American Society of Human Genetics 62nd Annual Meeting
November 6-10, 2012 San Francisco, California

POSTER ABSTRACTS

The program and abstract/poster board number next to each listing is followed by a **W** (Wednesday), or **T** (Thursday), or **F** (Friday) to indicate the day on which authors must be present at their poster boards. Posters will remain on the boards for all three days (Wednesday through Friday).

Session Title/Topic Area	*Start #*	*End #*
Genome Structure, Variation and Function	#412	#600
Pharmacogenetics	#601	#655
Metabolic Disorders	#656	#753
Therapy for Genetic Disorders	#754	#804
Development	#805	#854
Cytogenetics	#855	#980
Cancer Genetics	#981	#1279
Statistical Genetics and Genetic Epidemiology	#1280	#1583
Cardiovascular Genetics	#1584	#1715
Genetic Counseling and Clinical Testing	#1716	#1796
Ethical, Legal, Social and Policy Issues in Genetics	#1797	#1850
Genetics Education	#1851	#1863
Health Services Research	#1864	#1877
Complex Traits and Polygenic Disorders	#1878	#2369
Psychiatric Genetics, Neurogenetics & Neurodegeneration	#2370	#2661
Molecular Basis of Mendelian Disorders	#2662	#2966
Prenatal, Perinatal and Reproductive Genetics	#2967	#3034
Clinical Genetics and Dysmorphology	#3035	#3250
Evolutionary and Population Genetics	#3251	#3414
Epigenetics	#3415	#3525
Bioinformatics and Genomic Technology	#3526	#3735

POSTER AUTHOR SCHEDULE

Refer to the schedule below for presentation times and for the poster mounting;shremoval schedule. **Posters should remain up all three days.**

Wednesday, November 7

10:00 am– 10:30 am	Authors place posters on boards. Posters to remain up until Friday
10:00 am– 4:30 pm	Posters open for viewing
2:15 pm– 4:15 pm	**Poster Session I (W)**
	2:15 pm– 3:15 pm ***(odd poster board numbers; author must be present)***
	3:15 pm– 4:15 pm ***(even poster board numbers; author must be present)***

Thursday, November 8

7:00 am– 4:30 pm	Posters open for viewing
2:15 pm– 4:15 pm	**Poster Session II (T)**
	2:15 pm– 3:15 pm ***(odd poster board numbers; author must be present)***
	3:15 pm– 4:15 pm ***(even poster board numbers; author must be present)***

Friday, November 9

7:00 am– 4:30 pm	Posters open for viewing
2:15 pm– 4:15 pm	**Poster Session III (F)**
	2:15 pm– 3:15 pm ***(odd poster board numbers; author must be present)***
	3:15 pm– 4:15 pm ***(even poster board numbers; author must be present)***
4:15 pm– 4:30 pm	**Authors must remove posters**
4:30 pm	Exhibit Hall and Posters close

Capture of chromosome conformation changes in breast cancer cell lines. *C. Liu, C. Woo, P. Yim, S. Dong, J. Stevens.* MBS R & D, Life Technologies, Foster City, CA.

Global changes in the epigenetic landscape are a hallmark of cancer. The initiation and progression of cancer is now realized to involve epigenetic abnormalities along with genetic alterations.In this study, we use breast cancer, the most common cancer in women, as a model to capture the chromosome conformation changes and corresponding gene expression level changes. Two breast cancer cell lines compared are the estrogen receptor alpha positive, weakly invasive, luminal epithelial-like MCF-7 and the ERalpha-negative, P53 mutated, highly invasive, fibroblast-like MDA-MB-231. 3C (Chromosome Conformation Capture) allows us to analyze the folding of chromatin at a resolution beyond that provided by current microscopy techniques. With the 3C technique, we are able to identify the physical interactions between distant DNA segments and of chromatin loops that are formed. In this study, we focused on PLD1 that has been shown to involve in many critical cellular pathways, such as EGF, PDGF, insulin, serum as well as Arf, Rho, PKC etc. through the hydrolysis of phophatidylcholine to generate the lipid second messenger phosphatidic acid (PA) and choline. The region in this study spans 245 kb, including both gene body and upper regulatory regions. 1st introns as well as 2nd promoter regions were used as anchors to capture the long distance loop interactions. 3C mappings were compared between MCF-7 and MDA-MB-231. The differences in the interaction patterns were correlated with the PLD1 expression levels. In addition to the two cell lines comparison, both cell lines were treated with epigenetic agents 5-Aza-2'-deoxycytidine, the inhibitor of methyltransferase which results in DNA demethylation (hypomethylation) and Trichostatin (TSA), the histone deactylase inhibitors which disrupts normal chromatin structure. Cells were treated with 5-Aza-2'-deoxycytidine and TSA for 7 days and 2 days respectively. Chromosome conformation changes upon drug treatments were captured and compared between these two cell lines. Epigenetic alterations along with the cancer metastasis, such as chromosome conformation changes (3D changes) allows us to get better understanding of epigenetic mechanisms which lead to the potential therapeutic possibilities of epigenetic drugs, such as 5-Aza-2'-deoxycytidine and TSA. In the future, chromosome 3D changes can be used as signatures for both diagnostic and therapeutic treatments.

413F

Myc-induced anchorage of the rDNA intergenic spacer region to nucleolar matrix modulates growth-stimulated changes in higher-order rDNA architecture. *C. Shiue, A. Nematollahi-Mahani, A. Wright.* Clinical Research Center (KFC), Department of Laboratory Medicine and Center for Biosciences, Karolinska Institute, SE-141 86 Huddinge Sweden.

Chromatin domain organization and the compartmentalized distribution of chromosomal regions are essential for packaging of DNA in the eukaryotic nucleus as well as regulated gene expression. Nucleoli are the most prominent morphological structures of cell nuclei and nucleolar organization is coupled to cell growth. It has been shown that nuclear scaffold/matrix attachment regions often define the base of looped chromosomal domains in vivo and that they are thereby critical for correct chromosome architecture and gene expression. Here, we show regulated organization of mammalian rRNA genes into distinct chromatin loops by tethering to nucleolar matrix via the non-transcribed intergenic spacer region of the rDNA. The rDNA gene loop structures are induced specifically upon growth stimulation and are dependent on the activity of the c-Myc protein. Matrix attached rDNA genes are hypomethylated at the promoter and are thus available for transcriptional activation. Epigenetically silenced rDNA genes are not recruited to the matrix. c-Myc, which has been shown to induce rDNA transcription directly, is physically associated with the matrix-attached rDNA gene looping structures via the intergenic spacer sequence. Such a role of Myc proteins in gene activation has not been reported previously.

414W

CENcode: linear assembly and epigenetic annotation of human centromeres. *K.E. Hayden, J. Kent.* Center for Biomolecular Science and Engineering, University of California, Santa Cruz, CA 95064, USA.

Centromere sequences remain vastly underrepresented in our reference assemblies and, consequently, remain isolated and unaccountable in ongoing studies in the genome sciences. This disparity results from the challenge of predicting the linear order of multi-megabase-sized regions that are composed almost entirely of near-identical satellite DNA. The incomplete nature of the human genome complicates interpretation of short-read epigenetic datasets, and as a result centromere genomics remain largely isolated from studies involving kinetochore regulation and structure. Here, we present a linear prediction of human centromeres, representing a sequence organization and content in a single, reference individual. Using the human Y centromere as a model of this approach, we intersect short-read functional datasets, assigning available ENCODE sequence libraries within the context of a centromeric reference. As a result, we present a high-resolution study of centromeric sequences organization, thus presenting an opportunity to identify genomic features underlying sites of kinetochore assembly.

415F

Impact of genetic variation on genome-wide epigenetic profiles and gene expression phenotypes. *A. Reymond[1], H. Kilpinen[2], S. Waszak[3], A. Gschwind[1,4], E. Migliavacca[1,4], R.M. Witwicki[1], S. Raghav[3], A. Orioli[1], L. Romano-Palumbo[2], M. Wiederkehr[1], S. Turnherr[3], D. Hacker[3], M. Gutierrez-Arcelus[2], L.J. Core[5], J.T. Lis[5], N. Hernandez[1], B. Deplancke[3], E.T. Dermitzakis[2].* 1) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 2) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 3) Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland; 4) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 5) Department of Molecular Biology and Genetics, Cornell University, Ithaca, New York.

Recent advances in genome-wide profiling of chromatin state and transcription factor (TF) binding have identified specific chromatin signatures related to various classes of functional elements in different cell types. However, their genetic basis and degree of variability across individuals remain largely unknown. We have generated genome-wide enrichment profiles of i) DNA methylation, ii) RNA Pol II, TFIIB, MYC, and PU.1 DNA occupancy, iii) histone modifications H3K4me1, H4K20me1, H3K27me3, H3K27ac, and H3K4me3, in addition to transcriptome-wide mRNA, small-RNA and Global Run-On RNA sequencing data, from lymphoblastoid cell lines of two trios sequenced in high depth as part of the 1000 Genomes project. We analyzed the allele-specific effects of sequence variation on TF binding, histone modifications, and gene expression and discovered allele-specific signals for each of the assays (8–57% of accessible sites), many of which showed the same allelic direction of effect at overlapping loci (for e.g. H3K4me3 sites in RNA Pol II, rho=0.73). We additionally used the allele-specific information to study the parentally transmitted (genetic) effects in each assay, and discovered strong patterns of transmission of allelic effects from parents to child (for e.g. PU.1, MYC, and H3K4me3), ranging from 20% to 70% depending on the assay. We have extended our analysis to lymphoblastoid cell lines of 54 unrelated individuals from the 1000 Genomes CEU population for the majority of the assays to identify genetic effects affecting chromatin properties on a population level in a context of known regulatory variation. We are also exploring the combinatorial patterns of all 12 assays across individuals to further dissect the components of the general transcriptional state of the cells. Together, this study will significantly improve our understanding of the biological landscape around regulatory and other functional elements of the genome, and provide better means to interpret the heritability and molecular basis of phenotypic diversity, such as disease susceptibility, in humans.

Capturing long-range chromatin interactions of chromatin regulatory elements. *N. Heidari, D.H. Phanstiel, W. Soon, M.P. Snyder.* Genetics, Stanford, Palo Alto, CA.

There is increasing evidence to suggest that long-range interactions between specific chromosomal regions play important roles in a diverse array of biological phenomena including immune response, gene regulation, and the development of human disease. Chromosomal folding brings together distal regulatory elements including enhancers, promoters, and insulators and these interactions have been shown to correlate with gene expression as well as translocation breakpoints in human cancer. However, methods to study these interactions have only recently been developed and are rapidly evolving. Chromatin conformation capture-based methods (3C, 4C, 5C, 6C, and Hi-C) allow for the detection of genome-wide chromosomal interactions while another variant, Chromatin Interaction Analysis by Paired-End Tag Sequencing (ChIA-PET), includes a chromatin immunoprecipitation step, and focuses on detection of interacting regulatory elements bound by a specific transcription factor or chromatin-associated protein. We have developed a robust ChIA-PET workflow as well as novel data analysis pipeline to characterize long-range chromatin interactions. A novel ChIA-PET analysis pipeline, chiapetter.py, was written to analyze the data. The pipeline was written in the programming language python and can be executed on either a desktop computer or a linux cluster for increased throughput. The pipeline consists of five major steps including: “linker parsing”, “mapping”, “(paired end tag) PET characterization”, “peak calling”, and “interaction calling”. It uses random shuffling of PETs to filter interactions to a fixed false discovery rate of 5%. This workflow has been applied to characterize protein-mediated long-range interactions of several regulatory factors as well as nuclear matrix proteins in chronic myelogenous leukemia (K562) as a workhorse cell line. Each experiment was performed in duplicates and was acquired at an average read depth of 99.5 million PETs per experiment. The vast majority of the peaks detected by ChIA-PET were also detected by a ChIP-Seq. Analysis of the RAD21 data set revealed 5,657 high confidence (FDR = 0.05) interactions comprising 5231 intrachromosomal and 336 interchromosomal interactions. With this methodology in place, we are prepared to explore biological questions including chromatin structural and functional variation in cancer, and other disease biology.

417F

PRDM9 directs genetic recombination away from functional genomic elements. *K. Brick[1], F. Smagulova[2], P. Khil[1], RD. Camerini-Otero[1], G. Petukhova[2].* 1) Genetics & Biochemistry Branch, NIDDK, National Institutes of Health, Bethesda, MD; 2) Uniformed Services University of Health Sciences, Department of Biochemistry and Molecular Biology, Bethesda, MD, USA.

Recombination initiates with the formation of programmed DNA double strand breaks (DSBs) at a small subset of genomic loci called hotspots. Elegant recent studies in mouse and human have determined that PRDM9, a meiosis-specific histone H3 methyl-transferase is involved in DSB hotspot site determination (Parvanov et al. Science 2010; Baudat et al., Science 2010; Myers et al., Science 2010), likely thorough DNA binding of its zinc-finger domain. We have recently generated the first genome-wide DSB hotspot map in a metazoan genome and have shown that the majority of mouse DSB hotspots are associated with testis-specific H3K4me3 chromatin marks, potentially formed by PRDM9 (Smagulova et al., Nature 2011). Curiously however, Prdm9 knockout mice remain proficient at initiating recombination. In this work, we describe several straightforward experiments that elucidate the nature and extent of the role of PRDM9 in determining DSB hotspots locations.

We used a novel ChIP-Seq variant developed by our group to detect ssDNA bound by the meiotic recombinase DMC1 (Khil et al., Genome Res., 2012). Using this method, we precisely mapped the genome wide distribution of DSB hotspots in seven mouse strains and in their F1 progeny. While hotspots in mice sharing a *Prdm9* allele mapped to almost identical loci, hotspots in other mice were dependent on the DNA binding specificity of the *Prdm9* allele. Importantly, in *Prdm9* knockout mice, hotspots were at completely different locations than in wild-type, definitively illustrating that PRDM9 determines practically all DSB hotspot locations. Intriguingly, DSBs in the pseudo autosomal region - the site of an obligate recombination event in every meiosis - were found to be *Prdm9*-independent and present in all strains. In *Prdm9* knockout mice, DSBs still accumulated in hotspots however, in the absence of PRDM9, most recombination initiated at H3K4me3 marks at promoters or enhancers. These sites are rarely targeted in wild-type mice illustrating an important, unexpected role for PRDM9 in sequestering the recombination machinery away from functional genomic elements where the efficient repair of DSBs may be problematic.

ATRX interacts with the MRN complex to play a key role in the replication of non-canonical DNA structures associated with tandem repeats. *R. Gibbons, D. Clynes, C. Jelinska, H. Ayyub, D.R. Higgs.* Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, United Kingdom.

ATRX is an X-linked gene, originally identified in patients with a form of syndromal mental retardation (ATR-X syndrome), which encodes a protein of the SWI/SNF family. ATRX preferentially binds tandem repeats (TRs) at rDNA, satellite repeats and telomeres. Within euchromatin ATRX also binds to TRs associated with a subset of genes, some of which are dysregulated when ATRX is mutated and the change in expression is determined by the size of the TR, producing skewed allelic expression. This reveals the characteristics of the affected genes, explains the variable phenotypes seen with identical ATRX mutations, and illustrates a new mechanism underlying variable penetrance in human genetic disease. Many of the TRs are G rich and predicted to form non-B DNA structures (including G-quadruplex) *in vivo*. Since ATRX and its partner DAXX are involved in the deposition of the variant histone H3.3 at telomeres and pericentromeric heterochromatin, it has been proposed that during nuclear processes such as transcription and replication ATRX influences the formation and/or resolution of non-canonical DNA structures by modifying their nucleosomal context. Consistent with this, loss of ATRX is associated with a marked decrease in H3.3 and an increased DNA damage response at telomeres during S-phase of the cell cycle when unresolved G4 DNA may impede DNA replication. Here we show that ATRX co-localises and interacts with the MRN complex (RAD50, MRE11 and NBS1) that is known to play a central role in sensing and resolving DNA damage during replication. In the absence of ATRX we find that DNA replication is perturbed with an increased frequency of stalled replication forks. This in turn is associated with an increased frequency of double strand breaks and a subsequent DNA damage response. It appears therefore that a key role of ATRX is to facilitate replication through TR sequences, via an interaction with the MRN complex. At telomeres, where the tandem TTAGGG repeats are replicated in a unidirectional manner, stalled forks can only be rescued by recombination, consistent with the observation that many cell lines and tumors that use recombination to maintain viable telomeres (alternative lengthening of telomere [ALT] phenotype) have mutations in the *ATRX* gene. In keeping with the proposed role of ATRX and MRN in replication and repair, here we also show that re-expression of ATRX in ALT cell lines reverses their characteristic phenotype.

419F

Genome-wide copy number variation analysis of a Branchio-Oto-Renal syndrome cohort identifies a recombination hotspot associated with an EYA1 deletion and novel candidate genomic regions. *F. Alasti[1], P. Brophy[2], B. Darbro[2], J. Dierdorff[3], C. Nishimura[1], B. Cobb[3], J. Clarke[2], M. Hakeman[3], A. Bassuk[2], R.J.H Smith[1], J.R. Manak[2,3,4].* 1) Department of Otolaryngology, University of Iowa, Iowa City, IA 52242, USA; 2) Department of Pediatrics, Carver College of Medicine, University of Iowa, IA 52242, USA; 3) Department of Biology, University of Iowa, IA 52242, USA; 4) Carver Center for Genomics, University of Iowa, IA 52242, USA.

Branchio-oto-renal (BOR) syndrome is an autosomal dominant disorder characterized by branchial cleft cysts, external ear abnormalities, preauricular pits or tags and hearing loss accompanied by malformations of the kidney. Both point mutations and large/small deletions in EYA1 are identified in about 40% of patients with the BOR phenotype. Mutations in SIX1 and SIX5 are also associated with BOR syndrome. Array-based comparative genomic hybridization (aCGH) has been used successfully to identify CNVs associated with a large number of human diseases, although this technique has only been used to a limited extent for BOR affecteds. We thus performed high-resolution aCGH on a cohort of 35 BOR probands negative for mutations in the three known BOR-causing genes. In this cohort, we identified >1,000 rare and novel CNVs, including an ~2.7 Mb heterozygous deletion, with nearly identical breakpoints in 4 unrelated BOR probands that removes all of EYA1 and multiple downstream genes. Both the distal and proximal deletion breakpoints are flanked by LTR-ERV_class I retrotransposon elements, which creates a recombination hotspot for non-allelic homologous recombination (P = 0.009). In a fifth BOR proband, we identified a novel 5.7 kb deletion that removes the last exon of EYA1 and the entire 3' UTR. In total, 5 probands (14%) had deletions of all or part of EYA1; further demonstrating that deletion in this gene is rather common in BOR. In addition to the deletions affecting EYA1, several novel deletions in other genomic regions were identified in this patient cohort, suggesting the involvement of other genes in the pathogenesis of BOR. Multiple methods were used to prioritize potential BOR-associated genes affected by the novel deletions, including mining protein-protein interaction data to create a hypothetical human EYA1 interactome network. These separate networks were then combined into one large network that was significantly enriched for genes involved in both morphogenesis of the metanephric bud and development of the inner ear, providing strong evidence for novel candidate disease-causing genes associated with BOR.

Delineation of the reliability of in silico copy number variation (CNV) calls from different Illumina SNP arrays. *S. Herms[1,2], L. Priebe[1,2], F. Degenhardt[1,2], M.M. Noethen[1,2,3], S. Cichon[1,2,4], P. Hoffmann[1,2]*. 1) Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 2) Institute of Human Genetics, University of Bonn, Bonn, Germany; 3) German Center for Neurodegenerative Disorders (DZNE), Bonn, Germany; 4) Institute of Neuroscience and Medicine (INM-1), Structural and Functional Organization of the Brain, Genomic Imaging, Research Center Juelich, Juelich, Germany.

Illumina SNP arrays are widely used to identify common and rare susceptibility variants involved in the etiology of multifactorial diseases. Besides SNP-based genome wide association studies, SNP-arrays allow to in silico analyze Copy Number Variants (CNV). There has been a comprehensive discussion in the field to what extent in silico CNV calls are reliable. For individual associated CNVs, validation by quantitative PCR (qPCR) is usually performed which is labour-intense and requires large amounts of DNA. Moreover, it is almost impossible to qPCR-validate CNVs from in silico burden analyses which test the genome-wide frequency of CNVs between patients and controls. In order to get an objective overview of the reliability of in silico CNV calls and the influence of batch effects, we compared in silico CNV calls from a larger number of technical replicates which were genotyped as internal quality controls in different genotyping projects over the last three years. These data had been acquired on different Illumina arrays such as the Human660W, HumanOmniExpress, HumanOmni1S and HumanOmni1M-Quad. We compared these replicates on basis of genotypes and copy number variants to evaluate technical artifacts arising from batch effects. We will present data on deviances arising from quality parameters (e. g. gentrain score, logR ratio, B -allele frequency, intensity, chemistry batches) and the implications thereof.

421F

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: Detecting Copy Number Variation in a multi-ethnic cohort of 100,000. *C. Sabatti[1], Z. Zhang[2], Y. Banda[3], M. Kvale[3], T. Hoffman[3], S. Hesselson[3], H. Tang[4], P-Y. Kwok[2], C. Schaefer[5], N. Risch[3,5]*. 1) Department of Health Research and Policy, Stanford University, Stanford, CA; 2) Department of Statistics, UCLA, Los Angeles, CA; 3) Institute of Human Genetics, UCSF, San Francisco, CA; 4) Department of Genetics, Stanford University, Stanford, CA; 5) Division of Research, Kaiser Permanente, Oakland, CA.

The Genetic Epidemiology Research Study on Adult Health and Aging (GERA) cohort includes genotype information on over 100,000 individuals. Four ethnic-specific Axiom arrays were used to perform genome-wide genotyping on these subjects, including substantial numbers of individuals of European, Native American, Latino and East Asian background. Copy Number Variant (CNV) specific probes were not included in the array design, but information about DNA copy number can still be obtained from the raw signals of the genotyping reaction. We developed methods for detecting copy number variation from these data, and present the results of two focused analyses aiming to estimate the frequencies of CN polymorphisms in the four ethnic groups under study and the frequency of large sporadic or rare copy number variant events. For the first analysis, we worked with a set of CNP regions documented in the Database of Genomic Variants (http://dgvbeta.tcag.ca/dgv/app/home?ref=NCBI36/hg18) and dbVar (http://www.ncbi.nlm.nih.gov/dbvar/) that were covered by at least 10 SNPs on the Axiom platform. We inferred copy numbers for subjects from each of the ethnic groups under study and compared the estimated CNP frequencies across populations. For the second analysis, we identified subjects likely to harbor large CNVs by screening homozygosity patterns. We further analyzed raw signal from the genotyping experiments to confirm the presence of CNVs. Finally, we linked the information on the identified CNPs and CNVs to the extensive health-related phenotypic information available on these subjects in association analyses to detect copy number relationships with a variety of disease and risk factor outcomes.

422W

Genomic copy number variation affects brain structure volumes in schizophrenia. *T.H. Wassink[1], J. Manak[2], D. Rudd[1], E. Epping[1], F. Fleming[1], G. Zeien[1], S. Ziebell[1], B.C. Ho[1], N.C. Andreasen[1]*. 1) Dept Psychiatry, Univ Iowa Col Med, Iowa City, IA; 2) Dept Biology, Univ Iowa Col Med, Iowa City, IA.

BACKGROUND: Genomic copy number variation (CNV) is an important source of susceptibility variation for schizophrenia, accounting for ~10% of cases. Effects of CNVs on deeper aspects of the schizophrenia phenotype, however, have not been extensively investigated. We focused on brain structure, hypothesizing that patients with schizophrenia and disease-susceptibility CNVs would have more severe brain tissue deficits than patients with schizophrenia without such CNVs. METHODS: We screened for CNVs using the Nimblegen 2.1 million probe genome-wide microarray in 174 individuals with schizophrenia from whom we had previously obtained structural magnetic resonance (MR) brain imaging data. We used the Nexus suite of analysis tools to identify CNVs from the array data. CNVs were called “abnormal” if they were either a) known disease CNVs or b) novel, affected genes, and were > 500kb if deletions or > 1MB if duplications. CNVs were called “likely deleterious” if they were novel, affected genes, and were > 50 kb. The effects of CNVs were tested on cerebral lobe gray and white matter volumes and on cerebro-spinal fluid volume using ANCOVAs with appropriate covariates. RESULTS: 15 (8.6%) of patients had disease-susceptibility CNVs and 18 (10.3%) had suggestive CNVs. These included known CNVs such as 15q11.2 and 1q21.1 deletions, and numerous novel CNVs. ANCOVAs showed that patients with suggestive and abnormal CNVs showed similar patterns of brain volume differences in comparison to the non-CNV cases. Taken as a group, patients with CNVs had decreased frontal GM ($F=4.66$, $p=0.03$), frontal WM ($F=4.35$, $p=0.04$), temporal GM ($F=7.41$, $p=0.007$), and temporal WM ($F=9.27$, $p=0.003$) volumes in comparison to non-CNV patients. DISCUSSION: These data show first that CNVs defined as likely to be deleterious were associated with patterns of brain structure deficits that were similar to CNVs defined as abnormal. Second, the CNV cases taken as a group show a characteristic pattern of brain structure deficits that is distinct from non-CNV cases and that may suggest a helpful approach to subgrouping schizophrenia cases.

423F

The use of matepair sequencing in the detection of structural variation in patients with ID and/or congenital anomalies. *S. Vergult[1], E. Van Binsbergen[2], T. Sante[1], S. Nowak[1], O. Vanakker[1], S. Janssens[1], K. Claes[1], B. Poppe[1], N. Van der Aa[3], F. Roelens[4], A. De Paepe[1], F. Speleman[1], E. Cuppen[2], W. Kloosterman[2], B. Menten[1]*. 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherla; 3) Department of Medical Genetics, UA, Antwerp, Belgium; 4) Heilig Hart Ziekenhuis, Roeselare, Belgium.

Background: Structural variations have been recognized as an important cause of intellectual disability and congenital malformations for many years. The past decade array CGH has emerged as the technique of choice for the detection of copy number variants in patients with ID and congenital malformations. Despite the many advantages of array CGH (much higher resolution and amenity for automation), it has two major drawbacks: it does not provide any information on balanced rerarrangements, nor does it provide information of the genomic architecture of duplications/insertions. With the advent of next generation sequencing, matepair sequencing capable of detecting both unbalanced as well as balanced aberrations has been developed.

Methods: Matepair sequencing was performed on 56 patients with a chromosomal phenotype. Of these, 36 patients were shown to have a structural rearrangement detected with conventional karyotyping and/or array CGH. Twenty patients with a normal array profile were included.

Results: In all patients for whom an unbalanced aberration was detected with array CGH, the aberration was confirmed by coverage analysis of the matepair sequencing data. For the detected duplications and complex rearrangements the genomic nature of the aberration was revealed by cluster analysis, except for those caused by LCR mediated NAHR. Balanced rearrangements were detected in six out of eight selected patients with (apparently) balanced aberrations. Due to the fact that one of the breakpoints resides in a highly repetitive region, the aberration was not identified in the remaining two patients. In the patients with a normal array profile, no balanced or unbalanced pathogenic aberrations were detected by matepair sequencing.

Conclusion: For the first time we show that matepair sequencing can be used in a diagnostic setting to detect structural variations. All unbalanced rearrangements identified by array CGH were confirmed by matepair sequencing and the main advantage over array CGH, the detection of (apparently) balanced aberrations, is also clearly underscored by this study. Nevertheless, in the patients with no detected aberrations by array CGH, no causal aberration was detected by matepair sequencing.

At the crossroads of structure and function: SNP genotypes indexed by copy number yield novel eQTLs. *L.K. Davis, E.R. Gamazon, N.J. Cox.* Section Genetic Medicine, The University of Chicago, Chicago, IL.

Current analysis methodologies used in genome-wide association studies (GWAS) (at any given autosomal locus) collapse the homozygous (i.e., A/A), hemizygous (i.e., A/0) and duplicative (i.e., A/A/A) genotype states. This approach assumes that these classes of genotype are equivalent and treats the genotype variable itself as a whole and single variable that does not contain components. However, the knowledge of large-scale copy number variation (CNV) throughout the genome clearly suggests that component complexity exists within the genotype construct. We developed a simple local covariate approach that incorporates CNV status of SNP genotype into a standard regression model with the resulting analysis yielding effect sizes and p-values for 1) SNP genotype, 2) CNV genotype and 3) copy number indexed SNP genotype. We applied this method to an expression quantitative trait loci (eQTL) analysis of HapMap lymphoblastoid cell lines (LCLs) and found that by properly accounting for allelic dosage at deletion sites we dramatically increased power to detect associations in genome wide analysis of eQTLs. Results remained robust after removing regions of the genome known to harbor significant copy number and eQTL complexity (e.g., HLA region). In total, the results yielded improved p-values for 8,172 eQTL SNPs. Moreover, 101 completely novel additional trans eQTLs, that did not reach statistical significance in a previous standard GWAS, were discovered. This finding carries with it implications for the analysis of all GWAS and suggests that at least some portion of missing heritability may be recovered by indexing SNPs according to copy number status.

Extensive genetic variation in somatic human tissues. *M. O'Huallachain[1,2], K.J. Karczewski[1,3], S. Weissman[4], A.E. Urban[1,5], M. Snyder[1].* 1) Genetics Department, Stanford University, Stanford, CA; 2) Department of Molecular, Cellular and Developmental Biology, Yale University,; 3) Biomedical Informatics Training Program, Stanford University School of Medicine, Stanford, CA; 4) Department of Genetics, Yale University, New Haven, CT; 5) Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA.

Genetic variation between individuals has been extensively investigated, but differences between tissues within individuals are far less understood. It is commonly assumed that all healthy cells that arise from the same zygote possess the same genomic content with a few known exceptions in the immune system and germ line. However, a growing body of evidence shows that genomic variation exists between differentiated tissues. We investigated the scope of somatic genomic variation between tissues within humans. Analysis of copy number changes by high-resolution aCGH in diverse tissues from six subjects reveals a significant number of intra-individual genomic changes between tissues. Many of these events affect genes. Our results have important consequences for understanding normal genetic and phenotypic variation within individuals, and they have significant implications for both the etiology of genetic diseases such as cancer, and for immortalized cell lines that might be used in research and therapeutics.

426W

Copy Number Variations in a cohort of Brazilian Sickle Cell Anemia Patients with and without Cerebrovascular Accident. *G. Ananina[1], F. Menaa[1,2], M.A. Bezerra[3], A.S. Araujo[3], P.R.S. Cruz[1], G.P. Gil[1], F.F. Costa[2], M.B. Melo[1,2].* 1) Mol Biol and Genet Eng (CBMEG), Universidade Estadual de Campinas (UNICAMP), Campinas, São Paulo State, Brazil; 2) Hematology and Hemotherapy Center, University of Campinas/Hemocentro-Unicamp (Campinas, São Paulo State, Brazil); 3) Hematology and Hemotherapy Center of Pernambuco/HEMOPE (Recife, Pernambuco State, Brazil).

Backgound - Sickle cell anemia (SCA) is a blood disorder caused by the homozygous state of a single point mutation in the beta globin gene resulting in an abnormal form of hemoglobin (HbSS). SCA is characterized primarily by chronic anemia, however, severity varies considerably among individuals. The present study aims to investigate the association of genetic factors, particularly copy number variations (CNVs), with cerebrovascular accident (CVA), one of the most severe complications in SCA patients. **Materials and Methods** - SCA patients with and without CVA were recruited at two Brazilian centers of hematology: Hemocentro (Campinas, SP) and HEMOPE (Recife, PE). Recruitment methods and blood collection were approved by the Ethics Committee of FCM-UNICAMP (Campinas/SP, Brazil). Genotyping protocol was carried out using Affymetrix® Genome-Wide Human SNP 6.0 Array (Affymetrix Inc., CA, USA) following manufacturer's recommendations. CNVs calling was performed with Affymetrix Genotyping Console software. Only samples that passed the recommended control values: contrast QC > 0.4; median absolute intensity pairwise differences MAPD < 0.3, were used in the analysis. **Results** - An exploratory analysis of distribution of copy number (CN) events was performed to compare CVA-affected (n=18) and non-affected (n=16) subjects. The analysis was applied to all autosomal CN events (gains and losses) larger than 1 kb. We observed the following distribution of CN events per individual in the affected and non-affect cohorts, respectively: *max* number - 1927/576; *min* number - 107/88; mean - 583/256. Hence, the total number of autosomal CNVs per individual were higher in CVA-affected individuals than in the non-affected cohort. The augment of CNVs observed in the CVA-affected cohort occurred primarily due to the increase in the number of relatively small CN events (of the size less than 100 kb). The group of affected individuals also demonstrated higher variance in the number of CN events. **Conclusions** - Pathophysiology of CNVs is still poorly understood and copy number genomic disbalance potentially can affect expression of dosage sensible genes thus influencing complex phenotypic traits. As the next step we plan to expand our sample size and refine the analysis. **Acknowledgments**: CNPq, Brazil (573780/2008-0, 151463/2009-3, 158367/2011-1); FAPESP, São Paulo, Brazil (2008/57441-0); Laboratório Nacional de Luz Síncrotron (LNLS), Campinas-São Paulo, Brazil.

Prevalence and effects of the obesity associated deletion on chromosome 16p11.2 in the Swedish Obese Subjects (SOS) study. *J.C. Andersson-Assarsson, S. Romeo, L. Sjöström, L.M.S. Carlsson.* Department of Molecular and Clinical Medicine and Sahlgrenska Center for Cardiovascular and Metabolic Research, Sahlgrenska Academy at Gothenburg University, Vita Stråket 15, 41345 Gothenburg, Sweden.

Common obesity results from a combination of environmental and genetic factors. Studies have shown a very high heritability, up to 70%, for many obesity-related traits, including BMI and body fat. Much effort has been made to identify candidate genes and gene variants in common obesity, with some notable successes such as the discovery of the *FTO* gene. However, the majority of the heritability remains to be explained. Copy number variants (CNV) explain part of this “missing heritability”. They are an important source of genetic variability between individuals and have been associated with normal phenotypic diversity as well as with common diseases, including obesity. We and others have previously identified a rare CNV (a deletion) on chromosome 16 that give rise to a highly penetrant form of obesity. The aim of this study was to determine the frequency of the deletion and to evaluate its effects on baseline characteristics in the Swedish Obese Subjects (SOS) study. The SOS study started in 1987 and is a prospective, controlled, intervention study involving 4047 obese individuals; 2010 individuals have undergone bariatric surgery and 2037 conventional treatment (matched control group). DNA was available for 3678 individuals (1835 surgery cases (548 males, 1289 females) and 1843 controls (548 males, 1295 females)). Using genotyping and MLPA, we identified 14 individuals carrying the deletion (0.4%). This frequency is somewhat lower than in our previous study. However, the deletion is also associated with autism, schizophrenia and developmental delay and since psychiatric disabilities were an exclusion criteria in SOS we believe this can account for the lower frequency compared to previous studies. Of the 14 carriers of the deletion (6 males, 8 females), 9 underwent bariatric surgery (4 males, 5 females). Compared to individuals not carrying the deletion, baseline characteristics of the carriers of the deletion differed in terms of anthropometry, metabolism and social factors.

Molecular study of the inverted repeats responsible for triplication of the PLP1 locus. *C.R. Beck[1], C.M.B. Carvalho[1], J.R. Lupski[1,2,3].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Pelizaeus-Merzbacher disease (PMD, MIM #312080) is most commonly caused by an increased dosage of the gene PLP1. Recently, the presence of duplication-inverted triplication-duplication (DUP-TRP/INV-DUP) structures for this region has been described, and triplication of PLP1 that is flanked by duplications has also been observed. The common feature of these complex genomic rearrangements is the presence of a pair of inverted low copy repeats (LCRs) presumably mediating the rearrangement, with one of the breakpoints located within the inverted LCRs. Although the hypothesized mechanism for formation of this complex structure is DNA replication fork collapse followed by microhomology mediated template switching (FoSTeS/MMBIR) and break-induced replication (BIR) at a region of ectopic homology, to date no formal experimental demonstration at the PLP1 locus has been performed. Therefore, we sought to further characterize the inverted repeats responsible for the formation of the structure of DUP-TRP/INV-DUP, as well as to obtain further insights into the molecular mechanism underlying such alterations. Our observations indicate that the LCRs that mediate the DUP-TRP/INV-DUP rearrangements have predisposed the region for inversion, which is highly prevalent in the human population. Indeed, the human genome structural variation track of the UCSC genome browser indicates that 8 of 9 individuals contain fosmids on which paired-end sequencing indicates that they carry inversions at this location. Therefore, the hypothesized breakpoint for the BIR event within the LCRs could occur at two different locations depending on the original structure of the region. We have implemented further experimental analyses elucidating the structure and sequence of the rearrangements within the LCRs for four patients with PMD who carry DUP-TRP/INV-DUP rearrangements.

Novel sequence-based CNV detection framework allows fine-mapping of the CFH region in 150 Chinese Singaporeans with Age-related Macular Degeneration. *E. Bellos[1], L. Coin[1], T.Y. Wong[2], C.Y. Cheng[2], G. Cheung[2], M. Hibberd[3], V. Kumar[3], S. Davila[3].* 1) School of Public Health, Imperial College London, London, United Kingdom; 2) Singapore Eye Research Institute, Singapore; 3) Genome Institute of Singapore, Singapore.

Copy Number Variation (CNV) is pervasive in the human genome and has been shown to play a causal role in genetic diseases. Recent advances in sequencing technologies have provided the means for identifying genomic variation at an unprecedented resolution. A single next-generation sequencing (NGS) experiment offers a multitude of features that can be used to extract CNV signatures. These features comprise read depth, read pair distance and split reads, and exhibit varying degrees of sensitivity for detecting different types of variants. Achieving a high sensitivity across the CNV spectrum requires taking into account the strengths and weaknesses of each feature and incorporating them into a unified model. Here we present cnvHiTSeq, an integrative method for CNV discovery and genotyping that jointly analyzes multiple features of sequence data at the population level. cnvHiTSeq utilizes a population-haplotype framework to incorporate diverse data sources into a single probabilistic model. An hidden Markov model is used to capture the spatial properties of CNV across a single chromosome copy. To account for sample-independent variation in the data, cnvHiTSeq uses the population distribution of measurements to update the parameters of the model. By organically combining evidence from multiple features, cnvHiTSeq achieves sensitive and precise discovery of all CNV classes even from low-coverage data. Using data from the trio and low-coverage phases of the 1000 Genomes Project, our method identified considerably more variants than competing methods, while maintaining a low false discovery rate (FDR). cnvHiTSeq detects ~80% of all CNVs greater than 100bp with a FDR of 4.3% (9.8%) for deletions (duplications). Our unified approach also benefits from population-level modelling to achieve a high CNV genotyping accuracy of 98.2%. We applied cnvHiTSeq to a cohort of 150 Chinese Singaporeans with Age-related Macular Degeneration (AMD). The cohort comprises high-coverage sequence data of the extended 200kb CFH region. Though previously associated with AMD, this region remains hard to characterize as it contains complex patterns of CNV. The high-resolution obtained by cnvHiTSeq allowed us to fine-map CNV in the region and elucidate its complexity. Thus, we have demonstrated that cnvHiTSeq offers a complete solution to sequence-based CNV detection and genotyping, aiming to further our understanding of CNV impact on disease and evolution.

Incidental copy-number variants identified by routine genome testing in a clinical population. *P.M. Boone, Z.T. Soens, I.M. Campbell, P. Stankiewicz, S.W. Cheung, A. Patel, A.L. Beaudet, S.E. Plon, C.A. Shaw, A.L. McGuire, J.R. Lupski.* Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA.

Purpose: Mutational load of susceptibility variants has not been studied on a genomic scale in a clinical population, nor has the potential to identify these mutations as incidental findings, i.e. not related to the patient's current diagnosis and contributing to the “incidentalome”, during clinical testing been systematically ascertained. Methods: We analyzed data from chromosome microarray analysis (CMA), a method for genome-wide detection of DNA copy-number variations (CNVs) including deletion and duplication mutations, performed on DNA from 9,005 patients, fetuses, and their family members. CNVs encompassing or disrupting single genes were identified computationally and analyzed for their potential to confer predisposition to dominant, adult-onset disease. Multi-gene CNVs affecting dominant, adult-onset cancer predisposition syndrome genes were also assessed. Results: Of 1,812 single-gene CNVs present in our cohort, 83 occurred in 40 unique genes associated with dominant, adult-onset disorders and unrelated to the patients' referring diagnoses (i.e. incidental). Fourteen (17%) of these mutations are likely disease-predisposing, 25 (30%) are likely benign, and 44 (53%) are of unknown clinical consequence. When incidental CNVs spanning up to 20 genes were considered, 27 CNVs affected 17 unique genes associated with dominant, adult-onset cancer predisposition syndromes. Conclusion: CNV mutations potentially conferring susceptibility to adult-onset disease can be identified as incidental findings during routine genome-wide testing. Some mutations in known disease genes may be medically actionable, enabling disease surveillance or prevention; however, most incidentally observed single-gene CNVs are currently of unclear significance to the patient.

Parental age and burden of genomic copy number variation. *J. Buizer-Voskamp[1], H.M. Blauw[2], M.P.M. Boks[1], KR. Van Eijk[1,3], J.H. Veldink[2], E.A.M. Hennekam[3], J.A.S. Vorstman[1], F. Mulder[3], H. Tiemeier[4,5], A.G. Uitterlinden[4,6], L.A. Kiemeney[7], L.H. Van den Berg[2], R.S. Kahn[1], C. Sabatti[8], R.A. Ophoff[1,9].* 1) Rudolf Magnus Institute of Neuroscience, Department of Psychiatry, University Medical Center Utrecht, The Netherlands; 2) Rudolf Magnus Institute of Neuroscience, Department of Neurology, University Medical Center Utrecht, The Netherlands; 3) Department of Medical Genetics, University Medical Center Utrecht, The Netherlands; 4) Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 5) Department of Child and Adolescent Psychiatry, Erasmus Medical Center and Sophia Children's Hospital, Rotterdam, The Netherlands; 6) Department of Internal Medicine, Erasmus Medical Center, Rotterdam, The Netherlands; 7) Department of Urology, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands;; 8) 11Department of Health Research and Policy, Stanford University School of Medicine, Stanford, California, USA; 9) Center for Neurobehavioral Genetics, University of California, Los Angeles, California, USA.

Genomic copy number variations (CNVs) and increased parental age are both associated with the risk to develop neuropsychiatric disorders. As advanced parental age is associated with increase of germline *de novo* mutations, we studied the relationship between parental age and various types of CNV burden in a large population sample (n=6 773) from The Netherlands. Analysis of global measures as well as proxies for *de novo* CNV events in this unique sample, however, did not support a correlation between parental age and CNV burden in the offspring. While it remains possible that local genomic effects may exist for specific phenotypes, our results strongly suggest that global CNV burden and advanced parental age are independent risk factors for psychiatric disorders.

Genome-wide analyses of recurrent genomic rearrangements - identification of three novel genomic disorders. *P. Dittwald[1,2,3], T. Gambin[4], P. Szafranski[1], J. Li[1], R.S. Amato[5], M. Divon[6], K. Maliszewski[6], E.E. Dolgado Bohorquez[7], L. Elton[8], A.C-H. Tsai[9], D. Scott[1], S.-H.L. Kang[1], A.M. Breman[1], S.R. Lalani[1], C. Bacino[1], W. Bi[1], A. Milosavljevic[1], J.R. Lupski[1], A.L. Beaudet[1], C.A. Shaw[1], A. Patel[1], A. Gambin[2,10], S.W. Cheung[1], P. Stankiewicz[1]*. 1) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX;; 2) Institute of Informatics, University of Warsaw, Warsaw, Poland; 3) College of Inter-Faculty Individual Studies in Mathematics and Natural Sciences, University of Warsaw, Warsaw, Poland; 4) Institute of Computer Science, Warsaw University of Technology, Warsaw, Poland; 5) Department of Medical Genetics, Eastern Maine Medical Center, Bangor, Maine; 6) Lenox Hill Hospital, New York, NY; 7) Instituto de Referencia Andino, Bogota, Columbia; 8) Clinical Genetics, Specially for Children, Austin, TX; 9) Molecular and Medical Genetics, OHSU, Portland OR; 10) Mossakowski Medical Research Centre, Polish Academy of Sciences, Warsaw, Poland.

Using bioinformatic approaches, Sharp et al. (2005) predicted the genome-wide occurrence of 130 genomic rearrangements between directly oriented paralogous low-copy repeats (LCRs) > 10 kb in size, of > 95% DNA sequence identity, and located between 0.05–10 Mb apart from each other. To date, approximately 40 nonallelic homologous recombination (NAHR)-mediated rearrangements have been described as microdeletion and microduplication syndromes. Several other regions are thought to be pathogenic but have yet to be fully characterized. We queried our chromosomal microarray analysis database of 24,021 patients, in which all LCR-flanked regions are interrogated. The most common recurrent CNVs in our database are *NPHP1* duplications (214, benign variant), *CHRNA7* duplications (175, likely pathogenic with incomplete penetrance), and 22q11.2 deletions (161, pathogenic). After subtracting ~ 75% of cases, in which parental studies were not available, we found that out of 178 de novo recurrent CNVs, the most frequent are deletions in the DiGeorge syndrome (45), 16p11.2 autism (27), and Williams-Beuren syndrome (11) regions. Further, we analyzed various DNA features to correlate with recurrent CNV frequencies and to identify the NAHR recombination sites. We also bioinformatically analyzed the remaining unknown genomic regions flanked by directly oriented LCRs. Here, we report three novel recurrent and likely pathogenic genomic rearrangements. An ~ 1.7 Mb deletion in 2q12.2q12.3 was found in patients with developmental delay (DD) and dysmorphic features. It harbors *ST6GAL2*, previously associated with schizophrenia, and was mediated by an LCR 18.4 kb in size with 98.98% DNA sequence identity. An ~ 0.6 Mb deletion of 2q12.3 in patients with moderate DD and dysmorphic features, which encompasses the *SLC5A7* gene (choline transporter) was mediated by a 25.1 kb LCR with 97.62% sequence identity. An ~ 1.5 Mb deletion in 2q12.3q13 containing the *EDAR* and *RANBP2* genes was detected in a patient with skeletal anomalies. Heterozygous mutations in *EDAR* have been reported in patients with ectodermal dysplasia (OMIM 129490) and *RANBP2* mutations are seen in patients with necrotizing encephalopathy (OMIM 608033). This deletion was mediated by a 29.2 kb LCR with 97.53% sequence identity. These studies further elucidate the importance of NAHR-mediated genome instability in human disease and have resulted in the identification and characterization of three novel recurrent genomic disorders.

433F

DUF1220 Domain Copy Number Loss Implicated in 1q21-associated Microcephaly. *L. Dumas[1], M. O'Bleness[1], J. Davis[1,2], C.M. Dickens[1], N. Anderson[1], J.G. Keeney[1], J. Jackson[1], M. Sikela[1], A. Raznahan[4], J. Giedd[4], J. Rapoport[4], S.S.C. Nagamani[3], A. Erez[3], N. Brunetti-Pierri[5], R. Sugalski[6], J.R. Lupski[3], T. Fingerlin[2], S.W. Cheung[3], J.M. Sikela[1]*. 1) Department of Biochemistry and Molecular Genetics, Human Medical Genetics and Neuroscience Programs, University of Colorado School of Medicine, Aurora, CO; 2) Department of Epidemiology, University of Colorado School of Public Health, Aurora, CO; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) National Institute of Mental Health, National Institutes of Health, Bethesda, MD; 5) Telethon Institute of Genetics and Medicine, Naples, Italy and Department of Pediatrics, Federico II University of Naples, Italy; 6) Brooke Army Medical Center, San Antonio, TX.

