.20) using human buccal (n=4), blood (n=4) and placental (n=4) samples. Within Illumina-annotated shores, tissue differences in DNAm were noted in 20% of IC probes and 18% of IC shore probes but only 8% of HC probes. b) To aid in understanding how DNAm at different gene regions may be associated with a given condition, the following annotation was added for each probe: gene features (5'UTR, 1st exon, exon, intron and 3'UTR) and distance to closest transcription start site. c) We specified probes with SNPs in the C or G of the target CpG (~4%), since these are hypothesized to affect assessment of DNAm. Illustrating this, a trichotomous pattern of DNAm was observed in samples at a probe (cg09101062) with a predicted C/T SNP (rs4866831) at the target CpG; individuals assessed as unmethylated had a TT genotype (n=5), ~50% methylated had a TC genotype (n=5) and fully methylated had a CC genotype (n=2). d) In silico analysis showed 9–10% of probes hybridized to multiple genomic locations, thus we suspect these sites do not measure DNAm at one CpG. Specifically probes that cross-hybridize to sex chromosomes are of concern when male and female samples are analyzed together. As the assessment of DNAm in association with aspects of human health becomes more widespread, it is important for array data to be comprehensively analyzed in order to classify biologically relevant changes in DNAm.

3735F

Computer-aided detection of defects in Affymetrix CEL data files. *D.C. Edwards[1], A. Konkashbaev[1], A. Pluzhnikov[1], N.J. Cox[1], J.B. Tomblin[2], K.L. Mueller[2].* 1) Dept. of Medicine, The University of Chicago, Chicago, IL; 2) University of Iowa, IA.

Background: Genotyping array images such as Affymetrix CEL files can contain imaging defects that impair allele calling for all individuals in the calling batch. Manual identification of defective images can be time-consuming. We are developing an automated method to identify defective CEL files. Materials and Method: For algorithm development, we used a set of 144 CEL files from a recent GWAS conducted using the Affymetrix 6.0 platform, 36 of which contained visible defects such as dark spots, bright smudges, and bright streaks. Many of these defects were found to be more uniform than a typical region of a non-defective CEL file. To detect such defects, the variance in a square window is calculated at each pixel in the CEL file; regions in which this resulting variance is below a threshold are reported as detections, where the threshold is a fixed number k of standard deviations below the mean of the windowed variance values throughout the CEL file. The parameters of this detection algorithm, namely the window size (20 pixels) and number k (2), were chosen to minimize the number of false-positive (FP) image detections while still detecting the majority of such uniform defects. The detection algorithm was then applied to a set of 1337 CEL files from HapMap3, which was known to contain a number of such defective images, but would have been prohibitvely time-consuming to manually identify all of them. Results: For the given choices of algorithm parameters, 23 out of the 36 defective CEL images from the training GWAS were identfied, for a true-positive (TP) rate of 64%. Of the remaining 108 normal images, 36 contained false-positive detections, for a FP rate of 33%. In the HapMap3 dataset, we sampled 181 of the 832 images in which the algorithm produced detections; 54 of these were TP, and 127 FP. We also sampled 35 of the 505 images without detections; 10 of these were FN (containing at least one undetected defect), and 25 TN. The TP rate was thus 84%, and the FP rate 83%. Conclusion: It should be noted that the algorithm parameters were chosen manually, and some types of common defect (bright linear streaks) were not detectable with the variance threshold method. However, it is already capable of identifying important classes of defect, and we expect to be able to extend and improve the algorithm to address these issues.