DUF1220 protein domains show the largest human lineage-specific increase in copy number of any protein coding region in the human genome and map primarily to 1q21, where deletions and reciprocal duplications have been associated with microcephaly and macrocephaly, respectively. Given these findings and the high correlation between DUF1220 copy number and brain size across primate lineages (R2=0.98; p=1.8 × 10-6), DUF1220 sequences represent plausible candidates to underlie 1q21-associated brain size pathologies. To directly investigate this possibility, we used specialized bioinformatics tools developed for scoring highly duplicated DUF1220 sequences to implement targeted 1q21 array CGH on individuals (N=42) with 1q21-associated microcephaly and macrocephaly. We show that of all 1q21 genes examined (N=53), DUF1220 copy number shows the strongest association with brain size among individuals with 1q21-associated microcephaly, particularly with respect to the three evolutionarily conserved DUF1220 clades, CON1, CON2, and CON3 (CON1, p=0.0079; CON2, p= 0.0134;CON3, p=0.0116034). Notably, all DUF1220-encoding genes belonging to the NBPF family show significant correlations with FOC Z-score in the deletion group. In a similar survey of 1q21 copy number differences in a non-disease population we show that DUF1220 copy number exhibits the strongest correlation with gray matter volume (CON1, p=0.0246; CON2, p= 0.0334019). When comparing the arrayCGH results for disease and non-disease populations, only the DUF1220 sequences are consistently significant in both groups. Taken together these data strongly implicate DUF1220 copy number loss in the etiology of 1q21-associated microcephaly and are fully compatible with the view that DUF1220 domains function as key general effectors of evolutionary, pathological and normal variation in brain size.

The adult human body is composed of cells that by mutations of different kind have become more or less genetically divergent. These during life acquired changes are referred to as somatic genetic variation and are to be distinguished from the well studied inherited genetic variation. Somatic variation can manifest, for instance, as various forms of cancer but is still often ignored in studies, despite it being predicted ubiquitous. We have recently shown that structural somatic genetic variation accumulates in blood with age and is common also in phenotypically normal cells and people (Forsberg et al. 2012 PMID: 22305530). In brief, we studied age-stratified cohorts of 318 monozygotic (MZ) twins and 296 single-born subjects using SNP-array, and described age-related accumulation of copy number variation (CNV) in the nuclear genomes in vivo. Large structural aberrations were found in 3.4% of subjects older than 60 years but not in younger controls. Recurrent region- and gene-specific mutations were observed. Longitudinal analyses suggested variation in the rate of accumulation of clones carrying structural changes and a natural self-removal of aberrant cell clones from blood. We also showed that different sub-compartments of blood could be affected differently by structural changes. Important disease-related aspects emerge from our results. For instance, we observed in phenotypically normal people, somatic aberrations typical for myelodysplastic syndrome, suggesting that these aberrations represent a sub-clinical form of this disease. Our results may also help explain the age-related reduction of cell clone complexity in blood: a well described hallmark of immuno-senescence and aging. The mutations we describe likely provide the affected cells with a mild proliferative advantage, without transforming them into immortalized cancer clones. However, the proliferative advantage of a few cell clones could affect the overall complexity of clones present in the blood. To further describe how somatic variation contributes to human aging and development of late-onset disease we are now analyzing a substantial number of elderly people using a higher-density SNP-array platform. These samples are collected longitudinally and preliminary results support our published data. Thus, we confirm that cell clones in blood of normally aging people carry large somatic aberrations in high frequency. The progress of our project and new data will be presented at the meeting.

435F

Genome-wide scan of Common Copy Number Variant Regions in Post-Traumatic Stress Disorder. *G. Guffanti[1], A. Aiello[2], M. Uddin[3], D. Wildman[4], S. Galea[5], K. Koenen[5]*. 1) Department of Psychiatry, Columbia University, New York, NY; 2) School of Public Health, University of Michigan, Ann Arbor, MI; 3) Department of Psychiatry & Behavioral Neurosciences, Wayne State University, Detroit, MI; 4) Center for Molecular Medicine and Genetics and Department of Obstetrics and Gynecology, Wayne State University, Detroit, MI; 5) Department of Epidemiology, Columbia University Mailman School of Public Health, New York, NY.

Post-Traumatic Stress Disorder (PTSD) is a common heritable neuropsychiatric disorder of unknown etiology. CNVs represent a specific form of genetic variation that is crucially relevant to integrate the information made available by SNP microarray technologies in studies of complex traits. Since CNVs can cover whole gene loci, CNV dose-related effects may have a strong impact on important biological functions, e.g. alterations of protein expression levels and disruption of coding regions. We investigated the genome-wide distribution of CNVs in subjects exposed to traumatic events who developed PTSD and subjects exposed to the same traumatic events who did not develop PTSD using the HumanOmniExpress BeadChip. Participants were recruited from the Detroit Neighborhood Health Study (DNHS), a longitudinal cohort of predominately African American adults (18+) living in Detroit, Michigan and screened for lifetime trauma exposure. PTSD was assessed using a modified version of the PTSD checklist, a 17-item self-report measure of DSM-IV symptoms. After data quality control, 748 subjects were analyzed: 136 cases of PTSD and 612 controls who were exposed to traumatic events who did not develop PTSD. We detected a total of 26,335 autosomal CNVs using PennCNV algorithm. After filtering for CNVs with segment size shorter than 20 Kb, we included in subsequent analysis 9,210 CNVs with an average of 10.5 segments per subjects in cases and 12.1 in controls (average size of 86 Kb). We found higher number of CNVs of relatively short length (< 20 Kb) in DNHS sample, which is consistent with findings that report smaller haplotype blocks in African Americans. The burden analysis revealed no significant differences in CNVs frequencies or size overall and by CNV type between cases and controls. Out of the 9,210 CNV, 7,757 clustered in 884 CNV-Regions across all individuals. Comparison with data downloaded from the Database of Genomic Variants (DGV) revealed substantial overlap between our CNVRs and entries of single CNVs in the DGV. Within the CNVRs, 2,336 CNVs identified in our sample are not overlapping with DGV-CNVs. Of the 884 CNVRs, 130 are regions of duplication events, 468 of deletions and 287 of both duplications and deletions. Approximately half (49%) of our CNVRs are found to affect genes. To our knowledge, this is the first study that provides a comprehensive map of common CNVRs in PTSD on genome-wide scale. Further analyses are warranted to validate current findings.

436W

Genetic variation among somatic cells revealed by single nucleus sequencing. *I.M. Hall[1,2], M.L. Lindberg[1], J. Piper[3,4], K.J. Brennand[4], F.H. Gage[4], M.J. McConnell[3,4]*. 1) Department of Biochemistry and Molecular Genetics, University of Virginia School of Medicine, Charlottesville, VA; 2) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 3) Crick-Jacobs Center for Theoretical and Computational Biology, Salk Institute for Biological Studies, La Jolla, CA; 4) Laboratory of Genetics, Salk Institute for Biological Studies, La Jolla, CA.

The extent to which somatic genome variation contributes to diseases other than cancer is an important and unresolved question in human genetics. This question has been extraordinarily difficult to study at the genome-wide level due to the relatively large input DNA requirements of second generation sequencing instruments and the difficulty of isolating clonally defined cellular lineages from human somatic tissues. Single nucleus sequencing (SNS) overcomes these limitations. Building upon protocols developed for tumor samples, we have implemented a high-throughput and cost-effective SNS method that employs flow sorting, cell barcoding and minimal DNA amplification, and that can identify DNA copy number variants (CNVs) at megabase resolution from individual nuclei. We have applied this method to various post-mortem and cultured somatic cells from healthy human individuals. We find a surprisingly high incidence of aneuploidy and large CNVs. But, we have also identified insidious artifacts related to DNA amplification. Finally, we present preliminary results from ongoing efforts to perform deep whole-genome sequencing and comprehensive variant detection from single somatic cells.

Structural haplotypes and recent evolution of the human 17q21.31 locus. *R.E. Handsaker[1,2], L.M. Boettger[1,2], M.C. Zody[1,3], S.A. McCarroll[1,2].* 1) Harvard Medical School, Department of Gentics, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Genome Sequencing and Analysis Platform, Broad Institute, Cambridge, MA.

Structurally complex regions of the human genome are not yet understood. Human 17q21.31 is a particularly interesting such locus: it contains a megabase-long inversion polymorphism and many complex, previously uncharacterized copy-number variations (CNVs); it associates with fertility, female meiotic recombination rate, and neurological disease; and it appears to be under selection in Europeans. To elucidate how complex genome structures vary in populations, we developed a population-genetic approach based on (i) accurate typing of structural features in large populations and (ii) phasing of these structural features using populations and families to determine structural haplotypes.

We identified nine distinct structural forms of 17q21.31 segregating in the human population, each distinguished by the gain, loss, or rearrangement of a large genomic segment (>100 kb) relative to each of the other structural forms. These nine structural forms suggest a phylogeny that offers a structural history of this rapidly evolving locus.

We find that five of these structural forms, including forms of both the H1 and H2 inversion types) involve partial duplications of the *KANSL1* gene (formerly *KIAA1267*). These duplications have arisen independently on the H1 and H2 forms of the 17q21.31 inversion polymorphism and both have subsequently risen to high frequency (26% and 19%) in West Eurasian populations, although nearly absent in other parts of the world. The haplotypes around these duplications coalesce to recent ancestors (< 40 kya), suggesting that the parallel expansions in frequency of these duplications were recent. Both duplications produce novel, truncated transcripts of the *KANSL1* gene, whose *Drosophila* ortholog regulates the timing of the differentiation of female germ cells.

Relating complex structural alleles to phenotype is important. We show that these complex, multi-allelic structural forms - often assumed to be poorly captured by SNPs - can in fact be imputed from SNP genotypes with high accuracy using either existing methods that support bi-allelic markers or emerging methods that can directly impute multi-allelic variants. These approaches allow complex genome structures to be efficiently related to human phenotypes using existing genome variation data.

Population genetics of haptoglobin and haptoglobin-related protein: 50 years of human copy number variation. *E. Hollox[1], A. Menard[1], F. Yang[2], B. Fu[2], M. Sironi[3], R. Hardwick[1,2].* 1) Department of Genetics, University of Leicester, Leicester, United Kingdom; 2) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 3) Scientific Institute IRCCS E. Medea, Bosisio Parini, Italy.

Haptoglobin, coded by the HP gene, is a serum protein that acts as a scavenger for free heme, and haptoglobin-related protein (coded by the HPR gene) forms part of the trypanolytic factor targeting ApoL1 to the surface of trypanosome pathogens. Recent genome-wide association studies have shown association of a SNP in the intron of HPR with total cholesterol levels, supporting previous studies suggesting a link between haptoglobin and the risk of myocardial infarction. In 1962, Oliver Smithies and others showed that a common polymorphism of haptoglobin (with alleles Hp1 and Hp2) was the result of an intragenic duplication, later determined to be 1.7kb in size. Some studies have associated the Hp2 allele with susceptibility to malaria but this remains controversial. We reasoned that analysis of the global distribution of alleles at these two CNVs, and analysing the genomic region for signatures of natural selection, might shed light on any putative pathogen selection pressure. Here were determine global allele frequencies of this polymorphism using the Human Genome Diversity Project panel, and place it in the context of flanking SNP variation. We also use the paralog ratio test, fiber-FISH and sequence-read depth analysis to characterise the rare duplication of the HPR gene, and show that is at a frequency of 15% in certain West African populations. We also examine the case for natural selection in response to pathogen pressure at both copy number variable loci.

439F

Microduplication in 5p15.33 including *CLPMT1L* and *TERT* genes identified in a patient with cleft lip and palate, cardiopathy and urogenital abnormalities. *G. Izzo[1], E.L. Freitas[1], A.C.V. Krepischi[2], D.R. Bertola[1], M.R.S. Passos-Bueno[1], C. Rosenberg[1].* 1) Geneticts and Evolutionary Biology Department, Instituto de Biociencias USP, Sao Paulo, Brazil; 2) CIPE, Fundação Antonio Prudente, A.C. Camargo Hospital, Sao Paulo, Brazil.

Cleft of the lip with or without cleft palate (CL/P) are common birth defects of complex etiology and may lead to deleterious effects on language and communication skills, as well as on the appearance, leading to psychological issues for patients and their families. A number of genomic regions have been associated with CL/P, and the discovery of new candidate risk factors is essential for prognosis, management, and genetic counseling. In addition, several cases of CL/P often appear associated with genetic syndromes that involve additional birth defects, including developmental delay and/or mental retardation. Here we describe a patient with syndromic CLP. The major phenotypical abnormalities include dysmorphic facial features, neuro-psychomotor and developmental delay, hyperactivity and attention deficit disorder, atrio-ventricular septal defect, cryptorchid testes and micropenis. Array-CGH analysis revealed a rare interstitial microduplication on chromosome 5p15.33 (chr5:1,062,209-1,364,929; GRCh37/hg19) of approximately 300 kb encompassing five Refseq genes, including *TERT*, *CLPMT1L* and three *SLC* family members. This chromosomal abnormality was confirmed by real-time quantitative PCR. The CLPMT1L protein has a major domain homology with a protein previousy associated with CLP due to triggering an apoptotic pathway. Furthermore, *CLPMT1L* overexpression appears to lead to increased aptosis in vitro. In addition, *TERT* gene mutations have also been previoulsy associated with cardiopathies. Thus, we suggest that this microduplication has a causative relation with the patient phenotype. We are the first group to report an association of the *CLPMT1L* gene with the CL/P phenotype.

Integration of microarray and NGS generated data for copy number analysis. *R. Keshavan, S. Verma, S. Shams.* BioDiscovery Inc, Hawthorne, CA.

High-throughput genomic data generation technologies produce massive amounts of data at ever increasing rates. One of the major scientific obstacles now is efficient analysis of this data to establish a better understanding of the underlying biology. Although the growing volume and higher density microarrays were a challenge to efficient analysis, Next-Generation Sequencing (NGS) technologies have complicated the problem by orders of magnitude. In this paper, we will explore a single dimensionality of the analysis issue that is related to efficient aggregation, integration and visualization of copy number data generated by microarrays as well as NGS instrumentation. We will discuss methods for estimating copy number data from exome and whole genome sequencing data and combining this data with previously generated array data. We will described the areas of commonality and differences of each platform and show how such integrated approaches might lead into better analysis results.

Comparative performance of three algorithms in detecting CNV associated with obesity and non-alcoholic fatty liver disease. *W. Li[1], J. Littrell[1], S. Gawrieh[2], M. Olivier[1]*. 1) Biotechnology and Bioengineering, Medical College of Wisconsin, Milwaukee, WI; 2) Division of Gastroenterology and Hepatology, Department of Medicine, Medical College of Wisconsin, Milwaukee, WI.

Our research explores the potential role of copy number variation (CNV) in obesity and non-alcoholic fatty liver disease (NAFLD). CNV, which may take the form of addition or removal of paralogous segments from a genome, has been shown previously to be associated with diverse disease phenotypes, but its role in obesity and its associated co-morbidities is unclear. To assess this effect of CNV on obesity, we screened a set of Affymetrix SNP6 chips generated from a sample of 753 individuals from 354 families who had BMIs ranging from 13.8 to 84.71. In addition, we included 147 samples from unrelated morbidly obese individuals (BMI>40) with or without NAFLD. We analyzed our Affymetrix SNP6 data with three algorithms to identify CNV: (1) Affymetrix Genotyping Console (AGC); (2) PennCNV; and (3) cn.FARMS. The output from each algorithm was subsequently compared to identify a set of loci corroborated by each analysis. Comparisons of the three genotyping-algorithms reveal potential biases in each method. Results to date indicate that AGC tends to report the greatest number of loci. However, approximately 70% of these were not corroborated by competing methods. AGC loci also have a greater average length (170 ± 130 Kb) than those detected by other methods, suggesting a performance bias with respect to especially lengthy paralogous segments. In contrast, PennCNV detected loci with a smaller average length (12 ± 31 Kb) and, overall, identified fewer loci that were not corroborated by other algorithms. Pathway analysis of the set of corroborated loci suggests that several detected loci are metabolically linked to obesity or potentially interact with such loci or their encoded products. Forthcoming analyses will characterize proteins encoded by previously unstudied loci to determine their metabolic roles and potential causal role in obesity and obesity associated phenotypes.

Increased Rate of Rare Genic Copy Number Variants in Parkinson's Disease Among Ashkenazi Jews. *X. Liu[1], C. Cheng[2], S. Kisselev[3], H. Mejia-Santana[2], E. Louis[1,2,4,5], L. Cote[2], H. Andrews[6], C. Waters[4], B. Ford[4], S. Frucht[1], S. Fahn[1], K. Marder[1,2,4,7], J. Lee[1,2,5,8], L. Clark[1,3,8]*. 1) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, College of Physicians and Surgeons, Columbia University, New York, NY, USA; 2) Gertrude H. Sergievsky Center, College of Physicians and Surgeons, Columbia University, New York, NY, USA; 3) Department of Pathology and Cell Biology, College of Physicians and Surgeons, Columbia University, New York, NY, USA; 4) Department of Neurology, College of Physicians and Surgeons, Columbia University, New York, NY, USA; 5) Department of Epidemiology, Mailman School of Public Health, Columbia University, New York, NY, USA; 6) New York State Psychiatric Institute, Data Coordinating Center, New York, NY, USA; 7) Department of Psychiatry, Columbia University Medical Center, NYC, NY, USA; 8) Center for Human Genetics, College of Physicians and Surgeons, Columbia University, New York, NY, USA.

Background: Copy number variation (CNV) has been associated with neuropsychiatric and neurodegenerative disease. In Parkinson's disease (PD) patients, rare large genomic duplications or deletions have been observed in *SNCA* (*PARK1*), *Parkin* (*PARK2*) and DJ1 (*PARK7*) and Tyrosine Hydroxylase (*TH*). To date, only one genome-wide case-control study has assessed the contribution of CNVs to familial PD in a North American dataset. Method: We conducted a genome-wide scan for CNVs in a case-control dataset of Ashkenazi Jewish (AJ) origin (268 PD cases and 178 controls). Illumina 610/660 chip raw intensity array data was normalized using GenomeStudio. CNV calls and quality control were generated by PennCNV. Global genome wide burden analysis of rare CNVs (≤1% in the dataset,≥100 Kb) and rare CNV region were analyzed by PLINK. Ingenuity Pathway Analysis software (IPA) was used to search for biological relationships among the genic CNVs and known Mendelian PD genes. Result: A total of 986 rare CNVs were observed in our dataset of 432 subjects. CNVs in the PD genes like *SNCA*, *PARK2*, *DJ-1*, *PINK1*, *LRRK2* and *TH* were not identified. Overall global burden analyses did not reveal differences between cases and controls in CNV rate, distribution of CNV or number of genes affected by CNVs. Overall deletions (total CNV size) (P=0.019) and large CNVs (P=0.046) with length≥500kb were found 1.4 fold and 1.24 fold respectively more often in cases than in controls. For rare CNV regions, global burden was elevated and a significant association between PD and ovostatin 2 (*OVOS2*) was observed (Chr11p11.21)(P=0.028). 7 male sporadic PD cases with overlapping heterozygous duplications at *OVOS2* were found(CNV length range: 118Kb-148Kb), but not in 171 controls. A total of 81 PD cases carried a rare genic CNV (single occurrence or <5 PD cases as a cut-off) that was absent in controls. The IPA network identified *ATXN3*, *FBXW7* in the same disease pathway as *PARK2* (*Parkin*), *CHCHD3* and *SDF4* as *SNCA*, *HSF1* and *KLC1* as *MAPT* and *MBD3* as *PARK7* (*DJ-1*). Conclusions: Our study suggests that deletions (total CNV size) and large deletions (≥500Kb) are more frequent in cases than in controls and are associated with increased risk in PD. *OVOS2* was found as a significant risk factor for PD in the AJ population. We observed an increased rate of sporadic (de novo) and recurrent rare genic CNVs in PD cases and IPA analysis mapped those genic CNVs to known Mendelian PD networks.

A Map of Copy Number Variation in Admixed Populations in Xinjiang. *H. Lou[1], S. Li[2], R. Fu[1], X. Pan[2], L. Jin[1,2], S. Xu[1].* 1) CAS-MPG PICB, Shanghai, China; 2) MOE IBS, Fudan, Shanghai, China.

Xinjiang, the largest Chinese administrative division, is geographically located in Central Asia and played an important role historically in connecting Eastern Eurasian (EEA) and Western Eurasian (WEA). However, human population genomic studies in this region have been largely underrepresented in similar efforts both worldwide and within China. Especially, copy number variations (CNVs), which cover a large portion of human genome and are expected to harbour considerable genetic diversity that could contribute to neurological diseases and complex traits, have never been explored in any of the ethnic groups residing in Xinjiang. Here we investigated CNVs in the three major ethnic groups including the Kazakh (KZK), Kirgiz (KGZ) and Uyghur (UIG) with Affymetrix Genome-Wide Human SNP Array 6.0. A total of 1,461 CNV regions have been identified in 131 samples representing the three groups, and more than 70% of the CNVs could be also found in either of Eastern Eurasian or Western Eurasian popualtions. Interestingly, all the three groups have shown increased heterozygous deletions and duplications at both population level and individual level, as an expected consequence of population admixture. The estimated ancestral proportions inferred based on biallelic CNVs for KGZ, KZK and UIG were 63:37, 65:35 and 45:55 (EEA:WEA), respectively. These results were consistent with genetic relationship revealed by principle component analysis and phylogenetic analysis, KZK was closer to EEA, UIG was closer to WEA and KGZ was in the middle. The deletion and duplication allele frequency in the three groups also followed an admixture pattern, that is, a mixture of ancestral allele frequencies weighted by their contribution. Finally we identified ancestry biased and population specific CNVs which are likely to be involved in adaptation to local environment. Our study provided a first genome-wide perspective of CNVs three major ethnic groups in Xinjiang which will be valuable for both evolutionary and medical studies.

Human CNVs and ultraconserved elements (UCEs): a rapid progression to mutual exclusivity. *R.B. McCole, C.Y. Fonseka, C.-T. Wu.* Department of Genetics, Harvard Medical School, Boston, MA.

Ultraconserved elements (UCEs) are genomic regions showing exceptionally strong and unexplained levels of DNA sequence conservation between related species. We have hypothesized that UCEs function as `copy counters,' helping genomes to maintain exactly the correct number of chromosomes and the right amount of genetic information. This model predicts that perturbations in the copy number of UCEs will be highly deleterious to the cell and, ultimately, to the individual. Early tests of the model examined the co-occurrence (overlap) of UCEs with copy number variants (CNVs) and segmental duplications (SDs) in the human genome. These studies demonstrated that the profiles of human CNVs and SDs are highly depleted for UCEs, thereby lending support to our model. We have now extended these studies to address the following questions: How quickly do UCEs become depleted from human CNV profiles? When does this depletion occur? Does it require one or more rounds of human reproduction? Using new sets of UCEs and the most recent datasets of CNVs, we find that depletion is rapid and does not necessarily involve passage through the germline. These findings show that UCE depletion from human CNV profiles is an ongoing phenomenon in current human populations, possibly occurring during development, thus propelling the study of ultraconservation into the realm of human disease, including cancer, where genome instability is common. Funding from R01 GM085169-01A1, to C.-T. Wu.

445F

Prediction of 3551 human haploinsufficient genes. *S. Meader, F. Honti, C. Webber.* MRC Functional Genomics Unit, University of Oxford, Oxford, United Kingdom.

Haploinsufficient (HIS) genes are those for which the absence of one fully functioning copy in a diploid organism causes an abnormality. Many genes with causative roles in human disease, such as neurodevelopmental disorders and cancer, are haploinsufficient. Thus, the identification of causative disease genes from among a patient's genetic variants may be greatly aided if we are able to reliably and sensitively identify first which genes in the human genome are haploinsufficient. We sought to score haploinsufficiency likelihoods for as many human genes as possible. As training data, we employed a previously published set of 301 known human haploinsufficient disease genes, and collated a second set of 1266 genes whose mouse orthologues, when knocked out in a hemizygous state, produce an abnormal phenotype. Haplosufficient (HS) genes were taken from common human copy number variable regions. We evaluated a range of functional and evolutionary properties for these genes. From an evolutionary perspective, we found that haploinsufficient genes evolve at a slow rate over short evolutionary distances ($p = 1.5 \times 10\text{-}4$), and are more likely to be retained as 1:1 orthologues over longer evolutionary distances ($p = 1.0 \times 10\text{-}10$). We observed that HIS genes are significantly more likely to be highly expressed in fetal tissues ($p = 0.017$), and tend to be expressed in a tissue specific manner. HIS genes were also significantly enriched for involvement in complex formation ($p = 1.0 \times 10\text{-}8$), and were enriched for a range of Gene Ontology categories. Using both publically available (STRING) and in-house functional linkage networks, we demonstrated that HIS genes cluster very strongly with other known HIS genes in these networks ($p < 1.0 \times 10\text{-}5$). We trained a Support Vector Machine on these characteristics to classify ~17,000 genes as either HIS or HS and to provide an associated likelihood. With our training set derived from orthologues of HIS mouse genes, we demonstrate a high degree of accuracy in our predictions (AUC = 0.948, previously published best AUC = 0.812), with the strongest single predictor being our in-house functional linkage network. Overall, employing our most conservative data set, we predict 3551 genes within the human genome to be HIS.

446W

Prioritization of copy number variation loci associated with autism from AutDB: An integrative multi-study genetic database. *I. Menashe, E. C. Larsen, S. Banerjee-Basu.* MindSpec, McLean, VA.

Copy number variants (CNVs) are thought to play an important role in the predisposition to autism spectrum disorder (ASD). However, their relatively low frequency and widespread genomic distribution complicates their accurate characterization and utilization for clinical genetics purposes. Here we present a comprehensive analysis of multi-study, genome-wide CNV data from AutDB (http://mindspec.org/autdb.html), a genetic database that accommodates detailed annotations of published scientific reports of CNVs identified in ASD individuals. Overall, this study included 4,926 CNVs in 2,373 ASD subjects from 48 scientific reports, encompassing ~2.12×10-9 bp of genomic data. Remarkable variation was seen in CNV size, with copy number gains (CNGs) being significantly larger than copy number losses (CNLs), ($P = 3\times10\text{-}105$; Wilcoxon rank sum test). Examination of the CNV burden across the genome revealed 15 loci with a significant excess of CNVs among ASD subjects ($P < 10\text{-}5$). Altogether, these loci covered 15,846 kb of the genome and contained 170 genes. Specifically, eight loci included ≥2 genes, six loci encompassed only one gene, and one locus (9p23) did not include any known genes. Interestingly, our analysis indicates that 15q11.2–13.3, a genomic region prone to chromosomal rearrangements of various sizes, contains three distinct ASD susceptibility CNV loci that vary in their genomic boundaries, CNV types, and inheritance patterns. We anticipate that the results of our analysis will promote the clinical utility of these 15 loci and facilitate future investigation into the underlying mechanism of CNVs in ASD susceptibility.

Copy Number Variant analysis in a deeply phenotyped cohort of individuals with Intellectual Disability. *E. Mercier[1,2], Y. Qiao[3], J. Gillis[2], S. Lewis[4], E. Separovic[3], P. Pavlidis[2]*. 1) Graduate Program in Bioinformatics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Department of Psychiatry and Centre for High-Throughput Biology, University of British Columbia, Vancouver, British Columbia, Canada; 3) Department of Pathology, University of British Columbia, Vancouver, British Columbia, Canada; 4) Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada.

The goal of our project is to gain insight into phenotypic variability as it relates to features of copy number variants (CNVs) such as their number, type (unique or common), size, gene content and position. We analyzed a cohort of 64 individuals with idiopathic intellectual disability (ID). Thirty three subjects had unique CNVs (de novo or rare familial) while 31 had only common CNVs. In agreement with previous work, de novo CNVs were larger ($p= 1.5\times10^{-8}$) and encompassed more genes ($p= 8\times10^{-9}$) than common CNVs. In our cohort, unique CNVs were preferentially found within 5Mb of chromosome ends ($p<0.001$). An analysis of Gene Ontology categories for the de novo or non-commons CNVs did not provide substantial insight into functional commonalities linking the CNVs. In our preliminary analysis we used 9 coarse phenotype categories: abnormalities of prenatal and early postnatal development (systemic congenital abnormalities, birth and neonatal), facial dysmorphism, abnormalities of brain, extremities, skin, trunk, reproductive system as well as neurological abnormalities. To take an unsupervised multivariate approach to discovering patterns in the phenotype data, we applied K-means clustering. The optimal number of clusters was two (Calinsky criterion), which were designated Group 1 (31 individuals) and Group 2 (33). Features which distinguished these groups ($p<0.01$) included prenatal and systemic congenital abnormalities, birth and neonatal abnormalities, all which were enriched in group 1. However, there was no significant association of CNV features (e.g., de novo vs. common) with either group. Further analysis using all 97 fine phenotype entries as well as gene content analysis of the CNVs and their association with specific patterns of phenotype and/or gene pathways is under way.

448W

A novel susceptibility gene, UGT2B17, is associated with familial Ankylosing Spondylitis. *D. O'Rielly[1], M. Uddin[1], R. Inman[2], D. Gladman[2], W. Maksymowych[3], R. Yazdani[1], P. Rahman[1]*. 1) Faculty of Medicine, Memorial University, St. John's, Newfoundland, Canada; 2) University of Toronto, Toronto, Ontario, Canada; 3) Department of Medicine, University of Alberta, Edmonton, Alberta, Canada.

Ankylosing spondylitis (AS) exhibits a strong genetic predisposition that is only partially accounted for with SNP-based associations. To date, no structural variations such as copy number variations (CNVs) have been reported to be associated with AS. Our primary objective was to identify highly penetrant, novel CNVs associated with familial AS by employing a custom designed genome-wide microarray. We applied our custom microarray comprised with 2 × 1 million probes targeting rearrangement hotspots with a mean spacing of 280 bp on a large multiplex three generational Caucasian AS family of Northern European Ancestry. This family consisted of five (5) individuals affected with AS, two members with systemic lupus erythematosus (SLE), and three unaffected family members. An ethnically-matched control was used for hybridization. At least five (5) probes were required to call an aberration with an average intensity >0.25 for a duplication and <-0.25 for a deletion. For CNV's identified using the microarray, independent validation was carried out using quantitative PCR (qPCR) following Taqman assay protocols. Microarray analysis revealed complex rearrangements within AS patients in multiple regions that were absent in unaffected family members. The most compelling evidence for structural variation was for the UGT2B17 gene. Duplication of the UGT2B17 gene was present in all five (5) patients with AS (two males and three females) and in the family member diagnosed with SLE. This genomic gain was absent in unaffected family members. Validation using qPCR demonstrated complete concordance with the microarray results and revealed that all five (5) AS individual contains ≥2 copies of UGT2B17, whereas unaffected family members had only one copy. The population distribution among Caucasians of the UGT2B17 CNV is 0.15 for a deletion, 0.45 for one copy and 0.25 for two or more copies. The UGT2B17 gene encodes a key enzyme responsible for glucuronidation of androgens which can stimulate bone formation. Interestingly, deletion of UGT2B17 has been associated with osteoporosis, but this has not been replicated in an independent study. Given the proposed function of this gene in stimulating bone formation, it represents a high priority susceptibility gene in familial AS. Replication studies and further functional studies are warranted.

449F

Evolution of copy number variation in the rhesus macaque β-defensin region. *B. Ottolini[1], T. Schwarzacher[2], C.L. Bevins[3], J.V. Solnick[3], G. Doxiadis[4], E.J. Hollox[1]*. 1) Department of Genetics, University of Leicester, Leicester, United Kingdom; 2) Department of Biology, University of Leicester, Leicester United Kingdom; 3) Department of Microbiology and Immunology, School of Medicine, University of California, Davis CA; 4) Department of Comparative Genomics & Refinement, Biomedical Primate Research Center, Rijswijk, Netherlands.

Beta defensins are multifunctional secreted short peptides: they present antibacterial and antiviral action in many species, possess immune cell signal activity in humans, recruiting immature dendritic cells to infection sites, and control coat color in dogs and presumably in cattle. In humans the β-defensin region is known to be copy number variable (CNV) and contains six genes repeated as a block, with a diploid copy number between 1 and 12 and an approximate repeat length of 2.5 Mb. Although genome-wide comparative genomic hybridisation arrays (aCGH) provided evidence of this region also being CNV in chimpanzee and macaque, the extent and nature of CNV in different mammals remains unknown. The rhesus macaque (*Macaca mulatta*) is the most widespread non-human primate and represents a good model for immunity studies. Its genome has been sequenced, although there is poor assembly quality in repeated segments such as the β-defensin region. For all these reasons, we studied the genomic architecture of the rhesus macaque -defensin region using a variety of methods. We performed high-resolution aCGH on 16 non-related macaque individuals, PCR-based methods (Paralogue Ratio Test and microsatellite assay) on a cohort of 70 samples, and metaphase spread FISH and fibre-FISH on lymphoblastoid cell lines from 5 related individuals. Combining these approaches, we aimed to overcome the limitations of the assembly and to define an absolute copy number for this region in rhesus macaque. We present here preliminary results showing that only the region containing the human DEFB4 (DEFB2L) orthologue is CNV, while the rest of the genes show no variation. The repeated block encompasses only 8.5kb, considerably smaller than that found in humans, and this will be discussed in an evolutionary context. Also, we will present how the combined use of PCR-based and cytogenetic approaches allows absolute copy number calling and may be applied to other mammalian species to give insight into the genomic evolution of the β-defensin region.

Characterization of copy number variation involving the salivary agglutinin gene *DMBT1*. *S. Polley[1], D. Hains[2], E. Hollox[1]*. 1) Department of Genetics, University of Leicester, Leicester, Leicestershire, United Kingdom; 2) Nationwide Children's Hospital, Columbus, Ohio, USA.

Salivary agglutinin encoded by the gene *DMBT1* is a multifunctional protein with roles in innate immunity, regulation of inflammation and cell differentiation. The central region of *DMBT1* contains locus specific tandem repeated scavenger receptor cysteine-rich (SRCR) domains which bind to a broad spectrum of Gram-positive and Gram-negative bacteria as well as viruses. The main objective of the study was to characterize the copy number variation involving the DMBT1 gene. We have developed a cost effective, high throughput and easily reproducible PCR-based copy number typing system using the paralog ratio test (PRT) for estimating the exact copy number of SRCR domains in the *DMBT1* gene of different people. We validate that this method is accurate and precise when compared to array CGH and long-range PCR. The SRCR copy number estimation in different populations provides the pattern of genetic variation in SRCR domain of *DMBT1*. A worldwide analysis of SRCR copy number shows a high frequency of high SRCR copies in Africa and America and high frequency of low SRCR copies in East Asia, South Asia and Oceania. We are currently comparing copy number between healthy individuals and patients will help us to explain the genetic contribution of *DMBT1* (mainly SRCR copy number) to common inflammatory and infectious diseases.

Single exon deletion in *PCCA* gene in patient with Propionic Acidemia highlights challenges to clinical whole exome CNV analysis. *G. Scharer[1,2], G. Creadon-Swindell[2], E. Spector[2], C. Coughlin[1], T. Shaikh[1,3]*. 1) Dept. of Pediatrics-Division of Clinical Genetics & Metabolism, University of Colorado Denver SOM, Aurora, CO; 2) DNA Diagnostic Laboratory, Dept. of Pediatrics- Division of Clinical Genetics & Metabolism, University of Colorado SOM, Aurora, CO; 3) Colorado Intellectual and Developmental Disabilities Research Center, University of Colorado SOM, Aurora, CO.

The application of oligonucleotide arrays (aCGH) for the detection of genomic copy number variation (CNV) has become accepted clinical practice. This can include comprehensive whole-genome arrays that also cover exons of known disease genes, or those with dense, targeted coverage of selected genes. The latter type of arrays is especially useful to identify exonic deletions in autosomal recessive disorders, where standard sequencing has found only 1 disease causing mutation. Identification of a small CNV is typically based on a defined gain or loss in signal (log2) ratios of several consecutive probes by software analysis. Reporting threshold is generally set arbitrarily at 5 probes to decrease number of false positives, while accepting a decrease in sensitivity. Here we report the case of a patient identified by biochemical testing with propionic academia (PA), who was found with one point mutation only by Sanger sequencing in the *PCCA* gene. Subsequent targeted exonic deletion testing by aCGH utilizing a custom 135k oligonucleotide array (a minimum of 3 probes are placed in each exon) did not identify an exonic deletion after data analysis utilizing two commercial software packages at standard settings. Only after manual review a possible heterozygous 3 probe deletion was noted in exon-4 of the *PCCA* gene. Due to the small size of exon-4 (69 bp) and a relatively large intron-4 (43 kb) only 3 probes covered this coding region. Of note, the 3 probes in the adjacent exon-3 (48 bp) did not show loss of signal. Follow-up testing utilizing qPCR (Dual Realtime-PCR) did verify the heterozygous deletion of exon-4 in the patient, and hence confirmed the diagnosis of PA. This case highlights common difficulties in array design, but also the analytical challenges in identifying very small copy number variants in coding sequences. Simply lowering the reporting threshold to 3 or less probes would create too many false positives hits and make verification impractical. While manual review is possible in targeted CNV analysis (gene panels or single genes with a single point mutation), it is virtually impossible for arrays designed for whole exome/genome analysis. In addition to considering denser probe coverage in coding regions, coverage needs to be extended into intronic sequences, thus requiring high-density arrays carrying 1–2 million probes, i.e. for whole exome CNV analysis.

Identifying Autism Loci using Homozygosity Analysis and Copy Number Variation Analysis. *K.E. Schmitz-Abe[1,2,5], T.W. Yu[1–6], T.K. Kim[9], R.S. Hill[1–3,5], E.M. Morrow[4,7,8], M.E. Greenberg[5], K. Markianos[1,2,5], C.A. Walsh[1–6]*. 1) Division of Genetics, Department of Medicine, Children's Hospital Boston, Boston, Massachusetts, USA, 02115; 2) Manton Center for Orphan Disease Research, Children's Hospital Boston, Boston, Massachusetts, USA, 02115; 3) Howard Hughes Medical Institute, Children's Hospital Boston, Boston, Massachusetts, USA, 02115; 4) The Autism Consortium, Boston, Massachusetts, USA, 02115; 5) Harvard Medical School, Boston, Massachusetts, USA, 02115; 6) Department of Neurology, Massachusetts General Hospital, Boston, Massachusetts, USA, 02114; 7) Department of Molecular Biology, Cell Biology and Biochemistry, Brown University, Providence, Rhode Island, 02912; 8) Department of Psychiatry and Human Behavior, Brown University, Providence, Rhode Island, 02912; 9) UT Southwestern Medical Center 5323 Harry Hines Boulevard Dallas, Texas 75390.

Analysis of large Autism data sets has provided statistical and functional evidence for the role of rare deleterious variants, point mutations as well as copy number variants (CNVs). Although such lesions explain only a few percent of Autism Spectrum Disorders (ASD) they provide valuable insights in the diverse developmental errors that lead to ASD. Here we present strong statistical evidence for a mechanism rarely implicated before in ASD: copy number 0 CNVs (homozygous deletions). We performed CNV analyses in 213 consanguineous families from the Middle East (258 affected individuals, 552 unaffected individuals) using Affymetrix 6.0 and 500K SNP arrays, using five algorithms (Birdsuite, PennCNV, Affymetrix Genotyping Console, Nexus and Golden Helix) and requiring concordance of at least two calls. To distinguish between common and rare copy number events, we compiled a CNV catalog of 1,258 samples from the International HapMap project using the same analysis pipeline. Applying this pipeline to our dataset, we observe an excess of rare, homozygous deletions (p=0.008) in cases versus controls. This enrichment remains significant after controlling for overall homozygosity in cases vs. controls (p=0.02). The 27 homozygous deletions in 24 cases delete exons (13/27), just introns (3/27) or are apparently non-coding (11/27). Currently we are testing whether CNV0 events are present and play a similar role in the Autism Genetic Research Exchange (AGRE) Collection (1,258 affected, 1,746 unaffected) where homozygosity is much reduced but the sample size is much higher. Functional analysis of a large, previously reported CNV0 deletion near NHE9, (a gene that shows excess rare mutations in epilepsy and autism cases compared to controls) suggests that the deletion removes key regulatory sequences for NHE9 (Morrow et al, 2008). ChIPseq analyses reveal that mouse NPAS4 and CBP, transcriptional factors implicated in neuronal activity and contextual learning, are recruited by neuronal activity to bind sequences upstream of NHE9; human sequences orthologous to these binding sites are deleted by the previously reported CNV0 in this region, providing a biological mechanism by which this deletion likely disrupts the regulation of NHE9 expression by neuronal depolarization. Supported by the NIMH, NINDS, the Simons Foundation, and the HHMI.

Rare Exonic Deletions Contribute to Autoimmune Diabetes Susceptibility. *C. Shtir[1], D. Smith[1], H. Guo[1], J. Barrett[2], M. Hurles[2], N. Walker[1], V. Plagnol[3], J. Cooper[1], J. Howson[1], O. Burren[1], S. Rich[4], J. Todd[1]*. 1) JDRF/WT Diabetes & Inflammation Lab, Cambridge Inst Medical Research, Cambridge, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, UK; 3) University College London, London, UK; 4) University of Virginia, Charlottesville, VA, USA.

In this study we investigate rare deletions (DELs) in individuals diagnosed with type 1 diabetes (T1D) by analyzing 6,808 T1D cases, 9,954 controls, and 2,206 T1DGC families, genotyped on the high density ImmunoChip (iChip) array. Investigation of LRR distributions allowed correction of batch effects through principal components analysis (PCA). CNV calls were estimated based on PCA-corrected LRRs with PennCNV. We examined the burden of rare DELs at the iChip level, for all rare, genic, and exonic DELs, respectively. Based on candidate gene and GWAS studies we also examined 53 genomic regions that most convincingly implicate loci that alter T1D risk. Case-control Study: The median size of rare DELs across the iChip was 11kb for either cases or controls, and there was no correlation between gene-SNP density and number of rare DELs per gene (R2 = 0.05). We detected an excess of 4.2% case DELs at the 200kb threshold, with 12.5% case DELs vs. 8.3% control DELs [OR(CI)=1.77 (1.32,2.39);P=9.84E-05]. Rare DELs produced case-control ORs ranging from 1.24 to 1.35 (P=1.11E-04 to 2.65E-04) across the iChip, and from 1.51 to 2.33 in T1D regions (4.47E-07 to P=8.29-05), depending on whether all, genic, or exonic, rare DELs were studied. Non-T1D regions gave on average an OR of 1.1 (P>0.1). T1D regions remained significantly enriched, after 100K permutations from regression analysis with adjustment for gene size, DEL frequency and length. Family Cohort: T1D families reflect a different ascertainment from the case: control study, as affected offspring innately bear a stronger HLA heritability component. Affected offspring revealed a similar rare DEL load as the unaffected parents, at the iChip level and within T1D regions. However, 7.48% vs. 4.86% affected vs. unaffected offspring carried rare de novos [OR(CI)=1.58(1.07,2.41);P=1.91E-02], while transmitted DELs were detected in 19.37% vs. 17.29% affected vs. unaffected offspring [OR=1.14(0.91,1.45);P=2.4E-01]. These findings suggest that when de novo DELs arise in T1D offspring, they occur within an already compromised genetic background, surpassing a liability threshold beyond which an additional deleterious de novo mutation may predispose to T1D. Our results indicate a major new source of variation: rare, short, gene-disrupting CNVs for T1D and probably other common diseases, and highlight the necessity to analyse other diseases for which large numbers of samples have been typed using dense marker or probe arrays.

An atypical microduplication overlapping the C2orf27A gene at 2q21.1 co-segregates with Tourette Syndrome in a three generation family. *M. Uddin[1], D.D. O'Reilly[1], P. Rahman[1], T.R. Purchase[2], H. White[2], S. Luscombe[3], S.J. Moore[3], T.L. Young[1], K.A. Hodgkinson[1]*. 1) Faculty of Medicine, Memorial University, St. John's, Canada; 2) Pediatric Psychiatry, Health Sciences Centre, St. John's, NL, Canada; 3) Pediatric Development and Rehabilitation, Health Sciences, St. John's, NL, Canada.

Tourette syndrome (TS) is a developmental neuropsychiatric disorder characterized by the presence of both motor and verbal tics. TS may be accompanied by features associated with obsessive compulsive disorder (OCD), attention deficit hyperactivity disorder (ADHD) and poor impulse control. The general population prevalence of TS is between 0.3–1% and affect males more than females. It has a major genetic component with concordance rates for monozygotic and dizygotic twins estimated at 50–70% and 10–23% respectively. Despite numerous linkage and association studies no strong common candidate genes have been identified. Recent analysis of copy number variations (CNV) in TS show an association with genes previously implicated in autism although none have been reported unique to TS. We have begun an epidemiological study of families with TS in Newfoundland, and have ascertained one multiplex family. Five family members have been clinically diagnosed and the 6th is potentially affected (by collateral family history). The family includes four young siblings, their mother and maternal grandfather. Three of the siblings are significantly affected with concomitant OCD, ADHD and anxiety. The fourth has TS with fewer co morbidities. We designed a custom array CGH targeting genomic hotspots prone to rearrangements. The high density array included 2 × 1 million probes targeting regions with a mean spacing of 270bp. We found a common ~30kb microduplication overlapping the C2orf27A gene at 2q21.1 that co-segregates with the six affected family members. The atypical duplication breakpoint is 80kb larger in the three siblings with significant comorbidities. The fourth sibling, mother and grandfather have the smaller microduplication. The function of the C2orf27A gene is currently unknown. In summary, we have identified a CNV that co-segregates with Tourette syndrome in a multiplex family. The importance of this and other disease-associated CNVs to Tourette (and associated syndromes) pathogenesis is being explored by ascertaining other multiplex families from the Newfoundland population.

Detection of Copy Number Variation from Exomes in the DDD and UK10K Projects. *P. Vijayarangakannan, T. Fitzgerald, C. Joyce, S. McCarthy, M. Hurles, The DDD and UK10K projects.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Large-scale targeted-resequencing projects have become routine in studies that involve large sample sizes not only due to their cost and technological efficiency, but also to extend the analysis easily to a wider range of genetic abnormalities. The DDD (Deciphering Developmental Disorders) project and the UK10K project are two studies in the UK that aim to sequence thousands of individuals using whole-exome sequencing approaches. The DDD project aims to advance clinical genetic practice for children with developmental disorders through systematic development and application of latest microarray and next-gen sequencing methods. Starting from April 2012, the project aims to recruit 12,000 families in three years through the National Health Service Regional Genetics Services in the UK. The UK10K project aims to study diseases in 6000 patients caused by rare genetic changes in the human genome. Copy Number Variation (CNV) in the human genome has been implicated in a range of developmental disorders. Here, we report CoNVex, a novel algorithm for the detection of CNV from targeted-resequencing data. CoNVex utilises the read depth information in probe regions, compares it to a reference (median depth across samples) and detects copy number variable segments within the log2 ratio (of depth over median depth) using an error-weighted score and the Smith-Waterman algorithm. We have applied this to exome data from 230 DDD patient-parent trios. The DDD exome plus design includes probes that are used in the Agilent SureSelect 50Mb library in addition to custom probes. We evaluate the algorithm using the same samples for which exon-resolution aCGH and SNP array data are available for validation. We also compare our method to other exome-CNV calling algorithms. Our results show that CNV calling from exome data can have comparable resolution to single-chip aCGH for calling genic CNVs with high sensitivity and specificity.

Alterations in *RBFOX1*: Real finding or red herring? *L. Walters[1], A. Bailes[1], L. Erdman[1], A. McKinney[1], S. Ramsey[1], C. Weber[1], S. Hashimoto[1], L. Lamb Thrush[1,2], J. Atkin[2,3], G. Herman[2,3], S. Hickey[2,3], K. Manickam[2,3], C. Crowe[4], S. Thomas[5], C. Astbury[1,6], J. Gastier-Foster[1,2,6], S. Reshmi[1,6], R.E. Pyatt[1,6]*. 1) Department of Pathology and Laboratory Medicine, Nationwide Children's Hospital, Columbus, OH; 2) Department of Pediatrics, The Ohio State University, Columbus, OH; 3) Division of Molecular and Human Genetics, Nationwide Children's Hospital, Columbus, OH; 4) Division of Clinical Genetics, MetroHealth Medical Center, Cleveland, OH; 5) Center for Child Development, Wood County Hospital, Bowling Green, OH; 6) Department of Pathology, The Ohio State University, Columbus, OH.

RBFOX1/A2BP1 (OMIM 605104) encodes an RNA-binding protein with six isoforms that regulate splicing in a tissue-dependent fashion. It was first identified as a binding protein of ATXN2, suggesting a role in neurologic function. RBFOX1 is highly expressed in the brain, skeletal muscle, and the heart. Studies in mice have demonstrated a dynamic role for RBFOX1 in regulating neuronal excitation and calcium homeostasis, and knockouts are prone to spontaneous seizures. In humans, translocation-based alterations, which disrupt regulatory regions of the locus, produce a variable phenotype including developmental delay (DD), seizures, and mild dysmorphisms [Bhalla et al. 2004; Martin et al. 2007]. Smaller alterations, including both gains and losses, have been found in association with a variety of neuropsychiatric disorders, including ADHD, schizophrenia, autism, and DD [Elia et al. 2010; Xu et al. 2008; Sebat et al. 2007; Mikhail et al. 2011]. We present a series of 11 cases ascertained between 2009–2012 that showed copy number changes in the *RBFOX1* locus by array CGH. The alterations, both gains and losses, ranged in size from 50 kb to 970 kb and clustered around the third intron of the largest isoform. Most patients displayed neurologic dysfunction, including DD, behavioral problems, and ADHD, along with a highly variable degree of physical dysmorphism. In addition, several cases presented with congenital heart defects. The most severe of these had dextrocardia, single ventricle with double inlet left ventricle, and situs invertus abdominalis. This case is similar to a published report of an infant with dextrocardia, single ventricle, and situs solitus, along with other malformations, with an intragenic deletion of *RBFOX1* [Lale et al. 2011]. Previous studies have demonstrated that disrupting the first exon and intron of the long isoform causes decreased expression of all isoforms [Martin et al. 2007]. However, the impact of disrupting more distal introns has not yet been established. Unfortunately, evidence from the International Standards for Cytogenomic Arrays supporting dosage sensitivity for *RBFOX1* is lacking. Given the clustering of our array findings and the persistent, albeit variable, neurological phenotype, which is consistent with previously published reports, we conclude that alterations in *RBFOX1* may be a susceptibility factor for neuropsychiatric disease, although its role in congenital heart defects has yet to be established.

Analyses of copy number variation reveal putative susceptibility loci in MTX-induced mouse neural tube defects. *JH. Wang[1], XW. Wang[1], T. Guan[2], Q. Xiang[3], MS. Wang[3], Z. Zhang[3], Z. Guan[1], GL. Wang[1], ZQ. Zhu[1], Q. xie[1], GN. Li[1], J. Guo[1], F. Wang[1], ZG. Wang[3], B. Niu[1,2], T. Zhang[1].* 1) Department of biotechnology, Capital Institute of Pediatrics, Beijing, China; 2) Department of Biochemistry and Molecular Biology, Shanxi Medical University, Taiyuan, China; 3) Chinese Academy of Medical Sciences, Peking Union Medical College, Beijing, China.

Copy number variations (CNVs) are thought to act as an important genetic mechanism underlying phenotypic heterogeneity. Impaired folate metabolism is considered to be a risk factor for neural tube defects (NTDs). However, the precise nature of this link between low folate status and NTDs remains unclear. Using an array-comparative genomic hybridization (aCGH) assay, we investigated whether CNVs can be detected in the NTD embryonic neural tube tissues of of methotrexate (MTX)-induced folate dysmetabolism pregnant C57BL/6 mice, and validated the aCGH findings by RT-PCR. Prior to performing the experiments, this study was reviewed and approved by the ethic evaluation committee of Capital Institute of Pediatrics, Beijing, China. The CNVs were then comprehensively investigated by informatics methods for prioritize candidate genes. Dihydrofolate reductase (DHFR) activity of maternal serum was detected, and the concentrations of folate and relevant metabolites were analyzed using LC/MS/MS. Three high confidence CNVs on XqA1.1, XqA1.1-qA2 and XqE3 were found In the NTD embryonic neural tissues. DHFR activities, 5-methyltetrahydrofolate (5-MeTHF), 5-formyltetrahydrofolate (5-FoTHF) and S-adenosylmethionine (SAM) concentrations of maternal serum decreased significantly after MTX injection. Twelve putative genes and three microRNAs were selected as the candidates for susceptibility to MTX-induced NTDs and might play roles in the NTD pathogenesis. These findings indicated that CNVs were involved in MTX-induced NTDs by causing the disorder of folate metabolism and would shed new light on the pathogenesis of NTDs. Jian-Hua Wang, Xiu-Wei Wang, contributed equally to this manuscript. Corresponding author: Bo Niu, Ting Zhang.

Large range of copy number variation (CNV) for human alpha-defensin genes *DEFA1* and *DEFA3*: lower copy number is a risk factor for autoimmune diseases. *H. Wang[1], B. Zhou[1], YL. Wu[1], S. Bowden[1], R. Hoffman[1], J. Ahearn[3], D. Birmingham[2], B. Rovin[2], L. Hebert[2], A. Schwaderer[1], D. Hains[1], CY. Yu[1].* 1) The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Wexner college of Medicine, The Ohio State University, Columbus OH; 3) Allegheny Singer Research Institute, Temple University School of Medicine, Pittsburgh, PA.

Human α-defensins (DEFAs) are antimicrobial peptides important in innate immunity. The current version (v37.3) of Human Reference Genome sequence reveals a total of six functional genes and seven pseudogenes in the *DEFA* locus spanning 150 kb in size at chromosome 8p23.1. The functional genes include *DEFA3*, *DEFA1* and *DEFA1B*. Because these genes are highly homologous in sequence identities and have extensive inter-individual gene CNV, they are collectively referred to as *DEFA1A3*. The objective of this study is to copy-type the *DEFA1A3* in different racial groups and autoimmune diseases. Dot-plot analyses of genomic DNA sequences and long-range genomic mapping by PacI and PmeI digested DNA resolved by pulsed field gel electrophoresis revealed segmental duplications of 19.1 kb for the *DEFA1A3* genes. Using a 1.2 kb genomic DNA probe specific for 5' region of human *DEFA1A3* for Southern blot analysis, we detected seven polymorphic variants characterized by 8.7, 8.2, 7.0, 6.0, 4.5, 3.7 and 3.2 kb TaqI restriction fragments in human populations. The CNVs and associated polymorphisms of *DEFA1A3* have been characterized by TaqI genomic RFLPs in 657 human subjects, among them are 192 healthy Caucasians, 164 healthy African Americans and 302 autoimmune patients (183 type 1 diabetes (T1D) and 119 systemic lupus erythematosus (SLE)). The diploid gene copy number (GCN) for *DEFA1A3* in our study population varies from 4 to 17. While >85% of human subjects have a GCN between 5 and 9 copies, the distribution patterns of GCN are significantly different among groups ($p<0.0001$). Healthy African Americans have highest GCN with a mean of 7.41 (95% CI=7.15–7.67), compared to healthy Caucasians with a mean GCN of 7.03 (6.79–7.27). Both Caucasian SLE and T1D patients have a mean GCN of 6.7 and these autoimmune patients have significantly lower copy number of *DEFA1A3* than their race-matched controls ($p=0.03$). Further analyses revealed that the TaqI-8.7 kb *DEFA1A3* variant is specific for Caucasians, while the TaqI-3.2 kb variant is specific for African Americans. Moreover, the frequency of the TaqI-6.0 fragment is significantly lower in Caucasian SLE than in race-matched controls ($p=0.03$). In summary, the GCN for *DEFA1A3* is highly variable among human subjects and racial groups. Low copy number of *DEFA1A3* appears to be a common risk factor for autoimmune diseases.

Analysis of structural variation in the Genome of the Netherlands (GoNL) project. *K. Ye[1], V. Guryev[2], W. Kloosterman[3], L. Francioli[3], J.Y. Hehir-Kwa[4], E. Lameijer[1], A. Abdellaoui[5], J. de Ligt[4], V. Koval[6], N. Amin[6], F. van Dijk[7], L.C. Karssen[6], H. Mei[8], Genome of the Netherlands consortium.* 1) Leiden University Medical Center, Leiden, Netherlands; 2) Hubrecht Institute and UMC, Utrecht, Netherlands; 3) University Medical Center, Utrecht, Netherlands; 4) Radboud University Medical Centre, Nijmegen, Netherlands; 5) VU University Medical Center, Amsterdam, Netherlands; 6) Erasmus Medical Center, Rotterdam, Netherlands; 7) University Medical Center, Groningen, Netherlands; 8) Netherlands Bioinformatic Centre, Nijmegen, Netherlands.

The Genome of the Netherlands (GoNL) is a national collaboration that aims at characterizing genetic variations in the Dutch population of 250 families. Here we report on the pilot results of the structural variation analysis for 18 families. Our analysis employs several methodologies for detection of different types and size ranges of variants. Using GATK Unified Genotyper, we identified 1,459,968 small indels of which 23% are novel compared to 1000 Genomes phase 1 data, and 86% overlap with Pindel's short indel calls. In silico functional analysis indicates that 819 are causing premature stop codons and frameshifts in 749 genes. A combination of 4 approaches, read depth (CNVnator, DWAC-Seq), read pair (123SV, BreakDancer and GenomeSTRiP), split-read (Pindel), and de novo assembly (SOAPdenovo, CLC) ensures detection of structural variants of different types and size ranges. For example, we identified a 1.8 kb insertion absent in genome reference, but common in Dutch population (allele frequency=42%), while rare (5%) in 1000 Genomes project. Homozygous DNA segments were identified using PLINK and VCFtools. We performed hundreds of PCR/Sequencing assays to determine false-positive rate for each tool and to establish de novo mutation rate of indels and structural variants. The set of wide size range, multi-type, high-quality SVs calls, together with GoNL SNP set (reported separately) describes common genomic variants in the Dutch genomes. This variation catalogue is essential for understanding population history, interpretation of GWAS and analysis of other studies involving West-European samples.

Copy number variation of the Y chromosome in autism spectrum disorder. *R.K. Yuen[1,2], E. Kolomietz[3], M. Vlasschaert[3], A. Merkoulovitch[1,2], J.R. MacDonald[1,2], C.R. Marshall[1,2], S.W. Scherer[1,2].* 1) McLaughlin Centre, The Hospital for Sick Children, Toronto, ON, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 3) Division of Molecular Diagnostic Genetics, Department of Laboratory Medicine and Pathology, Mount Sinai Hospital, Toronto, ON, Canada.

Autism spectrum disorder (ASD) presents a complex and heterogeneous etiology with a strong genetic basis. While it affects 1 in 88 people, ASD has a strong gender bias and males are four times more likely to be on the spectrum than girls. Genetic mutations and copy number variations (CNVs) on the X chromosome have been associated with the ASD phenotype. However, the Y chromosome has not been well studied with respect to autism due to the fact that its complex and repetitive DNA sequence structure complicates typical analyses. Moreover, the existing microarrays do not provide a good coverage of probes along the Y chromosome. To investigate the CNV architecture of the Y chromosome in ASD, 32 male probands and their fathers along with 46 male controls were run on a custom Agilent 8×15K CGH array that we have developed. This array contains over 10K commercial and custom probes (size 44~60nt) with an average probe spacing of ~1.5kb across the euchromatic region of the Y chromosome. In our preliminary data, we found one *de novo* XYY male in ASD cases and a potential mosaic loss of chromosome Y in one male control. In addition to known CNVs in loci such as TSPY genes and partial AZFc region, we identified a novel CNV of ~10kb in the exonic regions of DAZ repeats in almost half of the male population (ASDs and controls). Although most of the CNVs in the probands are inherited and there is no significant difference between ASDs and controls for any CNVs detected, we found a de novo gain of a ~200kb region encompassing *TTTY20*, *FAM197Y2*, *TSPY1*, *TSPY3* and *TSPY4* in one proband from a simplex family. The copy number gain of this region was not observed in any of the male controls examined. The current findings suggest that large common CNVs on the Y chromosome are unlikely to be a major contributory cause of ASD, but some of the *de novo* CNVs detected may warrant further investigation. A larger sample cohort will be used for future studies of potential involvement of rare CNVs on the Y chromosome in ASD.

Novel method of CNV analysis in FcγR locus and its application to immune-related diseases. *A. Zhernakova[1, 2, 3], L. Franke[1], A. Ioan[2], G. Trynka[1], K. Fransen[4], R. Weersma[4], S. Rantapää-Dahlqvist[5], P. Gregersen[6], C. Wijmenga[1], T. Huizinga[2], R. Toes[2].* 1) department of department of Genetics, UMCG, Groningen, The NetherlandsGenetics, UMCG, Groningen, Netherlands; 2) department of Rheumatology, LUMC, Leiden, The Netherlands; 3) Complex Genetics Group, UMCU, Utrecht, The Netherlands; 4) department of Gastroenterology, UMCG, Groningen, The Netherlands; 5) Department of Public Health and Clinical Medicine/Rheumatology, Umea University, Sweeden; 6) Feinstein Institute for Medical Research, Manhasset, New York, USA.

Genetic variants near the FC-gamma receptor (FcγR) locus are associated with several immune-related diseases. However, most FcγR genes are located in complex regions of segmental duplications (SD) and they are therefore not well covered by the genotyping platforms. To be able to identify copy-number variants (CNVs) in this locus, we developed a method to analyse CNVs using principal component analysis of the raw intensity values of single nucleotide polymorphisms (SNPs) genotyped on the Immunochip platform. This platform includes 1,159 SNPs in the SD block of FcγR genes; of these only 140 (12%) passed our quality control for SNP analysis but their intensity values are informative for the CNVs estimation. We identified several CNV loci in the FcγR block. We confirmed our results via an independent method - arrayCGH genotyping - and observed a perfect correlation in CNV estimation between both methods. Next, we applied our method to case-control cohorts of rheumatoid arthritis (RA), celiac disease and inflammatory bowel disease (in total, 15231 individuals). We found no associations between CNVs with these diseases ($p > 0.05$), however individuals with RA more often had a rare complete deletion of FCGR3B. Additionally, by performing functional studies we observed a correlation between the number of FCGR3A gene copies and FCGR3 (CD16) expression on T-cells. Conclusion: We have developed a method to accurately estimate CNVs based on SNP intensity data that can be extended to other phenotypes and to other SD loci in the human genome. We have also established the functional effect of the number of copies of FCGR3A gene on the CD16 expression on T-cells.

462W

An improved diagnostic workflow using SNP arrays reveals novel insights into CNVs in mental retardation. *X. Zhou[2,1], JM. Wang[1], B. Wang[3], J. Wang[3], T. Ji[1], X. Zhang[2], X. Ma[3], Y. Jiang[1].* 1) Department of Pediatrics, Peking University First Hospital, Beijing; 2) Bioinformatics Division, Tsinghua National Laboratory of Information Science and Technology, Tsinghua University, Beijing; 3) National Research Institute For Family Planning, Beijing.

Chromsomal microarray analysis has been widely adopted among clinicians for the genetic testing of children with developmental delay or mental retardation (DD/MR). While copy number variants (CNVs) can be readily detected by array CGH or SNP chips, distinguishing pathogenic CNVs from benign CNVs is challenging and requires considerable skills. SNP arrays can also generate genotype information, but may suffer from low signal-to-noise ratio; so it is not clear how to make best use of this platform. We developed an improved diagnostic workflow for this task by introducing the following three innovations: (1) Combining CNV discovery and targeted genotyping to improve the sensitivity of detecting small CNVs; (2) Using an in-house database CNVs ascertained by similar platforms and computational protocols from over 5,000 samples; (3) Judging the pathogenicity of CNVs by the number of affected genes or cross-reference genes or chromosomal regions to a curated phenotype ontology. We applied our diagnostic workflow on 288 DD/MR patients genotyped with Illumina CytoSNP-12 bead arrays. We identified pathogenic CNVs in 38 patients (25 males, 13 females). In addition to very large CNVs or CNVs corresponding to known chromosomal syndromes, we were able to detect small CNVs (<250kb) in five patients (1.7%) disrupting a single gene, three of which were known to cause monogenic forms of DD/MR. Examining the patient's clinical record supported their pathogenicities. Most published studies used samples of European ancestry; conclusions drawn from previous studies remained to be replicated in other populations. In our cohort of Chinese patients, we replicated the previous finding that DD/MR patients, especially for those with multiple congenital anomalies, have higher burden of rare and large CNVs as compared with natural populations. Most large and rare CNVs were de novo, and preferentially originated from paternal germline mutations. But not all de novo CNVs can be pathogenic: the rate of de novo CNVs identified as non-pathogenic by our workflow was not significantly different from the natural populations. We also discovered in four cases, pathogenic CNVs were inherited from mothers; and one pathogenic CNV in the mother but not transmitted to patients. It can be explained if females are more tolerable to pathogenic CNVs than males.

Copy number variation in autism spectrum disorders. *B. Sheppard[1], C. Ladd-Acosta[1], B.K. Lee[2], J. Bonner[3], G. Windham[4], L. Schieve[5], L. Croen[6], A. Reynolds[7], D. Schendel[5], C. Newschaffer[2], M.D. Fallin[1].* 1) Department of Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 2) Drexel University School of Public Health, Philadelphia, PA; 3) Michigan State University Biomedical Research Informatics Core, East Lansing, MI; 4) California Department of Public Health; 5) Centers for Disease Control and Prevention, Atlanta, GA; 6) Kaiser Permanente Northern California Division of Research; 7) University of Colorado Denver School of Medicine, Denver, CO.

There is considerable emerging evidence for the role of copy number variation (CNV) in autism spectrum disorder (ASD) susceptibility. In order to further characterize variation in ASD, we assessed genome-wide CNV burden, genic CNV burden, and regional CNV associations at previously implicated loci in ASD cases compared to developmentally healthy controls from the Study to Explore Early Development (SEED). Approximately 900 subjects from the SEED cohort were genotyped at nearly 1 million single nucleotide polymorphic markers (SNPs) and nearly 130,000 monomorphic copy number probes on the Illumina HumanOmni1 array. A hidden Markov model (HMM) approach was then used to detect CNVs using the SNP array data. Burden was assessed by case-control differences in CNV rate and size, with respect to frequency, length, and type. Regional associations were preformed at previously implicated ASD loci, including 7q11.23, 16p11.2, 15q11.2-q13.1, 15q13.2-q13.3, 22q13, NRXN1, and CNTN4. Overall, cases exhibited larger CNVs when compared to controls, particularly large duplications. Six large (> 400 kb) genic CNVs were identified; two were found in CNTN4 and one in PARK2; both previously implicated ASD genes involved in neuronal-cell adhesion and ubiquitin pathways, respectively. However, no significant associations were detected in the seven previously implicated CNV and gene regions. These results support many previous findings, especially with respect to evidence for larger CNVs in cases compared to controls and large rare events affecting neuronal-cell adhesion and ubiquitin gene networks. Future research is needed to confirm these findings as well as to implicate additional genes and pathways that could elucidate the biological mechanisms involved in ASD. We hope to supplement this analysis with additional SEED samples in the near future.

Understanding revisions to the human reference genome and assembly model. *D. Church[1], P. Flicek[2], T. Graves[3], T. Hubbard[4], V. Schneider[1], The Genome Reference Consortium.* 1) Natl Ctr Biotech Infor/NIH, Bldg 45 rm 5AS43, Bethesda, MD; 2) EBI, Hinxton, Cambridge, UK; 3) The Genome Institute at Washington University, St. Louis, MO; 4) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

The publication, more than a decade ago, of an assembly for the human genome was a milestone event in biology. This resource has transformed basic and clinical research. One of the key insights into human biology made possible by the reference assembly was the discovery of an unrecognized degree of genetic variation among individuals. In today's era of whole genome sequencing, alignment of next generation sequencing reads against the high quality reference assembly remains a critical step in the interpretation of variation data. However, these analyses have made it increasingly clear that the linear chromosome models used in the human reference assembly do not always adequately represent the most variant and complex regions of the human genome. To address this issue, the Genome Reference Consortium (GRC; http://genomereference.org), the group overseeing the human reference assembly, developed a new assembly model. GRCh37, the current reference assembly, was the first to use this model, which has now also been implemented in the recently released mouse reference assembly, GRCm38. This model retains the intuitive linear chromosomes of previous assemblies, but now provides alternate assembly representations for more diverse and complicated genomic regions that are placed in a chromosome context via alignment. Assembly patches comprise the second key feature of the assembly model. Representing novel sequences and assembly corrections, the patches enable the GRC to provide timely updates to the reference assembly without disruptive coordinate changes. Like the alternate assemblies, the patches are stand-alone scaffold sequences placed in chromosome context via alignment. Released quarterly, there have been 10 patch releases associated with GRCh37, including more than 71 novel sequence representations and greater than 69 assembly corrections. We will show how the adoption of this assembly model has enabled GRCh37 to capture substantial amounts of human sequence not represented in previous assembly versions. We also will present data showing how the use of the alternate loci and patches improves the ability of the reference to act as an alignment substrate and discuss the need for new analytic resources to take advantage of these assembly features. Lastly, we will discuss ongoing GRC efforts to address assembly issues, including the use of single haplotype resources to resolve complex regions and 1000 genomes data to update rare or erroneous bases.

Evolutionary history and genome organization of DUF1220 protein domains. *M. O'Bleness[1], C.M. Dickens[1], D. Albracht[2], H. Kotkiewicz[2], T. Graves[2], R. Wilson[2], J. Sikela[1]*. 1) Biochemistry, Univ Colorado Denver AMC, Aurora, CO; 2) The Genome Institute at Washington University School of Medicine, St. Louis, MO, 63108 USA.

DUF1220 protein domains exhibit the most extreme human lineage-specific (HLS) copy number increase of any protein coding sequence in the human genome. From >270 copies in human, DUF1220 copy number markedly decreases as a function of a species evolutionary distance with human (125 in chimp, 35 in macaque, and 1 in mouse/rat) and shows a strong evolutionary correlation with brain size (R2=0.98; p=1.8 × 10-6). The dramatic HLS increase in DUF1220 copy number was driven by domain hyperamplification involving a 4.7 kb, tandemly repeated three DUF1220 domain unit called the HLS DUF1220 triplet. All copies of the HLS DUF1220 triplet lie in a dynamic genomic environment characterized by a pericentric inversion (1p12-1q21.2) and a polymorphic heterochromatin expansion (1q12) that are unique to the human genome. The great majority of DUF1220 sequences map to 1q21 and DUF1220 copy number loss has recently been implicated in 1q21-associated microcephaly, further strengthening the association of DUF1220 copy number and brain size. An accurate characterization of DUF1220 domains and their genome organization within the 1q21 region is critical to understanding the mechanism behind the HLS DUF1220 triplet expansion and its evolutionary importance. However a comprehensive analysis of DUF1220 domains and the gene family that encodes them (NBPF) has been hindered by the incomplete nature of the reference assembly of the 1q21.1-q21.2 region. As part of an effort to create accurate sequence assemblies of complex genomic regions, a new 1q21 assembly has been generated by targeted 1q21 sequencing of a haploid hyditiform mole BAC library. This new resource has allowed the 1q21.1-q21.2 region to be closed to just a few remaining gaps. Analysis of this new assembly, combined with the growing number of available primate genome assemblies, has allowed the most comprehensive evolutionary history of DUF1220 domains and their genomic organization to be generated.

Retrotransposition of gene transcripts leads to structural variation in mammalian genomes. *A.D. Ewing[1], T. Ballinger[1], D. Earl[1], D. Haussler[1,2].* 1) Center for Biomolecular Science and Engineering, University of California, Santa Cruz, CA; 2) Howard Hughes Medical Institute, University of California, Santa Cruz, CA.

Processed pseudogenes are a source of material for new gene formation on evolutionary time scales. Most prior work on pseudogene discovery involves comparing copies that are present in reference genome assemblies to their parent genes. Here, we explore pseudogene insertion variants that are present as segregating insertions in the germlines of individual humans and mice. Through analysis of whole-genome sequence data, we find evidence for 39 retroposed transcripts in the genomes of one or more of over 900 humans sequenced at low coverage as part of the 1000 Genomes Project, but not present in human reference assembly GRCh37. Similarly, we find evidence for 755 pseudogene insertions at distinct locations present in one or more of 17 inbred mouse strains but not present in the C57BL/6J reference assembly NCBI m37, and 23 pseudogene insertions across a cohort of 10 chimpanzee genomes not present in the panTro2 reference genome assembly. Many of these insertions are new members of existing pseudogene families whose progenitors are highly and widely expressed, and the majority of these insertions have detectable hallmarks of processed pseudogene formation. Using these data, we estimate the rate of novel germline pseudogene formation in humans at roughly 1 new pseudogene for every 6000 individuals.

Whole genome sequencing of iPS cells reveals somatic mutation arising at latest stages of reprogramming. *M. Cortes, J. S. Seo*. Seoul National University College of Medicine, GMI, Seoul, South Korea.

Purpose: Fibroblasts Induced to pluripotency with the four factors are going trough different steps of development, with an uncertain fate at the beginning of Area 51 (Day 8 to 15) as described by Nagy A. & al. (Nature 2011), whereas their fate seems determinate after Day 16. We therefore performed a whole genome sequencing (WGS) at high throughput of stages before, between and after Area 51 to understand mechanisms involved in the reprogramming process. Methods: We generated a WGS with the Next Generation Sequencer (NGS) Illumina HighSeq 2000 at a high coverage of 28.95X of 6 samples, primary iPSC (1iPS), three intermediate stages of reprogramming from 1iPSC to the secondary iPSC (2iPSC) at Day 0 (D0), Day 11 (D11) and Day 18 (D18) and finally of the secondary iPSC. Databases were generated with MySQL to store and handle the analyses of large data files from the NGS; CNVs were called with CNVnator, Breakdancer and SNSD (publication ongoing). We also performed SNPs genotyping with our in-house SNPs caller. Results: Unlike recent published data, we identified more than 6 millions mutations per sample and we found 379 de novo non synonymous SNPs (nsSNPs) arising at a later stage of reprogramming, for which Gene Ontology (GO) revealed that 3 genes Nkap, Pcm1 and Fgfr2 responsible for stem cell development differentiation and division. Meanwhile early stage of reprogramming didn't show more than 32 de novo nsSNPs affecting cell membrane proteins. With SNSD we found 6,028 germline CNV losses present in all stages of reprogramming, where 28 Genes identified with DAVID are involved in Cell morphogenesis in the differentiation process (p-value 4.5E-37). We found 11 intragenic somatic CNVs arising between 1iPSC and 2iPSC, one gene affected Prox1 is directly involved in stem cell maintenance, thus our analysis with Breakdancer shows an increase of Copy Number when cells are entering Area 51 followed by a dramatic decrease in Copy Number at D18, the end of Area 51. Conclusion: Unlike previously reported, our results show that later stages of reprogramming contain more genetic aberrations than early stages, thus we discovered SV in Nkap, Pcm1, Fgfr2 and Prox1 that could influence stem cell fate at the end of Area 51. The way these findings change the understanding of the iPSCs genome alter approaches to induced pluripotent stem cells and provide a new look at mechanisms responsible for reprogramming to pluripotency.

Possible genomic impact of SVA retrotransposon in humans similar to that in gibbons. *T. Hara, Y. Hirai, H. Hirai, A. Koga.* Primate Research Institute, Kyoto University, Inuyama City, Japan.

The superfamily Hominoidea (hominoids) comprises the following two families: Hominidae (hominids) and Hylobatidae (gibbons, also called small apes). SVA transposon is a composite retrotransposon that shares a common lineage with that of hominoids and is considered to have been generated by the fusion of three genetic elements: SINE-R, a variable number of tandem repeat (VNTR) sequence, and *Alu*. This retrotransposon has been reported to cause various human diseases, including Fukuyama muscular dystrophy and X-linked dystonia-parkinsonism. We have recently discovered two SVA-related genetic occurrences that probably affect the genome structure of gibbons.

One occurrence was the large-scale expansion of tandem repeat sequences in the centromere regions in the hoolock gibbon (*Hoolock hoolock*). The repeat sequences are 40 kb or more in length and are carried by 28 of the 46 chromosomes of the somatic cells. The sequences consist of 35- to 50-bp repeat units and exhibit a sequence similarity with the VNTR region of SVA. Thus, it has been inferred that the large-scale tandem repeats in the centromere regions were derived from the SVA transposon, or that the repeat sequences served as a source for SVA. If the former is true, similar events may also occur in the human genome due to the presence of numerous SVA copies scattered throughout.

The second occurrence observed was the proliferation of a new composite retrotransposon in the genome of the white-cheeked gibbon (*Nomascus leucogenys*). The basic structure of this transposon is the same as that of SVA with one prominent difference being the presence of part of a single-copy nuclear gene in place of the SINE-R region. Thus it has been inferred that the new retrotransposon was formed in the gibbon genome independent of SVA but by similar mechanisms. The copy number of this new retrotransposon was estimated to be of the order of 10^2 and probably exceeds the copy number of SVA in the same genome; thus, it may have a higher transposition frequency than SVA. It is suggested that formation of new composite retrotransposons could also occur in the human genome due to the presence of respective solo elements.

Functional studies of tandem repeat variation in the human genome using multiplexed capture and high-throughput sequencing. *A. Guilmatre[1], G. Highnam[2], D. Mittelman[2, 3], A.J. Sharp[1].* 1) Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Virginia Bioinformatics Institute, Virginia Tech, Blacksburg, VA; 3) Department of Biological Sciences, Virginia Tech, Blacksburg, VA.

Tandem repeats (TRs) are stretches of DNA sequence comprised of two or more contiguous copies of a sequence of nucleotides arranged in a head-to-tail pattern, and comprise ~2% of the human genome. They are characterized by a high mutation rate due to replication slippage, and represent an important source of genetic variation in most genomes. A recent study in yeast showed that genes containing TRs in their promoters display high transcriptional divergence and that variations in repeat length were associated with changes in expression level, suggesting a functional role for TRs in regulating gene expression. However, TRs have long been considered as mere junk DNA, and due to a number of technical issues in genotyping them remain poorly studied. Furthermore, GWAS provide little information on repeat variation because most TRs are poorly tagged by SNPs. To date, whole-genome sequencing is the only high-throughput technique enabling large-scale TR genotyping but it remains expensive. Therefore, to facilitate studies of the role of TR variations in human, we have developed a method to perform targeted enrichment and high-throughput sequencing of TRs, and applied this to study TRs located in gene promoter regions in the human genome. By adapting the exome capture method to enrich TR regions and using a specific bioinformatic pipeline designed for genotyping TRs from sequencing reads (Fondon et al 2012, PLoS One v7:e33036), we attained a mean of 319 reads per target. One third of these completely span the TR and were therefore informative, allowing >4,000 promoter-associated TRs to be genotyped, of which 79% were polymorphic. Our method allows multiplexing of ≥8 individuals per lane of HiSeq, enabling the cost-effective study of thousands of repeats on a population level. We are also estimating potential PCR biases by sequencing hydatidiform moles that are homozygous genome-wide, studying inheritance patterns using trios, and utilizing PCR-free library preparation to ensure genotype accuracy. Based on the success of our preliminary experiments we are currently studying the effect of TR variations on local gene expression by performing sequencing of TRs in HapMap individuals. These studies will give major insights into the functional effects of TR variations in the human genome.

Meta-analysis with dbGaP Data on Genome-wide Association Studies for Alzheimer's Disease. *J. Kim.* Ilsan hospital, Koyang, South Korea.

The genome-wide association studies (GWAS) usually find risk genes with low odd ratios because they target common variants. The GWAS of Alzheimer's disease (AD) found several risk genes during recent five years. However, the odd ratios of these genes for AD are so low that we cannot explain the heritability of AD, yet. The imputation with 1000 genomes can be an alternative solution. The 1000 genomes project provides detail human genome and rare variants. We will try to find rarer SNPs related with AD by using imputation of 1000 genomes. The most strong association was found in ApoE. The other assocciated genes for Alzheimer's disease were CR1 and CD2AP which were founded in other GWAS studies.

471F

A survey of the mutational load in genes associated with rare Mendelian disorders and autism. *A.R. Rao, S.F. Nelson.* Department of Human Genetics, UCLA Geffen School of Medicine, Los Angeles, CA.

In this study, we surveyed the number of individuals in human populations with a severely protein-damaging rare variant in genes associated with a rare Mendelian disorder or autism. Genetic variants that severely disrupt protein function are of clinical interest, and it is important to accurately predict whether a variant is a genuine loss of function (LoF) variant. Since we expect these variants to be rare, the abundance of such variants in a given gene across a human population provides a basis for validating whether they are in fact severely protein-damaging. We combined data from the 1000 Genomes Project, which included exomes of 1092 individuals, and the NIEHS Environmental Genome Project, which consisted of the exomes of 95 samples. For each gene with a known inheritance model, we calculated the number of individuals that are heterozygous or homozygous for the minor allele of a variant predicted to be protein-damaging. Under the assumption that rare deleterious missense mutations—predicted to be damaging by various protein function prediction methods—, stop codon gain/loss, inframe codon gain/loss, splice site disrupting and frameshift variants are protein-inactivating, the number of individuals with supposed disruptions in protein function far exceed our expectation, given the known prevalence of various Mendelian disorders. If we exclude the missense mutations and inframe codon loss/gain variants, the number of individuals with a LoF variant in a given gene is closer to the expected value. Additionally, the remaining variants in genes with surprisingly large counts may be filtered further, e.g. stop gain variants may be vetted based on their proximity to the end of a gene. Our results suggests that most missense mutations that are predicted to be deleterious are not severely damaging and may simply increase risk towards common, complex disease, at most. Furthermore, our method of analysis illustrates how one may filter LoF variants beyond the common method of comparing minor allele frequencies, in future studies that aim to discover the gene for a rare Mendelian disorder of unknown cause.

472W

Inferring mechanisms of indel mutation from whole genome sequence. *I.HC. Turner[1], Z. Iqbal[2], G. McVean[1,2].* 1) Department of Statistics, University of Oxford, Oxford, United Kingdom; 2) The Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford, OX3 7BN, United Kingdom.

Mutations in DNA arise through the combination of damage, errors during replication (e.g. slippage) and transcription, and the cell pathways that attempt to repair DNA damage. Although the mutational signatures of DNA repair mechanisms are understood in specific cases in model organisms, their relative contributions to the germline are unknown. Inferring contributions from sequence data has previously been impossible as mutation discovery was biased towards shorter events and by the use of a reference genome. We use a new variant discovery method based on de novo assembly to provide unbiased variant discovery from whole genome sequence, thereby allowing us to reason about underlying cellular processes (focusing on those causing insertions and deletions).

We made variant calls in humans (85 Luhya from the 1000 Genomes Project [1]), chimpanzees (10 from PanMap [2]) and in birds. These calls consistently show that twice as many deletions as insertions have occurred, although their size distributions are similar. Almost all insertions (90%) are tandem and most (93%) non-tandem events are deletions. The high incidence of micro-homology in deletions, between flank ends and deletion edges, indicates a 2bp homology requirement for error-prone DNA repair. Indels of size 4bp occur at an increased rate in some species, possibly due to up-regulation and preference of the Ku pathway. Increases in the number of variants at the 3' end of genes may be evidence of Transcription Associated Mutagenesis in the germline.

From a variant's sequence and context we infer the most likely pathway responsible. Using this we quantify the relative effect of cellular processes on the genome. We describe a statistical model to explain double-stranded break repair by the Non-Homologous End Joining (NHEJ) pathway, which we parameterize using discovered variants. The model can explain the mutation patterns between species, and is validated by comparison with experimental data.

A complex rearrangement of the OCA2 gene in two unrelated albino patients. *B. Arveiler[1,2], E. Lasseaux[1], D. Cailley[1], M.L. Vuillaume[1,2], C. Rooryck[1,2], A. Rouault[1], J. Toutain[1], D. Lacombe[1,2], F. Morice-Picard[1,2].* 1) Service de Génétique Médicale, CHU de Bordeaux, Bordeaux, France; 2) Univ Bordeaux Segalen, Maladies Rares: Génétique et Métabolisme (MRGM), EA4576, Bordeaux, France.

Oculocutaneous albinism (OCA) is an autosomal recessive disease characterized by hypopigmentation of the skin, hair and eyes. Molecular analysis allows to classify patients, depending on the gene that is mutated, into OCA1 (TYR gene), OCA2 (formerly called P gene), OCA3 (TYRP1) and OCA4 (SLC45A2). We routinely perform an exhaustive analysis of the 4 genes, including a search for point mutations and for intragenic microrearrangements. Deletions and duplications are investigated using ultra-high resolution array-CGH, in which the 4 genes are covered at a density of 1 probe/102bp on average (1). We report two patients with a complex rearrangement. In patient 1 mutation p.Asn489Asp was identified in the heterozygous state. Array-CGH analysis indicated the presence of two heterozygous deletions restricted to introns 2 and 20 respectively, the intervening segment being present in two copies. Both deletions were inherited from her mother, thus indicating that both deletions were on the same allele. The patient's father was heterozygous for the p.Asn489Asp mutation. Patient 2 was heterozygous for the same deletions of introns 2 and 20 as patient 1. No other mutation was found. The patient's mother did not harbor these deletions. His father was not available for study. Remarkably, the 5' breakpoint of the intron 2 deletion and the 3' breakpoint of the intron 20 deletion seemed to be at the same position as the breakpoints of an intron 2–20 deletion that we identified previously in three patients of polish origin (1). A haplotype analysis showed that the deletions in patients 1 and 2 were on the same haplotype as that associated with the intron 2–20 deletion in the polish patients. This suggested that instead of having a bipartite deletion the patients may in fact have the “polish” intron 2–20 deletion, with the intervening segment being inserted somewhere else in the genome. A PCR-sequence analysis performed with primers located on each side of the intron 2–20 deletion confirmed that patients 1 and 2 indeed harbored the “polish” deletion. FISH analysis using a probe covering the exon 3–20 segment identified no exogenous signal, but two signals at the OCA2 locus, therefore suggesting that the intervening segment was inserted inside of, or immediately next to, the OCA2 gene. High throughput sequencing of the entire 15q11–13 region is underway to determine the exact nature of the rearrangement(s). (1)Rooryck et al., Hum Genet (2011) 129:199–208.

A four base pair insertion in WNT16a identified through exome sequencing is associated with type 2 diabetes. *L. Been[1], M. Fortner[1], E. Howard[2], M. Lerner[3], D. Brackett[4], D. Sanghera[1].* 1) Pediatrics/Gen, Univ Oklahoma HSC, Oklahoma, OK; 2) Cell Biology, Univ Oklahoma HSC, Oklahoma, OK; 3) Surgery, Univ Oklahoma HSC, Oklahoma, OK; 4) Veteran Affairs, VA Medical Center, Oklahoma, OK.

Several *in vitro* and *in vivo* studies have shown that many components of the WNT pathway are involved in β cell proliferation, insulin secretion, and production of glucogon-like peptide-1 (GLP-1). We hypothesize that any alternation in WNT pathway will have profound consequences in insulin secretion and generation of new β cells, as this pathway needs to be tightly regulated. A four base pair frame-shift insertion in the *WNT16a* gene was detected in the conserved region through a genome-wide exome sequencing carried out on two participants (one type 2 diabetic (T2D) case and one control). A genetic screening of this insertion in 1,512 consisting of 792 type 2 diabetic cases and 720 normoglycemic control individuals suggested that the number of carriers of this insertion did not differ significantly among cases (18%) than in controls (15%) (p=0.128). However, the insertion carriers showed significantly higher levels of serum C-peptide (β=0.087, p= 0.001) when compared to the wild type carrier. In gene expression studies on 18 human pancreatic tissues, our data revealed a 2.86 fold increase in the expression of WNT16a among insertion carriers compared to non-carriers. Further *in vitro* transfection assays reformed by cloning ~1.2-kb 5' region of the putative *WNT16a* promoter into luciferase reporter vector showed 70 fold increase in promoter activity associated with the insertion carriers as compared to the wild-type carriers. The WNT signaling regulates and stabilizes β catenin binding with *TCF7L2*,which is critical for expression of *GLP-1* and many other genes involved in β cell development, our results suggest that *WNT16a* insertion may play a significant role in T2D pathogenesis by altering the transcription of WNT pathway genes involved in glucose homeostasis.

Obstetric complication-associated ANXA5 promoter polymorphisms affect gene expression via DNA secondary structures. *H. Inagaki[1], S. Ota[1], H. Nishizawa[2], H. Miyamura[1,2], K. Nakahira[3], M. Suzuki[1], S. Nishiyama[2], Y. Udagawa[2], I. Yanagihara[3], H. Kurahashi[1].* 1) ICMS, Fujita Health University, Toyoake, Aichi, Japan; 2) Dept Obstetrics and Gynecology, Fujita Health University, Toyoake, Aichi, Japan; 3) Dept Developmental Medicine, Osaka Medical Center and Research Institute for Maternal and Child Health, Izumi, Osaka, Japan.

Recent findings have highlighted the possibility that polymorphisms within the annexin A5 gene (ANXA5) promoter contribute to the etiology of various obstetric complications. However, the underlying mechanisms are unknown. In our present study, the transcriptional activity of the ANXA5 gene promoter was examined in the context of G-quadruplex formation. The M2 haplotype of the promoter polymorphisms that confers a high risk of onset for these disorders shows lower activity and less expression of ANXA5 mRNA. This gene promoter region has a motif that potentially forms a G-quadruplex structure, and the M2 allele possesses less potential than the major allele. The promoter activity determined by luciferase reporter analysis correlated with the in vitro G-quadruplex propensity estimated by circular dichroism. Treatment with a G-quadruplex ligand inhibited this promoter activity. The ANXA5 promoter region was found to be hypomethylated even on the M2 allele. Taken together, our data indicate that the M2 allele instigates G-quadruplex-mediated transcriptional regulation and consequently downregulates the placental anticoagulation factor annexin A5 levels, leading to obstetric disorders. Our data lend support to the developing paradigm that genomic variation affects gene expression levels via DNA secondary structures leading to the disease susceptibility.

The Influence of Genomic Context on Mutation Patterns Inferred from Extremely Rare Variants. *V.M. Schaibley[1], M. Zawistowski[2], D. Wegmann[3], D. Kessner[4], M.G. Ehm[5], M.R. Nelson[5], P.L. St. Jean[5], G. Abecasis[2], J. Novembre[4], S. Zöllner[2], J.Z. Li[1].* 1) University of Michigan, Department of Human Genetics, Ann Arbor, MI, 48109; 2) University of Michigan, Department of Biostatistics, Ann Arbor, MI, 48109; 3) School of Life Sciences, École Polytechnique Fédérale de Lausanne, Switzerland; 4) University of California Los Angeles, Department of Ecology and Evolutionary Biology, Los Angeles, CA, 90095; 5) GlaxoSmithKline, Quantitative Sciences, Research Triangle Park, NC, 27709.

Spontaneous mutations drive human genome evolution and disease patterns, but our understanding of the mutation process is limited. Previous studies have shown correlations between both nucleotide diversity in humans and inter-species substitution rates with local GC content and recombination rate, suggesting that genomic context impacts mutation patterns. However, these data are influenced by natural selection, biased gene conversion, and demographic history. A new approach to studying spontaneous mutation patterns is to examine extremely rare variants, which have arisen recently and therefore are relatively less affected by the potentially confounding effects of demography, selection, and biased gene conversion. We utilized rare variant data that was previously obtained by sequencing the exons of 202 genes in genomic DNA samples of >14,000 individuals to identify genetic associations with disease. This dataset contains >19,000 variants with an allele frequency $\leq 10^{-4}$ in individuals of European ancestry. We quantified the effect of GC content and recombination rate on the total mutation rate and each mutation subtype (GC>AT, GC>TA, etc.). Our results show that mutations, as inferred from rare variants, toward a G or C base pair (AT>GC or AT>CG) are less likely in regions of high GC content. This trend is not observed among common variants or substitutions. Rather, the probability of observing a common variant or substitution toward an A or T base (GC>AT or GC>TA) is decreased in GC-rich regions, which is not seen in rare variants. This suggests that GC content influences the initial mutation and the fixation probability of an existing variant differently. Our results also show that recombination rate has little effect on rare variants, but a significant impact on common variants and substitutions, especially the AT>GC and AT>CG subtypes, consistent with biased gene conversion primarily driving correlations between inter-and intra-species diversity with recombination. Understanding the spontaneous mutation process and the genomic context effects will aid in our understanding of observed patterns of DNA variation and in the subsequent interpretation of the downstream genotype-phenotype analyses. Our study demonstrates that rare variants emerging from deep sequencing studies substantially expand the data available for studying spontaneous mutation patterns.

Sequencing the Unsequenceable: Expanded CGG Repeats in the Human *FMR1* Gene. *P. Hagerman[1,2], J. Eid[3], P. Peluso[3], D. Rank[3], J. Yin[1], L. Hickey[1], E. Loomis[1]*. 1) Department of Biochemistry and Molecular Medicine, University of California, Davis, School of Medicine, Davis, CA; 2) MIND Institute, University of California, Davis, Health System, Sacramento, CA; 3) Pacific Biosciences, Menlo Park, CA.

Alleles of the *FMR1* gene with more than 200 CGG repeats generally undergo methylation-coupled gene silencing, resulting in fragile X syndrome, the leading heritable form of cognitive impairment. Smaller expansions (55–200 CGG repeats) result in elevated levels of *FMR1* mRNA, which is directly responsible for the late-onset neurodegenerative disorder, fragile X-associated tremor/ataxia syndrome (FXTAS). For mechanistic studies and genetic counseling, it is important to know with precision the number of CGG repeats; however, no existing DNA sequencing method is capable of sequencing through more than ~100 CGG repeats, thus limiting the ability to precisely characterize the disease-causing alleles. The recent development of single molecule, real-time sequencing represents a novel approach to DNA sequencing that couples the intrinsic processivity of DNA polymerase with the ability to read polymerase activity on a single-molecule basis. Further, the accuracy of the method is improved through the use of circular templates, such that each molecule can be read multiple times to produce a circular consensus sequence (CCS). We have succeeded in generating CCS reads representing multiple passes through both strands of repeat tracts exceeding 700 CGGs (>2 kb of 100 percent CG) flanked by native *FMR1* sequence, with single-molecule readlengths exceeding 12 kb. This sequencing approach thus enables us to fully characterize the previously intractable CGG-repeat sequence, leading to a better understanding of the distinct associated molecular pathologies. Real-time kinetic data also provides insight into the activity of DNA polymerase inside this unique sequence. The methodology should be widely applicable for studies of the molecular pathogenesis of an increasing number of repeat expansion-associated neurodegenerative and neurodevelopmental disorders, and for the efficient identification of such disorders in the clinical setting. New data will be presented at the Annual Meeting.

Three novel NR5A1 gene mutations in patients with 46,XY karyotype and disorders of sex development. *H.C. Fabbri[1], J.G. Andrade[2], A.T. Maciel-Guerra[2,3], G. Guerra-Junior[2,4], M.P. de Mello[1]*. 1) Centro de Biologia Molecular e Engenharia Genética (CBMEG), UNICAMP, Campinas, Brasil; 2) Grupo Interdisciplinar de Estudos da Determinação e Diferenciação do Sexo (GIEDDS), UNICAMP, Campinas, Brasil; 3) Departamento de Genética Médica, UNICAMP, Campinas, Brasil; 4) Departamento de Pediatria, UNICAMP, Campinas, Brasil.

Disorders of sex development (DSD) is the term used for congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical. The DSD with 46,XY as karyotype are characterized by ambiguous or female external genitalia, dysgenetic testes, and the presence or absence of Mullerian structures. Among them, we can mention the 46,XY DSD (previous male pseudohermaphrodite, XY male undervirilization, or XY male undermasculinization) and the XY gonadal dysgenesis. The gonadal dysgenesis refers to a set of abnormalities in individuals who have dysgenetic gonads caused by defects in genes involved in the embryonic gonadal development. Several genes participate in the cascade of sex determination and differentiation, and defects in some of them may lead to dysgenesis. SRY is the first candidate gene to be investigated is such cases, however only 15% present mutations in SRY gene. The NR5A1 gene, which encodes the SF-1 transcriptional regulator, has been described as resposible for DSD phenotypes. Variations in NR5A1 had been identified in association with DSD, hypospadias, anorchia, male infertility, female primary ovarian insufficiency and, in some cases, with adrenal tumors and endometriosis. In this study we report the molecular evaluation of NR5A1 gene in 67 Brazilian patients with XY gonadal dysgenesis. Direct sequencing of the 7 exons, including the promoter region and intron/exon boundaries and 3'UTR was performed. The study reveled three novel heterozygous mutations. Two of them had been identified in patients with 46,XY partial gonadal disgenesis: the c.94G>A nucleotide change within exon 2 resulted in p.S32N mutation and the C.1138+1G>T which is located in the splice donor region of intron 6. The p.C65Y resulted from the c.195G>A within exon 3 and was identified in three siblings with 46,XY DSD. Both p.S32N and p.C65Y occur within SF-1 DNA-binding domain and might interfere with its transcriptional activity. The c.1138+1G>T suppresses the consensus splice donor site and probably leads to exon 7 skipping. The findings described here show the variability in phenotype presentations for different NR5A1 mutations. Therefore, more research must be done to elucidate the important role of NR5A1 in DSD patients.

479F

A deletion and a novel nonsense SRY mutation in 46,XY Brazilian patients with disorder of sex development. *CSC. Piveta[1, 5], BPB. Araújo[2], PD. Pereira[2], FB. Coeli-Lacchini[1], AT. Maciel-Guerra[3,4], G. Guerra-Junior[3,5], IL. Monlleó[2], MP. de Mello[1]*. 1) CBMEG, UNICAMP, Campinas, São Paulo, Brasil; 2) Universidade Estadual de Ciências da Saúde de Alagoas, Brasil; 3) Grupo Interdisciplinar de Estudos da Determinação e Diferenciação do Sexo (GIEDDS). Universidade Estadual de Campinas, São Paulo, Brasil; 4) Departamento de Genética Médica.Faculdade de Ciências Médicas da Universidade Estadual de Campinas, São Paulo, Brasil; 5) Departamento de Pediatria. Faculdade de Ciências Médicas da Universidade Estadual de Campinas,São Paulo, Brasil.

Keywords : SRY, disorders of sex development, deletion, nonsense mutation. DSD (Disorders of sex development) are among the most common genetic diseases in humans and are characterized by incomplete or disordered gonadal or genital development, leading to divergences between genetic, gonadal and phenotypic sex, especially in individuals with 46,XY karyotype. In humans, male or female sexual development primarily depends on the presence or absence of the SRY gene (sex-determining region on Y) located on the short arm of the Y chromosome. The SRY gene contains a single exon and encodes a 204-amino-acid protein whose central 79 amino acids encode a HMG box (High Mobility Group) DNA binding domain. This transcription factor binds to target DNA sequences and bends it. The main regulatory activity of the SRY gene results from its DNA interaction and DNA flexing ability. Beside its regulatory role, SRY contains important sequences for SRY protein nuclear signaling. The majority of SRY mutations leading to XY gonadal dysgenesis occur within the HMG domain, predominantly causing defective binding to target DNA sequences or impairing the ability of the SRY protein to bend DNA. The objective of the present study was to investigate mutations in SRY in two Brazilian patients with XY gonadal dysgenesis. Genomic DNA was obtained from peripheral blood leukocytes and polymerase chain reaction (PCR) of SRY was performed. The first case presented total deletion of SRY gene sequences although other Y-chromosome sequences were preserved. A nonsense mutation within the HMG-box of the SRY gene was identified in the second patient: a cytosine was replaced by a thymine at position 340 (c.340C>T), resulting in the replacement of the glutamine (CAG) codon at residue 114 of by a stop codon (TAG) (p.Q114X). This mutation occurred de novo because the father is a normal male who carries a normal SRY copy. This point mutation is been described here for the first time. It can be assumed that this point mutation will result in a truncated nonfunctional SRY protein or that the protein will not translated due to the activation of the nonsense-mediated mRNA decay mechanism. Both hypotheses can explain the female phenotype and the 46,XY gonadal dysgenesis.

Whole genome sequencing in autism identifies hotspots for germline mutation. *J. Michaelson[1,2], H. Zheng[4], M. Gujral[1], Y. Shi[4], D. Malhotra[1,2], X. Jin[4], D. Greer[1], A. Bhandari[1], R. Corominas[2], A. Peoples[1,2,5], A. Koren[6], S. McCarroll[6], L. Iakoucheva[2], Y. Li[4], J. Wang[4], J. Sebat[1,2,3].* 1) Beyster Center for Genomics of Psychiatric Diseases; 2) Department of Psychiatry; 3) Department of Cellular Molecular Medicine, University of California, San Diego, La Jolla, CA 92093, USA; 4) BGI-Shenzhen, Shenzhen, China; 5) Trinity College Dublin, Ireland; 6) Department of Genetics, Harvard Medical School, Cambridge, MA.

De novo mutation plays an important role in Autism Spectrum Disorders (ASDs). Notably, most disease-associated copy number variants (CNVs) are characterized by high mutation rates and moderate-to-high penetrance. Extrapolating from these observations, we hypothesize that hypermutability is a general property of the major risk loci in ASD, and may also include nucleotide substitution hotspots. Clear evidence for the latter is lacking however because the magnitude of variability in base substitution rates is not known. We investigated global patterns of germline mutation by whole genome sequencing of 10 monozygotic (MZ) twins concordant for ASD and their parents, and we examined the genetic association of genes and nucleotide substitution hotspots with disease in independent datasets. A total of 581 germline *de novo* mutations (DNMs) were detected in 10 MZ twin pairs, and DNMs displayed a remarkably non-random positioning in the genome ($P < 10^{-10}$). We applied a simple statistical approach to clustering mutations and defined > 20 regions where DNMs occur at significantly high density. Notably, some hotspots included genes that have been previously implicated in ASD. Five of the 26 genes found in our study were impacted by mutations in an independent dataset from recent exome sequencing studies of ASD (7 DNMs in cases and 0 in controls), a higher degree of gene overlap than would be expected by chance ($P=10^{-7}$). In addition, ASD cases showed a 3-fold enrichment of DNMs in hotspots compared to controls. The observed distribution of DNMs could be explained in part by intrinsic properties of the genome. On the whole, DNMs were biased toward regions with reduced GC-content, low nucleosome occupancy, and we observed a weak bias toward late-replicating, heterochromatic regions. However, DNMs were also enriched within certain high-GC features, including recombination hotspots and transcribed sequences. Our findings suggest that rates of nucleotide substitution vary widely throughout the genome as a function of DNA sequence elements and their chromatin states. In addition, regional hypermutability is a significant factor shaping patterns of genetic variation and disease risk in humans.

Molecular Basis of Male Infertility: An Indian Perspective. *H. Sharma[1], R. Prasad[1], R. Mohan[2], S.K. Singh[2].* 1) Dept. of Biochemistry, PGIMER, Chandigarh, India; 2) Dept.of Urology, PGIMER, Chandigarh, India.

The majorities of males affected with Cystic Fibrosis (CF) are infertile due to high incidence of mutated Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) gene, leading to congenital absence of Vas-deference (CAVD) and is considered as genital form of Cystic Fibrosis. However clinically affected CF patients present spectrum of genital phenotypes ranging from impaired spermatogenesis to CAVD and obstruction in reproductive tract other then vas-deferens or epididymis. Recently research has been focused to investigate the role of CFTR other then vas formation. The Present study was undertaken to establish the spectrum and frequency of CFTR mutation in Indian infertile male population and to understand the possible involvement of CFTR gene in the etiology of male infertility other than CAVD. Blood samples from infertile males due to CBAVD (n=25), obstructive Azospermia (n=25) and oligospermia or non-obstructive azoosermia(n=100) were used for genomic DNA isolation and screening mutations in seven exons (2,3,4,7,8,10,12) hot spots of CFTR gene. Delta F-508, N1303K, R553X, G551D, G542X, 621+1G>T and W1282X were the other known most common mutation screened in Indian infertile males through allele specific ARMS PCR analysis. IVS8-Poly T allele polymorphism was also determined in all infertile male patients. Out of 25 CBAVD males 20 (80%) were found to have mutation in one allele of CFTR gene in remaining 5 (20%) mutation could not be identified. Among 25 cases of obstructive azospermia 17(68%) were found to have mutated CFTR allele where as among 100 oligospermic or Non obstructive azospermia males only 17% were found to have mutation in CFTR gene. Delta F-508 (9.5%) and IVS8 (5T) allele (22%) were the most common mutations identified in Indian infertile male population. Moreover the increased frequency of CF mutations in males with reduce sperm quality and quantity and in males with azospermia without CBAVD suggest CFTR protein may be involved in the process of spermatogenesis or sperm maturation apart from playing critical role in the development of epididymal gland and vas-deferens.

Phase-defined complete HLA genotyping by amplicon sequencing and read-backed phasing. *K. Hosomichi, T. Hayano, I. Inoue.* Division of Human Genetics, National Institute of Genetics, Mishima, Shizuoka, Japan.

The human leukocyte antigen (HLA) region, the 3.8-Mb segment of the human genome at 6p21, has been associated with more than 100 different diseases, mostly autoimmune diseases. Recently, the HLA region attracts attentions because strong drug adverse effects are associated with particular HLA alleles. Due to the complex nature of the HLA genes, classical direct sequencing method could not comprehensively elucidate genomic makeup of the HLA genes. We applied long ranged PCR to amplify six HLA genes (*HLA-A, -B, -C, DPB1, -DQB1* and *-DRB1*) followed by Nextera DNA Sample Preparation Kit and multiplex sequencing with MiSeq sequencer (illumina). 150 bp paired-end reads were aligned to the 6 HLA gene segments of hg19 on a condition that maximum 20 mismatches per read are allowed. In each heterozygous SNV position called from the first alignment, we classified the alleles using read-backed phasing : two alleles were divided into two phased haplotypes using information of the variants set on each paired-reads. According to these two phased haplotypes, we created two new self-reference sequences from an individual, which were applied for second stage alignment. After the second stage alignment, two HLA gene sequences based on phased SNVs and Indels were identified. Taking advantages of sequencing distantly separated fragments of a chromosome by paired-end sequencing at high depth read, and highly polymorphic nature of HLA genes, unambigous phasing becomes possible by a series of methods consisting of two alignment steps and read-backed phasing. Notably our phasing method does not require the IMGT/HLA database for creating HLA gene sequence unlike thus far HLA typing methods using Next-gen sequencers. In conclusion, we are able to determine the phase-defined complete HLA gene sequences including intron, upstream and downstream regions, even though alleles are rare or novel.

Characterization of sequence variants from the first direct-to-consumer exome pilot project. *A. Shmygelska, E. Harrington, C. McLean, A. Chowdry, B. Naughton.* 23andMe Inc, Mountain View, CA.

We present the analysis of exomes of forty-five individuals. This data set represents a subset of 23andMe's exome pilot project data sequenced at high coverage (80x) using the Agilent SureSelect 50Mb targeted exome capture platform. We summarize the number and pattern of genetic variants emerging from the study, which is to our knowledge the first direct-to-consumer exome project. We focused particularly on loss of function (LoF) variants, i.e., variants predicted to disrupt the function of protein-coding transcripts. In order to assess functional potential of the variants, we developed a filtering and annotation pipeline that ensures that variants called meet quality control measures (including coverage depth, genotype quality, and sequence uniqueness). An average exome has ~30,000 called variants in the exonic regions, ~700 of which are LoFs. This category includes frame shifts, stop gains and losses, start losses, and splice site modifications. Non-synonymous substitutions represent ~11,000, and synonymous substitutions account for ~12,000 variants. We identified and characterized a set of high-quality LoF variants (~400 per exome) including their occurrence in a set of genes involved in Mendelian disorders, disruption of protein domains, frequencies, evolutionary conservation, and functional classes of LoF-containing genes. We found that rare mutations (< 5% allelic frequency) are located more often than expected in domains present in membrane-associated proteins. As did previous studies, we found that in a healthy individual the number of variants predicted to substantially impact proteins is on the order of hundreds and most are carried in the heterozygous state. We also found that LoF-containing genes are enriched to encode drug-metabolizing enzymes, particularly cytochrome P450 (CYP) genes (18 out of 57 genes coding for various CYPs contain LoFs, adjusted p=4.4e-5), and transport proteins (ATP-powered pumps, transporters, and ion channels; adjusted p= 8.8e-4). Additionally, we replicated previous findings of LoF enrichment in olfactory receptor and immune response genes. CYPs are a major enzyme class involved in the oxidative metabolism of a diverse set of molecules, including drugs, dietary chemicals and endogenous compounds. Together with ATP-binding cassette pumps, solute carrier transporters, and ion channels, CYPs play a key role in adverse drug interactions. We discuss further analysis of the LoFs found in drug response genes.

Targeted Sequencing Applications and Project Design. *R. Fulton.* The Genome Institute, Washington University School of Medicine, 4444 Forest Park Boulevard, St. Louis, MO.

With significant advances in DNA sequencing technology and targeted sequencing techniques, there has been an explosion in genomic applications exploiting these platforms. DNA sequencing not only has become significantly higher throughput and less expensive, but it also produces digital outputs that can be used for interpretation of sample characteristics, thus enabling many new applications. This presentation outlines current capabilities, including timelines, general cost ranges, example applications, lessons learned, and project highlights involving targeted sequencing projects, in an effort to spark collaborations and interactions aimed at further exploitation of these technologies for genomic discovery. Target designs range from gene lists and/or chromosomal regions identified through various research efforts including genome wide association studies, literature searches, or related studies. These regions can range from tens of kilobases to tens of megabases of targets, with study designs also varying from family studies, quantitative trait studies, case control studies, or sample panels as examples. Human genetics projects such as age-related macular degeneration, allelic spectrum of metabolic disorders, cleft lip, breast and prostate susceptibility, and retinitis pigmentosa highlight successes in discovery. Validation and extension successes are demonstrated by cancer resequencing efforts involving Acute Myeloid Leukemia, ovarian cancer, and breast cancer; while pediatric cancer, AML, and breast cancer project applications show the power of deep digital read counts, and demonstrates the ability to show clonality, copy number, and clonal progression.

Inverted low-copy repeats and genome instability: A genome-wide analysis. *T. Gambin[1], P. Dittwald[2,3], C. Gonzaga-Jauregui[4], C. M. B. Carvalho[4], J. R. Lupski[4,5,6], A. Gambin[2,7], P. Stankiewicz[4,8].* 1) Institute of Computer Science, Warsaw University of Technology, Warsaw, Poland; 2) Institute of Informatics, University of Warsaw, Warsaw, Poland; 3) College of Inter-Faculty Individual Studies in Mathematics and Natural Sciences, University of Warsaw, Warsaw, Poland; 4) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Dept of Pediatrics, Baylor College of Medicine, Houston, TX; 6) Texas Children's Hospital, Houston, TX; 7) Mossakowski Medical Research Centre, Polish Academy of Sciences, Warsaw, Poland; 8) Dept of Medical Genetics, Institute of Mother and Child, Warsaw, Poland.

To date, about 40 unstable genomic loci flanked by directly oriented LCRs have been associated with recurrent deletions and reciprocal duplications causing genomic disorders. Inverse Paralogous LCRs (IP-LCRs) can also cause genome instability both by acting as nonallelic homologous recombination (NAHR) substrates, in this case mediating balanced inversions of the intervening genomic intervals, and by facilitating complex DUP-TRP/INV-DUP rearrangements. When disrupting an overlapping dosage sensitive gene(s), balanced inversions can lead to abnormal phenotypes. We delineated the genome-wide distribution of IP-LCRs greater than 1-kb in size and 95% sequence identity and mapped the intersecting genes that overlap at least one of the IP-LCRs; such genes can be disrupted by the inversion rearrangement. Remarkably, 12.1% of the human genome is potentially susceptible to instability via NAHR-mediated inversions and 942 genes, 99 of which are on the X chromosome, are predicted to be disrupted secondary to such an inversion! Additionally, IP-LCRs larger than 800-bp with at least 98% sequence identity (DTIP-LCRs) were recently implicated in the formation of complex genomic structures consisting of DUP-TRP/INV-DUP by a replication-based mechanism involving a template switch between such inverted repeats. We identified 1,551 DTIP-LCRs in the human genome that could facilitate DUP-TRP/INV-DUP formation and contribute to genomic complexity. Remarkably, 1,445 disease associated genes are at risk of undergoing copy-number gain as a consequence of susceptibility to formation of a DUP-TRP/INV-DUP complex rearrangement. Our data implicate inverted LCRs as a human genome architectural feature that could potentially be responsible for genomic instability associated with many human disease traits.

DNA from 1D to 3D: Effect of single nucleotide change on DNA conformational structure. *P.W. Yim, C. Liu, C. Woo, Y. Shi, J. Stevens, S. Dong.* Life Technologies, Foster City, CA.

Single Nucleotide Polymorphisms (SNPs) have been used as effective biomarkers for disease association and susceptibility. However, not all SNPs occur in exons, and the effect of a SNP in an intron or other non-coding regions of the DNA is unclear. We hypothesize that a noncoding or intronic SNP alters chromatin organization, which may then lead to changes in gene regulation and expression. In this work, we screened seven cell lines with 12 SNP assays in the PLD1 gene for heterozygosity. Breast cancer cell line MCF-7 exhibited heterozygosity for five of the 12 SNPs. Clustering between each of these SNPs and the rest of the PLD1 gene were analyzed using the TaqMan® 3C Chromosome Conformation Kit. For qPCR, two TaqMan genotyping probes were included in the same reaction and each probe was used to monitor allele-specific interaction. Our results revealed divergent interaction profiles for each allele of the SNPs. Although the interaction to some sites showed no difference, difference in the interaction frequency was observed between the two alleles for many sites. A comparison of the expression of the PLD1 gene showed lower expression for the heterozygous MCF-7 cell line when compared to the homozygous MDA-MB-231 cell line. Such analyses of the changes in the primary DNA sequence and their effects on the three dimensional DNA conformational structure can lead to new insights into the genetic cause of disease and open up new therapeutic approaches.

487F

Analysis of Dinucleotide Mutation Rates and Composition of Human Genome. *G. Zhang[1], D.W. Nebert[1,2].* 1) Human Genetics Division, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Environmental Health and Center for Environmental Genetics (CEG), University of Cincinnati Medical Center, Cincinnati, OH.

Mutation is the ultimate source of genetic variation; knowledge about the magnitude and mechanism(s) of nucleotide mutation is fundamental to our understanding of evolution of the human genome. It has been known for decades that nucleotide mutation is not random but rather highly dependent on neighboring nucleotides. A well-established example is the high mutation rate of 5-methylcytosine (5mC) to thymine (T) in the methylated CpG dinucleotide and consequent genome-wide underrepresentation of CpG. In this study we systematically investigated mutation rates and genome-wide relative abundance of dinucleotides. Specifically, we estimated dinucleotide mutation rates by two different approaches: 1) comparison between the non-polymorphic human reference sequence and ancestral sequence inferred from non-human primates; and 2) substitution patterns of almost 40 million SNPs from The 1000 Genomes Project. These two methods produced consistent (R^2=0.98) estimates on dinucleotide mutation rates; the observed pattern of dinucleotide substitutions was similar among intergenic, intronic and exonic regions - except for a significantly lower mutation rate of CpG in exonic regions. Detailed examination revealed a transition-to-transversion ratio (Ts/Tv=3.6) and substantially greater transition (24-fold) and transversion (4-fold) rates in CpG than in non-CpG dinucleotides. Also, we found higher rates of transversion between non-complementary nucleotides (A/C, G/T) than transversion between complementary nucleotides (A/T, G/C), and higher mutation rates of purine/pyrimidine or pyrimidine/purine dinucleotides than purine/purine or pyrimidine/pyrimidine dinucleotides. Under a steady-state Markov chain model, we calculated the expected dinucleotide composition, based on estimated dinucleotide mutation rates. The expected frequencies of dinucleotides agreed well with the observed frequencies for intergenic (R^2=0.92) and intronic regions (R^2=0.88) but not for exonic regions (R^2=0.37), which exhibited a much higher-than-expected CpC, GpG, GpC and CpG content. These results demonstrate that, in addition to the hypermutability of CpG dinucleotides, nucleotide mutation rates are specific for different dinucleotides. This phenomenon primarily shapes the observed genome-wide frequencies of dinucleotides - except for exonic regions, in which molecular mechanisms other than mutation appear to be responsible for maintaining the higher-than-expected G/C content.

The L141R and G153D variations associated with exfoliation glaucoma do not affect enzymatic functions of the lysyl oxidase-like protein 1 (LOXL1. *Y. Kim, S. Kim.* Dept Biochem, Wonkwang Univ Sch Med, Iksan, South Korea.

Lysyl oxidase-like gene 1 (LOXL1) is a copper-dependant amine oxidase that plays an essential role in biogenesis of the extracellular matrix through regulating formation of collagen and elastin fibers in connective tissues. LOXL1 is secreted into the extracellular matrix and become enzymatically active after proteolytic cleavage of the N-terminal propeptide region by BMP-1. Recently, two nonsynonymous SNPs of LOXL1, L141R and G153D that are located in the propeptide domain of LOXL1, have been reported to significantly increase susceptibility to exfoliation glaucoma (XFG). XFG is characterized by progressive accumulation of abnormal microfibrillar deposits in the anterior segments of the eye. To assess the effects of the L141R and G153D variations, we generated 4 different haplotype variants of LOXL1 across L141R and G153D, using oligonucleotide-directed mutagenesis. In amine oxidase assays, the four different haplotype variants of LOXL1 did not show statistically significant differences in amine oxidase activity toward collagen I and elastin. In addition, the L141R and G153D variations did not affect the proteolytic processing of LOXL1 in cultured cells. These results are consistent with recent genetic findings on the reversal of risk alleles of R141L and G153D in different ethnic backgrounds, suggesting that other unknown genetic factors or molecular mechanisms may be more relevant to the development of XFG.

Exploration of HIV susceptibility by exome sequencing. *S. Liu[1], W. Scott[1], D. Dykxhoorn[1,2]*. 1) Hussman Institue of Human Genomics, University of Miami, Miami, FL; 2) Department of Microbiology and Immunology University of Miami Miller School of Medicine.

Human Immunodeficiency Virus (HIV) is a highly lethal lentivirus which is responsible for a tremendous amount of suffering and death in the United States and throughout the world. By attacking the host's immune system, HIV leaves the infected individual susceptible to a wide variety of opportunistic infections. However, population risk of HIV varies. Why and how individuals differ in their susceptibility to HIV remains largely unanswered. Understanding what provides natural protection against HIV is critical in the effort to develop effective strategies to combat HIV. For this purpose, we performed whole exome sequencing on a cohort of highly exposed seronegative (HESN) individuals, long-term nonprogressors (LTNP), and rapid progressors (RP) using the Illumina HiSeq 2000. The resulting data was processed and annotated with BWA, GATK, and SeattleSeq. SNP Variants and indels were filtered and a comparison was performed between different groups. Comparing the HESN individuals with the HIV+ individuals (LTNP and RP)will facilitate the identification of protective factors that inhibit HIV infection, while comparing between LTNP and RP reveals genes that regulate viral progression in host cells. Our initial study shows that rs78424385 and rs56000326 (both on pseudogene POLR2J4 which encoding variant of hRPB11 subunit of RNA polymerase II) occurs at a much higher frequency among LTNPs than they do in the RP group. RNA polymerase II is known to transcribe proviral DNA into RNA which will be packaged into virions. Nucleotide polymorphisms which affect the function of RNA polymerase II are likely to be related to the rate of viral replication. Studying the relationship between HIV susceptibility and gene variants will not only increase our understanding of the mechanism underlying HIV infection and progression but will also help to identify therapeutic targets that could help to prevent viral transmission.

490W

Linkage disequilibrium analysis of polymorphisms of FRAS1 Related Extracellular Matrix 1 (FREM1). *J.F. Tuff[1], N. Kaplonski[1], V. Ly[1], B. Liang[1], S. Tyler[1], F.A. Plummer[1,2], M. Luo[1,2]*. 1) National Microbiology Laboratory, Winnipeg, MB, Canada; 2) University of Manitoba, Medical Microbiology, Winnipeg, Canada.

Objective: A low-resolution genome wide SNPs analysis of the Pumwani Sex Worker (ML) cohort identified an intronic single nucleotide polymorphism (SNP) in FREM1 (rs1552896) to be highly correlated with the HIV-exposed seronegative (HESN) phenotype. To identify putative causal SNPs, we conducted comprehensive gene sequencing, and targeted re-sequencing, of FREM1. Design: FREM1 (176,330bp) was PCR-amplified with 22 overlapping amplicons for 69 patients selected to enrich for rs1552896 genotypes. Amplicons were pooled and sequenced with Genome Sequencer FLX™ (Roche). SNPs showing significant LD with rs1552896 were identified based on a Logarithm of the Odds (LOD) score ≥ 2.0 as determined by Haploview v4.2. Targeted PCR and sequencing was then carried out on a larger sample set (n=643) to confirm the LD of SNPs identified by pyrosequencing. Results: Full-gene pyrosequencing of FREM1 identified 2198 SNPs. Eighty of these SNPs were found to be in LD with rs1552896 (LOD score range: 2.05–54.92). The targeted re-sequencing confirmed LD between rs1552896 and two exonic SNPs: rs2779500 (LOD: 4.99, V439L, 4649bp 5' to rs1552896) and rs1353223 (LOD: 3.30, I499V, 1170bp 5' to rs1552896). The SNP showing the strongest LD with rs1552896 was rs2642404 (LOD: 54.92), an intronic SNP located 4735bp 5' to rs1552896. SNP rs1353223 is a particularly interesting candidate as it is predicted to introduce a novel 5' splice site (Alamut) and to cause a functionally damaging amino acid substitution to FREM1 (SIFT). Conclusions: A combination of full gene sequencing and targeted re-sequencing of FREM1 identified two exonic SNPs and one intronic SNPs in close proximity to, and in LD with, rs1552896. The function of these SNPs will be further investigated.

Exome sequencing of subjects with familial 1q21.1 CNV and variable phenotype. *C. Harvard[1,2], F. Mo[3], F. Tang[1,2], Y. Qiao[1,2], S. Hamilton[4], S. Marles[5], B. McGillivary[4], C. Colins[3], M.E.S. Lewis[4], P. Pavlidis[6], E. Rajcan-Separovic[1,2]*. 1) Pathology & Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada; 2) Child & Family Research Institute, Vancouver, BC, Canada; 3) Vancouver Prostate Centre, Vancouver, BC, Canada; 4) Department of Medical Genetics, Vancouver, BC, Canada; 5) Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MN, Canada; 6) Centre for High-throughput Biology Michael Smith Laboratories, UBC, Vancouver, BC, Canada.

We performed whole exome sequencing (WES) for two families with a familial 1q21.1 CNV and variable degree of learning difficulty and phenotypic abnormalities in search for underlying genetic causes of the clinical heterogeneity seen in individuals with this CNV. We hypothesize that pathogenic mutation(s) in genes from the 1q21.1 CNV are present on the intact allele of the more symptomatic individuals. Family 1 consists of a trio (proband with 1q21.1 duplication, carrier father, and mother) while family 2 consists of three individuals with a 1q21.1 CNV deletion (proband, mother and grandmother) and two unaffected family members (father and sibling). Methods: Agilent's Sure Select exome capture kit (50 MB) was used to generate libraries sequenced on a Hiseq2000. Reads were mapped using BWA v.0.5.9 and variant calls made using SOAPsnp and SAMtools. Novel SNPs and indels with potential functional consequence, high conservation, and read depth were considered as putatively pathogenic, particularly if they were associated with changes in the expression of the associated gene obtained by whole genome expression analysis for five subjects with the 1q21.1 CNV. Results: None of the candidate pathogenic variants overlapped with the 1q21.1 CNV, ruling out the role of a secondary exonic mutation within this CNV in a more severe phenotype in the two probands. There were more than 60 novel putatively pathogenic mutations occurring de novo in the probands who had a 1q21.1 deletion and 1q21.1 duplication respectively, or shared between the probands and their less affected relatives. The comparison of these mutations with gene expression data identified a mutation within a gene from 1q23.3 with a role in stress response, which was shared between two 1q21.1 dup CNV carriers and associated with abnormal gene expression in both. Selection of additional candidate mutations is ongoing as well as their confirmation. Although the role of copy number changes of genes within 1q21.1 CNV in phenotypic variability can not be excluded, WES offers opportunities to identify other genetic changes that may be involved in modifying the phenotype of 1q21.1 CNV carriers, particularly if they are involved in response to environment.

Deep resequencing of the NOS2 gene suggests multiple potential mechanisms underlying the association of several complex diseases with a common synonymous SNP. *L. Wang[1,2], J. Santos[1], A. Dressen[1], A. Mehta[1], M. Pericak-Vance[1,2], J. Vance[1,2], W. Scott[1,2].* 1) Hussman Institute for Human Genomics, Univ Miami,Miller Sch Med, Miami, FL; 2) 2. Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miller School of Medicine.

Three reports have confirmed an association between Parkinson disease (PD) risk and a common synonymous SNP rs1060826 (minor allele frequency (MAF) = 45%) in the NOS2 gene. The SNP has also been associated with other diseases, including age-related macular degeneration (AMD), autism, and tuberculosis. Furthermore, rs1060826 modifies the effect of cigarette smoking on both PD and AMD. We sought to identify the genetic variant(s) underlying the association and gene-smoking interaction at rs1060826. We performed deep sequencing of the 53 kb genomic region of NOS2 including introns, exons and promoter region. To increase our chance of finding the causative variant(s) accounting for the association at rs1060826, we selected individuals who are homozygotes for the risk and protective allele of rs1060826 (N=42 for each group). To overcome the substantial sequence homology between NOS2 and its segmental duplication (SD) regions, we used long-range PCR with primers outside the SD to capture NOS2 genomic region for massively parallel sequencing using the Illumina Hi-Seq2000. More than 300 variants, including small insertions/deletions, were found. Half of these variants were novel. The results to date suggest several potential functional mechanisms that could explain previous observations at rs1060826. First, we discovered that rare and less common functional variants are enriched on the background of rs1060826 G allele, including nonsynoymous variants, 3'UTR variants affecting miRNA binding, and a splicing site variant. The MAF of these variants ranges from 0 to 20% in the Caucasian population surveyed in the NHLBI Exome Sequencing Project. Second, we found a novel 12 bp intronic substitution (GTCCCGTACCTG to GCCTCCTGAG) that is in perfect linkage disequilibrium with rs1060826 and is 300 bp away from the closest exon. Finally, comparison of RNA and DNA sequence revealed that rs1060826 is an active RNA-editing site. To test whether the functional variants appeared in the rs1060826 G allele background collectively account for the association at rs1060826, we are genotyping them in large PD and AMD data sets and conducting individual and burden tests of association. Future studies will determine whether the intronic substitution directs allelic-specific splicing or transcription and whether the RNA editing at rs1060826 affects translation efficiency, as well as how these modifications mediate genetic association and gene-smoking interaction in complex diseases.

493F

Characteristics and analysis of exonic SNPs and indels discovered by low-pass and exome sequencing. *J. Schmidt, J. Gollub, J. Barts, C. Davies, B. Wong, R. Shigeta, G. Hsiao, M. Nitzberg, E. Shell, J. Peete, S. Hsu, A. Kohli, T. Ha, D. Brown, L. Bellon, T. Webster.* Informatics, Affymetrix, Santa Clara, CA.

Exome sequencing of over 12,000 individuals by the Exome Chip Design Consortium and the 1000 Genomes exome sequencing project (including both low coverage and exome sequencing) has revealed a large number of low-frequency SNPs and indels in or near the exome. While SNPs discovered by low-pass sequencing are becoming increasingly reliable, much work remains to be done on indels. Distinguishing true indels from false discoveries remains a challenge. We developed the Affymetrix® Axiom® Exome Genotyping Array to interrogate nearly 300,000 SNPs and 30,000 indels and have analyzed these variants by genotyping 1,249 individuals from four major populations (East Asian, European, African, and Latino) on the array and comparing the results to genotypes published by the 1000 Genomes Project. Genotyping array technologies are mature and have been employed to screen populations for the presence of known SNPs and (more recently) indels, with overall accuracy of >99.5%. They can therefore be employed as an accurate and inexpensive high-throughput analysis and validation tool to be used in conjunction with sequencing. We found excellent concordance to sequencing-derived calls of heterozygote SNP genotypes down to very low minor allele frequency. In the current state of the art, indels on the other hand appear to be prone to false discovery through sequencing. Interestingly, we found that even in the absence of detailed sequencing data, the number of independent sequencing efforts in which an indel was discovered was highly predictive of array validation (and hence indicating a much lower false positive rate), with a much lesser dependence on the frequency of the indel. We also analyzed the distribution of types of SNPs and indels in the various populations. We observed that non-synonymous variants (as compared to synonymous, UTR and intronic variants) have a significantly higher occurrence in variants private to a given population. This observation remains valid even after accounting for the fact that variants present in all four populations generally have a higher allele frequency than those private to just one of the populations. These results demonstrate the value of genotyping arrays for efficient validation of sequencing-derived variant discoveries and subsequent analysis. Genotypes are available from the Affymetrix website as well as the 1000 Genomes ftp site. We thank 1000 Genomes Project and the Exome Chip Design Consortium for access to their data.

Somatic mosaicism in the blood compartment of a 115-year-old woman. *H. Holstege[1], D. Sie[2], W. Pfeiffer[3], T. Nicholas[4], M.A. Miller[3], T. Harkins[5], C. Lee[5], T. Ross[5], B. Ylstra[2], H. Meijers-Heijboer[1], M. Reinders[6], G. Holstege[7], E. Sistermans[1], S. Levy[4]*. 1) Dept of Clinical Genetics, VU University Medical Center, Amsterdam, Netherlands; 2) Dept of Pathology, VU University Medical Center, Amsterdam, Netherlands; 3) San Diego Supercomputer Center, UCSD, La Jolla, USA; 4) Scripps Translational Science Institute, San Diego, USA; 5) Life Technologies, Beverly, MA, USA; 6) Delft Bioinformatics Lab, Delft University of Technology, Delft, The Netherlands; 7) Center for Uroneurology, University Medical Center Groningen, Groningen, The Netherlands.

The somatic mutation rate in human tissues is currently unknown. Using DNA sequencing technologies, we sought to detect somatic mutations acquired and retained in the blood compartment during a human lifetime. Therefore, we compared the blood and brain genomes (both >60x read depth) of a 115-year-old woman. This individual provides a unique opportunity to study the number, type, and location of somatic mutations exhibited in distinct tissues during a long and healthy life.

In a first analysis, we used a set of sequence filtering procedures to detect SNVs and indels that had a different genotype in blood and brain. We detected ~200 SNVs and ~20 indels that were heterozygous in blood, but not present in brain, consistent with our hypothesis that the higher rate of cell division in blood results in more blood-specific somatic mutations. Further experimental validation of these SNVs and indels by a secondary sequencing technology (>1000 × read depth) in blood, brain, and 9 other tissue types, confirmed 98% of these somatic mutations in blood but not in brain. Notably, lung tissue possessed a low variant allele frequency in these loci, presumably due to vast lymphocyte infiltration in this tissue.

The somatic origin for these variants is supported by their absence in dbSNP, by their heterozygosity, by their occurrence only in blood and not in brain, and by their lower mean variant allele frequency compared with heterozygous SNVs shared between blood and brain. This somatic mosaicism suggests that these loci emanate from a subset of the cells in the blood compartment. Several biological causes for the origin of these somatic mutations are currently being investigated.

Even though there were many heterozygous insertions shared between blood and brain, the putative somatic indels were nearly all deletions. This suggests that deletions are more readily acquired than insertions during DNA replication or DNA repair.

In this first effort to detect somatic mutations we analyzed only non-repetitive genomic regions. Extrapolation of the validated variants to the whole genome implies at least 800 somatic SNVs in the healthy blood compartment, which is almost 30-fold higher than the *de novo* mutation rate between two generations and immeasurably higher than the mutation rate in the healthy brain. Such a variable mutation rate between healthy tissues has implications for future genomic studies.

High-Resolution Melting Analysis of *STAT3* Involved in Autosomal Dominant Hyper IgE Syndrome (HIES) using Bulge-Inducing Primers to Eliminate Polymorphisms and Snapback Primers for Genotyping. *M.T. Seipp[1], N.H. Augustine[2], A. Kumanovics[1,2], H.R. Hill[1,2,3,4], C.T. Wittwer[1,2]*. 1) Advanced Technology Group, ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Department of Pathology, University of Utah, UT; 3) Department of Pediatrics, University of Utah, UT; 4) Department of Medicine, University of Utah, UT.

Introduction: Autosomal dominant HIES is caused by mutations in *STAT3*, a 7.5 kb gene located on chromosome 17. Mutations can occur in any of the 23 coding exons as well as the associated splice sites. Gene scanning by high resolution (HR) melting analysis can be used to target the critical sequence areas and allow the detection of any variation from the expected DNA sequence. Exons with variant melting curves can be identified and further evaluated by genotyping or sequence analysis. **Methods:** Initial primer design for the 23 exons was done using Idaho Technology LightScanner Primer Design software. When known single nucleotide variants (SNVs) were likely to contribute to melting curve variations, primers were modified to either exclude polymorphisms by inducing a loop bulge, or explicitly genotyped by adding on 5'-genotyping tails to form snapback primers. PCR was performed on the BioRad C1000 followed by high resolution melting analysis on the Idaho Technology LightScanner. After this initial variant scanning, the samples were diluted 1:10 with water so that intra-molecular hairpins were favored for snapback genotyping. A second melting analysis of the diluted products was performed to specifically genotype any variants targeted by the snapback primers. Sequencing was only performed in the rare case of a melting curve variation not identified by snapback genotyping. Sixteen patients with autosomal dominant HIES along with 96 non-HIES DNA samples were scanned for mutations and genotyped for common variants. **Results:** Amplicons with polymorphisms that were eliminated by bulge-inducing primers had melting curves identical to the wild type sequence. When variants were detected by scanning in amplicons with snapback primers, the second melting analysis of the hairpin identified common heterozygous and homozygous variants, drastically reducing the need for sequencing. *STAT3* mutations were found in all affected individuals. The mutations were found in exon 13, exon 20 and exon 21. All other exons were found to match the expected wild type HR melting profiles. All 96 non-HIES samples lacked *STAT3* disease associated mutations. **Conclusion:** All HIES mutations from 16 HIES patients were identified. The combination of HR scanning with bulge-inducing primers and snapback genotyping decreases the sequencing burden of by over 99%. Sequencing was required in <0.5% of all amplicons and the assay could be completed in <4 hours.

PON-P: Integrated Predictor for Pathogenicity of Missense Variants. *M. Vihinen[1,2,3], A. Olatubosun[2,3], J. Väliaho[2,3], J. Härkönen[2,3], J. Thusberg[2,3]*. 1) Department of Experimental Medical Science, Lund University, Lund, Sweden; 2) Institute of Biomedical Technology, University of Tampere, Finland; 3) BioMediTech, Tampere, Finland.

High throughput sequencing data generation demands methods for interpreting the effects of genomic variants. Numerous computational methods have been developed to assess the impact of variations because experimental methods are unable to cope with both the speed and volume of data generation. To harness the strength of currently available predictors, the Pathogenic-or-Not-Pipeline (PON-P) integrates 5 predictors to predict the probability that non-synonymous variations affect protein function and may consequently be disease-related. Random forest methodology-based PON-P shows consistently improved performance in cross-validation tests and on independent test sets, providing ternary classification and statistical reliability estimate of results. PON-P may be used as a first step in screening and prioritizing variants in order to determine deleterious ones for further experimentation. PON-P is freely available at http://bioinf.uta.fi/PON-P.

Data Submissions to EBI Variation Archives. *I. Lappalainen, V. Kumanduri, J. Almeida-King, L. Skipper, J.D. Spalding, M. Maguire, P. Flicek.* EMBL-EBI Wellcome Trust, Cambridge, United Kingdom.

The European Bioinformatics Institute (EBI) provides public archives that allow scientists to deposit genetic and phenotypic data from the peer reviewed or community research projects. The data, together with study protocols, are archived, indexed and made available to the research community in a consistent format using applicable data standards. The archives issue permanent identifiers for all submitted data allowing explicit referral in publications. These identifiers are also used for cross referencing data stored in different archives for the same project and to integrate archived data into other scientific resources at the EBI such as the Ensembl. The appropriate archive at the EBI depends on the type of informed consent.

For data with full consent, the Database of Genetic Variants archive (DGVa) is repository for all types of genomic structural variants (SV) or copy number variations (CNV) in all species. The resource has a data model designed to capture and describe the abundant complexity of current SV discovery and genotyping experiments. The archived studies are made available in GVF format and the variants can be accessed using Ensembl or Biomart. DGVa and the peer archive dbVar, at NCBI, exchange data monthly. The collaboration with the DGV resource at the University of Toronto will result in a high-quality curated reference set for normal human SV and CNV variation. The April 2012 DGVa release includes more than 90 studies and 10 million SV/CNV variants.

The European Genome-phenome Archive (EGA) provides a permanent archive for all genetic and phenotypic data that may be potentially identifiable. EGA contains data collected from individuals for the purpose of medical or genetic research and whose consent agreements prevents open, public data distribution. The data access decisions are made by a data access commitee and not by the EGA project. Once DAC authorization to the data has been granted, the EGA provides secure tools for downloading and decrypting the authorized files and general support for questions related to the data content. May 2012 data from more than 190 studies and 150 000 samples have been submitted to the EGA and made available to authorized researchers. These studies include array-based genotyping experiments as well as raw DNA sequence data from re-sequencing or transcriptomics projects.

498W

The power of large numbers: frequencies of rare pathogenic mutations in the 23andMe database. *E.R. Chang, D.A. Hinds, N. Eriksson, J.M. Macpherson, C.B. Do, B.T. Naughton.* 23andMe, Inc., Mountain View, CA.

23andMe, with over 150,000 genotyped customers, is in a unique position to accurately estimate the carrier frequencies of rare pathogenic mutations. Accurate, population-specific estimates of mutation frequencies facilitate effective and efficient carrier screening. We present population-specific carrier frequencies for several rare, autosomal recessive conditions. 23andMe's large database, consisting primarily of research participants not selected for any particular disease phenotype, reveals that some mutations that were thought to be associated only with certain populations are also present in additional populations at comparable rates. For instance, the mutation G269S, a late-onset Tay-Sachs mutation, was thought to be found predominantly in individuals of Ashkenazi ancestry. Our data suggest, however, that this mutation occurs in individuals of Eastern European ancestry at a higher frequency than in individuals of Ashkenazi ancestry. Such findings demonstrate the power of a large genetic database in which information about genetic ancestry, self-reported ancestry, and country of residence are all used to estimate population-specific and clinically meaningful statistics.

Finding from CAGI: The Critical Assessment of Genome Interpretation, a community experiment to evaluate phenotype prediction. *S. Brenner[1], S. Repo[1,3], J. Moult[2], C. CAGI participants[2].* 1) Univ California, Berkeley, Berkeley, CA; 2) IBBR, University of Maryland, Rockville, MD; 3) EMBL-EBI, Wellcome Trust Genome Campus, Hinxton, Cambridgeshire, CB10 1SD, UK.

The Critical Assessment of Genome Interpretation (CAGI, ˋk-jēˊ) is a community experiment to objectively assess computational methods for predicting the phenotypic impacts of genomic variation. In this assessment, participants are provided genetic variants and make predictions of resulting phenotype. These predictions are evaluated against experimental characterizations by independent assessors. The CAGI experiment culminates with a community workshop and publications to disseminate results, assess our collective ability to make accurate and meaningful phenotypic predictions, and better understand progress in the field. A long-term goal for CAGI is to improve the accuracy of phenotype and disease predictions in clinical settings. The CAGI 2011 experiment consisted of 11 diverse challenges exploring the phenotypic consequences of genomic variation. In two challenges, CAGI predictors applied the state-of-the-art methods to identify the effects of variants in a metabolic enzyme and oncogenes. This revealed the relative strengths of each prediction approach and the necessity of customizing such methods to the individual genes in question; these challenges also offered insight into the appropriate use of such methods in basic and clinical research. CAGI also explored genome-scale data, showing unexpected successes in predicting Crohn's disease from exomes, as well as disappointing failures in using genome and transcriptome data to distinguish discordant monozygotic twins with asthma. Complementary approaches from two groups showed promising results in predicting distinct response of breast cancer cell lines to a panel of drugs. Predictors also made measurable progress in predicting a diversity of phenotypes present in the Personal Genome Project participants, as compared to the CAGI predictions from 2010. CAGI is planned again for 2012 and we welcome participation from the community. Current information will be available at the CAGI website at http://genomeinterpretation.org.

Polymorphic Regulation of Gene Expression by the Histone Demethylase KDM4C. *B.L. Gregory[1], V.G. Cheung[2,3].* 1) VMD-PhD Combined Degree Program, University of Pennsylvania, Philadelphia, PA; 2) Departments of Pediatrics & Genetics, University of Pennsylvania, Philadelphia, PA; 3) Howard Hughes Medical Institute.

Histone demethylases are chromatin modifiers whose biochemical activities are characterized, yet their target genes remain largely unknown. In this study, we focus on KDM4C, a Jumonji demethylase that targets trimethylated H3K9 histone marks associated with transcriptional repression. Using genetic and molecular approaches, we identified and characterized target genes of KDM4C, allowing us to define its role in cell proliferation.

We measured gene expression in B cells from members of 45 large pedigrees, and then treated gene expression levels as quantitative traits in linkage and association analyses. We found extensive individual variation in the expression levels of *KDM4C*. Genetic analyses showed that *KDM4C* expression is regulated in cis by variants near the 3' UTR. These *KDM4C* alleles then influence the expression levels of nearly 100 genes in trans, including *CLTA*, *H3F3B*, *MEF2C*, *RNMT*, *RRP7A*, *TRA2B*, and *ZBTB25*. We followed up the genetic mapping results with functional studies. Using RNA interference, we found that knockdown of *KDM4C* led to a decrease in the expression levels of the target genes, confirming the regulator-target gene relationships. By chromatin immunoprecipitation, we found that KDM4C localized to the promoters of these genes, suggesting that KDM4C regulates the expression of these genes by direct binding. Individuals with higher *KDM4C* expression had more KDM4C promoter enrichment than individuals with lower *KDM4C* expression. By chromatin immunoprecipitation for di-methylated and tri-methylated H3K9, we showed that the demethylase activity of KDM4C is positively correlated with *KDM4C* expression level.

Among the targets of KDM4C are genes that play a key role in cell proliferation, including *RNMT* and *MYC*. To study the effect of *KDM4C* expression level on cellular phenotypes, we measured cell proliferation in individuals with high and low *KDM4C* levels. Growth curve measurements and BrdU assays show that cells from individuals with higher *KDM4C* expression grow faster than cells from individuals with lower *KDM4C* expression. In summary, our results reveal the interplay between DNA sequence variants and chromatin modifications in gene regulation. This is one of the first studies to identify common DNA sequence variants that affect epigenetic regulation of gene expression.

Mitochondrial Sequence Variation In Twins. *Y. Bouhlal[1], S. Martinez[1], H. Gong[1], K. Dumas[1], J.T.C. Shieh[1,2]*. 1) Division of Medical Genetics, Department of Pediatrics, University of California San Francisco, San Francisco, CA, USA; 2) Institute for Human Genetics, University of California San Francisco, San Francisco, CA, USA.

In applying genome-wide sequencing technologies to aid in disease investigation, it is increasingly important to resolve sequence variation in regions of the genome that may have homologous sequences. The human mitochondrial genome provides an opportunity to test sequencing and interpretation abilities given the potential for heteroplasmy, somatic variation, and homologous nuclear mitochondrial sequences or numts. Identical twins share the same mitochondrial DNA from early life, but whether the mitochondrial sequence remains the same is unclear. We compared adult monozygotic twins using high throughput-sequencing on blood-derived DNA and verified individual variants using fluorescent primer extension. We found 37 homoplasmic variants shared between the twin individuals. All shared variants were verified on pre-library genomic DNA samples. These studies supported highly identical genetic sequence in the absence of confirmed heteroplasmic somatic mutation. We detected a number of potential single nucleotide variants present at very low levels but with high sequence quality scores and read homology to the mitochondrial DNA. Such variants were assessed in pre-enriched mitochondrial DNA and suggest that numts can be effectively differentiated from mtDNA variation. We conclude that twin identity extends to the mitochondrial DNA, and it is critical to differentiate between numts and mtDNA in genome sequencing, particularly since heteroplasmy level can influence disease and phenotypes. Further studies on twin biology will aid in understanding how variation occurs and persists.

502W

Polymorphisms in primer binding site affect genotyping accuracy of *FCGR2B* rs1050501 in Caucasians. *J. M. Reynolds.* Clinical Pharmacogenomics Lab, Pfizer, Inc, Groton, CT.

A single nucleotide polymorphism (SNP) of *FCGR2B* called rs1050501 (c.695T>C, I232T) has been associated with susceptibility to Systemic Lupus Erythematosus (SLE) in Asians in several studies, but inconsistently in Caucasians. Many of the studies have used a forward primer that anneals to a site containing the SNPs rs2793082 and rs2793081. Since minor allele frequencies for rs2793082 and rs2793081 have not been reported in dbSNP or HapMap, they were estimated by testing HapMap01 (Caucasian), HapMap02 (Asian) and HapMap03 (African) gDNA samples. While the minor allele frequencies were estimated to be low in HapMap02 and HapMap03 samples, a minor allele frequency of 25% in the HapMap01 samples suggests the rs2793082 and rs2798301 SNPs are common in Caucasians. To determine if the accuracy of genotyping rs1050501 in Caucasians could be affected by using an amplification primer that anneals to the rs2793082 and rs2793081 region, Caucasian samples (n=84) were genotyped for rs1050501 with two Taqman® assays identical for all conditions, except the forward primer. The assays were designated rs1050501 Polymorphic to indicate the forward primer anneals to the rs2793082 and rs2793081 region, and rs1050501 Non-Polymorphic, to indicate the forward primer does not anneal to the rs2793082 and rs2793081 region. In comparing the two assays, it was found that the results were discordant for 14% of the samples. Six samples (7%) called T/C for rs1050501 in the Non-Polymorphic assay were called C/C in the Polymorphic Assay. All six samples were found to be heterozygous for rs2793082 and rs2793081. It appears that in the Polymorphic Assay there was amplification from only one allele. Six samples (7%) failed completely in the Polymorphic Assay, but were called by the Non-Polymorphic assay. All six samples were found to be homozygous for rs2793082 and rs2793081. In this case, the Polymorphic Assay was unable to amplify from either allele. It is possible that this polymorphic priming site has contributed to the inconsistent association of rs1050501 with SLE in Caucasian studies. Due to the high incidence of rs2793082 and rs2793081 in Caucasians and the evidence that using a primer annealing to this polymorphic region adversely affects rs1050501 genotyping accuracy, it is recommend that researchers discontinue the use of genotyping assays that include a forward primer that anneals to the rs2793082 and rs2793081 sites in Caucasian populations.

503F

Identification of rare variants contributing to pain sensitivity in the normal population: an exome sequencing study. *B. Zhang[5], F.M.K. Williams[1], S. Scollen[2], D. Coa[3], Y. Memari[4], C. Hyde[5], Y. Shi[3], J. Harris[1], I. Harrow[6], A. Malarstig[5], B. Dougherty[6], R. McEwen[6], J.C. Stephens[5], K. Patel[5], C. Menni[1], D. Hodgkiss[1], G. Surdulescu[1], W. He[5], B. Sidders[2], D. Ziemek[7], N. Soranzo[4], X. Jin[3,8], S.B. McMahon[9], S.L. John[5], J. Wang[3], T.D. Spector[1]*. 1) Dept Twin Research and Genetic Epidemiology, King's College London, UK; 2) Pfizer Limited, Neusentis, The Portway Building, Granta Park, Cambridge, UK; 3) BGI-Shenzhen, Shenzhen, China; 4) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK; 5) Pfizer Research Laboratories, Groton, Connecticut, USA; 6) Pfizer Global Research and Development, Sandwich, Kent UK; 7) Computational Sciences CoE, Worldwide R&D, Pfizer Inc, Cambridge, MA, USA; 8) China and School of Bioscience and Biotechnology, South China University of Technology, Guangzhou, China; 9) Wolfson CARD, Kings College London, Guys Hospital, London UK.

Sensitivity to pain varies considerably between individuals. Twin studies have shown pain sensitivity to be heritable. Increased sensitivity to experimental pain is also known to be a risk factor for developing chronic pain; a common and debilitating but poorly understood symptom. To understand genetic mechanisms underlying pain sensitivity objectively we explored in detail the genetic variation in individuals' response to experimental heat pain. First, quantitative sensory testing (QST) to heat pain was performed in 2,500 volunteers from the TwinsUK cohort. Singletons lying in the high and low parts (100 each) of the QST distribution were selected for exome sequencing to a depth of 70X, in a discovery set, and the selection process was repeated to provide a replication set. A combination of collapsing and allele sharing methods was used to test the association between single nucleotide variants (SNVs) identified and pain sensitivity. The function of the SNVs identified was further explored using network analysis. We found the distribution of SNVs detected was different between the pain sensitive and insensitive categories, with the insensitive showing higher frequency of rare variants (p=0.033). After merging datasets, we identified 138 unique genes harbouring a SNV with a 2nd lowest p-value <0.01. First we examined the functional annotations of these 138 genes using the online functional annotation tool DAVID. Nine high level GO terms were nominally significantly enriched in the gene list. We applied causal reasoning to our data, which uses a large curated database of directed regulatory molecular interactions to identify the most plausible upstream regulators of a gene set. Of the 138 genes 86 were present in our database of causal interactions, from which we identified 6 nominally significant regulatory networks. One of the regulatory networks, angiotensin II, was highly significant after Bonferroni correction (p=4.9×10-6). The causal network analysis associated 12 genes identified in the present study with angiotensin II. This pathway has been implicated in animal models and human studies of pain. Our study suggests that the angiotensin pathway may provide fruitful new targets in pain management. The approach of sequencing extreme exome variation in normal individuals has provided important insights into gene networks mediating pain sensitivity in humans and will be applicable to other common complex traits.

Discovering Retrotransposon Insertion Polymorphisms (RIPs) Associated with Human Phenotypes by TIP-chip. *T.D. Babatz[1,2,3,5], D. Avramopoulos[1,2], J.D. Boeke[1,2,5], K.H. Burns[1,2,3,4,5]*. 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Molecular Biology and Genetics, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Department of Oncology, Johns Hopkins University School of Medicine, Baltimore, MD; 5) HiT Center, Johns Hopkins University School of Medicine, Baltimore, MD.

Recent studies demonstrate that retroelements L1 and Alu are significantly more polymorphic between individual human genomes than previously appreciated. Retrotransposon insertion events can have functional impact, but the extent of this is not well understood, and consequences of relatively common polymorphisms are mostly unknown. Despite successes of genome-wide association studies (GWAS) in detecting highly significant and replicated associations of common genetic variants and common disease phenotypes, it is understood that the associated single nucleotide polymorphism (SNP) is typically not the causal variant. Rather, the trait-associated SNP (TAS) is tagging a haplotype on which resides a distinct functional variant conferring the phenotype association. Identifying these variants has been difficult, and most regions associated with disease have been intronic or intergenic, noncoding, and apparently nonfunctional. Our hypothesis is that a subset of GWAS SNPs tag a functional retrotransposon insertion polymorphism (RIP) common in the population conferring disease risk. To identify these variants, we are discovering L1 and Alu RIPs specifically in GWAS SNP intervals using transposon insertion profiling by microarray (TIP-chip). Our custom TIP-chip assays a 160 kb window spanning each of 1349 of the most significantly associated SNPs from 370 published GWAS. We expect to detect RIPs that are annotated in the human reference genome, RIPs reported in the database dbRIP and the 1000 genomes project, as well as RIPs that have not been previously described, all of which will be candidates for further study. Ten CEPH individuals from the HapMap project have been assayed using the targeted TIP-chip. The array includes 20 reference L1s and 32 reference Alu insertions for the purpose of evaluating array performance, all of which have been detected in the first four individuals studied. Of 49 reference L1s spanned by the intervals assayed on the array, 46 have been detected, suggesting robust array performance. We have gone on to PCR genotype candidate RIPs in 90 CEPH individuals and shown high LD with the respective TAS. Imputation of candidate RIP genotypes in larger populations and evaluation of linkage with trait-associated SNPs are ongoing.

Fork Stalling and Template Switching (FoSTeS) mechanism generates a novel rearrangement associated with Incontinentia Pigmenti. *M.I. Conte, S. Raimo, M. Paciolla, A. Pescatore, E. Esposito, M.G. Miano, F. Fusco, M.V. Ursini.* Institute of Genetics and Biophysics ABT, IGB-CNR, Naples, Italy.

Incontinentia Pigmenti (IP, OMIM 308300) is a X-linked dominant neuroectodermal disease, lethal in males, belonging to pathological condition also known as *genomic disorder*. IP is caused by recurrent or non-recurrent DNA rearrangements in the Xq28 *NEMO/IKBKG* locus or by point mutation in the *NEMO* coding region. *NEMO* encodes for the NEMO/IKKgamma protein, which acts as a regulatory subunit of the Inhibitor of the KappaB Kinase (IKK) complex required for the NF-kB (Nuclear Factor kappaB) activation pathway. The *NEMO* gene has a unique genomic organization: in the centromeric direction, it partially overlaps the *G6PD* gene; in the telomeric direction, it is part of a Low Copy Repeat (LCR1), whose duplicated copy, the LCR2, located in opposite direction to gene, contains its non functional copy *pseudoNEMO*, known to be a *reservoir* for mutation causing IP. Moreover, the entire *NEMO* locus is characterized by a high frequency of repeated sequences, micro/macro-homologies and tandem repeats. We previously demonstrated that such genomic architecture enhances the vulnerability of the locus to produce de novo genomic rearrangements through different mechanisms (NAHR, Alu-Alu recombination, Gene conversion). Indeed, abnormal recombination in *NEMO* locus may cause either pathological deletions, which may occur during the parental germline meiosis, or benign variants (MER67Bdup and IKBKGPdel), predisposing to the disease. Here, we describe a novel pathologic genomic rearrangement in IP locus generated by replication-based mechanism, named Fork Stalling and Template Switching (FoSTeS), which caused a complex deletion (36bp) in *NEMO* exon 4 that alters the open reading frame of NEMO protein synthesis producing a premature stop codon (p.Q145X). According to the FoSTeS based mechanism, breakpoint sequence analyses revealed an additional T nucleotide at junction point. In addition, the presence of two micro-homology sequences (CCAG) located at breakpoint sites and one non-B DNA structure (tetraplex) in the deleted region due to stretches of G oligonucleotides, may induce DNA strand lesions and facilitate a FoSTeS event able to generate the complex rearrangement. Taken together these findings indicated that other mechanisms than recombination, based on replication events, might enhance the vulnerability of the IP locus to produce *de novo* pathological IP alleles.

The ENCODE effort combining RNA-seq and RT-PCR-seq allows to catalog thousands of novel lncRNAs. *C. Howald[1], A. Tanzer[2], J. Chrast[1], F. Kokocinski[3], T. Derrien[2], N. Walters[1], J. Manuel Gonzalez[3], A. Frankish[3], B.L. Aken[3], T. Hourlier[3], J. Vogel[3], S. White[3], S.M.J. Searle[3], J. Harrow[3], T. Hubbard[3], R. Guigó[2], A. Reymond[1]*. 1) Center for integrative genomics, University of Lausanne, Lausanne, Switzerland; 2) Centre de Regulacio Genomica, Grup de Recerca en Informatica Biomedica, Barcelona, Spain; 3) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge.

Within the ENCODE consortium, GENCODE aimed to accurately annotate all protein-coding genes, pseudogenes and non-coding transcribed loci in the human genome through manual curation and computational methods. The continuously evolving GENCODE gene set now contains 53,934 genes of which 20,110 are coding, and 183,086 transcripts (GENCODE freeze version 12). Lower confidence transcribed loci were systematically experimentally evaluated by RT-PCR amplification followed by highly multiplexed sequencing readout, a method we coined RT-PCR-seq. 79% of all assessed junctions are confirmed by this evaluation procedure demonstrating the high quality of the annotation reached by the GENCODE gene set. We further took advantage of the 5 billion sequences deep transcriptome profiling generated by the Illumina “Human Body Map” in 16 human tissues to uncover 5918 novel gene models that do not overlap any loci depicted in GENCODE. They potentially represent new non-coding RNA genes or alternatively unannotated 5' or 3'UTR portions of known genes, as the vast majority of these models was shown to have poor coding potential using comparative genomics and mass spectrometry. We experimentally validated using RT-PCR-seq, 73% of the new HBM models, de facto enriching the complexity of the human genome annotation of non-coding RNA genes by more than 4000 novel genes. Similarly, we uncovered and validated another 3300 transcripts and 1850 novel gene models using the 5.5 billion RNA-seq reads from 15 human cell lines produced by the ENCODE consortium. Our findings demonstrate the effectiveness of unbiased RNA-seq combined with targeted RT-PCR-seq to uncover new genome features. These two technologies were simultaneously similarly paired to unravel expressed pseudogenes by the GENCODE consortium. Our RT-PCR-seq targeted-approach also has the advantage of identifying novel exons of known genes, as we discovered unannotated exons in about 11% of assessed introns. We thus estimate that at least 18% of known loci have yet-unannotated exons. Our work demonstrates that the cataloging of all the genic elements encoded in the human genome will necessitate a coordinated effort between unbiased and targeted approaches, like RNA-seq and RT-PCR-seq, as the latter method reaches exquisite sensitivity. For example, we validate 41% of extremely rarely transcribed exons that are not represented within deep transcriptome profiling.

507F

Evolution of microRNA-3'UTR interactions and their impact on whole transcriptome regulation. *A.Z. Pietrzykowski, E. Kruse, N. Kinstlinger, L. Tejeda, S. Hamza, Y. Wang.* Animal Sciences, Genetics, Rutgers University, New Brunswick, NJ.

MicroRNAs (miRNAs) constitute a novel group of short RNA molecules functioning as major regulators of gene expression. It has been shown that they play a fundamental role in a majority of biological processes including development, aging, pathogenesis of cancer, development of addiction as well as many other processes. Despite an exponential growth of our knowledge in this young field many aspects of their action are still undiscovered. miRNAs decrease protein synthesis by interaction with the 3' untranslated regions (3'UTRs) of mRNA transcripts. Typically, each miRNA can have several binding sites on tens or hundreds of 3'UTRs. This allows miRNAs to have a very robust effect but also can lead to competition between 3'UTRs for miRNA binding. The effect of sequestration of miRNAs by a single 3'UTR on the rest of the transcriptome is unknown. We determined the impact of this regulation in six different species using KCNMA1 gene transcripts as a model. KCNMA1 is a highly conserved gene found in many species from worms to humans. It encodes a pore-forming subunit of a potassium channel of high conductance (BK channel) important for the proper activity of many cell types. Sequences of KCNMA1 3'UTRs were extracted from C. elegans, D. melanogaster, D. rerio, G. Gallus, R. norvegicus and H. sapiens databases using Ensembl and the UCSC Genome browser. Multiple sequence alignment was performed using ClustalW. We observed a persistent elongation and increase in the number of 3'UTRs correlated with the increased complexity of each species. We used miRNA target prediction software to generate a list of miRNAs interacting with the KCNMA1 3'UTRs in each species. Next, we used the same software to identify the other 3'UTR targets affected by those miRNA. Circos plots were made to map the network of 3'UTR-miRNA-target interactions. Surprisingly, we observed that a single 3'UTR could have a very potent effect on the entire transcriptome. In humans it can influence around ninety percent of UTRs. This effect is lessened with decreasing organismal complexity. Our data sheds new light on the evolution of miRNA regulatory networks and is important for understanding the genome-wide effects of miRNA regulation of gene expression.

Let-7 coordinately down-regulates genes on the amino acid sensing pathway to repress mTOR and activate neuronal autophagy. *A.N. Dubinsky[1], S. Djakovic[1], R. Zahra[1], C. Hsu[1], B.E. Morrison[1], A.R. La Spada[1,2,3].* 1) Pediatrics, University of California, San Diego, La Jolla, CA; 2) Cellular & Molecular Medicine, University of California, San Diego, La Jolla, CA; 3) Neurosciences, University of California, San Diego, La Jolla, CA.

Autophagy is a cellular recycling pathway that removes misfolded proteins and damaged organelles by sequestration into double membrane autophagosomes and lysosome fusion. To date, the genetic and molecular events responsible for regulating the autophagy pathway remain incompletely understood. MicroRNAs (miRNAs) are one class of regulatory molecule capable of modulating gene expression. After developing a method of nutrient deprivation for autophagy induction in primary cortical neurons, we found that Dicer activity is required for this autophagy activation. We therefore performed a combined miRNA - gene expression microarray analysis and identified a set of miRNAs that undergo significant alteration upon nutrient deprivation induced autophagy activation in neurons. Transfection of miRNA mimics into primary neurons resulted in robust activation of autophagy, as determined by GFP-LC3 puncta formation and a shift in LC3-I to LC3-II upon immunoblotting, thereby identifying let-7f as a positive activator of neuronal autophagy. As nutrient deprivation promotes autophagy activation via mTOR inhibition, we analyzed the PI3-kinase - Akt signaling pathway in neurons transfected with let-7f mimics, and noted that although mTOR and its targets are inactive, Akt was phosphorylated, ruling out a role for suppression of the insulin signaling pathway in let-7f-mediated autophagy induction. In silico analysis of our microarray expression data and of published argonaute HITS-CLIP targets of let-7f in the cortex, however, yielded a set of genes (Slc7a5, Map4k3, RragD) on the amino acid sensing pathway, upstream of mTOR, as predicted let-7 targets, which we confirmed by qRT-PCR analysis of let-7f transfected cortical neurons, and by evaluation of let-7 3'-UTR target sites in luciferase reporter assays. As knock-down of these let-7 targets is sufficient to induce autophagy in primary neurons, and injection of let-7f lentiviral vectors into the brains of GFP-LC3 mice is sufficient to induce neuronal autophagy in vivo, our results indicate that let-7f coordinately down-regulates positive activators of the amino acid sensing pathway to repress mTOR and thus promote autophagy activation in the CNS.

Deep sequencing of hypoxic breast cancer reveals deregulation of non-coding RNAs, non ploy-A RNAs and natural anti-sense transcripts. *H. Choudhri[1, 2], C. Camps[1], J. Shoedel[3], S. Oikonomopoulos[1], L. Winchester[4], F. Buffa[4], D. Moralli[1], E. Volpi[1], P. Ratcliffe[3], A. Harris[4], D. Mole[3], J. Ragoussis[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Biochemistry Department, Faculty of Science, King Abdulaziz University, Jeddah, Saudi Arabia; 3) Henry Wellcome Building for Molecular Physiology, University of Oxford, Oxford, United Kingdom; 4) Medical Oncology Department, John Radcliffe Hospital, University of Oxford, Oxford, United Kingdom.

Hypoxia is associated with poor prognosis in breast cancer. In this study, we investigated the hypoxia transcription landscape, PolII activity and histone markers (H3K4me3 and H3K4me1) of an ER positive breast cancer cell line [MCF7] grown in hypoxia and normoxia using next generation of ribo- depleted RNA, mRNA, small RNA and ChIP sequencing. We found that about 7.3 percent of the annotated genome is differentially expressed in hypoxic stress, which includes 1138 up regulated and 240 down regulated Refseq transcripts (fold >1.5). We have established a computational pipeline of strand specific ribo-depleted RNA-seq data analysis and revealed deregulation of a range of non coding transcripts including piwiRNA, miRNA, sn/snoRNA, long noncoding RNA (lncRNA) under hypoxia. To define which hypoxic altered genes are dependent on, hypoxia-inducible factor (HIF), we suppressed HIF-alpha subunits in hypoxic MFC-7 cells using siRNA and subjected them to mRNA-seq. We identified 1585 non lnc-RNAs, including natural anti-sense transcripts (NATs), to be differentially expressed, and a substantial number of HIF dependent transcripts (n=59) that were not reported before as hypoxia regulated genes. The differential expression of selected regulatory transcripts, including lncRNA (NEAT1, MALAT1), NATs and non poly-A mRNA (H3J, H3C) were validated in panel of hypoxic breast cancer cell lines. We characterized two significant up regulated NATs (aSPAG4 and aCELSR2) in hypoxia and found that these transcripts are long (>200bp), lack of protein coding frames, localized in nucleus, and HIF dependent. A number (42) of novel un-annotated hypoxia induced transcripts were also detected in hypoxic MCF-7 cells. The presence of active histone markers (H3k4me3 and H3Kme1) at TSS of NATs and novel transcripts validates these findings. In addition, small RNA-seq revealed 107 differentially expressed miRNAs showing both direct regulation through HIF or through post transcriptional mechanisms. Four lnc-RNAs and one non polyA RNA were analysed further using 148 breast tumors and found to be associated with clinicopathological parameters such as triple negative or HER2 positive status. This is the first study to report genome-wide HIF dependent transcription, including non coding RNAs, at single base pair resolution. The combined dataset represents a resource in our efforts to functionally annotate the genome and identify novel pathways to develop therapies for breast cancer.

Integrative annotation and functional characterization of human long non-coding RNAs in bladder cancer. *W. Tang, L. Prokunina-Olsson.* LTG, DCEG, NCI, NIH, Bethesda, MD.

Massively parallel transcriptome sequencing (RNA-seq) has allowed advances in the characterization and quantification of global transcription from simple model organisms to humans. This new strategy helps to explore the complexity of the transcriptome which encompasses a multitude of known and unknown protein-coding and non-coding RNA components. There is growing evidence of importance of long non-coding RNAs (lncRNAs), which are frequently aberrantly expressed in various human cancer types, suggesting potential role of lncRNAs in modulating the tumorigenesis. However, the biological functions of vast majority of these non-coding transcripts remain unknown. In our pilot study, we performed RNA-seq to investigate and characterize the entire transcriptome of three pairs of human muscle-invasive bladder tumors and adjacent normal tissues. We identified hundreds of differentially expressed coding genes between tumor and normal tissues, particularly, genes from pathways responsible for metabolism of xenobiotics, such as aryl hydrocarbon receptor (AHR) and the cytochrome of P450 (CYP1A1) pathways. We also explored expression profiles of 3468 annotated lncRNAs, and observed that some of these lncRNAs were differentially expressed between tumor and normal tissues. Specifically, we found a set of lncRNAs located 25kb downstream of AHR gene highly expressed in normal tissues (adjusted p-value < 0.01) and strongly correlated with AHR expression (r=0.94). AHR is a ligand-activated transcription factor that mediates the toxic actions of polycyclic aromatic and halogenated compounds. These chemicals are well-known carcinogens present in tobacco smoke and implicated in bladder cancer etiology. The activation of AHR pathway could enhance xenobiotic-induced toxicity and trigger carcinogenesis. Recent study also indicated AHR dependency may co-occur with MAP kinase activation in some NRAS-mutant cancer cells, and that elevated AHR may serve as a mechanistic biomarker for enhanced MEK inhibitor sensitivity. Future work will focus on confirming that lncRNAs close to AHR gene could modulate AHR transcription activity to affect the AHR signaling pathway, integrate annotation and functional characterization of these lncRNAs, and further address their effects on MEK inhibitor sensitivity.

MicroRNA-xx regulates vascular smooth muscle cell phenotypes and prevents neointimal formation. *Y. Wang[1], H. Wang[2], Y. Liao[3, 4, 5], P. Tsai[1], K. Chen[1], H. Cheng[1], R. Lin[6, 7], S. Juo[1, 8].* 1) Department of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Biological Sciences, National Sun Yat-Sen University, Taiwan; 3) Graduate Institute of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Section of Neurology, Taichung Veterans General Hospital, Taiwan; 5) Department of Neurology, National Yang-Ming University School of Medicine, Taiwan; 6) Department of Neurology, Kaohsiung Medical University, Kaohsiung, Taiwan; 7) Department of Neurology, Kaohsiung Medical University Hospital, Taiwan; 8) Department of Medical Research, Kaohsiung Medical University Hospital, Taiwan.

Aims- Proliferation and migration of vascular smooth muscle cells (VSMCs) can cause atherosclerosis and neointimal formation. MicroRNAs have been shown to regulate cell proliferation and phenotype transformation. We discovered abundant expression of microRNA-xx in VSMCs and conducted a series of studies to identify its function in the cardiovascular system. Methods and Results- MicroRNA-xx expression was initially found to be altered when VSMCs were treated with oxLDL. Using cellular studies, we found that microRNA-xx reduced VSMC proliferation, migration and syntheses of interleukin(IL)-1β, IL-6 and IL-8. Using bioinformatic prediction and experimental studies, we showed that microRNA-xx could repress the expression of Cdc42, CCND1, and FGF1 genes. Using the rat model, we found that microRNA-xx gene carried by adenovirus substantially reduced the neointimal formation in the balloon-injured carotid artery. In situ hybridization confirmed the presence of microRNA-xx in the treated arteries but not in the placebo treated arteries. The experiment of immunohistochemistry for Cdc42 protein showed abundant Cdc42 in the neointima of treated arteries. Conclusions- We identified that microR-xx plays a role in the cardiovascular system by inhibiting VSMC proliferation, migration and proinflammatory biomarkers. MicroRNA-xx may have the potential to reduce the neointimal formation in patients receiving stenting or angioplasty.

Comparative analysis of strand-specific RNA sequencing approaches. *D. Munafo, P. Liu, C. Sumner, L. Apone, B. Langhorst, E. Yigit, L. Merrill, F. Stewart, E. Dimalanta, T. Davis.* New England Biolabs, Inc., Ipswich, MA.

RNA-Seq is a powerful technique that allows for sensitive digital quantification of transcript levels, enables the detection of noncanonical transcription start sites as well as termination sites, alternative splice isoforms and transcript mutation and edition. Standard “next-generation” RNA-sequencing approaches generally require double-stranded cDNA Synthesis, which erases RNA strand information. Synthesis of a randomly primed double-stranded cDNA followed by addition of adaptors for sequencing leads to the loss of information about which strand was present in the original mRNA template. The polarity of the transcript is important for correct annotation of novel genes, identification of antisense transcripts with potential regulatory roles, and for correct determination of gene expression levels in the presence of antisense transcripts. This work investigates the performance of different strategies for strand-specific (directional) RNA-Seq using next generation sequencing platforms. One is based on direct RNA-adaptor ligation and the second strategy uses the labeling of the second strand cDNA with dUTP and posterior excision. We also examine the effect of different RNA fragmentation methods (divalent cations plus heat versus enzymatic fragmentation) as well as strategies for ribosomal RNA removal. This work provides a comparative analysis (library complexity, continuity of gene coverage, strand specificity and 3'and 5'-end bias analysis) of different approaches for strand-specific RNA-sequencing.

513F

microRNAs modulating the expression of FMR1 mRNA: implications in the pathophysiology of FXTAS. *S. Zongaro[1], R. Hukema[2], L. Davidovic[1], S. D'Antoni[3], M.V. Catania[3], R. Willemsen[2], B. Mari[1], B. Bardoni[1]*. 1) CNRS UMR7275, Valbonne, PACA, France; 2) Erasmus MC Dept. of Clinical Genetics Rotterdam - The Netherlands; 3) Institute of Neurological Sciences National Research Council (CNR) - Catania - Italy.

FMR1 is the gene coding for FMRP (Fragile X Mental Retardation Protein), a RNA-binding protein modulating the expression of a subset of neuronal mRNAs. Silencing of FMRP expression in Fragile X (FXS) patients is due to the hypermethylated expansion of a CGG repeat (>200) localized in the 5' UTR and of the CpG island of *FMR1*, blocking its transcription. The CGG repeat number is polymorphic in the normal population (between 6 et 50 repeats) and it increases up to 55–200 in individuals carrying the premutation. While *FMR1* is silenced in FXS, its expression is elevated (2–8 fold) in individuals carrying the premutation that may develop a late onset neurodegenerative disorder, namely Fragile X Associated Tremor Ataxia (FXTAS). FXTAS patients develop ataxia, parkinsonism, peripheral neuropathy, essential tremor, progressive memory and executive functions deficits (that can be correlated to a reduced hippocampal volume), anxiety and autonomic dysfunction. Moreover, generalized brain atrophy and white matter disease was also observed in FXTAS patients. A KI mouse model for FXTAS exists that recapitulates most of the features of this disorder. The physiopathology of FXTAS remains largely not understood. Nuclear inclusions have been observed throughout the brain of patients as well as in the animal model. These inclusions contain *FMR1* mRNA. Due to the importance of fine tuning regulation of *FMR1* expression during neuronal development, we studied the molecular mechanisms regulating the level of its mRNA. We report here the analysis and the characterization of some microRNAs that target the 3'UTR of *FMR1* mRNA *in vivo*, modulating the expression of this mRNA in post-natal neuronal maturation and, in particular, at the synaptic level. Interestingly, the expression of one of these microRNAs is reduced in brain of FXTAS mice, suggesting an implication in the development/evolution of this neurodegenerative disorder. Detailed characterization of these microRNAs will be presented. Furthermore, the possibility to use them as a treatment for FXTAS and to better characterize the physiopathology of this disorder will be discussed.

DYSFUNCTION OF miRNAs BIOGENESIS IN ASSOCIATION WITH NEURONAL DIFFERENTIATION IN FOCAL CORTICAL DYSPLASIA. *S.H. Avansini[1], F.R. Torres[1], D.B. Dogini[1], F. Rogério[3], A.C. Coan[2], R. Secolin[1], C.S. Rocha[1], A.F. Costa[3], A.L.F. Costa[2], A.C.S Piaza[3], L.A.M. Reis[3], E.P.L Oliveira[2], H. Tedeschi[2], L.S. Queiroz[3], F. Cendes[2], I. Lopes-Cendes[1]*. 1) Medical Genetics, UNICAMP, Campinas, SP., Brazil; 2) Neurology, UNICAMP, Campinas, SP., Brazil; 3) Anatomical Pathology, UNICAMP, Campinas, SP., Brazil.

MicroRNAs (miRNAs) are small noncoding RNAs which regulate post-transcriptional gene expression. Focal cortical dysplasia (FCD) is a malformation of cortical development which affects up to 36% of patients with drug-resistant epilepsy and its etiology is still not well understood. The objective of the present work is to investigate a possible role of miRNA regulation in FCD.We used brain tissue obtained after surgery for the treatment of medically refractory seizures from nine patients with FCD (four patients with FCD type IIa and five patients with FCD type IIb). In addition, we used cortical tissue from autopsy as controls (n=5). Total RNA was isolated with RecoverAllTM kit (Ambion) and RNA integrity was assessed by Agilent RNA Pico Chip Kit and Bio-Analyzer 2100.MiRNA expression profile was assessed by Affymetrix GeneChip platform miRNA array. Background correction, summarization and normalization were performed by RMA function. MiRNA expression was analyzed using RankProd (FDR $p < 0.05$). Results were validated using qPCR to evaluate miRNAs and their target genes. Our array analysis identified 39 miRNAs downregulated when patients and control group were compared and only one upregulated. Decreased expression of three miRNAs was confirmed by q-PCR, and when FCD type IIa and type IIb groups were compared we found that hsa-miR-31 was differentially expressed. Furthermore, we observed that DICER, key protein required for the biogenesis of microRNAs was found differently expressed and involved with neuronal differentiation. Thus our results show strong biological evidence that neuronal differentiation pathways are indeed involved in the pathophysiology of FCD. In addition, we identified a different miRNA expression signature in different FCD histological subtypes.

Genome-wide miRNA signatures of human longevity. *A. ElSharawy[1], A. Keller[2, 5], F. Flachsbart[1], A. Wendschlag[3], G. Jacobs[4], N. Kefer[3], T. Brefort[3], P. Leidinger[5], C. Backes[5], E. Meese[5], S. Schreiber[1,6], P. Rosenstiel[1], A. Franke[1], A. Nebel[1]*. 1) sequencing/mutation detection, Institute of Clinical Molecular Biology, Kiel, Kiel, Germany; 2) Biomarker Discovery Center, Heidelberg, Germany; 3) Febit biomed gmbh, Heidelberg, Germany; 4) Biobank Popgen, Institute of Experimental Medicine, Christian-Albrechts-University, Kiel, Germany; 5) Department of Human Genetics, Saarland University, Medical Department, Homburg, Germany; 6) Clinic for Internal Medicine I, University Hospital of Schleswig-Holstein, Kiel, Germany.

Little is known about the functions of miRNAs in human longevity. Here, we present the first genome-wide miRNA study in long-lived individuals (LLI) who are considered a model for healthy aging. Using a microarray with 863 miRNAs we compared the expression profiles obtained from blood samples of 15 centenarians and nonagenarians (mean age 96.4 years) with those of 55 younger individuals (mean age 45.9 years). Eighty miRNAs showed aging-associated expression changes, with 16 miRNAs being up-regulated and 64 down-regulated in the LLI relative to the younger probands. Seven of the eight selected aging-related biomarkers were technically validated using quantitative RT-PCR, confirming the microarray data. Three of the eight miRNAs were further investigated in independent samples of 15 LLI and 17 younger participants (mean age 101.5 and 36.9 years, respectively). Our screening confirmed previously published miRNAs of human aging, thus reflecting the utility of the applied approach. The hierarchical clustering analysis of the miRNA microarray expression data revealed a distinct separation between the LLI and the younger controls (p-value <10-5). The down-regulated miRNAs appeared as a cluster and were more often reported in the context of diseases than the up-regulated miRNAs. Moreover, many of the differentially regulated miRNAs are known to exhibit contrasting expression patterns in major age-related diseases. Further in silico analyses showed enrichment of potential targets of the down-regulated miRNAs in p53 and other cancer pathways. Altogether, synchronized miRNA-p53 activities could be involved in the prevention of tumorigenesis and the maintenance of genomic integrity during aging. (Aging Cell, 2012).

Background & Aims: The application of interferon-based therapy reduces the risk for cirrhosis and improves survival of chronic hepatitis C (CHC) patients particularly in those who achieve a sustained virological response (SVR). Of the host determinants, age, gender, race, insulin resistance, host immune responses and genetic predispositions might significantly affect the achievement of SVR. Several studies have shown that some specific MicroRNAs (miRNAs) sets are associated with the clinicopathological features of liver disease, such as cirrhosis, hepatitis B and C virus infection, hepatocellular carcinoma metastasis, recurrence, and prognosis. Recently, Disease-associated miRNA in peripheral blood mononuclear cells (PBMC) have been described for several diseases. Thus, PBMC-contained miRNAs have a great potential to serve as non-invasive markers. We aim to discover PBMC-contained miRNAs associated with interferon-based therapy response. Methods: We used a two steps method to find miRNA associated with interferon-based therapy response. 1) Performing expression profile of 754 miRNAs in PBMC of 13 typical CHC responders and non-responders by QPCR-based array; 2) Validating candidate miRNAs in an independent 48 CHC patients by QPCR. Results: Four miRNAs with fold change greater or less than four, which were selected for validation. miR-X was expressed significantly lower in non-SVR patients (p=0.0163). Considering IL28B rs8099917 genotype, the most powerful SVR baseline predictor, miR-X was also significantly associated with SVR (OR=2.74, p=0.0055). Combined miR-X and IL28B rs8099917 genotype can improve positive predictive value than IL28B genotype alone. Conclusions: PBMC-contained miRNAs, miR-X has a great potential to serve as non-invasive markers for predicting SVR of CHC patients.

Copy number variation of miRNA in individuals with intellectual disability. *Y. Qiao[1, 2], C. Harvard[1], E. Mercier[3], S. Lewis[2], P. Pavlidis[3], E. Rajcan-Separovic[1]*. 1) Dept Pathology (Cytogenetics), BC Child and Family Res Inst, University of British Columbia, Vancouver, BC V5Z 4H4, Canada; 2) Dept Medical Genetics, BC Child and Family Res Inst, University of British Columbia, Vancouver, BC V6H 3N1, Canada; 3) Centre for High-throught Biology, 177 Michael Smith Laboratiories, University of British Columbia, Vancouver, BC V6T 1Z4, Canada.

MicroRNAs (miRNA) are a family of short non-coding RNAs regulating over 60% of human protein coding genes (miRNA target genes) by post-transcriptional regulation of gene expression. Over 1500 miRNAs have been identified in the human genome and numerous miRNAs are spatially and temporally expressed in the nervous system indicating their potential roles in brain functions. Recent evidence suggests that miRNA copy number change can cause aberrant miRNA expression and/or regulation of their target genes in subjects with intellectual disability (ID) and congenital abnormalities. In order to understand the correlation between miRNAs and copy number variants (CNVs) better, we searched for the prevalence of miRNAs in CNVs detected in a cohort of 206 ID probands and a cohort of 32 cognitively normal subjects. Using the Galaxy intersection web tool (https://main.g2.bx.psu.edu/) in our ID cohort, we found 50 miRNAs in 23 de novo CNVs covering 65 Mb of the genome (on average 3.13 miRNAs/CNV or ~1miRNA/Mb), whereas 52 miRNAs were found in 233 common CNVs covering 118.6 Mb of the genome (on average 0.22 miRNA/CNV, or 0.5 miRNAs/Mb). In the same ID cohort, 14 miRNAs were detected in 58 unique familial CNVs covering 38.1 Mb (0.24 miRNAs/CNV, or 0.5 miRNA/Mb). In cognitively normal controls, a total of 21 miRNAs were detected in the 67 common CNVs covering 35.4 Mb of the genome (on average 0.31 miRNAs/CNV, or 0.6miRNA/Mb). miRNA database searches (http://www.microrna.org/microrna/) showed that the expression of miRNA from de novo CNVs was highest in adult hippocampus, neuroblastomas and heart. One detected miRNA (hsa-mir-124-3), integral to a CNV on chromosome 20q13.33, is the most abundant microRNA expressed in neuronal cells, and is most highly expressed in adult hippocampus and cerebellum. For a comparable number of miRNAs from the common or familial CNVs, expression in the brain was not reported. Our findings revealed a two-fold increase in miRNA content in de novo versus either familial or common CNVs in subjects with ID.Their expression pattern supports a possible role of miRNA copy number change in cognition and/or CNV-mediated developmental delay.

Novel Human Variation in MicroRNAs associated with Disease, Biomarkers, and Drug Metabolism. *R.Afi. Rawlings-Goss, S. Tishkoff.* Genetics, University of Pennsylvania, Philadelphia, USA.

MicroRNAs (miRNA) are evolutionarily conserved regulators of gene expression, which have a significant role in human development and disease. Under and over-expression of specific miRNA have been associated with a wide variety of diseases and disorders including but not limited to leukemia, myopathy, melanoma, lupus, Alzheimer's, neurodegenerative diseases and most forms of cancer. Additionally, there are several clinical trials pursuing the utility of miRNAs as biomarkers, gene therapy agents, and effectors of drug metabolism. As miRNA progress toward therapeutics, population specific variation in miRNA sequences have the potential to answer questions concerning viability of drug targeting, and variability of drug metabolism among different populations. Here we analyze a worldwide panel of participants representing 15 distinct populations from around the world, with a focus on African populations, to assess novel human variation in miRNAs of interest.

The tale about MIR147B regulate Catalase AEI by one SNP in the 5'-UTR. *Z. Wang[1], B. Wang[1], K. Zhang[1], L. Jin[2], W. Huang[1]*. 1) Department of Genetics, Shanghai-MOST Key Laboratory of Health and Disease Genomics, Chinese National Human Genome Center, Shanghai 201203, People's Republic of China; 2). MOE Key Laboratory of Contemporary Anthropology and Center for Evolutionary Biology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, People's Republic of China.

miRNAs affect a variety of signaling pathways, and in traditonal, miRNAs bind through imperfect base pairing to the 3'- UTR of their target mRNAs and interfere with translational output. The allelic expression imbalance (AEI) can be measured in individuals heterozygous for a transcribed polymorphism. Here we show that miRNA miR-147b interacts with the 5' untranslated region of mRNAs encoding Catalase proteins.We have found that three variants (rs769214/ rs7943316/ rs1049982) in the promoter and 5'-UTR region of Catalase are predominant in Chinese Han, and they form two major haplotypes (CATH1: G-A-T; CATH2:A-T-C), and the CATH1 haplotype significantly decreased essential hypertension susceptibility in Chinese Han, and more interesting rs1049982 could serve as a marker for AEI. The expression levels of CATH1 and CATH2 individuals will be shifted in different oxidative stress conditions. miRNA target prediction showed that MIR147B can regulate CAT AEI through the SNP in the 5'- UTR. Luciferase reporter constructs carrying CATH1 (pGL3-CATH1) and CATH2 (pGL3-CATH2) were cotransfected with MIR147B precursor molecule/negative control or MIR147B inhibitor/negative control into Hela and ECV-304 cell lines, separately. Reporter expression was analyzed using the Dual-Luciferase Reporter Assay. We found the MIR147B precursor molecule can down regulated the luciferase expression level both pGL3-CATH1 and pGL3-CATH2. More interestingly, the transcriptional activity of pGL3-CATH2 was significantly reduced than pGL3-CATH1 in all cell lines ($p<0.05$). Compared with the negative control, when we cotransfected with MIR147B precursor molecule pGL3-CATH1 luciferase expression decreased to 44.7%, and pGL3-CATH2 decreased to 27.3%($p=0.019$)in Hela cell lines, and pGL3-CATH1 luciferase expression decreased to 56.1%, and pGL3-CATH2 decreased to 44.3%($p=0.005$). But compared with the negative control, there were no significantly change when we cotransfected with MIR147B inhibitor. We can draw the conclusion that the MIR147B interacts with the CAT 5'-UTR, rs1049982 indeed affects regulation of CAT expression by in vitro. And MIR147B had a higher binding affinity for the “C” genotype than for the “T” genotype. Thus, rs1049982 is a unique SNP that resides in a miRNA-gene regulatory loop. More in-depth understanding of the mechanisms by MIR147B regulate CAT AEI by rs1049982 will give us a charming story.

520W

Inactivation of the *miR-183/96/182* cluster results in syndromic retinal degeneration: The *miR-183/96/182* cluster is required for normal function of the retina and other sensory organs. *S. Xu[1], S. Lumayag[1], C. Haldin[1], C. Cowan[1], B. Kovacs[1], P. Larsen[2], D. Valle[3], P. D. Witmer[3]*. 1) Ophthalmology/Neurological Sci, Rush Univ Med Ctr, Chicago, IL; 2) Biosciences Division, Argonne National Lab, 9700 South Cass Ave, Lemont, IL; 3) McKusick-Nathans Institute of Genetic Medicine; Johns Hopkins University, School of Medicine, Baltimore, MD.

Previously, we identified a highly conserved, intergenic, sensory organ-specific, paralogous miRNA cluster, the *miR-183/96/182* cluster, located within ~4 kb on mouse chromosome 6qA3.3. Developmentally, expression of the *miR-183/96/182* cluster is minimal in embryonic retina, increases after birth and peaks in adult retina where it is specific to photoreceptors and follows a diurnal expression pattern. Although recent reports have demonstrated the importance of *miR-96* in hearing, the functions of this miRNA cluster in retina are still elusive. To explore this question, we first determined the genomic structure of the *miR-183/96/182* cluster gene. We provide evidence that the *miR-183/96/182* cluster gene spans more than 15 kb in the genome and is alternatively spliced with at least two transcripts, one of which has the potential to encode small peptides. The *miR-183/96/182* cluster resides in the intron of the cluster gene. We then characterized a mouse gene-trap embryonic stem cell clone, in which the gene-trap construct was inserted downstream of the first exon of the cluster gene, interrupting the expression of the *miR-183/96/182* cluster of the gene-trapped allele, designated as *miR-183C^{GT}*. Using this gene-trap clone, we generated a mouse model, designated as *miR-183C$^{GT/GT}$*. We show that the *miR-183/96/182* cluster gene is inactivated in homozygous *miR-183C$^{GT/GT}$* mice. These animals have early-onset defects in both scotopic and photopic ERGs and progressive retinal degeneration. Even before overt retinal degeneration, expression profiling revealed global gene-expression changes in the retina of *miR-183C$^{GT/GT}$* mice compared to their littermate controls. Genes known to be important in synaptogenesis and synaptic transmission, as well as phototransduction pathways are significantly enriched in dysregulated genes suggesting that the *miR-183/96/182* cluster is essential for the final functional differentiation, including synaptic connections of the photoreceptors. In addition to retinal defects, the *miR-183C$^{GT/GT}$* mice showed early onset of vestibular dysfunction, including a typical circling behavior and unstable gait. We therefore conclude that complete inactivation of the *miR-183/96/182* cluster results in syndromic retinal degeneration; and the *miR-183/96/182* cluster is required for normal function of the retina and other sensory organs.

Micro-RNA Analysis in Human Ocular Scleral Tissue. *T. Young[1, 2], X. Luo[1, 2], F. Hawthorne[2], S. Feng[2], P. Gonzalez[1]*. 1) Ophthalmology, Duke Univ Eye Ctr, Durham, NC; 2) Center for Human Genetics, Duke University, Durham NC.

MicroRNAs (miRNAs) are expressed in a developmentally regulated and tissue-specific manner. Since miRNA target function studies for the eye will be performed in ocular tissue culture cells, it is important to profile them for miRNA expression and targeting. We profiled affected target genes for selected microRNAs important for regulation of extracellular matrix modeling in an adult human ocular scleral wall fibroblast cell line. Peri-limbal human scleral fibroblast cells (HSFCs) were cultured from postmortem human corneal rings. Mir- 21, mir-29b, mir-200c and mir-let-7F miRNAs were transfected into HSFCs. Whole genome gene expression profiling of transfected HSFCs was performed using the Human HT12-v4.0 Illumina Beadchip. Expression data was generated by using Illumina Genomestudio software. After background subtraction, data were log2 transformed. Sample outliers were removed using principle component analysis and the Hoteling T2 test with 95% confidence interval. The intensity data were normalized by Quantile normalization. The exact Wilcoxon rank sum test was performed to identify differentially expressed genes. The Benjamin and Hochberg false discovery rate procedure controlled at the 0.05 level was used to determine statistical significance. Selected genes with high fold changes were confirmed by quantitative real time PCR (qPCR). Gene expression profiling revealed 1,100 genes which were down- (482) or up-regulated (618)with at least a 2-fold change. qPCR confirmed down-regulated changes of Col4A1, Col3A1, SERPINA3, MFAP4, and TGFβ2 genes. Up-regulation was confirmed for the ANXA10, DUSP6, BMP2, FOS, SEMAF4, LUM, and ERG1 genes. Scleral extracellular matrix regulators showed high regulation from miRNA. This data can potentially be used for scleral wall remodeling alterations in ocular disorders of with scleral wall elasticity.

Founder mutation in a transposable element leads to the identification of a long noncoding RNA in a progressive infantile encephalopathy. *A. Henrion Caude[1], P. Munier[2], E. Benko[3], S. Hanein[1], E. Westhof[4], N. Boddaert[5], I. Desguerre[6], S. Bandiera[1], M. Girard[1], D. Rodriguez[7], A. Munnich[1], M. Fähling[3], S. Lyonnet[1], F. Cartault[1,2].* 1) Genetics, Inserm U781 - Necker Hospital, PARIS, France; 2) Department of Genetics, Université de La Réunion, Centre Hospitalier Régional de La Réunion, Saint-Denis, LA REUNION, France; 3) Institut für Vegetative Physiologie, Charité-Universitätsmedizin Berlin, BERLIN, Germany; 4) Institut de Biologie Moléculaire et Cellulaire du Centre National de la Recherche Scientifique, Université de Strasbourg, STRASBOURG, France; 5) Département de Radio-Pédiatrie, Necker Hospital, PARIS, France; 6) Département de Neurologie Pédiatrique, Necker Hospital, PARIS, France; 7) Service de Neuropédiatrie, Hôpital Armand Trousseau, PARIS, France.

Familial recurrence of an extreme phenotype of infantile anorexia in a Caucasian isolate in Reunion Island led us to suspect autosomal recessive inheritance of the disease. Here, we report homozygosity mapping of the locus of this syndrome, called Ravine. Complete DNA sequencing of the 400-kb linkage locus revealed a point mutation in a primate-specific retrotransposon that was transcribed as part of a unique long noncoding RNA, which was expressed in the brain. In vitro knockdown of this RNA increased neuronal apoptosis, consistent with the inappropriate dosage of this RNA in vivo and with the phenotype. Moreover, structural analysis of the sequence revealed a small RNA-like hairpin that was consistent with the putative gain of a functional site when mutated. We assessed the global impact of the mutation by transcriptomic analysis of brain samples, and discuss the different mechanisms that could underlie the effect of the mutation. We believe that this work could contribute in the understanding of the significance of subtle variations in retrotransposons.

Human single nucleotide polymorphisms influence non-coding RNA expression. *V. Magadi Gopalaiah[1], H-J. Westra[1], J. Karjalainen[1], D.V. Zhernakova[1], B. Hrdlickova[1], R. Almeida[1], A. Zhernakova[1], M.H. Hofker[3], J. Fu[1,2], S. Withoff[1], L. Franke[1], C. Wijmenga[1].* 1) Department of Genetics, University Medical Center Groningen, University of Groningen, Groningen, Netherlands; 2) Department of Epidemiology, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands; 3) Department of Pathology and Medical Biology, Molecular Genetics, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands.

Genome-wide association studies (GWAS) have been successful in identifying approximately 7,000 disease or trait predisposing single nucleotide polymorphisms (SNPs). Surprisingly, only 5% of these SNPs are located within protein coding regions and remaining 95% are located within non-coding regions. Approximately 50% of GWAS associated SNPs affect the expression of nearby protein coding genes. However, most of the human genome is transcribed to produce not only protein coding transcripts but also large numbers of non-coding RNAs. It is unknown whether GWAS associated SNPs can influence the expression levels of non-coding RNAs. Large intergenic non-coding RNAs (lincRNAs) are non-coding transcripts of more than 200 nucleotides long and are recognized as key regulators of many biological processes including gene expression. Recently Cabili et al. have described a catalogue containing more than 8,000 lincRNAs that makes these the largest subclass of the non-coding transcriptome. We hypothesized that GWAS associated SNPs can affect the expression of lincRNAs, thereby providing a novel disease mechanism. To test our hypothesis we performed eQTL mapping on 2,360 human lincRNA-probes using genome-wide gene expression and genotype data of 1,240 peripheral blood samples. We also investigated tissue-dependent eQTLs for lincRNAs using data from four different primary non-blood tissues obtained from 85 individuals. We tested whether SNPs that affect the levels of lincRNA expression are associated with diseases or traits. Finally, we predicted the function(s) of a subset of eQTL-affected lincRNAs using GeneNetwork database that is based on co-expression data, extracted from approximately 80,000 Affymetrix microarray experiments. We obtained 5,106 unique SNPs that affected the expression of 124 lincRNA probes mapping to 117 unique lincRNA genes in peripheral blood. We observed 4, 9 and 117 specific lincRNA eQTLs in liver, saturated adipose tissue and blood, respectively. In total we found 142 eQTL-probes from 5 different tissues. Our results clearly indicate that there is a strong genotype-lincRNA expression correlation in a tissue dependent manner ($P < 1.4E-04$ to 3.5E-198). A considerable number of these eQTLs are GWAS associated SNPs (12% of the eQTL-affected lincRNAs). Our study provides future direction to refine GWAS associated regions and we expect that RNA-sequencing data that is expected to become available in the near future will confirm our observations.

524W

Identifying Source Locations for Alu Transcripts within Human Testes. *S. Linker[1], P. Deininger[2], D. Hedges[1].* 1) HIHG, University of Miami, Miami, FL; 2) Tulane University, New Orleans, LA.

Alu retrotransposons comprise approximately 10% of the human genome. While their transcription has been associated with the cellular stress response, and they have been demonstrated to serve as promoters for functional miRNAs, relatively little is known concerning which specific Alu loci are transcribing and what factors regulate their activity. Previous work in this area has been hindered by technical obstacles, such as cross-hybridization of homologous templates from different sources during PCR and contamination from Pol-II sequences from gene transcripts. These technical hurdles have limited the ability to uniquely identify transcript sources for the purpose of studying their regulation. To circumvent these issues, we have developed a high-throughput method of RNA-Seq preparation that combines a unique oligo extension with plasmid-based amplification. Using this method, we uniquely identified 890 Alu transcription locations from human testes samples. The transcripts originating from these sources were consistent with Pol-III transcripts, as evidenced by depletion of Pol III terminators within the Alu-promoted transcript and enrichment of terminators proximal to the end. As expected, younger AluY was the most transcriptionally active subfamily, exhibiting a four-fold enrichment over expectation based on genomic density. AluY can be further subdivided by age, and within those subclasses, the youngest elements are the most transcriptionally active. Specifically AluYd8, AluYb8, and AluYa5 are enriched 159X, 56X, and 46X over expectations respectively. Further consistent with the transcription of the youngest elements is the fact that transcript source locations exhibit reduced nucleotide divergence from their subfamily consensus sequence. Lastly, the regions surrounding the transcriptionally active Alu were analyzed to extract potential regulatory motifs. We found that transcribing Alu are depleted for several binding motifs. Most significantly, a depletion was observed in the transcription repressor REST, which recruits heterochromatin forming complexes. In summary, we have developed a high throughput next generation sequencing based method for identifying authentic Alu transcripts. We believe our method will greatly facilitate the study of Alu transcription, allowing for a better understanding of their regulation and enabling further examination of their potential functional and pathogenic roles.

525F

The genetic basis of human drug response variation. *M. Kaganovich, D. Spacek, M. Snyder.* Genetics, Stanford University, Stanford, CA.

We have developed a method to assess the functional variation in drug response in lymphoblastoid human cell lines (lcls) in a high-throughput and efficient manner. Four hundred LCLs from various ethnic backgrounds were exposed to chemotherapy agents and their growth response was assayed. The resulting functional variation was associated to genetic differences as measured by the 1000 Genomes Project (1KGP). Our technique and results contribute to nascent inquiries into the functional consequences of human genomic differences found by studies such at the 1KGP and PGP studies.

Dietary protein regulates gene expression of amino acid-degrading enzymes through PPARα. *A.V. Contreras[1], C. Rangel[1], V. Ortiz[2], G. Aleman[2], B. Palacios[2], E. Tejero[1], N. Torres[2], A.R. Tovar[2]*. 1) Instituto Nacional de Medicina Genómica (INMEGEN), México DF, México; 2) Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, México DF, México.

Peroxisome proliferator activated receptor alpha (PPARα), which is a member of the PPAR family, is a nuclear receptor that functions as a ligand-activated transcription factor in response to dietary signals. The effects of PPARα ligands, such as fatty acids, are have been demonstrated in several tissues, particularly in liver, modulating the expression of enzymes for fatty acid oxidation, but recent evidence suggests that also regulates amino acid oxidation. The amino acid catabolism is regulated by hepatic amino acid-degrading enzymes (AADE), however it is not known whether PPARα regulates the expression of AADE. Thus, the aim of this work is to study whether PPARα controls the gene expression of AADE. With this purpose, we use PPARα null mice and age-matched male C57BL6 mice that were fed diets with 3 different dietary protein concentrations (6, 20 or 50%) in a restricted feeding scheme for 8 days. RNA was extracted from liver to assess the whole genome expression using microarrays (Mouse Gene 1.0 ST Array, Affymetrix), and serum was used to measure glucose, free fatty acids, insulin and glucagon. We found that in WT mice the gene expression of AADE, such as *Histidine ammonia-lyase*, *Glutamic-oxaloacetic transaminase 1*, *Argininosuccinate synthase 1*, *Serine dehydratase* and *Urocanase domain containing 1*, was proportional to the increase in dietary protein concentration. In contrast, in PPARα null mice this effect was absent, even more, for these genes we did not observed significant differential expression between groups fed 6 and 50% of protein. Moreover, some AADE such as *Kynureninase*, *Ornithine aminotransferase* and *Aminocarboxymuconate semialdehyde decarboxylase*, and the *Hepatocyte nuclear factor 4 alpha* (*HNF4α*) showed higher gene expression on PPARα null mice than C57BL6 mice. Network analysis suggests that PPARα regulates the expression of AADE genes through HNF4α interaction. PPARα functions as a metabolic sensor to preserve amino acids by stimulating fatty oxidation. Amino acids may be spared differently in the body depending of the dietary fat, as well as the type of fatty acids mobilized from adipose tissue.

527F

Patterns of allele-specific gene expression in ten human tissues. *K.R. Kukurba[1,2], T. Nance[3], R. Piskol[1], M.H. Tan[1], J.B. Li[1], S.B. Montgomery[1,2]*. 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Pathology, Stanford University, Stanford, CA; 3) Department of Mathematics, Stanford University, Stanford, CA.

Allele-specific gene expression (ASE) is the product of gene regulatory variation, chromatin state and nuclear environment. ASE effects have been recently described as important markers of causal regulatory variants and capable of modifying protein-coding loss-of-function mutation. However, studies of ASE have been limited to few cell types leaving many questions regarding the tissue-specificity and overall systemic impact of ASE unanswered. In order to address these questions, we have investigated ASE patterns in ten divergent tissues (cerebellum, colon, frontal lobe, heart, small intestine, liver, lung, pancreas, skeletal muscle and stomach) from a single individual collected post-mortem. ASE was measured using RNA-sequencing (RNA-Seq) data where near-complete ascertainment of coding heterozygous positions was obtained from exome sequencing. Using this data, we report the prevalence and effects of allelic imbalance on tissue differentiation and its evolutionary implications in cell-type identity. We also report essential quality control statistics aimed at eliminating common sources of error when identifying ASE from RNA-Seq and exome sequencing data. We demonstrate the efficacy of filtering by removing potential PCR duplicates, heterozygous loci in intergenic and indel regions, sites with low base quality scores (<30) and with high exome sequencing allele bias. As hypothesized, the shared allelic effects between tissues reflect the embryonic lineage map. In addition, we detected 36 genes across the ten tissues which display monoallelic expression. For two genes in particular, NDN and MAP2K3, monoallelic expression was detected in all 10 tissues. NDN is a known imprinted gene that is only expressed from the paternal allele. MAP2K3 has evidence of allelic expression in humans and mice and allelic methylation in humans. Genes that may selectively escape inactivation in one or more tissues are also observed and may suggest novel escape mechanisms. Furthermore, we also report the tissue- specificity and direction of allelic effects influencing loss-of-function mutation. These findings highlight how regulatory variation influences tissue phenotypes and, ultimately, human phenotypic complexity.

528W

Gene expression variation in the response of human monocyte-derived dendritic cells to LPS and influenza dNS1 stimulation. *M.N. Lee[1,2,3], C. Ye[1], A.C. Villani[1], W. Li[1,3], P.I. Chipendo[4], M.H. Lee[4], P.L. De Jager[1,2,4], C.O. Benoist[2,4], A. Regev[1,5,6], N. Hacohen[1,2,3]*. 1) Broad Institute, Cambridge, MA; 2) Harvard Medical School, Boston, MA; 3) Massachusetts General Hospital, Boston, MA; 4) Brigham and Women's Hospital, Boston, MA; 5) Massachusetts Institute of Technology, Cambridge, MA; 6) Howard Hughes Medical Institute.

Substantial baseline gene expression variation observed in human populations, in both cell lines and primary cells, have been associated with genetic variation in cis and in trans. To fully understand the functional role of genetic variation on gene expression, several recent studies have begun comparing the association patterns observed in stimulated conditions, such as radiation-treated lymphoblastoid cell lines and tuberculosis-infected primary human dendritic cells, to their corresponding baseline profiles. Like other expression quantitative trait loci (eQTL) studies, these response QTL studies could be confounded by environmental and technical factors, which limit their utility. We designed and conducted a serial replication experiment to assess the reproducibility of stimulating primary human monocyte-derived dendritic cells. Primary cells were isolated from a healthy cohort and stimulated with two different innate immune ligands: LPS (receptor: TLR4) and influenza dNS1 (receptors: RIG-I and TLR3). Genome-wide expression profiles before and after stimulation were assayed using the Affymetrix GeneChip Gene 1.0 ST array. Using a linear mixed model comparing the interindividual variation between 30 individuals versus the intraindividual variation within 12 individuals collected several months apart, we found 572, 314 and 240 genes that have significant interindividual variation (FDR less than 0.2) at baseline, after LPS stimulation, and under flu infection, respectively. Taking the difference in expression between the baseline and stimulated matched samples as a quantitative trait, we further identified 601 and 642 genes that have significant interindividual variation (FDR less than 0.2) in the LPS and flu responses. These results point to a remarkably high reproducibility of human innate immune responses, and suggest that there could be a substantial genetic component underlying them. We compared our set of genes to two known eQTL studies. We show statistically significant overlap with eQTLs identified in both studies suggesting that these genes are likely to have a genetic component. We further genotyped our cohort using the Illumina HumanOmni1-Quad and HumanExome at over 1M SNPs. Even with limited sample number, we were able to map expression quantitative traits to cis SNPs at genome-wide significance. A statistically significant number of these cis eQTLs overlap those previously identified, further validating our approach and results.

Gene expression profiling in a large cohort of Europeans with Sjögren's syndrome reveals viral, immune, and interferon-related pathways. *J.A. Ice[1], H. Li[1,2], J.A. Kelly[1], I. Adrianto[1], S.B. Glenn[1], K.S. Hefner[3], E.S. Vista[4], D.U. Stone[2], R. Gopalakrishnan[5], G.D. Houston[2], D.M. Lewis[2], M.D. Rohrer[5], P. Hughes[5], J.B. Harley[6,7], C.G. Montgomery[1], J. Chodosh[8], J.A. Lessard[9], J-M. Anaya[10], B.M. Segal[11], N.L. Rhodus[5], L. Radfar[2], M.B. Frank[1], R.H. Scofield[1], C.J. Lessard[1,2], K. Moser Sivils[1]*. 1) Arthritis & Clinical Immunology, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Hefner Eye Care and Optical Center, Oklahoma City, OK; 4) University of Santo Tomas Hospital, Manila, Philippines; 5) University of Minnesota, Minneapolis, MN; 6) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 7) Department of Veterans Affairs Medical Center, Cincinnati OH; 8) Harvard Medical School, Boston, MA; 9) Valley Bone and Joint Clinic, Grand Forks, ND; 10) Universidad del Rosario, Bogotá, Colombia; 11) Hennepin County Medical Center, Minneapolis, MN.

Sjögren's syndrome (SS), characterized by symptoms of dry eyes and mouth, is a progressive autoimmune exocrinopathy present in 0.7–1% of Europeans. To better understand the molecular pathways involved in SS pathophysiology, we performed global gene expression profiling (GEP) using peripheral blood on 48803 probes from the Illumina HumanWG-6 v3.0 BeadChip in 201 SS cases and 76 healthy controls. Analyses were performed in the R Bioconductor suite. After quality control, 20342 probes (in 15607 genes) were quantile normalized and Welch's t-tests, q-values, and fold change (FC) calculated. Differentially expressed (DE) genes were selected by: q<0.05; and FC >1.25 or <0.87. Pathway analysis for DE genes was carried out in Genomatix. In total, 2380 genes were DE (0.05<q<5.5×10E-21). The most significant canonical pathways in DE genes were apoptotic DNA-fragmentation/tissue homeostasis (6/11 genes; p=5.1×10E-4) and regulation of Wnt-mediated beta catenin signaling/target gene transcription (18/32 genes; p=3×10E-3). DE genes were involved in several biological processes, including translational termination (40/93 genes; p=4.3×10E-17), viral transcription and genome expression (49/140 genes; p=3.3×10E-16), innate immune response (93/418 genes; p=1.3×10E-14), and type I interferon-mediated signaling (31/70 genes; p=5.6×10E-14). *OTOF* was the most upregulated gene in SS cases (FC=86.57), while HS.567460 was the most downregulated (FC=0.36). Nearly all DE genes in viral pathways were downregulated with the notable exception of *SP100* (q=7.852×10E-8, FC=1.43), an interferon-inducible protein believed to play a role in transcriptional regulation and the innate immune response following viral infection toward which antibodies are made in primary biliary cirrhosis. Several DE genes overlap with genetic associations identified through genome-wide association studies in SS, including the MHC genes *TRIM38* (q=7.44×10E-12, FC=1.38), *TAP1* (q=5.62×10E-11, FC=1.41), and *TAP2* (q=7.15×10E-16, FC=1.52), in addition to those identified previously by candidate gene approaches, including *IL1RN* (q=4.26×10E-6, FC=1.41), Fas (q=1.23×10E-3, FC=1.27), and *EBF1* (q=1.69×10E-3, FC=1.42). These results highlight alterations in immunologically-relevant pathways in SS, potential to reveal several new candidate expression quantitative trait loci, and provide focus for the development of novel hypotheses for further studies of this complex autoimmune disorder.

A normalization procedure for removal of residual multiplex PCR amplification bias from ultra-deep sequencing of the TCR repertoire. *M.J. Rieder[1], C. Carlson[1,2], A. Sherwood[1], R. Emerson[1], C. Desmaris[1], M. Chung[1], J. Parsons[1], M. LaMadrid-Herrmannsfeldt[1], D. Williamson[1], R. Livingston[1], H. Robins[1,2]*. 1) Adaptive Biotechnologies, Seattle, WA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

The human adaptive immune system is a primary defense against the vast world of potential pathogens. To counter this enormous pathogenic diversity, B and T cells constituting the adaptive immune system rearrange surface receptors such that each rearrangement has the potential to code for a different amino acid sequence. For the T cell receptor (TCR), the CDR3 regions are formed by rearrangements of Variable and Joining (VJ) segments for the α chain and Variable, Diversity, and Joining (VDJ) segments for the β chain, in addition to nucleotide insertions/deletions at these junctions, creating the vast diversity in the TCR repertoire. As the adaptive immune system functions in part by clonal expansion, accurately measuring the changes in total abundance of each clone is vital for understanding the dynamics of an adaptive immune response. We developed an optimized multiplex PCR assay for gDNA rearrangements at the TCRβ locus that allows for quantitative assessment of each clonotype using ultra-deep DNA sequencing. This multiplex PCR consisted of 54 V segment and 13 J segment primers designed against all V-J gene segments of TCRβ. To produce an accurate quantitative assay, we need our assay to faithfully output the correct abundance of each clone from an arbitrary sample of T cells. We created a controlled, gold standard input template by synthesizing a single set of 702 oligonucleotides spanning all V-J gene pairs and mixing these at equal ratios. Using this standard as the template input, we first assessed the amplification bias using a PCR reaction containing equimolar ratios of TCRβ V-J primers. We performed additional experiments to assess 1) the independence of each specific V and J primer in the presence of a pools of complimentary primers (i.e. pools of all V or J primers) 2) cross-amplification due to variation in primer concentration (10-fold range) and 3) detection of specific spike-in oligonucleotides. Our results showed that V and J primers showed near complete independence with little interaction. We iterated through different primer rebalancing formulations producing nearly equal amplification across a large dynamic range as assessed by Illumina sequencing. Residual amplification bias following PCR optimization was computationally corrected to further improve the quantitation of the assay. Quantification of clones using this assay allows for accurate and robust tracking of TCRβ repertoire dynamics over time and between tissue types.

Expression QTL analysis of a gene expression signature which predicts advanced non-alcoholic fatty liver disease. *M. Garrett[1], C. Moylan[1], J. Gibson[1], H. Yang[3], H. Pang[3], A. Dellinger[3], A. Suzuki[1], H. Tillmann[1], C. Guy[1], M. Abdelmalek[1], S. Murphy[2], A. Diehl[1], M. Hauser[1], A. Ashley-Koch[1].* 1) Department of Medicine, Duke University Medical Center, Durham, NC; 2) Department of Obstetrics and Gynecology, Duke University Medical Center, Durham, NC; 3) Department of Biostatistics and Bioinformatics, Duke University Medical Center, Durham, NC.

Non-alcoholic fatty liver disease (NAFLD) is associated with obesity and the metabolic syndrome and affects over one third of American adults. A subset of NAFLD patients develop advanced disease associated with liver injury, scar tissue (fibrosis), and cirrhosis, increasing risk for liver-related mortality, including primary liver cancer. Several genes have been associated with NAFLD, but determination of their function in the disease process has been difficult. We hypothesized that expression quantitative trait loci (eQTL) analysis would improve the identification of causally related genetic variants by integrating SNPs with gene expression. Patients with biopsy-proven NAFLD were selected based on fibrosis stage (mild NAFLD: stage F0-F1 vs. advanced NAFLD: stage F3-F4). Genomic data, including genotype (Cardiometabolic SNP array, Illumina), methylation (Human Methylation450 BeadChip, Illumina) and expression (Human U133 Plus 2.0 GeneChip, Affymetrix) were available for 69 patients. We identified a novel 64-gene expression signature differentiating advanced and mild NAFLD, confirmed in a validation data set. Using ANOVA, cis-eQTL analysis was conducted with transcript levels from this signature and SNPs within 1 MB of the expression probe midpoint, while controlling for gender, age at biopsy, diabetes and BMI. SNPs falling directly within expression probes were excluded. Empirical p-values were generated from permutation testing. 28 SNPs significantly predicted transcript levels ($p<0.001$), including those for CD24P2 (3 independent SNPs), COL1A2 (1 SNP), CYBRD1 (1 SNP) and ID4 (23 SNPs in 3 haplotype blocks). CD24P2 is a pseudogene which does not appear to produce a functional protein. COL1A2 encodes the pro-alpha2 chain of type 1 collagen, a fibrilar collagen found in most connective tissues. CYBRD1 is a ferric-chelate reductase present at the brush border of duodenal enterocytes. All 23 SNPs predicting ID4 expression lie distally within or near the CDKAL1 gene, previously associated with type 2 diabetes. Both ID4 and CKDAL1 are involved in regulation of cell cycle transitions. Interestingly, COL1A2, CDKAL1 and ID4 also exhibit reduced methylation and increased gene expression in advanced versus mild NAFLD patients. The eQTLs that we identified provide important insight into pathologic processes contributing to advanced NAFLD and are significantly enriched for tissue repair, insulin resistance and cell fate decisions.

Bead-based method for capturing specific microRNA in human urine: A non invasive way of detecting clinical conditions. *M. Rath, Tom. Xu, Chris. Trinh, Kathy. Tran, Junko. Stevens, Shi. Amy, G. Marie-Pierre.* Genetic Analysis Integration System R&D, Life Technologies, Foster city, CA.

Research shows that MicroRNA is much more stable and intact than mRNA in various extracellular body fluids such as plasma and urine. Due to this stability, microRNAs in urine samples can be a great promise as a non-invasive way to discover important new biomarkers for a wide range of diseases and biological processes. However, getting microRNA profiles from such samples can be challenging. Life Technology has developed a highly efficient and simplified bead based strategy (TaqMan® miRNA ABC Purification Kit; Cat# 4473087 and 4473088) for rapid purification of microRNA (miRNA) from small inputs of all human sample types including body fluids such as Urine, saliva, cerebro spinal Fluid, FFPE, solid tissues, and cell cultures sample type. In this study, we measured the presence of microRNAs in human urine samples using TaqMan® Array Human MicroRNA A & B cards. A total of 150miRNAs were detected using a Cq cutoff of 35 for TaqMan® Human MicroRNA Array A v3.0 and 79 miRNAs were detected using TaqMan® Human MicroRNA Array B v2.0 in Urine samples. In addition, our profiling data from two pregnant donors indicated gestational age-dependent changes in the expression for 13 miRNAs from TaqMan® Array Human MicroRNA panel A. The validation of these miRNAs with RT-qPCR was found in accordance with the screening result. In this study we have also investigated the expression of miR143 and miR145 in urine samples of patient with balloon injured arteries in comparison to normal artery. Scientific data published by Dr. Chunxiang Zhang showed down regulation of miR-145 in balloon- injured arteries and demonstrated that miR-145 is a critical modulator of vascular smooth muscle cell (VSMC) phenotype.Our result confirmed significant down regulation of these two microRNAs in urine samples of patient with balloon injured arteries in comparison to normal artery. Our method demonstrates the successful purification of specific microRNAs from urine samples without using hazardous organic extractions such as phenol and chloroform. Our result indicated an excellent run to run reproducibility. TaqMan® miRNA ABC Purification Kit; Cat# 4473087 and 4473088 Kit can be used to profile miRNA expression and characterize variances in miRNA species by various downstream applications such as Real Time PCR and miRNA sequence analysis. Profiling urinary microRNAs offers a non-invasive approach and therefore may hold the promise for the development of valuable clinical tools.

Experimental Depletion and Regeneration of Human Mitochondrial DNA to Investigate Its Role in Nuclear Gene Regulation. *S. Kumar, C. Bellis, M.P. Johnson, H.H.H. Goring, T.D. Dyer, J. Blangero, J.E. Curran.* Genetics, Texas Biomedical Research Institute, San Antonio, TX.

Research on mitochondria has evolved from bioenergetics to biogenesis, the genetic functions of mitochondrial DNA (mtDNA), and diseases associated with mitochondrial dysfunction. Although these areas continue to be investigated vigorously, a new era in mitochondrial research has emerged that concerns the role of mitochondria in intracellular signaling - a process that is likely to have far-reaching implications in development, aging, disease, and environmental adaptation. Retrograde regulation is the general term for mitochondrial signaling, and is broadly defined as cellular responses to changes in the functional state of mitochondria. Previously, using complete mitochondrial genome sequences and genome-wide transcriptional profiles of the San Antonio Family Heart Study (SAFHS) individuals we identified approximately 350 transcripts that are highly likely influenced by mitochondrial sequence variation. Among these were several expected cis-effects on mitochondrial transcripts such as *MTCO1* (mitochondrial genome-wide $p = 4\times10^{-34}$) and many dramatic novel trans-effects on the nuclear genes *CENPN* ($p = 1\times10^{-70}$), *PRPH* ($p = 2\times10^{-64}$), *CBX1* ($p = 1\times10^{-61}$), and *TRIM65* ($p = 2\times10^{-43}$) among others. To further investigate the cellular responses to the changes in the functional state of mitochondria, we generated 20 different functional states of mitochondria by depleting and regenerating mitochondrial DNA (mtDNA) experimentally in two lymphoblastoid cell lines from our SAFHS individuals. Real-time quantitative PCR analysis of mtDNA content in these 20 stages of generated cells revealed that their mtDNA content varies from 0.01 to 160 per cent of the original cells content, depending on their functional state as defined by the stage of mtDNA depletion/regeneration. Thus, using this method we can experimentally model the functional state of mitochondria and its influence on nuclear genome. We have performed whole genome gene expression analysis of these 20 stages of generated cells in two cell lines to confirm our original genetically driven findings and to identify novel nuclear genes influenced by the various experimentally generated functional states of mitochondria, to better understand retrograde regulation and inter-individual variations in response. Our results suggest that this experimental approach represents a valuable tool for detecting the impact of mitochondrial genes on nuclear gene regulation.

Primary Mitochondrial Diseases Dysregulate the Transcriptional and Post-transcriptional Regulatory Systems in a Tissue-specific Pattern. *Z. Zhang[1], M. Tsukikawa[1], E. Polyak[1], J. Ostrovsky[1], C. Clarke[1], E. Place[1], E. Rappaport[1], G. Reiner[2], M. Yudkoff[1,3], R. Naviaux[2], R. Haas[2], J. Baur[3], M. Falk[1,3]*. 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of California San Diego, San Diego, CA 92103; 3) University of Pennsylvania Perelman School of Medicine, Philadelphia, PA 19104.

Primary mitochondrial respiratory chain (RC) diseases are an increasingly recognized but poorly understood class of genetic disease that impair basic cellular energy metabolism. Due to the highly heterogeneous etiology, severity, and range of multi-systemic manifestations that typify RC disorders, therapies are generally empirically based and focused on supplementing residual mitochondrial capacity. **METHODS**: To identify a common cellular response to primary RC that might improve mechanistic understanding and therapeutic opportunities for RC disease sequelae, we systematically analyzed collective transcriptomic profiles from skeletal muscle biopsies and fibroblast cell lines (FCLs) from a diverse sample of human mitochondrial disease subjects relative to controls. **RESULTS**: Our data showed that individuals with diverse causes of primary RC dysfunction share a distinctive transcriptomic pattern from that of controls. Interestingly, global changes of patient transcriptomes have the opposite direction in muscle biopsy and FCLs, suggesting that different cell types have unique responses to a deficiency of energy metabolism. Exon-level investigations identified a large number of alternative 5'-UTRs, 3'-UTRs, and transcript isoforms in the RC disease group. A particularly strong association existed between differential 3'-UTR levels and the presence of AU-rich elements (AREs), which are protein-binding motifs within 3'-UTRs that regulate mRNA stability and translation efficiency. Genes with AREs were more likely to have 3'UTRs elevated in patient muscle and reduced in FCLs. The ribosomal protein (RP) genes also illustrated a strikingly distinctive pattern in RC disease. Patient muscles had higher cytosolic RP transcription and lower mitochondrial RP transcription, while FCLs showed the opposite trend. Our data collectively suggest that an mTOR-centered regulatory network plays an essential role in mediating the cellular response to mitochondrial diseases. Indeed, the most significantly up-regulated gene in patient muscle, *RHEB*, is a direct regulator of mTORC1 function. **CONCLUSIONS**: Our systems biology approach strongly demonstrates that transcriptional, post-transcriptional and translational dysregulation occurs in primary mitochondrial disease in a tissue-specific fashion. Recognizing the central role of nutrient sensing signaling pathways in the cellular response to mitochondrial RC disease may offer novel therapeutic opportunities.

Genetic Variation in Expression Response to Endoplasmic Reticulum Stress in Human B-cells. *W. Bernal[1,2], M. Morley[2], V. Cheung[3]*. 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Philadelphia, PA; 3) Howard Hughes Medical Institute, Chevy Chase, MD.

Endoplasmic recticulum (ER) stress is caused by excessive demands on the protein-processing capacity of the ER; inefficiencies in response to ER stress lead to various human diseases. In this project, to study the role of ER stress in disease susceptibility, we identified the genes and pathways involved in ER stress response in human cells, assessed individual variation in these pathways, and mapped DNA sequence variants that influence ER stress response. We exposed cultured human B-cells from 131 normal individuals to tunicamycin, a chemical inducer of ER stress, for 8 hours. Then, using microarrays, we measured expression levels of genes and identified 1,523 ER-stress responsive genes whose expression levels changed at least 1.5-fold on average among 131 individuals. The results also revealed extensive individual differences in ER stress response. For example, across our subjects, the expression responses of canonical ER stress sensors IRE1 and PERK vary by 4-fold and 3-fold, respectively. Similarly, the expression responses of *XBP1* and *DDIT3* (CHOP), which encode key ER stress transcription factors, vary by 5-fold and 9-fold. These results suggest that variation exists not only in sensing of ER stress but also in the extent of ER stress response. To gain insight into pathways that underlie individual differences in expression response to ER stress, we constructed a coexpression network using pairwise correlations. *KDELR2*, which encodes a receptor that retrieves ER proteins from the Golgi, is the most highly connected gene in the network. The *KDELR2* subnetwork is enriched for ER-associated degradation (ERAD) and rRNA transcription, which suggests a role for *KDELR2* in ER stress response beyond ER protein retention.

To understand the basis of individual differences in ER stress response, we carried out a genetic mapping study in B-cells from members of 15 large families. We measured expression responses to ER stress and treated them as quantitative phenotypes in genetic linkage and association studies. We focused our analysis on 778 ER stress-responsive genes and identified DNA sequence variants that regulate the response of 497 of the genes, including *KDELR2*. Of the 497 regulatory relationships identified, 349 were informative when combined with the coexpression network. In this presentation, I will discuss our findings with respect to individual variation in response to ER stress and its underlying genetic regulation.

Dynamic network connectivity mapping of T-cell activation in Caucasians and African Americans identifies a common set of asthma-associated hub genes. *J. Chu[1], W. Qiu[1], V. Carey[1], K. Barnes[2], C. Ober[2], F. Martinez[2], R. Lemanske[2], A. Liu[2], S. London[2], S. Weiss[1], B. Raby[1]*. 1) Channing Lab, Brigham & Women's Hosp, Boston, MA; 2) on behalf of the Asthma BRIDGE consortium.

CD4+ T-cell activation represents a sentinel event in the expression of allergic and asthmatic responses. Though individual molecular components of this process have been characterized, more holistic, system-wide descriptions using transcriptome network mapping in large populations has not been performed. We set out to characterize and compare the gene networks in resting and stimulated human CD4+ peripheral blood lymphocytes, and define those focal modules most radically altered upon activation. A subset of subjects participating in the Asthma BRIDGE initiative from six clinical centers provided whole blood samples, from which PBMCs were isolated and plated in split samples. 25ul of PHA (@5ug/ml) was added to 50% of wells (stimulated samples). At 24 hours, cells were harvested and CD4+ cells and RNA were isolated. Expression profiling was performed using the Illumina Human HT12 array. Following data QC and preprocessing procedures, we used differential connectivity mapping procedures (Chu et al. BMC Systems Biology 2011) and compared the transcriptome networks of the stimulated and unstimulated samples to define regulatory modules that undergo restructuring during T-cell activation. Expression data from 98 non-Hispanic whites and 157 African Americans were available for analysis. We noted widespread differences in the topographical landscape of the CD4+ lymphocyte transcriptome following stimulation, identifying 216 gene hubs that each demonstrated differential connectivity to no fewer than 50 genes. 86 genes were identified in both the white and African American samples, representing a reproducible set of regulatory modules with altered topography (i.e. altered gene-gene co-expression patterns) upon T-cell activation. These 86 genes are enriched for genes involved in antigen processing and presentation (p=3.0E-04) and those with genetic variants associated with immune-related diseases. Among the most differentially connected genes were UTS2, GSTM1, HLA-C, ARG1 and HLA-DRB1, all of which have been implicated in the genetics of asthma. In conclusion, we have described the network topography underlying T-cell activation, and have identified a reproducible set of 86 gene hubs with substantially altered connectivity upon stimulation. As many of the genes on this list are known asthma genes, the remainder should be prioritized for further evaluation as therapeutic targets in the treatment of allergic and autoimmune disease.

537F

Immunity genes and pathways are associated with human microbiome composition at host body sites. *R. Blekhman[1,2], J. Goodrich[1,3], K. Huang[4], R. Bukowski[5], Q. Sun[5], R.E. Ley[1,3], D. Gevers[4], A.G. Clark[1]*. 1) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY; 2) Department of Neurology and Neuroscience, Weill Cornell Medical College, New York, NY; 3) Department of Microbiology, Cornell University, Ithaca, NY; 4) Genome Sequencing and Analysis Program, The Broad Institute of MIT and Harvard, Cambridge, MA; 5) Computational Biology Service Unit, Cornell University, Ithaca, NY.

Recent advancements in high-throughput sequencing technologies have unveiled wide variability in the communities of microbial species that inhabit the human body. Shifts in the species composition of the human microbiome have been associated with multiple chronic conditions, including diabetes, inflammatory bowel disease, and obesity. Although the human microbiome is influenced by environmental factors, a strong host genetic influence is also expected in the interaction between humans and bacteria through the immune system and metabolic pathways. However, to date, there are no comprehensive studies examining the interactions between human genetic variation and the composition of this microbial ecosystem on a genome- and microbiome-wide scale. Here, we report a genome-wide association study aimed at identifying human genomic loci correlated with levels of different bacteria in various body sites. To do so, we used shotgun metagenomic sequencing data from the Human Microbiome Project, and extracted non-bacterial sequence reads that were labeled as “host contamination.” By mapping these reads to the human genome, we achieved a 10x mean coverage and identified 4 million SNPs in 93 human individuals for which extensive metagenomic data is also available. Despite the small sample size, a genome-wide association approach successfully identified a number of loci in the human genome that show significant associations with microbiome composition at 15 host body sites. These loci are enriched with genes and pathways involved in host immune response, which likely play a role in promoting inflammation in the host as a response to bacterial infection. In addition, we show that many of these pathways are also enriched in a replication study examining gut microbial composition in a separate population. Our results highlight the role of common genetic variation in controlling the composition of the human microbiome and the importance of host immunity in determining bacteria levels across the body. Furthermore, the associations discovered here might be a starting point toward understanding the complex interaction between host genetic variation and the microbiome in susceptibility to common autoimmune diseases.

Ribosome footprints on Williams syndrome region genes in the mouse brain. *R. Weiss[1], M. Howard[1], L. Dai[2], J. Korenberg[2]*. 1) Human Genetics, Univ Utah, Salt Lake City, UT; 2) Center for Integrated Neuroscience and Human Behavior, Brain Institute, Univ Utah, Salt Lake City, UT.

The advent of quantitative methods to measure global gene expression levels, most recently RNA sequencing, has greatly increased our ability to create a global picture of cellular processes. However, until recently no comparable technology existed to examine genome-wide protein synthesis (translational) activity. Translation is also a level at which a general response to distress caused by genomic imbalance may be regulated to maintain cellular homeostasis, and may be a novel point for therapeutic intervention. Williams syndrome (WS) is a CNV disease caused by a *de novo* hemizygous deletion of 25–28 genes on Chr7q11.23 and is characterized by a distinct pattern of cognitive effects. Global transcriptome profiling in WS has shown a *cis* effect at the transcript level in the deleted region, as well as transcript-level perturbations in a proximal gene network comprised of physically interacting gene products and their associated pathways. But since perturbations in protein expression can arise due to combined changes in mRNA abundance and translational activity on individual mRNAs, we approached the problem by applying the novel technique of ribosome profiling in a multi-tissue comparison of adult tissues from C57BL/6J mice and assessed the transcriptional and translational state of genes in skeletal muscle, heart, liver and brain. Ribosome-mRNA complexes were isolated from snap frozen adult mouse tissues, and after nuclease (RNase) digestion, the ~30 nt ribosome-protected mRNA fragment "footprints" were characterized by deep sequencing using an Illumina sequencer. We observed regions of active translation in WS transcripts that were characterized by dense footprints in CDS regions, but also specific footprints in a subset of 5' UTRs. The location of ribosome footprints in the 5' UTR of Cyln2 were conserved across tissues and located at an AUG codon initiating the translation of short upstream open reading frame prior to the main AUG start codon. This pattern is characteristic of other genes and may be related to the translation efficiency of the main CDS. These results suggest an additional level of gene expression control in the WS region may be susceptible to alteration by copy number changes. Ribosome profiling may have wider utility for interpreting how CNVs alter the abundance of their encoded protein(s) and their secondary effects on the abundance of proteins expressed from other regions of the genome.

Regulatory mutations in the 5'UTR of *NMNAT1*, encoding the nuclear isoform of nicotinamide nucleotide adenylyltransferase 1, cause Leber Congenital Amaurosis. *F. Coppieters[1], A. Baert[1], C. Van Cauwenbergh[1], M. Bauwens[1], S. De Jaegere[1], T. de Ravel[2], F. Meire[3], N. Abdelmoula Bouayed[4], L. Florentin-Arar[5], B.P. Leroy[1,6], E. De Baere[1]*. 1) Center for Medical Genetics Ghent, Ghent University, Ghent, Belgium; 2) Center for Human Genetics, Leuven University Hospitals, Leuven, Belgium; 3) Hôpital Des Enfants Reine Fabiola, Brussels, Belgium; 4) Department of Histology, Medical University of Sfax, Sfax, Tunis; 5) Molecular biology and cytogenetics, Lito Maternity Hospital, Athens, Greece; 6) Department of Ophthalmology, Ghent University Hospital, Ghent, Belgium.

Leber Congenital Amaurosis (LCA) is the earliest and most severe inherited retinal dystrophy (RD). Recently, coding mutations in *NMNAT1* uncovered this gene as the causal disease gene for the LCA9 locus (Pierce *et al.*, ARVO Meeting 2012), mapped a decade ago (Keen *et al.*, 2003). *NMNAT1* encodes the nuclear isoform of the nicotinamide nucleotide adenylyltransferase 1. The goal of this study was twofold. First, we aimed to identify the causal genetic defect in an LCA9-linked consanguineous Sub-Saharan African family. Second, we wanted to determine the contribution of *NMNAT1* mutations in a pre-screened LCA population.

Starting point of this study was a consanguineous family with 3 affected and 1 unaffected sibling in which genomewide IBD mapping identified an IBD region of 14 Mb encompassing LCA9. Sanger sequencing of the *NMNAT1* transcription unit identified a homozygous 5'UTR variant, c.-70A>T, which segregated with disease in the family and was absent in 265 healthy controls. This variant was predicted to alter secondary structure formation of the 5'UTR. Sequencing of c.-70A>T on cDNA of leukocytes revealed loss of heterozygosity in the parents and the healthy sib, suggesting *NMNAT1* mRNA degradation. Subsequent sequencing of *NMNAT1* in 76 unrelated probands with LCA or early-onset RD revealed mutations in 5 additional probands. Of note, a second 5'UTR variant, c.-69C>T, was found in homozygous state in a Moroccan LCA patient. Interestingly, it is located 1 nucleotide downstream of c.-70A>T and predicted to cause similar aberrant 5'UTR folding. A phenotypic evaluation of both families revealed LCA with evolutive macular involvement. In addition, two probands were compound heterozygous for the common missense variant p.Glu257Lys and a novel missense mutation predicted to affect protein function (p.Met69Val and p.Tyr181Cys). Two other probands were found to carry a single heterozygous missense variant (p.Arg188Trp and p.Asn18Ser). Resequencing of the entire genomic region is currently ongoing to exclude a deep intronic mutation.

In conclusion, this study sustained the role of coding *NMNAT1* mutations in LCA. Moreover, the identification of two neighboring, potentially pathogenic 5'UTR variants in *NMNAT1* makes this the first study to link 5'UTR regulatory variants to LCA with macular involvement. Overall, this study may impact upon the role of 5'UTR variations in other RDs in general.

540W

Disruption of a cis-acting microRNA site in FMR1 results in reduced translation of an FMRP reporter. *J. Suhl[1], R. Muddashetty[2], G. Bassell[2], S. Warren[1,3]*. 1) Human Genetics, Emory University, Atlanta, GA; 2) Cell Biology, Emory University, Atlanta, GA; 3) Biochemistry and Pediatrics, Emory University, Atlanta, GA.

Fragile X (FX) syndrome is the most common inherited form of intellectual disability (ID) and the leading known genetic cause of autism spectrum disorder. In a vast majority of FX cases, the gene responsible for the syndrome, FMR1, is silenced by hypermethylation that is triggered by expansion of an unstable CGG repeat in the promoter. However, few FX patients have been identified who exhibit normal repeat length, but harbor conventional mutations. Recently, we performed high throughput sequencing of FMR1 from 963 developmentally delayed and/or autistic males with normal repeat length, revealing a number of novel variants. Here, we report the functional analysis of a variant, identified in 6 patients but absent in controls (locally tested and databases), located in the 3'UTR of FMR1 (c.*746T>C) that is predicted to disrupt the interaction of miR-548p by interfering with seed region binding. A patient 3'UTR containing this variant causes a 25–40% decrease in reporter expression compared to a control, while mRNA levels remain unchanged, suggesting FMR1 is post-transcriptionally regulated via the 3'UTR. In support of the microRNA hypothesis, we find that the patient transcript co-immunoprecipitates poorly with AGO2 as compared to the control. Strikingly, we have found that the control reporter expression in cultured rat cortical neurons show a marked increase following synaptic stimulation that is entirely lost with the mutant reporter. Thus, activity-dependent translation of FMR1 in the postsynaptic space, recognized for a number of years but poorly understood, may be regulated by the microRNA pathways and that the c.*746T>C mutation appears to abrogate the local synthesis of FMRP following synaptic activity. Since this variant was seen in 0.6% of the patients studied, it may represent a new, clinically significant, variant of FMR1 and suggests that FMR1 sequencing in addition to repeat length determination could be warranted to rule out FMR1 involvement.

Is the biosynthesis of the major phospholipid class phosphatidylcoline in mammalian cells regulated by micro-RNA? *K. Hokynar, S. Hänninen, M. Hermansson, P. Somerharju.* Institute of biomedicine, Department of biochemistry and developmental biology, P.O.Box 63 (Haartmaninkatu 8), 00014 University of Helsinki, Helsinki, Finland.

Mammalian cells and cell organelles are surrounded by lipid bilayers formed mainly of phospholipids (PL), of which over 50 % are species of phosphatidylcolines (PC) and the rest include phosphatidylethanolamines, -inositols and -serines. In higher eukaryotes different cell membranes and membrane leaflets have specific PL compositions that are essential for proper cellular functioning and vitality and thus kept within narrow limits. Homeostasis of PL is maintained by biosynthesis, degradation, remodeling of acyl chains and interorganelle transport. Dozens of enzymes are involved in synthesis and degradation of PLs, but only little is known about their regulation at the transcriptional and post-transcriptional/translational level. MicroRNAs (miRNA) regulate gene expression post-transcriptionally by repression of translation or/and decay of the mRNA. miRNAs have been shown to be involved in many biological processes such as development and differentiation, recently also in regulation of cholesterol, fatty acid and glucose homeostasis. Our aim is to study whether miRNAs participate in the homeostasis of PLs in mammalian cells. HeLa cells were depleted of microRNAs by silencing the expression of enzymes Dicer1or Drosha by siRNA, after which the rate of PC biosynthesis was assessed by a method using deuterium labeled choline precursors and mass spectrometric (MS) analysis. Silencing of miRNA biogenesis resulted in an increase of PC synthesis (16 % in Dicer and 14 % in Drosha silenced cells). We also examined the expression levels of enzymes involved in PL biosynthesis and degradation after silencing of Dicer1 or Drosha. There was no significant change in the expression of PL degrading enzymes iPLA2β and iPLA2δ, neither at the mRNA nor protein level. However, silencing of miRNA synthesis resulted in an increase of expression of certain enzymes involved in PC synthesis (CDS1, CDS2 and SGMS2). In conclusion the biosynthesis of PC and the expression of certain PC biosynthetic enzymes increased in HeLa cells after silencing of miRNA biogenesis. These results suggest that miRNAs might be involved in the regulation of homeostasis of mammalian cell membrane PL content by effecting - directly or indirectly - the enzymes involved the biosynthesis of phosphatidylcholine.

Poly(A) binding protein nuclear 1 (PABPN1) levels affect alternative polyadenylation. *E. de Klerk[1], A. Venema[1], S.Y. Anvar[1], J.J. Goeman[2], O. Hu[1], J.T. den Dunnen[1], S.M. van der Maarel[1], V. Raz[1], P.A.C. `t Hoen[1].* 1) Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Medical Statistics and Bioinformatics, Leiden University Medical Center, Leiden, Netherlands.

The choice for a polyadenylation site (PAS) determines the length of the 3'-untranslated region (3'-UTRs) of an mRNA. Inclusion or exclusion of regulatory sequences in the 3'-UTR may ultimately affect gene expression levels. Poly(A) binding protein nuclear 1 (PABPN1) is involved in polyadenylation of pre-mRNAs. A repeat expansion in PABPN1 causes oculopharyngeal muscular dystrophy (OPMD), a late onset and progressive muscle disorder. Microarray expression profiling of mice overexpressing expanded-PABPN1 showed alternative PAS usage in 8% of the interrogated genes. We hypothesized that previously observed disturbed gene expression patterns in OPMD muscles may have been the result of an effect of PABPN1 on alternative PAS usage. To explore PAS usage on a genome-wide level, we developed a single molecule PAS sequencing method. We identified 2,012 transcripts with altered PAS usage. In the far majority, alternative more proximal PAS were used. This resulted in overall shortening of 3'-UTRs and increased expression for most of the transcripts. We recapitulated these changes in PAS usage in myogenic cells by low overexpression of expanded but not wild-type PABPN1. Since expanded-PABPN1 is known to be trapped in intranuclear inclusions, we investigated the effect of shRNA mediated downregulation of PABPN1. We found that reduced Pabpn1 levels also resulted in shortening of 3'-UTRs. Our data suggest that PABPN1 is involved in PAS selection. We propose therefore that reduced availability of functional PABPN1 in OPMD muscles results in use of alternative, proximal PAS, leading to large-scale deregulation of gene expression.

Identification of human RNA editing sites using publically available RNA-sequencing data. *G. Ramaswami, J.B. Li.* Department of Genetics, Stanford University, Stanford, CA.

Background: RNA editing plays an essential role in normal functioning of the nervous system. Post-transcriptional modification of adenosine to inosine (A-to-I) is the most common form of editing in mammals. The emergence of high-throughput RNA sequencing (RNA-seq) has resulted in a plethora of publically available RNA-seq datasets from various human tissues. This is a powerful resource for identification of A-to-I editing sites. Recently, we developed a strategy to accurately identify RNA editing sites by comparing the sequence differences between RNA-seq and coupled genomic DNA sequencing. Although this method was effective, its major drawback is the requirement of DNA sequencing data from the same individual to discriminate RNA editing sites from SNPs. This prohibits its wide application to the multitude of publically available RNA-seq datasets, because these data samples often do not have matched DNA sequence available. **Methods:** In this study, we developed two separate, but related methods to detect RNA editing sites using RNA-seq data by itself. Both of our methods rely on RNA-seq data from multiple individuals. In the first method, RNA variants are called in each sample, and all common SNPs are removed. To distinguish RNA editing sites from rare SNPs in the remaining RNA variants, we require the variants to be shared among multiple individuals because RNA editing is often biologically conserved. In the second method, the RNA-seq data are pooled to achieve higher read coverage, enhancing sensitivity for calling RNA variants. We eliminate rare SNPs by requiring a minimum frequency for RNA variants. We applied our two methods to identify human RNA editing sites using RNA-seq data from 40 lymphocyte cell lines and 50 brains. **Results:** In lymphocytes, we detected over 100,000 RNA editing sites in repetitive elements and over 1,000 editing sites in non-repetitive sequences. In brains, we detected over 300,000 RNA editing sites in repetitive elements and over 5,000 editing sites in non-repetitive sequences. Overall, we identify over 300,000 novel A-to-I editing sites, including many edits that modify protein-coding sequence. **Conclusions:** In this study, we were able to identify numerous A-to-I RNA editing sites in an extremely cost-effective manner by utilizing publically available RNA-seq data. Identification of novel A-to-I editing sites will be a significant step towards understanding how RNA editing regulates critical biological processes.

Human ADAR proteins regulate RNA editing and gene expression as revealed in systems study. *I. Wang, J. Toung, A. Richards, E. So, Y. Zhao, W. Ankener, J. Devlin, Y. Liu, V. Cheung.* V Cheung Lab, Univ Pennsylvania, Philadelphia, PA.

ADAR family of adenosine deaminases mediates A-to-G RNA editing. Previously, it was thought that RNA editing is rare. However, recent deep sequencing of DNA and RNA has revealed that such events may be more common than previously known. In this study, we carried out DNA and RNA deep sequencing, RNA interference, RNA-immunoprecipitation (RNA-IP) and mass spectrometry in human B-cells to examine the functions of ADAR proteins. By coupling DNA and RNA sequence analyses with ADAR RNA-IP, we uncovered over 60,000 sites where the adenosines (A) are edited to guanosines (G); over 90% of these were previously unknown editing sites. These editing sites are found in mRNA and long non-coding RNAs (lncRNAs). Most of them are found in Alu repeats and in 3' UTRs of genes. Hyperediting is rather common; over 200 genes contain more than 50 A-to-G editing sites within each gene. ADAR gene knockdowns showed that in addition to editing, ADAR affects expression levels of several thousand genes and a number of microRNAs. The effects on gene expression occur in an editing-independent manner, suggesting ADAR proteins play important roles in cellular processes other than editing. Using proteomic approach, we identified more than 100 proteins in the ADAR protein complex. These ADAR-interacting proteins include splicing factors, heterogeneous ribonucleoproteins, several members of the dynactin protein family and other proteins involved in RNA processing. Our data support that ADAR functions together with other proteins and regulates multiple cellular processes including gene expression. Previously, we identified RNA-DNA sequence differences beyond the traditional A-to-G editing events. By ADAR gene knockdowns, we showed that while ADAR proteins mediated A-to-G editing, they do not play a role in other types of RNA-DNA sequence differences. In this presentation, I will describe results from genomic, transcriptomic and proteomic analyses which allowed us to identify tens of thousands of unknown A-to-G editing sites and to characterize ADAR's roles in gene regulation. The presentation will focus on findings that underscore the complexity of RNA processing and suggest that there are co- or post-transcriptional mechanisms yet to be determined.

Integrating functional and computational genomics to develop neuronal regulatory vocabularies. *X. Reed[1], L. Taher[2], G.M. Burzynski[1], C. Fletez-Brant[1], D. Lee[1,3], D.S. Gary[4], M.A. Beer[1,3], I. Ovcharenko[2], A.S. McCallion[1]*. 1) McKusick-Nathans Institute of Genetic Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD; 2) Computational Biology Branch, National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, Bethesda, MD; 3) Johns Hopkins University, Department of Biomedical Engineering, Baltimore, MD; 4) International Center for Spinal Cord Injury (ICSCI), Kennedy Krieger Institute, Baltimore, MD.

The brain is a complex tissue comprising an array of cell types that express thousands of gene products. Disregulation of gene expression can give rise to phenotypic variation that may manifest as disease/risk. The genetics of many brain disorders, including Parkinson's disease, are poorly understood. By elucidating the encryption of transcriptional regulatory control we will gain insight into the molecular basis of cognitive variation and disease. To address the need for a neuronal regulatory vocabulary we initially used a machine learning approach to create a classifier that predicts sequences that may act as enhancers in the hindbrain. The classifier is trained on conserved enhancers previously shown to direct expression in the hindbrain, and looks for motifs enriched therein. Using the classifier we identified 40,000 sequences predicted to act as enhancers in the hindbrain. 51/55 (93%) predicted enhancers directed expression within the CNS of mosaic embryos, and 30/34 (88%) of stable lines show consistent expression in the hindbrain. Encouraged by this and other genome-wide enhancer classifier progress in our lab, we analyzed CNS ChIP-seq data available on the Human Epigenome Atlas. We called peaks for H3K4me1, a histone modification associated with active enhancers, in various sub-populations of the human brain (*substantia nigra*, temporal lobe, hippocampus, and anterior caudate). To identify those features that are specifically important in the substantia nigra we removed all sequences that were found within any of the other datasets. The remaining H3K4me1 flanked regions were run through an SVM classifier (Lee, Karchin, Beer 2011) to identify k-mers (motifs) that were overrepresented in the dataset. The ROC AUC is 65%, and the top k-mers returned correspond to binding sites for NR4A2 and FOXA2, transcription factors known to be important in the development of dopaminergic neurons. We selected ten regions which were located near genes characteristically expressed in dopaminergic neurons, or near SNPs which have been associated with Parkinson's disease, to be tested for enhancer function in zebrafish. These sequences are the focus of ongoing *in vivo* functional analyses and contribute to the larger search for neuron-specific vocabularies. To this end we have also initiated ChIP-seq analyses on *ex vivo* isolated and purified neuronal subpopulations, including cortical, striatal, cerebellar and hippocampal. We will discuss our progress in these efforts.

546W

Transcriptome genomic analysis using RNA-seq in three tissues of a twin cohort. *A. Buil[1,2], A. Brown[3], M. Davies[4], A. Viñuela[4], M. Gallardo[5], D. Glass[4], M. Blasco[5], R. Durbin[3], T.D. Spector[4], E.T. Dermitzakis[1,2] for the EUROBATS Consortium.* 1) Department of Genetic Medicine and Development, University of Geneva, Geneva, Switzerland; 2) Institute of Genetics and Genomics in Geneva, University of Geneva, Geneva, Switzerland; 3) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 4) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 5) Telomeres and Telomerase Group, Molecular Oncology Program, Spanish National Cancer Centre (CNIO), Madrid, Spain.

We used RNA-seq data from a sample of twins to address the question of tissue specificity and genetic architecture of the regulation of gene expression. We used the EUROBATS project sample which consists of around 400 twin pairs with RNA extracted from fat, LCLs and skin. For each sample we sequenced the mRNA using 49bp paired-end sequencing in an Illumina HiSeq (2330 samples in total). Currently, we have analyzed a pilot set of samples from 200 individuals in the three tissues (600 samples). We obtained 18M exonic reads per sample on average. We quantified reads to known exons and used imputed genotypes from Hapmap II to discover cis eQTL. We observed 1901 genes with at least a significant cis eQTL in fat, 1776 in LCL and 1816 in skin (FDR=10%). That is an increase of 15% compared to eQTLs found with the same samples but using microarray gene expression measures. We also found that between 35% and 50% of the eQTL are shared among two tissues and that 25% of them are shared by the three tissues. RNA-seq data allows the quantification of allele specific expression (ASE). We performed a binomial test for each individual at each heterozygous site controlling for various confounders such as reference mapping bias. At a 10% FDR we observed that 9.5% of the heterozygous sites had a significant ASE effect in fat, 9.3% in LCL and 9.1% in skin. We also found that 8.8% of the significant ASE sites were present in the same individual in all three tissues and that the direction of the ASE ratio was consistent. Finally, using the ASE ratios of each sample at every heterozygous site, we defined an ASE distance among samples. We observed that the ASE distance is smaller for samples from the same tissue than for samples from different tissue. We also found that the ASE distance is smaller for MZ twins than for DZ twins and for DZ twins than for unrelated individuals. Given the useful twin structure of the data we plan to develop this ASE distance metric further in order to define the relative contribution of genetic to genetically independent epigenetic effects on allele specific expression. With the analysis of the whole dataset we will obtain more precise results for cis eQTL discovery and ASE analysis. At the same time, the larger dataset will allow us to look for trans eQTL in the three tissues. Furthermore we will determine the transcript structure of each tissue and the tissue specific genetic determinants of alternative splicing.

The genetics of gene expression, splicing and transcriptional efficiency through Poly-A selection and ribosomal depletion RNA sequencing in humans. *M. Pala[1,2,6], M. Marongiu[2], A. Mulas[2], R. Cusano[2], F. Crobu[2], F. Reinier[3], R. Berutti[3,6], M.G. Piras[2], C. Joens[3], D. Schlessinger[5], G. Abecasis[4], A. Angius[2], S. Sanna[2], F. Cucca[2,6,7], S.B. Montgomery[1,7].* 1) Stanford University, Stanford, CA; 2) Istituto di Ricerca Genetica e Biomedica (IRGB), CNR, Monserrato, 09042, Italy; 3) CRS4, Advanced Genomic Computing Technology, Pula, Italy; 4) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 5) Laboratory of Genetics, National Institute on Aging, Baltimore, Maryland, USA; 6) Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy; 7) co-senior authors.

Most genome-wide association study (GWAS) signals fall within non-coding regions and are thus hard to interpret. Recent RNA-seq studies have demonstrated multiple modes of impact of GWAS variants on expressed transcripts. Notably, expression quantitative trait loci (eQTLs) for many human genes are emerging as informative intermediate phenotypes and it has been shown that genetic variants can affect not only overall gene expression but may alter individual transcripts. These isoform eQTLs can function at the level of alternative splicing, alternative polyadenylation sites or regulatory variation in alternative promoters, resulting in a combination of transcriptional, co-transcriptional (e.g., splicing), and post-transcriptional (e.g., RNA stability) mechanisms. In order to study in detail both transcriptional and post-transcriptional mechanisms regulating eQTL targets, we sequenced RNA from peripheral blood mononuclear cells for 80 Sardinian individuals enrolled in the SardiNIA cohort study with both poly-A selection and ribosomal depletion protocols. For each individual, an average of 50M of pair-end reads (51+51 nucleotides) was produced. We report the diversity of eQTLs observed in the Sardinian founder population, their relationship to other European populations and their implications on existing GWAS data. Furthermore, from the ribominus depletion protocol, we get significant amounts of unspliced, pre-mRNA, allowing us to profile, in combination with the poly-A selection protocol, the levels of both exonic and intronic sequences and uniquely report genetic effects on transcriptional efficiency. The same individuals have also been whole genome sequenced and characterized longitudinally for >200 quantitative traits, with measurements repeated in follow-up visits giving the possibility to cross compare different sources of data. Overall, this study offers unique opportunities to refine eQTLs in the founder Sardinian population, but also can improve our understanding of the genetic basis of transcriptional regulation and its impact on human phenotypic variation.

Quantification of chitinase transcripts in human tissues. *M. Ohno, K. Tsuda, M. Sakaguti, Y. Sugahara, F. Oyama.* Dept Applied Chemistry, Kogakuin Univ, Hachioji, Tokyo, Japan.

Chitin is the second abundant polysaccharide in nature. It is an integral component of the fungal cell walls, the exoskeletons of crustaceans and insects, and the microfilarial sheaths of parasites. Although mammals do not have chitin and its synthase, genes encoding chitotriosidase and acidic mammalian chitinase (AMCase) and their translation products have been found in both human and mouse. Recent studies have shown an association between the mammalian chitinase and inflammatory lung diseases. For instance, chitotriosidase levels were elevated in the plasma of Gaucher disease and the bronchoalveolar lavage fluid of smokers with chronic obstructive pulmonary disease (COPD). AMCase expression and activity is upregulated in allergic airway responses in mouse models of asthma. Little is known, however, about the mutual regulation of the chitinases in human. We quantified expression levels of the chitinases and reference genes on the same scale using quantitative real-time RT-PCR system. Both chitinases were expressed in all tissues. Chitotriosidase mRNA was predominantly expressed in lung. AMCase mRNA was also highly expressed in lung, but their expression level was one third of the chitotriosidase. Our study shows that chitotriosidase plays a central role in human lung.

549F

Two functional variants in the promoter region of UBE2L3 confer risk for Systemic Lupus Erythematosus. *S. Wang[1], G.B. Wiley[1], F. Wen[1], J. Warner[1,2], J. Robertson[1], J.M. Guthridge[1], M. Dozmorov[1], J.D. Wren[1], J.A. James[1,2], P.M. Gaffney[1].* 1) Oklahoma Medical Research Foundation, Oklahoma city, OK; 2) College of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Systemic lupus erythematosus (SLE) is an autoimmune disease with diverse clinical manifestations characterized by the development of pathogenic autoantibodies and target tissue damage. Genome-wide association (GWA) studies have identified genetic variants in the UBE2L3 region associated with SLE in Europeans and Asians, and we recently reported the association of a functional risk haplotype in the region of UBE2L3 with SLE that increases mRNA expression of UBE2L3. To discover and characterize functional variants carried on the SLE associated UBE2L3 risk haplotype, electrophoretic mobility shift assay (EMSA) was performed to test the differential binding affinity of variants in and around the promoter region of UBE2L3 to the nuclear proteins prepared from five different types of cell lines, including, U937, THP1, HEK293T, HeLa, and EBV-transformed B cell lines. SNPs were prioritized for functional testing using Genomatix and Genome Runner. A proportion of the cells were subjected to the preparation of nuclear proteins and the isolation of total RNAs. The rate of growth of EBV transformed B cell line was calculated by counting the total number of cells every 24 hours. Messenger RNA expression of UBE2L3 was determined using quantitative RT-PCR and normalized to a control gene (HMBS). Data obtained by EMSA demonstrates that two variants (rs140490 and rs2266959) function in regulating transcription factor binding. The variant rs140490 binds EBV cell-type dependent nuclear protein complex with enhanced affinity (P=0.0031). The binding of the protein complex to the variant region increases mRNA transcription of UBE2L3 in a time-dependent manner. In contrast, rs2266959 results in a reduced affinity of binding (P= 0.0014) to a common nuclear protein complex present in multiple cell lines. Here, we observed evidence for two functional alleles of UBE2L3: rs140490 is located in the promoter region that enhances the affinity of binding to a EBV cell-type specific protein complex in a time-dependent manner; rs2266959 is located in the first intron of UBE2L3 that results in a reduced affinity of binding to a common nuclear protein complex from different cell lines. Our data suggest that functional variants on the UBE2L3 risk haplotype are responsible for the gene expression phenotype. Further characterization of the functional variants of UBE2L3 will help to understand the role this risk haplotype plays in SLE pathogenesis.

A 660 kb deletion centromeric to the lamin B1 gene (*LMNB1*) mimics LMNB1 duplication and causes adult-onset autosomal dominant leukodystrophy. *E. Giorgio[1], D. Robyr[2], E. Di Gregorio[1,3], D. Lacerenza[1], G. Vaula[4], A. Brusco[1,3], S.E. Antonarakis[2], A. Brussino[1].* 1) University of Torino - Dpt of Genetics, Biology and Biochemistry, Torino, Torino, Italy; 2) Department of Genetic Medicine and Development, University of Geneva Medical School and University Hospitals of Geneva, Geneva, Switzerland; 3) SCDU Medical Genetics, AOU S.Giovanni Battista, Torino, Italy; 4) Department of Neuroscience, AOU S.Giovanni Battista, Torino, Italy.

We report a position effect mutation in the lamin B1 locus due to a genomic deletion centromeric to the gene that moves a cryptic enhancer closer to the *LMNB1* gene, resulting in its overexpression, and mimicking Adult-onset Autosomal Dominant LeukoDystrophy (ADLD). ADLD is a rare central nervous system demyelinating disease presently associated to lamin B1 (*LMNB1*) gene duplication. We collected a large Italian pedigree segregating an autosomal dominant form of late onset leukodystrophy clinically overlapping ADLD. Linkage analysis mapped the disease to the LMNB1 locus, although *LMNB1* was not duplicated or mutated. However, *LMNB1* was overexpressed in fibroblasts both at mRNA and protein level as in reported ADLD patients. Using array-CGH analysis, we identified a 660 kb deletion located approximately 66 kb centromeric to the *LMNB1* gene, that we hypothesised alters *LMNB1* gene expression. The deleted segment spanned three genes, *GRAMD3*, *ALDH7A1* and *PHAX*, and its boundaries were defined within two Alu repeats. shRNA silencing assays on HeLa cells showed *GRAMD3*, *ALDH7A1* and *PHAX* knockdown did not affect *LMNB1* expression. To search for non-coding regulatory elements, we performed circular chromosome conformation capture (4C) on fibroblasts from a patient and a healthy control, using lamin B1 promoter as a bait. We identified four potential regulatory regions: region A, located within the deletion (0.12 Mb centromeric to *LMNB1* gene), which interacted with the promoter both in the patient and the control DNA, and regions B, C and D (0.77, 1.9, and 2.0 Mb centromeric to the *LMNB1* gene and upstream of the deletion), whose interaction was present in the patient only. Using a dual-luciferase assay, each putative regulatory region was cloned into the reporter vector (a modified pGL4.10) upstream of the lamin B1 promoter. Two regions behaved as enhancers: region A and B: both were not previously reported as *LMNB1* enhancers and are not evolutionary conserved. Therefore, in our patients, the presence of the deletion takes away region A in one of the two alleles, bringing region B closer to *LMNB1* and substituting region A in its enhancer activity. Given that dual luciferase assay demonstrates that region B is stronger than region A (luciferase signal changes from 2.8 to 3.4 fold vs. control) we speculate this is causing lamin B1 overexpression. Our results confirms that mutations in regulatory elements may be important determinants of Mendelian phenotypes.

Variation in Transcription Factor Binding Among Humans. *F. Grubert[1,2], M. Kasowski[1,2], C. Heffelfinger[2], M. Hariharan[1,2], A. Asabere[1,2], S. Waszak[3], L. Habegger[4], J. Rozowsky[5], M. Shi[1,2], A. Urban[2,6], M. Hong[2], K. Karczewski[1], W. Huber[3], S. Weissman[6], M. Gerstein[4,5,7], J. Korbel[3,8], M. Snyder[1,2].* 1) Dept Genetics, Stanford University, Stanford, CA; 2) Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT; 3) Genome Biology Research Unit, European Molecular Biology Laboratory, Heidelberg, Germany; 4) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 5) Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT; 6) Department of Genetics, Yale University School of Medicine, New Haven, CT; 7) Department of Computer Science, Yale University, New Haven, CT; 8) European Molecular Biology Laboratory-European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton CB10 1SD, UK.

Differences in gene expression may play a major role in speciation and phenotypic diversity. We examined genome-wide differences in transcription factor (TF) binding in several humans and a single chimpanzee by using chromatin immunoprecipitation followed by massively parallel sequencing. The binding sites of RNA polymerase II (Pol II) and a key regulator of immune responses, nuclear factor kB (p65), were mapped in 10 lymphoblastoid cell lines, and 25 and 7.5% of the respective binding regions were found to differ between individuals. Binding differences were frequently associated with single-nucleotide polymorphisms and genomic structural variants, and these differences were often correlated with differences in gene expression, suggesting functional consequences of binding variation. Furthermore, comparing Pol II binding between humans and chimpanzee suggests extensive divergence in TF binding. Our results indicate that many differences in individuals and species occur at the level of TF binding, and they provide insight into the genetic events responsible for these differences.

552W

Widespread R-loop formation in the human genome: implications for epigenetic control and beyond. *Y. Lim, P. Ginno, P. Lott, I. Korf, F. Chedin.* Molecular and Cellular Biology, University of California, Davis, CA.

Long R-loop structures can form upon transcription through GC-skewed sequences when a G-rich RNA is transcribed. As we recently showed, unmethylated CpG islands (CGI) promoters - the main promoter class in the human genome - are characterized by a sharp rise in GC skew immediately downstream of the transcription start site and represent prominent hotspots of R-loop formation. Co-transcriptional R-loop formation was further proposed to directly contribute to the protection of CGI promoters from DNA methylation, a prevalent epigenetic mark associated with transcriptional silencing. We have now computationally profiled GC skew patterns using a high-sensitivity iteration of the SkewR Hidden Markov Model and measured R-loop formation genome-wide using DNA:RNA immunoprecipitation coupled to high throughput sequencing (DRIP-seq) in human fibroblasts. This analysis reveals the following novel characteristics. (1) GC skew patterns at the 5'-end of genes can distinguish between four broad promoter classes with distinct, genetic, epigenetic, and ontology signatures, including a class of promoters highly associated with developmentally-regulated transcription factors. (2) The X chromosome shows evidence for depletion of promoter GC skew over its evolutionary history and R-loop formation is accordingly reduced on the X, consistent with this chromosome undergoing broad silencing during X-inactivation. (3) In addition to the 5'-end of genes, GC skew and R-loop formation are prevalent at the 3'-end of thousands of genes, particularly genes located in gene-dense regions. This observation is consistent with recent evidence suggesting that R-loop formation is required for efficient transcription termination at the 3'-end of genes. Overall this works indicates that GC skew patterns and R-loop formation play important roles in defining the boundaries of human genes, ensuring proper transcription initiation and termination, and molding gene neighborhoods along human chromosomes.

Genome-wide transcriptome profiling reveals the functional impact of rare de novo and recurrent CNVs in autism spectrum disorders. *R. Luo[1,2], S. Sanders[3], Y. Tian[4], I. Voineagu[5], N. Huang[6], S. Chu[7], L. Klei[9], C. Cai[1,8], J. Ou[5], J. Lowe[5], M. Hurles[6], B. Devlin[9], M. State[3], D. Geschwind[1,2,5], ACE network consortium.* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Center for Autism Research and Treatment, Semel Insittute, University of California Los Angeles, Los Angeles, CA 90095, USA; 3) Programs in Neurogenetics and Human Genetics and Genomics, Child Study Center and Departments of Psychiatry and Genetics, Yale University School of Medicine; 4) Interdepartmental Ph.D. Program in Bioinformatics, University of California Los Angeles; 5) Neurogenetics Program, University of California, Los Angeles; 6) Wellcome Trust Sanger Institute, Hinxton, Cambridge; 7) Department of Statistics, Carnegie Mellon University; 8) Department of Biostatistics, David Geffen School of Medicine, University of California; 9) Department of Psychiatry, University of Pittsburgh School of Medicine.

Autism Spectrum Disorder (ASD) is a disorder of neural development that is characterized by deficits in social interaction, communication, and the presence of restricted and repetitive behavior. Recent studies have found that rare Copy Number Variants (CNVs) are a major contributor to ASD pathophysiology. However, the functional impact of these rare variants is largely unexplored. We reasoned that if autism is caused in some cases by CNVs, genes within the CNVs may exhibit significant up- or down- regulated expression, and such genes could be identified by microarray analysis of gene expression. To highlight pathogenic CNVs and functional alterations in gene expression, we performed functional genomic profiling in lymphoblast cell lines from 439 discordant siblings from 244 Simons Simplex families analyzed on the Illumina Human Ref8 version3 chip. The distribution of gene expression was analyzed in autistic probands and unaffected siblings. Genes that were two or three standard deviations (SDs) from mean population expression levels were deemed potential outlier (dysregulated) genes. Our results show that outlier genes identified in probands, but not in unaffected siblings, fall into neural-related pathways. By combining expression data with CNV data from the same population (Sanders et al. 2011), we demonstrate that outlier genes are significantly enriched within the most pathogenic CNVs (rare de novo CNVs). This analysis suggests that deletions at 3q27, 3p13 and 3p26 and duplications at 2p15 and 3q14, all of which show a significant enrichment in outlier genes compared to genome background, are likely new ASD susceptibility loci. We analyzed gene expression in multiple individuals harboring one of three recurrent CNVs (16p11.2 microdeletions, 16p11.2 microduplications, and 7q11.23 duplications) and find that each harbors a distinct set of dysregulated genes and pathways. Our analyses also show that specific genes, including within the 16p CNV interval TAOK2, CORO1A, KCTD13 and QPRT, are correlated with differences in head circumference. This study is the first to provide evidence that pathogenic structural variants lead to transcriptome alterations in ASD at a genome-wide level and demonstrates the utility of this approach for prioritization of genes for further downstream functional analysis.

Transcriptional alterations underlying variable phenotypic expressivity associated with 16p11.2 microdeletion/microduplication syndrome within multiplex autism families. *I. Blumenthal[1], J.Z. Levin[3], Y. Shen[1,5,6], C. Ernst[1], C.C. Morton[3,5,7], J.F. Gusella[1,2,3], M.E. Talkowski[1,3,4]*. 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Department of Genetics, Harvard Medical School, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 4) Department of Neurology, Harvard Medical School, Boston, MA; 5) Department of Pathology, Massachusetts General Hospital, Boston, MA; 6) Department of Laboratory Medicine, Children's Hospital Boston, Boston, MA; 7) Departments of Obstetrics, Gynecology and Reproductive Biology, Brigham and Women's Hospital, MA.

Autism spectrum disorder (ASD) is a complex, heterogeneous developmental disorder affecting approximately 1% of the population. Collectively, recurrent microdeletions and duplications represent the largest known risk factor for ASD. Of these, copy number variation (CNV) of a 593kb region of 16p11.2 is among the highest contributors to ASD, accounting for approximately 1% of all cases. However, the penetrance and phenotypic expressivity associated with deletion or duplication of the region are highly variable with deletion presenting a stronger effect than duplication. In this study, we describe the precise consequences of 16p11.2 dosage imbalance on mRNA expression within the 16p11.2 region, and its regulatory impact on other transcripts both in cis and in trans. We performed strand-specific RNA sequencing on lymphoblasts of a unique cohort with 35 individuals from 7 families sourced from the Autism Genetic Resource Exchange (AGRE). Each family harbors a segregating 16p11.2 microdeletion or microduplication and heterogeneity of both genotype and phenotype, *e.g.* some individuals with ASD are discordant for the CNV, while others with 16p11.2 dosage imbalance are discordant for phenotype. Pair-wise comparisons of sequencing data within and between families uncovered significant differential gene expression in cases compared to individuals without a 16p11.2 CNV. Notably, while deletions were associated with a uniform mRNA reduction of genes within the 16p11.2 region (~0.5X normal expression), duplications were associated with a more heterogeneous outcome, ranging from 1.2-2X normal expression. CNVs within the 16p11.2 region also lead to significant genome-wide expression changes; 379 genes were significantly dysregulated in concordant affected individuals from deletion families while only 135 genes had altered expression in duplication families, though there was meaningful overlap in loci between groups. Our analyses show broad alterations in gene expression regulation resulting from recurrent, reciprocal dosage imbalance of 16p11.2 with impact on a spectrum of functional loci from chromatin modifiers, transcriptional regulators and long non-coding RNAs. Analyses of patient-specific induced pluripotent stem cell lines, neural progenitor cells and mature neurons are ongoing, however these studies provide insight into the transcriptomic alterations that may underlie variable phenotypic expression resulting from structural alterations of 16p11.2.

Differential reduced expression of IRS-1 in visceral and subcutaneous adipose depots in morbidly obese and type2 diabetic subjects and their correlation with metabolic profiles with 2 novel mutations sequenced in Asian Indians. *M. Sharma[1], K. Luthra[1], S. Aggarwal[2], N. Vikram[3], A. Misra[4]*. 1) BIOCHEMISTRY, ALL INDIA INSTITUTE OF MEDICAL SCIENCES, NEW DELHI, DELHI, India; 2) SURGERY, ALL INDIA INSTITUTE OF MEDICAL SCIENCES, NEW DELHI, DELHI, India; 3) MEDICINE, ALL INDIA INSTITUTE OF MEDICAL SCIENCES, NEW DELHI, DELHI, India; 4) Fortis-C-DOC Centre of Excellence for Diabetes, Obesity, Metabolic Diseases and Endocrinology, Centre of Internal Medicine (CIM), Fortis Hospital, New Delhi, India.

We looked for differential expression of IRS-1 at regional fat depots (visceral and subcutaneous) in morbidly obese diabetic patients, and correlate genotype-phenotype traits if any, in the above subjects. A total of 35 morbidly obese (BMI>40Kg/mSuperscript Text2) in presence of co-morbidities and 15 non-obese as controls (BMI<25Kg/m2) adipose tissue were obtained from subjects undergoing Bariatric surgery and elective abdominal surgery respectively. Total RNA isolated from RNeasy lipid extraction kitand expression checked in Real-Time qPCR. Biochemical parameters were assessed in the subjects. Genotyping of IRS-1 Gly972Arg was performed by PCR-RFLP. Sequencing of whole exon of IRS-1 with respective primers was carried out to scan for any novel variations. Informed consent was signed from each subject.The morbidly obese subjects showed a marked increase in serum insulin levels and the lipoprotein fractions except, HDL-C. We observed a decrease in the mRNA expression of IRS-1 in the adipose tissue of the visceral and subcutaneous depots in the morbidly obese subjects than controls (non-obese), with a marked reduction in the visceral adipose tissue as compared to the subcutaneous adipose tissue of the morbid obese subjects. We did not observe any correlation between the IRS-1 expression in the adipose tissue and the IRS-1 Gly972Arg polymorphism. A salient finding of this study was the presence of two novel variations in IRS-1 gene, not reported previously: one, in the codon 1102 with GAG>AAG, a non-synonymous mutation, encoding lysine in place of glutamate in the morbid obese subjects with insulin resistance. The other novel variation, a deletion at codon 658, at 1979bp was observed (submitted to Genbank). Our observation of a substantial reduction in the expression of IRS-1 in the visceral and subcutaneous adipose tissues of the morbidly obese and diabetic subjects strongly suggest that the IRS-1 expression may serve as a novel marker for predicting the insulin responsiveness in the adipose tissue. This may further be confirmed by performing functional studies. Such studies may be of importance in unraveling the effect of alterations in the distribution of localized fat in the subcutaneous vs. visceral adipose tissues and its influence on insulin action, particularly at the level of IRS-1. Besides, the novel mutations sequenced, alone or in combination with other reported mutations in the IRS-1 may contribute substantially to develop obesity and/or T2DM.

Quantitative analysis of the human beta cell transcriptome. *A.C. Nica, H. Ongen, J. Irminger, S. Dupuis, A. Planchon, L. Romano, S.E. Antonarakis, P.A. Halban, E.T. Dermitzakis.* Genetic Medicine & Development, University of Geneva, Geneva, Switzerland.

We present here the first detailed description of the human beta cell transcriptome using deep coverage RNA sequencing (RNA-seq), perform the first comparison of beta cell - islet expression profiles and offer initial insights into the genetic control of beta cell gene expression. We collected islets from 11 cadaveric pancreata of individuals without documented diabetes and FACS sorted islet cells to obtain “beta cell” (approx. 90% pure) and beta-cell depleted “non-beta” (N=5) populations. All RNA samples were deep-sequenced, attaining an unprecedented transcriptome resolution (~ 200 million quality filtered reads per sample). As expected, insulin (INS) is by far the most abundantly transcribed gene, followed by INS-IGF2 and IGF2, making up ~ 39%, 9% and 3% of the total nuclear beta cell transcriptome respectively. While the relative percentages are lower, this ranking is maintained in the islet (INS 27%, INS-IGF2 5%, IGF2 1.6%). The ranked correlation between beta cell and islet-expressed genes is high (Spearman rho = 0.934) and we estimate that 85% of the variance in beta cell gene expression can be explained by using islet expression as proxy. Beta cells and islets separate markedly from non-beta cells, with insulin, IGF-2, glucagon, transthyretin, pancreatic polypeptide and somatostatin driving most of this separation. In addition to RNA-seq, we have performed medium depth (16 ×) whole-genome sequencing for 7 of the 11 samples, followed by variant calling and 1000 Genomes based imputation. We detect an abundance of significant allelic differences in transcript levels at heterozygous sites (9% of total sites tested, corresponding to 55.42% of the genes), highly overlapping in beta and islet cells (89.11% estimated median enrichment of significant beta cell ASE pvalues in islets and 88.11% vice-versa). A subset of significant ASE sites maps to diabetes-associated genes, with a significant enrichment (Fisher's pvalue: 0.015) for genes associated with fasting glucose/insulin levels. Furthermore, we note a significant ASE enrichment at heterozygous expression quantitative trait loci (eQTLs) discovered in other tissues compared to homozygous eQTLs, suggesting that a proportion of previously documented regulatory variants are also active in beta cells. Given these, we provide here a valuable resource to the community, helping our understanding of the genetics of both type 1 and type 2 diabetes.

Novel sequence motif regulates pluripotency. *Y. Song[1], S. Bao[1], G. Niu[1], Y. Zhao[2], H. Zhu[3].* 1) Dept Biochemistry, Univ Hong Kong, Hong Kong, China; 2) 6th Affiliated Hospital, Sun Yat Sen Univeristy; 3) Dept microbiology, Univ Hong Kong, Hong Kong, China.

The pluripotency of embryonic stem cells (ESCs), combined with theoretically unlimited self-renewal characteristic, has greatly promoted the development of ESCs applying in regenerative medicine and organ transplantation fields. Deciphering the mechanisms of pluripotency would offer a much deeper understanding of the specific reprogramming process of ESCs. In our study, we tried to understand the networked regulations on the genomic level. Thanks to recently developed next-generation sequencing technologies, genome-wide maps of chromatin state has been established. The patterns of mammalian chromatin can offer insights into the locations and functions of underlying regulatory elements and genes. Here, we tried to recognize the specific regulatory sequence characteristics from the open chromatin signals on ES cells' genome. After obtaining `informative' ESC-specific open chromatin (OC) bins, which were open chromatin sequences with length around 500 bp and expressed significantly higher in ESCs than other tissues, we applied MEME's `discriminative motif discovery' model to extract ESC-specific OC motifs. Then we filtered motifs that were conserved with each other and significantly more enriched in ESC OC bins compared with non-ESC OC bins. Around 60 sequence motifs were disclosed and we found that there is bias of nucleotide occurrence in some of the identified ESC open chromatin regions. This knowledge spreads us a much clearer image about the short and specific sites, which would introduce TF-DNA interactions in vivo and maintain pluripotent stability, on the human genome. Furthermore, such knowledge may also help us design novel functional elements that could be in response to the inside environmental signals in the pluripotent cells.

Quantitative expression analysis of mouse chitinases: acidic mammalian chitinase is the major transcript in stomach. *F. Oyama, M. Ohno, K. Tsuda, M. Sakaguchi, Y. Sugahara.* Dept Applied Chemistry, Kogakuin Univ, Hachioji, Tokyo, Japan.

Two active chitinolytic enzymes, chitotriosidase and acidic mammalian chitinase (AMCase), have been identified in mouse and human, although mammals do not have chitin and chitin synthase. Since these chitinolytic enzymes are upregulated in Gaucher disease or mouse models of asthma, both chitinases have been regarded primarily as a host-defense mechanism against chitin-containing pathogens and/or play important roles in the pathophysiology. Little is known, however, about mutual regulation of gene expression between chitotriosidase and AMCase in vivo. Here we set up a real-time PCR system capable of quantifying expression levels among the chitinases and reference genes. We found that both chitinases mRNAs are predominantly expressed in mouse stomach. Mouse tissues express more AMCase mRNA than chitotriosidase mRNA, whereas chitotriosidase mRNA was prevalent only in eyes. In stomach, AMCase mRNA is expressed 7–10 fold higher than those of housekeeping genes and expressed comparative level with pepsinogen C (progastricsin) mRNA, a major component of the gastric mucosa. Thus, AMCase mRNA is a major transcript in mouse stomach, suggesting that AMCase functions as a digestive enzyme breaking down polymeric chitin in gastric juice.

The Japanese firefly, Luciola cruciata, gene: small intron and their insufficiency of splicing in CHO cells. *M. Ishii[1,3], R. Kojima[1], S. Fukuda[1], M. Sakaguchi[1], Y. Sugahara[1], M. Kamaya[2,3], F. Oyama[1,3].* 1) Biotechnology Laboratory, Department of Applied Chemistry, Faculty of Engineering, Kogakuin University, 2665-1 Nakano, Hachioji, Tokyo 192-0015, Japan; 2) Enviroment Analytical Chemistry Laboratory, Department of Environmental and Energy Chemistry, Faculty of Engineering, Kogakuin University, 2665-1 Nakano, Hachioji, Tokyo 192-0015, Japan; 3) The Firefly-Breeding Project at Hachioji Campus, Kogakuin University, 2665-1 Nakano, Hachioji, Tokyo 192-0015, Japan.

Most genes in eukaryotes are interrupted by non-coding sequences called intron. So far, they had been considered as unimportant sequences which are to be removed from an unspliced precursor RNA in order to generate the functional mRNA. Recently, it has been shown that intron also has important functions, to increase mRNA and protein levels in mammalian cells. In this study, we cloned and sequenced the genomic and cDNA clones of the Japanese firefly, L. cruciata. The luciferase gene contains six introns, all of which were very short; the longest (intron 1) was 98 bases in length, and the smallest (intron 5) was only 44 bases in length. Next, we examined the effect of the small introns on the expression levels of the luciferase in mammalian cells. The luciferase gene (with 6 introns) and cDNAs (without introns) were inserted into mammalian expression vectors and transiently expressed in CHO cells respectively. We found that the luciferase gene didn't give enzymatically active firefly luciferase, whereas cDNA normally did. RT-PCR analysis also indicated that luciferase pre-mRNA transcribed from the gene was detected without splicing in the CHO cells. These results suggest that firefly small introns are insufficient to be spliced in mammalian cells.

Expression QTL interactions in a cohort of 869 individuals reveals sex specific, cis-cis, trans-cis and trans-trans interactions. *J. Bryois[1], A. Buil[1], DM. Evans[2], DF. Conrad[3], SM. Ring[2], M. Hurles[3], P. Deloukas[3], GD. Smith[2], ET. Dermitzakis[1].* 1) University of Geneva, Geneva, Switzerland; 2) University of Bristol, Bristol, UK; 3) The Wellcome Trust Sanger Institute, Cambridge, UK.

In order to better understand how genetic variations affect gene expression we mapped 2'543'887 imputed SNPs and 3329 copy number variants (CNVs) to gene expression in LCLs in 869 individuals from the ALSPAC cohort. We find 3890 genes with a variant affecting gene expression in cis (FDR= 4.1%) and 167 genes with a variant affecing gene expression in trans (FDR= 9.9%). We find that cis-eQTLs are mainly driven by SNPs while trans-eQTLs are largely driven by CNVs. 47 genes with a cis-eQTLs, that is also a trans-eQTL, show a strong enrichement in immune GO terms but no enrichment in transcription regulation GO terms, suggesting that immunity and other traits might be under the same genetic control. The large sample size of the data set allows investigating how the effect of the discovered eQTLs can be conditional to other varaiables, such as other SNPs or the sex of the individuals. Using a linear model with an interaction term, we find that 176/51 (5%FDR) of the best cis/trans-eQTLs per gene act in a sex specific manner. We also looked for cis-cis interactions using SNPs marginally (pvalue ≤ 10-3) and independently associated to the same gene and found 133 cis-cis interactions (5% FDR). Trans-cis interactions were also investigated, which lead to the discovery of 6 trans-cis interactions (5% FDR) when both SNPs are affecting the same gene, 31 interactions (5% FDR) when the model explains the expression of the cis regulated gene and 4 interactions (5% FDR) when the model explains the expression of the trans regulated gene. We also looked for trans-trans interactions and found 9 interactions (5% FDR) when both SNP are independently associated to the same gene, no interaction for genes regulated by a trans-eQTL (excluding trans-eQTLs affecting the same gene) and 20 interactions (5% FDR) for all genes not regulated by a trans-eQTL. Finally we are investigating if cis/trans eQTLs are also GWAS SNPs and if they interact with GWAS SNPs, as this could give clues on the possible mechanism leading the SNPs to the diseases.

Tissue-specific effects of genetic variation and DNA methylation on gene regulation. *E.T. Dermitzakis[1,2], M. Gutierrez-Arcelus[1,2], S.B. Montgomery[3], T. Lappalainen[1,2], H. Ongen[1,2], A. Yurovsky[1,2], J. Byrois[1,2], A. Buil[1,2], T. Giger[1,2], L. Romano[1,2], A. Planchon[1,2], E. Falconnet[1,2], I. Padioleau[1,2], C. Borrel[1,2], A. Letourneau[1,2], P. Makrythanasis[1,2], M. Guipponi[1,2], C. Gehrig[1,2], S.E. Antonarakis[1,2].* 1) Dept of Genetic Medicine and Development, University of Geneva, Geneva, Switzerland; 2) Institute of Genetics and Genomics in Geneva (iGE3), Geneva, Switzerland; 3) Dept of Pathology, Stanford University, Stanford, California, United States of America.

Multiple studies have demonstrated the importance of genetic variants affecting gene expression (eQTLs) and initial limited studies have identified genetic variants affecting local DNA methylation levels (mQTLs). Moreover, DNA methylation is known to be associated with gene silencing, and more recently with active gene expression when present within the gene body. Yet the mechanisms by which genetic variation and DNA methylation affect gene expression and tissue specificity are not well understood. In this study, we use a cohort of approx. 180 newborn Caucasian individuals who we genotyped (2.5 million SNPs) and for whom we measured mRNA levels through RNA-seq in three cell-types derived from cord blood and umbilical cord: lymphoblastoid cell lines, T-cells and fibroblasts. For approx. 100 samples of each of the three cell-types, we have assayed DNA methylation levels in more than 400,000 CpG sites through bisulfite conversion and bead chips. We characterized the tissue-specificity of > 4000 eQTLs discovered in the three tissues, allele-specific expression, mQTLs and eQTMs (methylation-expression associations). We also identified frequent differences in alternative splicing between different tissues, as well as genetic variants and, intriguingly, a modest amount of methylation sites affecting splicing patterns. Additionally, we tested the contribution of different mechanistic models for the interplay between genetic, epigenetic effects and gene expression. We provide evidence for synergistic interactions between SNPs and methylation sites to expression. We also found a that in the majority of cases a SNP affects gene expression and DNA methylation independently, but also a number of cases in which the SNP effect on gene expression is mediated through methylation, or the SNP affects gene expression which in turn modulates DNA methylation. Finally, we describe the mechanistic differences between patterns of methylation associated with increase and decrease of gene expression. Overall, our results provide insights into the genetics and epigenetics involved in gene regulation in several cell-types and in samples coming from a unique time point in development. We highlight the importance of studying and integrating different dimensions of information for better understanding complex traits.

Multi-scale Integration Systematically Connects Disease-Associated Variants to Molecular Pathology. *K.J. Karczewski[1,2], J.T. Dudley[3], R. Chen[3], A.J. Butte[3], M. Snyder[2].* 1) Biomedical Informatics Training Program, Stanford University School of Medicine, Stanford, CA; 2) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 3) Division of Systems Medicine, Department of Pediatrics, Stanford University School of Medicine, Stanford, CA.

Genome-wide association studies have discovered many genetic loci associated with disease, but the molecular basis of these associations is often unresolved. Genome-wide regulatory and gene expression profiles measured across individuals and diseases reflect downstream effects of genetic variation, and may allow for functional annotation of disease-associated loci. Here, we present the first systematic approach effort to combine disease association, transcription factor binding, and gene expression data to assess the functional consequences of variants associated with hundreds of human diseases. In an analysis of genome-wide binding profiles of NFκB, we find that disease-associated SNPs are enriched in NFκB binding regions overall, and specifically for inflammatory mediated diseases, such as asthma, rheumatoid arthritis, and coronary artery disease. Using genome-wide binding variation information for 8 fully sequenced individuals, we find regions of NFκB binding correlated with disease-associated variants in a genotype-specific and allele-specific manner. Furthermore, we show that this binding variation is often correlated with expression of nearby genes, which are also found to have altered expression in independent profiling of the variant-associated disease condition. In this systematic approach, we close a major loop in biological context-free association studies and assign putative function to many disease-associated SNPs.

Analysis of primary Natural Killer cells reveals multiple novel cell-specific eQTL. *S. Makino[1], B.P. Fairfax[1,2], E. Ng[1], J.C. Knight[1].* 1) Wellcome Trust Centre for Human Genetics, Oxford, University of Oxford, OX3 7BN, United Kingdom; 2) Oxford Cancer Centre, Churchill Hospital, Oxford, OX3 7LJ, United Kingdom.

We have previously demonstrated that the majority of eQTL in freshly purified primary $CD19^+$ B-cells and $CD14^+$ monocytes are specific to these cell types. Here we further investigate the specificity of eQTL in the different cellular subsets that compose peripheral blood mononuclear cells by analysing gene expression in $CD56^+$ Natural Killer (NK) cells. NK cells form a vital arm of the innate immune response with a crucial role in immune surveillance, demonstrating immunoreactivity to virally infected and malignantly transformed cells. Identification of loci that regulate gene expression in these cells should further inform our understanding of how common genetic variants impact on innate immune responses and disease susceptibility.

NK cells were purified from freshly prepared peripheral blood mononuclear cells using a negative selection protocol. Individuals were genotyped at >730,000 loci using Illumina OmniExpress beadchips. Gene expression profiles from NK-cells, in addition to monocytes and B-cells concurrently purified from the same individuals, were assayed using Illumina HT-12 whole genome expression arrays (116 individuals, 348 arrays). To perform eQTL analyses we used ANOVA methodology, incorporating principal components from expression profiles as covariates.

Using this approach we find that at a false discovery rate of 0.01, we observe a total of 41,177 SNP-probe pairs in *cis* across all 3 cell types, 71% of which were unique to a specific cell-type and 11.7% of which were shared amongst all 3 cell-types. NK-cells demonstrated a greater number of eQTL than the other 2 cell-types and showed marginally greater overlap in-terms of shared eQTL with myeloid derived monocytes than lymphoid derived B-cells. Examples of the most significant novel NK cell specific eQTL include those forming to the basic helix-loop-helix protein encoding gene *TCF25*, rs1007932, $P=7\times10^{-38}$; the golgi associated gene *COG5*, rs34325395, $P=5.3\times10^{-40}$ and the vaccinia H1-related phosphatase encoding DUSP3, rs1234612, $P=2.7\times10^{-36}$.

This analyses further informs our understanding of how common genetic variation can modulate gene expression in defined cell populations and thus impact upon human health and disease susceptibility.

564W

The impact of polymorphisms within probe sequences on expression QTL studies. *A. Ramasamy[1,2], D. Trabzuni[2,3], R.J. Gibbs[2,4], A. Dillman[4], D.G. Hernandez[2,4], S. Arepalli[4], R. Walker[5], C. Smith[5], A.A. Shabalin[6], Y. Li[6,7], A.B. Singleton[4], M.R. Cookson[4], J. Hardy[2], M. Ryten[2], M.E. Weale[1], North American Brain Expression Consortium and UK Brain Expression Consortium.* 1) Medical and Molecular Genetics, King's College London, London, London SE1 9RT, United Kingdom; 2) Reta Lila Weston Institute and Department of Molecular Neuroscience, UCL Institute of Neurology, Queen Square, London WC1N 3BG, UK; 3) Department of Genetics, King Faisal Specialist Hospital and Research Centre, PO Box 3354, Riyadh 11211, Saudi Arabia; 4) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD, USA; 5) MRC Sudden Death Brain Bank Project, University of Edinburgh, Department of Neuropathology, Wilkie Building, Teviot Place, Edinburgh, EH8 9AG; 6) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA 27599; 7) Department of Genetics, Department of Biostatistics, Department of Computer Science, University of North Carolina, Chapel Hill, NC, USA 27599.

BACKGROUND: Polymorphisms in the target mRNA sequences can greatly affect the binding affinity of microarray probe sequences, leading to false positive and false negative expression QTL signals (eQTLs) with any other polymorphisms in linkage disequilibrium. **METHOD:** We provide the most complete solution to date to this polymorphism-in-probe problem, by using SNPs and indels from the 1000 Genomes project (March 2012) and SNPs from the NHLBI Exome Sequencing Project to identify common polymorphisms (frequency >1% in Europeans) in probe sequences using two commonly-used microarray panels (the gene-based Illumina Human HT12 array and the exon-based Affymetrix Human Exon 1.0 ST array). We assessed the impact of probes containing polymorphisms in cerebellum and frontal cortex tissues of 438 neuropathologically normal individuals (curated by the UK and North American Brain Expression Consortia) on the number of declared cis-QTLs (defined as within 1Mb of transcription start site of the associated transcript). **RESULTS:** Only 5.3% of the probes in the Affymetrix Human Exon array (25-mer probe design) contained SNPs or indels but these accounted for 50–90% of the declared cis-eQTLs (depending on the significance threshold and tissue type). Similarly, 11.4% of the probes in the Illumina array (50-mer probe design) contained polymorphisms and these accounted for 20–52%. The strongest cis-eQTLs observed were those arising from probes with polymorphism, which implies that choosing a more stringent significance threshold would simply enrich for a higher proportion of false positives. About half of these false positives would not have been discovered if we had used a less complete variation panel (HapMap release 28). Finally, we confirm by conditional analysis on polymorphism-in-probe genotype that the majority (>93%) of these suspect cis-eQTLs are indeed false positives. This is true even if the polymorphism is not in high linkage disequilibrium with polymorphism in probe, so LD filtering should not be used to try and recover suspect cis-eQTLs. **CONCLUSIONS:** Researchers working on eQTLs should be aware of this important technical artefact and use the latest variation panel available to identify suspect eQTLs. LD filtering should not be used. Published eQTL studies with insufficient correction for this problem could contain a significant proportion of false positives, and this motivates a re-analysis of earlier studies using more stringent criteria.

PGC-1α regulates TFEB to promote autophagy-lysosome mediated turnover of aggregate-prone neurodegenerative disease proteins. *T. Tsunemi[1], B.E. Morrison[1], T.D. Ashe[1], A.R. La Spada[1,2,3]*. 1) Pediatrics, University of California, San Diego, La Jolla, CA; 2) Cellular & Molecular Medicine, University of California, San Diego, La Jolla, CA; 3) Neurosciences, University of California, San Diego, La Jolla, CA.

A number of neurodegenerative disorders result from misfolded proteins that accumulate in the CNS and yield neuron dysfunction, degeneration, and cell death. We recently found that the transcription factor PPARγ co-activator 1α (PGC-1α) promotes the turnover of mutant huntingtin (htt) protein in Huntington's disease, and determined that a normal autophagy pathway is required for PGC-1α to prevent htt protein aggregation and neurotoxicity. As a normally functioning autophagy pathway is critical for maintaining protein quality control in the CNS, we hypothesized that a potential link might exist between PGC-1α transactivation and enhanced autophagy-lysosome pathway activity. A transcription factor, known as TFEB, promotes the expression of genes in the autophagy pathway as well as genes required for lysosome biogenesis and function, identifying TFEB as a major node in the regulation of the entire autophagy-lysosome pathway. To evaluate the role of TFEB in PGC-1α-mediated htt protein turnover, we measured TFEB expression levels in HD in vitro and in vivo models, and found that polyQ-expanded htt repressed the TFEB gene expression - an effect that was rescued by PGC-1α. Chromatin immunoprecipitation analysis of the TFEB promoter localized PGC-1α occupancy to a proximal region, enabling us to derive a TFEB promoter-reporter construct. When we studied TFEB transactivation in ST-Hdh striatal-like cells with this promoter-reporter construct, we observed significant repression of TFEB promoter activity in Q111/Q111 homozygous cells, and again documented that PGC-1α expression could dramatically rescue this repression. We then tested if TFEB expression could prevent htt protein aggregation in Neuro2a cells expressing htt-104Q protein, and observed marked TFEB-dependent reductions in htt aggregate formation. To clarify the pathway relationship between PGC-1α and TFEB, we tested if PGC-1α required TFEB to limit htt aggregate formation or if TFEB required PGC-1α to limit htt aggregate formation. Importantly, we found that TFEB is capable of reducing htt aggregation when PGC-1α is knocked down, but that PGC-1α in the presence of TFEB knock-down no longer reduced htt aggregation. Our findings indicate that PGC-1α promotes htt protein turnover and aggregate suppression by co-activating the expression of TFEB, and places PGC-1α upstream of TFEB in the transcriptional regulation of the autophagy-lysosome pathway.

The SLE associated TT>A polymorphism downstream of TNFAIP3 demonstrates lower affinity for NF-κB and SATB1 and reduced enhancer activity. *F. Wen[1], A.K. Templeton[2,3], S. Wang[1], J.M. Guthridge[1], M.B. Humphrey[3], P.M. Gaffney[1]*. 1) Arthritis $ Clinical Immunology, Oklahoma City Medical Research Foundation, Oklahoma City, OK; 2) Microbiology & Immunology, University of Oklahoma Health Science Center, Oklahoma City, OK; 3) College of Medicine, University of Oklahoma Health Science Center, Oklahoma City, OK.

Systemic lupus erythematosus (SLE) is a complex human autoimmune disease influenced by both genetic and environmental factors. The tumor necrosis factor alpha inducible protein 3 (TNFAIP3) gene encodes the ubiquitin-modifying enzyme A20, which negatively regulates NF-κB activity and genetic variants in the region of TNFAIP3 are associated with SLE in multiple populations. We recently described a functional TT>A polymorphic dinucleotide, 42kb downstream of the TNFAIP3 promoter that demonstrates reduced affinity for a nuclear protein complex that includes NF-κB. To further characterize the nuclear protein complex that engages the TT>A polymorphic region we used electrophoretic mobility shift assay supershift (EMSA-SS) with antibodies predicted to be in the complex. EMAS-SS was performed in both monocytoid derived (THP1) and B-lymphocyte derived (EBV transformed lymphocytes) cell lines under various stimulation conditions. EMSA-SS results were confirmed using chromatin immunoprecipitation followed by quantitative-PCR. To evaluate enhancer function we cloned a 340bp DNA sequence surrounding the TT>A polymorphism into a luciferase mini-reporter plasmid and measured luciferase expression in HEK293 and THP1 cells following stimulation. EMSA-SS with antibodies to NF-κB subunits determined that p50, p65, and cRel along with the protein, SATB1 were present in the complex. Binding patterns were also cell-type specific and differed between cells of monoctyoid and B lymphocyte origin. To confirm the EMSA-SS results with an orthogonal method, we performed ChIP with anti-p50 antibody, followed by qPCR with primers flanking the TT>A polymorphism. Our data demonstrated a statistically significant decrease ($p<0.05$) in the amount of protein bound to the TT>A variant region and confirmed the EMSA-SS results. The TT>A region demonstrated evidence of enhancer function with relative luciferase activity 5.1 fold higher than the empty vector for the reference construct (TT) while the polymorphic construct (-A) demonstrated a statistically significant ($p<0.001$) loss of enhancer activity (2.4 fold). In summary, these results demonstrate that the region containing the TT>A polymorphism functions as an enhancer may predispose to SLE through attenuation of recruitment of NF-κB subunits and SATB1 that modulate long-range transcriptional regulation of A20.

Transcriptome and genome sequencing uncovers functional variation in human populations. *T. Lappalainen[1], M. Sammeth[2], N. Kurbatova[3], J. Monlong[2], M. Friedländer[4], M.A. Rivas[5], T. Wieland[6], O. Karlberg[7], M. Barann[8], P.A.C. 't Hoen[9], T. Griebel[2], M. Sultan[10], D. MacArthur[11], E. Lizano[2], T. Strom[6], S. Schreiber[8], H. Lerach[10], S.E. Functional interpretation of genetic variants discovered in human genome sequencing is essential to understand human phenotypic variation. We sequenced mRNA and small RNA of LCLs from 465 individuals from CEU, TSI, GBR, FIN and YRI populations of the 1000 Genomes samples, with a median 52M mapped reads per sample for mRNA and 1.5M for miRNA. Our 203 replicate samples allowed us to measure technical variation in high precision. In our analysis, we first characterized human transcriptome variation in unprecedented depth. We show how the total number of expressed genes increased from a median of 400 miRNA and 13.3K protein-coding genes in a single individual to a total of 1651 and 20.1K in the entire sample, with nearly every individual expressing some unique genes. We discovered almost 200 novel miRNA genes, unannotated splice junctions and novel transcriptionally active regions, many of which were rare in the population. In most genes, individual differences in splicing contributed more (63%) to the total variation than differences in total gene expression levels. Furthermore, the combination of high-quality transcriptome and genome sequencing data gave us the opportunity to characterize both common and rare regulatory variants. We discovered over 5000 genes with common eQTLs and hundreds with splicing QTLs (FDR < 10%), and show that indel variants are more likely to affect gene expression than SNPs ($p < 10^{-4}$). The enrichment of eQTL variants in regions with regulatory annotation ($p < 10^{-10}$) points to causal regulatory variants and sheds light on functional mechanisms underlying eQTL effects. We uncovered rare regulatory effects by allele-specific expression analysis, showing that they have higher effect sizes ($p = 10^{-15}$) and account for a large proportion of variation between individuals. Finally, we characterized transcriptome effects of hundreds of loss-of-function variants in our dataset. In addition to functionally validating variants predicted to cause e.g. nonsense-mediated decay or disrupt splice-sites, we developed models to improve functionality predictions of previously unseen variants base on their properties. Altogether, this study takes us beyond cataloguing putative functional variants towards understanding and predicting the cellular effects of variants in the human genome.

Impact of private variants on human transcriptome architecture. *X. Li[1], K. Karczewski[2], K. Smith[1], K. Kukurba[2], S. Montgomery[1,2]*. 1) Pathology, Stanford University, Palo Alto, CA; 2) Genetics, Stanford University, Palo Alto, CA.

Recent explosion of human population size has created abundances of variants segregating only in small groups of people. Without the test of natural selection, these rare variants can potentially have stronger functional consequences and may underlie susceptibility of many complex diseases. However the actual effect sizes of these variants are still poorly understood due to their very low recurrence rate in a population. To systematically evaluate the functional effects of rare variants, we build a deep catalog of variants private to an extended three-generation family of 17 individuals from whole genome sequencing data and have linked them to transcriptome architecture. We use whole transcriptome (mRNA) sequencing to construct a comprehensive cellular landscape of transcriptional activities across multiple hierarchies including expression levels of an entire gene, abundances of different isoforms, novel transcripts and allele specific expression. We yield a regulatory map between different types of variants (SNPs and indels) to their cis-acting and trans-acting targets and quantify their enrichment in each functional category. We also conduct a comprehensive assessment of heritability of these effects through their transmission from parents to children. Estimation of degree of heritability and segregation patterns of rare variants on a functional level provides important insights towards a thorough understanding of their phenotypic implications in human populations.

Predicting disease-relevant *cis*-regulatory SNPs (*cis*-rSNPs) via tissue-specificity of allelic expression and chromatin state. *N. Light[1], V. Adoue[1], P. Lundmark[2], B. Ge[1], T. Kwan[1], A. Syvänen[2], T. Pastinen[1].* 1) Human Genetics, McGill University, Montreal, QC, Canada; 2) Medical Sciences, Uppsala University, Uppsala, Sweden.

Over 80% of complex disease-associated variants, discovered by GWAS, are located in non-coding regulatory regions of the genome. Regulatory variants have largely been identified through eQTL mapping; however, direct assessment of *cis*-regulatory SNPs (*cis*-rSNPs), which affect up to 30% of RefSeq transcripts, requires an allele-specific (AS) approach. *cis*-rSNPs explain more than 50% of population variance in allelic expression (AE) in LCLs, with up to 70% of *cis*-rSNPs being shared between tissues. Recent mapping of human epigenomic data in disease-relevant cell-types, by the ENCODE and Roadmap Epigenomics Project consortiums, has allowed for chromatin context-dependent analyses of *cis*-regulatory variation. Categorizing *cis*-rSNPs, mapped in accessible cell-types, by tissue-specificity and chromatin state will be essential for optimally predicting their disease-relevance. In order to characterize *cis*-rSNP by cell-type specificity, we mapped *cis*-rSNPs in 70 fibroblast (FB) cell lines, 188 purified monocyte (MNC) samples, and 118 HapMap LCLs (55 CEU, 63 YRI), using phased genotypes and AE differences measured on Illumina 1M/2.5M BeadChips. To investigate chromatin state, we generated AS-ChIP data for 5 known regulatory-associated histone marks, including enhancer-associated H3k4me1 (me1) and active promoter-associated H3k4me3 (me3), in fibroblast and LCL trios, using Illumina HiSeq in addition to 1M/2.5M/5M BeadChips. Differentiating *cis*-rSNPs by tissue-specificity of AE association and chromatin state, reveals a 3–4 fold enrichment of MNC-specific *cis*-rSNPs in MNC-specific me1 or me3 peaks, which is not observed in shared peaks. Transcripts exhibiting similar RNA-seq expression across LCL, MNC and FB samples, show significant enrichment for shared associations. Filtering *cis*-rSNPs mapped in LCLs by shared overlap with a shared MNC chromatin state, similarity of LCL and MNC expression and/or overlap with transcription factor binding sites, significantly enriched for SNPs with stronger association to AE in FB. Intersecting AE-mapped *cis*-rSNPs with GWAS catalog SNPs shows a large enrichment of immune-related diseases/traits for LCL and MNC-specific *cis*-rSNPs. In contrast, FB-specific associations showed a depletion of immune system-related GWAS hits. Our data suggests leveraging functional genomic data from disease-relevant tissues with AE-mapped *cis*-rSNPs from accessible cell-lines, may be a potentially powerful tool for predicting disease-relevant variants.

Characterization of the basic regulatory elements involved in the regulation of OTC gene expression in human. *O. Luksan[1], L. Dvorakova[2], M. Jirsa[1].* 1) Institute for Clinical and Experimental Medicine, Praha, Czech Republic; 2) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague, and General University Hospital in Prague.

Ornithine carbamoyltransferase deficiency (OTCD; OMIM 311250), X-linked disease caused by the lack of enzyme catalyzing the synthesis of citrulline, is the most common inherited defect of the urea cycle. Clinical diagnosis based on the mutation analysis of *OTC* coding regions fails in 20–25% of patients. In such cases, the disease may be caused by gross gene rearrangements or defects in regulatory regions of the gene. We previously reported the pathogenic effect of a single nucleotide substitution c.-366A>G found in the promoter of a patient manifesting OTCD. We also demonstrated that the liver-specific regulation of OTC expression is dependent on the interaction of a 793 bp promoter with a strong enhancer located 9 kb upstream the translation start side (TSS). The aim of our recent study is a detailed characterization of the promoter and enhancer regions. Using the Dual Luciferase Repoter Assay (Promega, Madison, Wi) with pGL3 constructs containing enhancer sequence and promoter variants truncated from the 5`-end, we specified the core promoter region. Promoter core, delimited from the 3'-end by the transcription start site located 95 bp upstream the initiation codon, is formed by a sequence of 173 base-pairs containing three positive and a negative *cis*-acting element. The Cis1+ positive regulatory element was found in a short sequence of 35 bp located close to the transcription origin and reaching 80% of the activity of complete promoter. Another regulatory elements Cis2+, Cis3- and Cis4+ were localized within the positions 128–179 bp, 180–219 bp and 220 –269 bp upstream the TSS. We set up an innovated DNase I footprinting method based on the capillary electrophoresis of fluorescently labeled fragments after DNase I cleavage of investigated DNA. The comparative analysis of electropherograms obtained for DNA samples incubated with Hep-G2 nuclear extract and controls (without nuclear extract) revealed four protected regions corresponding to Cis1+ and Cis2+ elements. Two of them showed a strong similarity with the sequence motifs recognized by HNF-4 transcription factor, which was previously reported to have a key role in the regulation of *OTC* expression in the rat. No protected regions were observed within the sequences encompassing Cis3- and Cis4+ elements so far. These regions are currently being studied in a set of gel shift assays. Financial support: GA UK 251168_99910.

Regulatory impact of alternative polyadenylation in human B-lymphoblastoid cells. *O.K. Yoon, T.Y. Hsu, J.H. Im, R.B. Brem.* Molecular and Cell Biology, University of California, Berkeley, CA.

Gene expression varies widely between individuals of a population, and regulatory change can underlie phenotypes of evolutionary and biomedical relevance. A key question in the field is how DNA sequence variants impact gene expression, with most mechanistic studies to date focused on the effects of genetic change on regulatory regions upstream of protein-coding sequence. By contrast, the role of 3' RNA processing in regulatory variation remains largely unknown, owing in part to the challenge of identifying functional elements in 3' untranslated regions. In this work, we conducted a genomic survey of transcript ends in lymphoblastoid cells from genetically distinct human individuals. Our analysis mapped the cis-regulatory architecture of 3' gene ends, finding that transcript end positions did not fall randomly in untranslated regions, but rather preferentially flanked the locations of 3' regulatory elements, including miRNA sites. The usage of these transcript length forms and motifs varied across human individuals, and polymorphisms in polyadenylation signals and other 3' motifs were significant predictors of expression levels of the genes in which they lay. Independent single-gene experiments confirmed the effects of polyadenylation variants on steady-state expression of their respective genes, and validated the regulatory function of 3' cis-regulatory sequence elements that mediated expression of these distinct RNA length forms. Focusing on the immune regulator IRF5, we established the effect of natural variation in 3' RNA processing on regulatory response to antigen stimulation. Our results underscore the importance of two mechanisms at play in the genetics of 3'-end variation: the usage of distinct 3'-processing signals and the effects of 3' sequence elements that determine transcript fate. Our findings suggest that the strategy of integrating observed 3'-end positions with inferred 3' regulatory motifs will prove to be a critical tool in continued efforts to interpret human genome variation.

Identification of a novel CFTR mRNA isoform in nasal epithelial cells. *A. Hinzpeter[1,2], A. de Becdelièvre[1,3], E. Bieth[4], F. Brémont[5], C. Costa[1,3], C. Gameiro[3], A. Aissat[1,2], M. Goossens[1,2,3], P. Fanen[1,2,3], E. Girodon[1,3].* 1) U955, INSERM, Créteil, France; 2) Université Paris-Est, Créteil, France; 3) GH Henri Mondor, Department of Genetics, APHP, Créteil, France; 4) Purpan Hospital, Department of Genetics, Toulouse, France; 5) Pediatric CF Center, Department of Pediatric Pulmonology, Toulouse, France.

Nasal polyposis (NP) starting early in life and/or permanently infected is uncommon. In children, it leads to suspect cystic fibrosis, a recessive disorder caused by mutations in the *CFTR* gene and characterized by a large phenotypic spectrum. In atypical phenotypes, extensive analysis at the gDNA level of the *CFTR* coding regions occasionally fails to identify mutations, which may lie in deep intronic or regulatory regions and affect the normal splicing or transcriptional regulation.

We studied a 12y-old child with isolated NP, no lung or digestive disease, and a negative sweat test. He was found to be heterozygous for c.2551C>T (p.Arg851*), a nonsense mutation inherited from his father. Analysis at the mRNA level performed in the child and his parents showed qualitative and quantitative abnormalities. A partial skipping of exon 15 was observed in the patient and his father, associated with the c.2551C>T mutation. Quantitative analysis (TaqMan gene expression assay) showed a significant increase of about 30% of total CFTR mRNA in the patient and his mother, as compared to 3 healthy controls. Search for a regulatory mutation by sequencing led to identify the c.-2954G>A variant in the *CFTR* promoter region. This variant, previously reported in dbSNP 135 with a low frequency in the European population (0.34%), increases *CFTR* promoter activity as assessed by luciferase assays. This effect could be related to the total CFTR mRNA increase observed in the patient. However, this mRNA variant could be non functional. Indeed, 5'RACE analysis of the proband's mRNA showed the presence of a transcript in which the canonical exon 1 was replaced by the alternative exon 1a. Two mRNA isoforms including alternative exons have been previously described in the developing fetal lung: -1a,1a,2to27 and -1a,2to27, which were not predicted to encode a fully functional channel but are hypothesized to have regulatory functions. We describe here for the first time *in vivo* a third isoform 1a,2, which expression could be favored by the c.2954G>A variant.

CFTR gene regulation and its impact on the lung development is far from being elucidated. Mutations affecting regulation can explain atypical forms of cystic fibrosis or CFTR-RDs. The search for such mutations could be of particular interest in NP, and contribute to understand the physiopathology of NP in the cystic fibrosis context.

Cytokine induced genetic-epigenetic interactions at autoimmune thyroiditis susceptibility gene variants. *M. Stefan[1,3], W. Zang[1], M. Keddache[2], Y. Tomer[1,3]*. 1) Mount Sinai School of Medicine, New York, NY; 2) University of Cincinnati, Cincinnati, OH; 3) James J Peters VA Medical Center, Bronx, NY.

Autoimmune thyroid diseases (AITD) result from interactions between genetic and environmental factors. Several AITD susceptibility loci have been identified through genome-wide association studies (GWAS), but the causal variants remain undefined. Recent evidence suggests that epigenetic mechanisms modulate the complex interplay between genes and intra- and extra-cellular factors to trigger pathological autoimmune responses. Since cytokines are key mediators of tissue inflammation and infiltration we tested the hypothesis that inflammatory cytokines promote thyroid cell dysfunction through epigenetic modifications of AITD-genes. One prime cytokine in the etiology of AITD is interferon alpha (IFNa), which has also been shown to precipitate AITD when used as therapeutic agent in the context of infection. We have previously shown that IFNa increases mRNA expression of major AITD susceptibility genes in both cell lines and a transgenic mouse model of IFNa thyroid over-expression. We now mapped modifications of histone patterns [histone H3 mono- and tri-methylated at Lys-4, (H3K4me1 and H3K4me3)] induced by IFNa at these loci using ChIP-seq in human thyroid cells. Integration of the ChIP-seq with global gene expression data showed that significantly up-regulated pathways included genes characterized by H3K4me3 enrichment in the 5'-regions, demonstrating a correlation between H3K4me3 and pathway activation by IFNa. Most upregulated genes/pathways participate in innate immunity and host defense response. IFNa induced enrichment of H3K4me1 in intronic and 5' gene regions. We used the potential of H3K4me1 to mark regulatory regions to identify functional AITD-associated single nucleotide polymorphisms (SNPs). H3K4me1 peaks mapped at two SNPs in thyroglobulin (TG) and thyroid stimulating hormone receptor (TSHR) genes. Interestingly, the TG SNP was previously shown by us to map within a transcription factor binding site for interferon regulatory factor-1 that modulate the TG promoter in an allele-dependent manner. Using ChIP, luciferase reporter and siRNA assays we show now that the intronic TSHR SNP delineate a regulatory element that decreases promoter's activity. Our results demonstrate that an un-biased genome-wide epigenomic screening can pinpoint the disease-associated variants and their mechanism.

DMD transcript imbalance regulates dystrophin levels. *P. Spitali[1], J.C. van den Bergen[2], B. Wokke[2], A.A.M Janson[3], R. van den Eijnde[3], J.J.G.M Verschuuren[2], J.T den Dunnen[1], P.A.A 't Hoen[1], A. Aartsma-Rus[1]*. 1) Human Genetics, Leiden University Medical Center, Leiden, Zuid-Holland, Netherlands; 2) Neurology, Leiden University Medical Center, Leiden, Zuid-Holland, Netherlands; 3) Prosensa Therapeutics.

Duchenne and Becker muscular dystrophies (DMD and BMD) are caused by respectively out-of-frame and in-frame mutations in the dystrophin encoding *DMD* gene. Molecular therapies targeting either the pre-mRNA, such as antisense oligonucleotides (AONs), or the mRNA, such as read-through of stop codons, are in clinical trials and show promising results. The effect of these approaches will depend on the stability and expression levels of the DMD mRNA in skeletal muscles and heart. We report that the DMD transcript is more abundant in heart compared to skeletal muscles, in mouse and man. We show that the transcript shows a significant 5'-3' imbalance in wild type mice, which is more pronounced in the *mdx* mouse model carrying a nonsense mutation. Reading frame restoration via antisense-mediated exon skipping did not correct this imbalance. Finally, we demonstrate that transcript balance, but not transcriptional rate is an important determinant for dystrophin protein levels in 22 Becker patients. We suggest that the availability of the entire transcript is a key factor to determine protein abundance and this may influence the outcome of mRNA targeting therapies.

575F

Protein inhibitor of activated STAT3 (PIAS3) Modulates the Activity of Anterior Segment Dysgenesis Transcription Factors in Trabecular Meshwork Cells. *T. Footz, L. Huang, M. Walter.* Dept. Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Development of the ocular anterior segment is controlled by complex gene regulatory pathways that lead to severe functional and dysmorphic defects when perturbed by gene mutation. Recently, an evolutionarily-conserved network of physically-interacting transcription factors has been described which includes PAWR, PITX2, FOXC1 and FOXC2. Mutations of the latter three genes cause a variety of anterior segment phenotypes, with increased risk of developing glaucoma, a typically late-onset progressive neurodegeneration that is one of the principle causes of blindness worldwide. A yeast two-hybrid screen was performed to discover additional interacting proteins of the established regulatory network that are expressed in trabecular meshwork cells of the human anterior segment. The protein inhibitor of activated STAT3 (PIAS3) was identified as a FOXC2-interacting protein. PIAS3 is a regulator protein that affects the function of transcription factors involved in cell proliferation and apoptosis. Molecular investigations (expression analyses, reporter assays, immunofluorescence microscopy and DNA mobility shift assays) were performed to reveal the functional consequences of interactions of the anterior segment gene network members with PIAS3. In a manner similar to PAWR, overexpression of PIAS3 also serves to affect the ability of FOXC1, FOXC2 and PITX2 to transcriptionally activate target genes. Our analyses reveal that key protein interactions underlie the complex regulatory network necessary for human eye development. Disruptions to this network have profound consequences that lead to glaucoma.

Statin induced alternative splicing in HepG2 cells. *C. Stormo[1], M.K. Kringen[2], O.K. Olstad[1], J.P. Berg[1,3], A.P Piehler[4]*. 1) Dept of Medical Biochemistry, Oslo University hospital, Ullevål, Norway; 2) Dept of Pharmacology, Oslo University Hospital, Ullevål, Norway; 3) Institute of Clinical Medicine, Faculty of Medicine, University of Oslo, Norway; 4) Fürst Medical Laboratory, Oslo, Norway.

Background: Genomic diversity is greatly expanded by the process of alternative splicing, where introns are removed and exons ligated to form various mature mRNA transcripts from a single gene. Recently, alternative splicing was suggested as a mechanism underlying cholesterol homeostasis and regulation of 3-Hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR), the pharmacologic target of lipid lowering drugs (statins). In this study, we sought to comprehensively investigate alternative splicing mediated by atorvastatin and to potentially highlight novel pathways related to cholesterol homeostasis and statin treatment. Methods: HepG2 liver cells were treated with or without 10 μM atorvastatin for 24 hours. cDNA was hybridized to Affymetrix GeneChip Human Exon 1.0 ST Array. Analysis of gene expression and alternative splicing was done by Partek Genomic Suite software. Only “core” RefSeq genes were considered. Potential alternative splicing events were validated by PCR and gel electrophoresis, and RT-qPCR with SYBR Green dye. Results: We found 142 genes ($p<0.01$) of the 17,151 “core” Refseq genes to have different splicing pattern in statin-treated HepG2 cells compared to non-treated cells. Eight genes were selected for validation. RT-PCR analysis, however, could only confirm one gene (FADS2) with two alternative splicing events; a FADS2 splice variant with an alternative exon 1 (FADS2-exons_1b-12) and a truncated transcript with an extended exon 10 variant (FADS2-exons_1a-10), corresponding to GenBank ID AF108658 and BC009011, respectively. The upregulation (ranging from 1.2-to 2.1 fold change) of the canonical FADS2 variant (FADS-exon1a_12) and the two alternatively spliced variants after atorvastatin treatment was confirmed in both HepG2 liver cells and a human lymphoblastoid cell line by RT-qPCR. Discussion/Conclusion: The human FADS2 gene, encoding delta-6-saturase, is clustered with family members FADS1 and FADS3. Genetic variation in the FADS gene cluster has shown to affect human polyunsaturated fatty acids (PUFA) and long-chain PUFA blood levels which are related to various disease processes, including cardiovascular disease. In this study, we have identified two alternatively spliced FADS2 variants that are responsive to atorvastatin treatment in vitro. These preliminary results may indicate a role of alternative splicing of FADS2 in a statin treatment regimen.

Functional RNA Editing Sites Identified by Comparative Transcriptome Analysis. *R. Zhang[1], G. Ramaswami[1], L.P. Keegan[2], T. Deng[1,3], M.A. O'Connell[2], J.B. Li[1].* 1) Department of Genetics, Stanford University, Stanford, California, USA; 2) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, Western General Hospital, Edinburgh, UK; 3) Department of Structural Biology, Stanford University, Stanford, California, USA.

Adenosine to inosine (A-to-I) RNA editing is required for normal brain function and early embryonic development. However, this important phenomenon is poorly explored, partially due to the lack of identification of functionally significant RNA editing sites. Recently, RNA editing identification has been facilitated by the next generation sequencing technologies, by delineating the sequence differences between matched RNA and genome sequencing from the same individual. Here we introduce a cross-species transcriptome comparison method to accurately identify functionally conserved RNA editing events from RNA sequencing (RNA-seq) data alone. We applied this method to Drosophila and primate lineages. In Drosophila species, ~95% of the conserved RNA variants are A-to-G mismatches, indicative of A-to-I editing. We identified 1,329 exonic A-to-I editing sites in Drosophila melanogaster, 849 of which have not been previously reported. In the primate lineage, we identified 22,748 and 668 conserved exonic A-to-I sites in Alu and non-Alu regions, respectively, including 295 sites that lead to amino acid changes. Our findings demonstrate the power of comparative transcriptomics to identify functionally significant RNA editing sites.

Meta-analysis of Transcriptome Data using Pathway-based Approach Reveals Biologically Relevant Asthma Genes. *T. Mersha, S. Amirisetty, G. Hershey.* pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Asthma is a disease of chronic airway inflammation that affects over 300 million individuals worldwide including 20 million in the U.S. While the causes of asthma are not fully understood, genetic differences may be partly responsible for the variations in asthma susceptibility. Using microarray experiments, many independent groups have identified differentially expressed genes (DEGs) between healthy versus asthmatic patients. However, there is little overlap in the DEG lists identified among different experiments due to variation from random noise, biological and experimental differences, and differences in the extraction and handling of RNA samples. Therefore, a statistics-based meta-analysis is necessary to identify a set of genes that are consistently dysregulated among multiple independent microarray studies. A recent search of asthma-related expression data in the GEO dataset yielded 1379 experiments of which 1190 were human specific (http://www.ncbi.nlm.nih.gov). In this study, we focused our meta-analysis and network/pathway analysis on the 5 microarray human data sets, which had individual experiment sample sizes of over 100. Of the 5534 genes analyzed, 550 (12%) were up-regulated and 456 (8%) were down-regulated. Many key genes including SERPINB2, CLCA1 and P2RY14 were up-regulated and MUC5AC/MUC5B mucins and C6 were down-regulated. These genes were involved in inflammatory diseases, mucus over-production, airway obstructions, immunological diseases, and hypersensitivity responses. Meta-analytic dataset and network/pathway analysis of publicly available databases provide a starting point to identify biologically plausible potential candidate genes linked to asthma and to explore the mechanistic basis for the observed expression patterns in asthma.

Whole transcriptome analysis of Velocardiofacial Syndrome (VCFS) using next-generation sequencing. *Y. Zhang[1], J. Jin[2], X. Zhu[3], M. Haney[3], Y. Kluger[2], S. Weissman[1], A. Urban[3].* 1) Genetics, Yale Univ School of Medicine, New Haven, CT; 2) 2. Yale University School of Medicine, Department of Pathology, Biological and Biomedical Sciences, 300 George Street, New Haven, CT; 3) Stanford University Department of Psychiatry and Behavioral Sciences and Department of Genetics, 1050A Arastradero Road, Stanford, CAWhitney.

Velocardiofacial Syndrome (VCFS) is a relatively common genomic disorder, typically caused by the heterozygous deletion of 3 million basepairs of genomic DNA sequence on chromosome 22q11. There are various developmental defects including neurodevelopmental disorders such as early onset schizophrenia, autism spectrum disorders (ASD) and learning disabilities; however, the combinations and severity of symptoms vary widely between patients with no clear genetic basis to such variability, and for most symptoms there are several plausible potential candidate genes amongst the at least 50 genes within the typical deletion boundaries, but none that have been identified yet as the clear and sole cause of any given symptom. Here we report on RNA-Sequencing analyses of VCFS using 2nd-generation sequencing (Illumina HiSeq 2000). For 5 lymphoblastoid cell lines from VCFS patients as well as 9 HapMap control cell lines, we carried out very deep RNA-Seq analysis (up to 100 million mapped 2×100bp paired-end constructs per cell line transcriptome). We performed cluster analysis for the 200 genes most differentially expressed between patients and controls, with the results showing a clear separation of the patient group from the control group. Among those 200 genes, 56 genes were down-regulated and 144 genes were up-regulated in VCFS samples. There are 38 genes within the 3 Mbp deletion region of VCFS on chromosome 22q11 that are expressed above a threshold of 0.5 FPKM and of those 10 genes are significantly down regulated ($P < 0.05$, ratios $< = 0.5$) in patients versus controls. The gene expression patterns also show evidence of gene dosage compensation for some genes, as well as under- or over- compensation for others. The mechanisms controlling such effects will have to be studied in detail on the molecular level in follow-up work.

Genome-wide search for novel human uORFs and N-terminal protein extensions using ribosomal footprinting. *J. Hampe[1], C. Fritsch[1], A. Herrmann[1], M. Nothnagel[2], K. Szafranski[3], K. Huse[3], S. Schreiber[1], M. Platzer[3], M. Krawczak[2], M. Brosch[1].* 1) Department of Internal Medicine I, University-Hospital Schleswig Holstein, Kiel, Germany; 2) Institute for Medical Informatics and Statistics, University-Hospital Schleswig Holstein, Kiel, Germany; 3) Genome Analysis Group, Fritz Lipmann Institute for Age Research, Jena, Germany.

So far, the annotation of translation initiation sites (TISs) has been based mostly upon bioinformatics rather than experimental evidence. We adapted ribosomal footprinting to puromycin-treated cells to generate a transcriptome-wide map of TISs in a human monocytic cell line. A neural network was trained on the ribosomal footprints at previously annotated AUG translation initiation codons (TICs), and used for the ab initio prediction of TISs in 5062 transcripts with sufficient sequence coverage. Functional interpretation suggested 2994 novel upstream open reading frames (uORFs) in the 5' UTR (924 AUG, 2070 near-cognate codons), 1406 uORFs overlapping with the coding sequence (116 AUG, 1290 near-cognate) and 546 N-terminal protein extensions (6 AUG, 540 near-cognate). The TIS detection method was validated on the basis of previously published alternative TISs and uORFs. On average, TICs in newly annotated TISs were significantly more conserved among primates than control codons, both for AUGs ($p<10^{-10}$) and near-cognate codons ($p=5.9\times10^{-7}$). The derived transcriptome-wide map of TISs will help to explain how human proteome diversity is influenced by alternative translation initiation and regulation.

Variation in protein levels and its genetic determination in human lymphoblastoid cell lines. *L. Wu, S.I. Candille, Y. Choi, H. Tang, M. Snyder.* Genetics Dept, Stanford University, Stanford, CA.

Gene expression varies among individuals and among populations. Correlations between cis-acting genetic variants and RNA levels have been demonstrated in many studies of individual genes and genomes. Less well-characterized are the determinants of variation in protein levels. Quantitative correlation between levels of mRNA and corresponding protein are modest, indicating that at least some mechanisms of gene regulation might influence protein levels directly. Proteome-wide measurements of protein levels are required to understand how genes are regulated by mechanisms that do not act directly through modulating mRNA levels. Here we use isobaric tandem mass tag (TMT) quantitative mass spectrometry to determine relative protein levels in lymphoblastoid cell lines from 95 individuals genotyped in the HapMap Project: 53 of European ancestry, 33 of Nigerian ancestry, and 9 of East Asian ancestry, including 10 European trios and 9 African trios. A total of 12,089 proteins were quantified based on unique peptide ratios. We characterized protein variation between sexes and among individuals and populations, and found evidence for the heritability of protein levels. Using genetic association analyses between protein levels and SNPs (single nucleotide polymorphisms), we identified a number of cis pQTLs (protein quantitative trait loci), including variants not detected by previous transcriptome studies. We also measured protein covariation among individuals to detect networks of coexpressed proteins. Our results show that quantitative mass spectrometry-based proteomic technology can detect proteome differences among individuals, reveal genetic variants that influence protein levels and contribute to the exploration of the role of co-expressed proteins in cellular processes.

The impact of loss of function variants on the transcriptome. *M.A. Rivas[1], T. Lappalainen[2], M. Sammeth[3], D.G. MacArthur[4], N. Kurbatova[5], T. Wieland[6], M. Lek[4], T. Griebel[3], M. Whole genome and exome sequencing studies are rapidly driving exploration of the genetic architecture of human disease and related phenotypic traits. However, with these advancements come challenges in the interpretation of the functional effects of genetic variation that will be essential to our ability to map genes to disease and related phenotypes. Variants that create premature termination codons or PTC, commonly referred to as loss of function, are most likely to have phenotypic effects. Despite their predicted effect on protein structure the cellular consequences are not well characterized. We present a systematic analysis of loss of function variants and their impact on the transcriptome by combining DNA sequence and sequenced mRNA of LCLs from 465 individuals from the 1000 Genomes Project.

In our analysis we focus on genetic variants with in silico annotation predictions of loss of function. Allele-specific expression analysis indicates widespread nonsense-mediated mRNA decay (NMD). We subdivided the variants according to whether they were predicted to trigger NMD according to the “50 nt rule”. Allelic ratios for the mutations that are predicted to escape or trigger NMD differ significantly (P=2e-7), suggesting that NMD generally requires an exon junction >50nt downstream of the PTC mutation. Moreover, 40% of variants predicted to trigger NMD had no deviation in allelic ratios (>0.4). Thus, we are developing models to understand why these variants escape NMD. Furthermore, we investigated whether the loss of mRNA molecules by NMD could be compensated by higher expression of the wild-type allele to maintain normal gene expression levels; the individuals affected by NMD showed suggestively lower expression levels (measured by RPKM (P=.08)). Interestingly, 38% of individuals who had PTC and evidence of ASE had expression levels higher than the median of individuals who did not have the PTC. This is surprising and suggests that there is some mechanism to compensate the decay. Additionally, we characterized effects of splice-site variants, including exon skipping, intron retention, and subsequent NMD. Our analysis implies that even variants with most severe predicted effects need functional validation and modeling to enable better application to disease studies. This study offers the promise of unprecedented understanding of the impact of loss of function variants on the transcriptome.

Sequence-based variation in gene expression is a key driver of disease risk. Common variants regulating expression in cis have been mapped in many eQTL studies typically in single tissues from unrelated individuals. We have undertaken a comprehensive analysis of gene expression across multiple tissues (subcutaneous fat, whole skin and lymphoblastoid cell lines) sampled from 856 female twins from the MuTHER (Multiple Tissue Human Expression Resource) Study. This large set of mono- and dizygotic twins allows systematic dissection of genetic(cis and trans) and non-genetic effects on gene expression. We demonstrate that cis-regulatory effects account for ~30–36% of heritability of gene expression, but up to 40% of cis-heritability, or 12% of total heritability, is unaccounted for by common cis-variants (ie those identified in genotypes imputed to the HapMap2 reference panel). This indicates that 1) a substantial amount of cis-heritability is driven by rare or low frequency regulatory variants or non-additive effects that remain to be discovered and 2) the majority (~60%) of regulatory variation acts in trans. The missing cis-heritability has intriguing implications for genome-wide association (GWA) signals in cases where the effect of the lead SNP is mediated via a cis-eQTL, i.e. if a GWA variant is an eQTL and affects disease risk by modulating expression of a gene, any additional rare variant modulating expression of the same gene in the same tissue should also affect the same trait. This leads us to predict that on average an additional 40% of signal remains to be discovered at cis-eQTL GWAS loci (of which we identify 358 in this study). We further identify several replicating trans-variants which act predominantly in a tissue-restricted manner and may regulate the transcription of many genes.

Genome-Wide Expression Profiles (GWEPs) have been assayed in a growing number of cohort studies, but few attempts have been made to meta-analyse and cross-validate expression datasets. Consequently, many expression studies have been under powered. Therefore, we established a large-scale multi-cohort GWEP meta-analysis. The aim of this study was to robustly identify novel gene expression signatures associated with age and sex, two major risk factors for many diseases. We analyzed 6,993 European-ancestry PAXgene (whole-blood) samples from 6 cohort studies (RS, FHS, EGCUT, KORA, SHIP, INCHIANTI). GWEPs were quantile-normalized, log2-transformed, probe-centered and sample-z-transformed prior to analysis. In the discovery stage we meta-analysed age- and sex-associated signals for samples hybridized to an Illumina or Affymetrix array separately. All analyses were adjusted for plate ID, RNA quality, fasting- and smoking status, and cell counts (when available). The age analysis was additionally adjusted for sex. All significant signals were cross-validated between the Illumina and Affymetrix platforms. We examined the top-associated GWEPs in 3 additional studies: HVH (n=348), GARP (n=134), and NIDDK/PIMA (n=1457). We identified 396 age-associated transcripts with p<1E-5 and same direction in both platforms. *NELL2*, a protein kinase C-binding protein, was the most significant result with gene expression levels decreasing with age (Illumina p=8.2E-81, Affymetrix p=3.2E-64). *NELL2* is involved in cell growth regulation and differentiation, and there is evidence for developmental fluctuation in puberty. We identified 347 transcripts differentially expressed between males and females(p<1E-5, same direction both platforms), of which >200 show mapping to sex chromosomes. The top autosomal gender-differentiated transcript is *DACT1*, which has higher mRNA levels in females (Illumina p=2.4E-47, Affymetrix p=1.6E-75). *DACT1* is an antagonist of beta-catenin and prior work indicates it to be differentially methylated in testes. It is a biomarker for semen and *DACT1* knockout mice showed developmental defects. Both the *NELL2* and the *DACT1* signals were replicated in all 3 additional cohorts. With the GWEP meta-analysis, we gained power relative to individual cohort analyses, and were able to identify novel replicable significant age- and sex- associated loci. These loci may have implications for age-related disease biology, gender biology, and in sample forensics.

Simplified sample preparation and streamlined library preparation method for deep sequencing Ribosome Protected mRNA Fragments. *R. Vaidyanathan[1], S. Kuersten[1], A. Radek[1], S. Swami[2], D. Vo[3], L. Penalva[3]*. 1) Epicentre, Madison, WI; 2) Illumina, Hawyard, CA; 3) University of Texas Health Science Centre at San Antonio, Dept. of Cellular and Structural Biology, San Antonio, TX.

Musashi1 (Msi1) is an evolutionarily conserved RNA-binding protein that has been implicated in a variety of cellular processes such as stem cell maintenance, nervous system development, and tumorigenesis. Msi1 is highly expressed in many cancers including glioblastoma, and has been implicated in neurogenesis, neurodegenerative diseases, and is emerging as a potential therapeutic target in both regenerative medicine and cancer. We are using the method of ribosome profiling to understand the regulatory role of Msi1 at the level of translation. Conventional RNA abundance measurements using microarrays or high-throughput RNA-sequencing reflect protein levels for transcripts that are not subjected to translation control. The isolation of translating ribosomes (polysomes) and the analysis of the associated mRNA fragments resulting from the foot-printed ribosomes (RNase protected monosomes) provide a better measure of translation rates to estimate the copies of the synthesized protein. Furthermore, comparison of total mRNA to the Ribosome Protected mRNA Fragments (RPF) can provide quantitative analysis of the translationally active verses repressed pools of transcripts present at a particular time or condition. A small hairpin (sh) RNA was used to knock down the Msi1 functions in the glioblastoma cell line U251. We prepared footprinted monosomes from these cells and constructed libraries from ribosome protected mRNA fragments for analysis by deep sequencing. The goal is to perform a comparative analysis of transcripts from actively translating ribosomes in shMsi1 cells versus control cells to identify direct mRNA targets of Msi1 and better understand how this RNA binding protein regulates translational control in the nervous system.

Genetics and Epigenetic Regulation of Eukaryotic Transcriptome. *Y. Wakabayashi[1, 4], T. Ni[1], D. Corcoran[2], W. Yang[3], U. Ohler[2], W. Peng[3], C. O'Donnell[4], j. Zhu[1]*. 1) Genetics and Development Biology Center, NHLBI, NIH, Bethesda, MD; 2) Institute for Genome Sciences & Policy, Duke University Medical Center, Durham, NC; 3) Department of Physics, George Washington University, Washington, DC; 4) Framingham Heart Study, NHLBI, NIH, Framingham, MA.

Emerging sequencing technology has provided unprecedented throughput for monitoring transcriptome complexity. In particular, alternative regulations in multiple steps of mRNA biogenesis, including but not limited to transcriptional initiation, pre-mRNA splicing and polyadenylation, have been shown to serve as major contributors for variant transcript production. One fundamental question is how genetic and epigenetic codes are wired in the genome to control tissue and/or cell-specific gene expression. We have developed several sequencing-based technologies to investigate differential promoter usage, antisense transcription and alternative 3'-end formation of eukaryotic transcriptomes. Our early work showed that Drosophila promoters, similar to that of mammalian ones, exhibit “peak” and “broad” initiation patterns. Further analyses demonstrated that core promoter motifs as well as their location preferences, in together with local chromatin structure, play important roles in promoter choices. In addition, a compendium of genomics data has also been collected to investigate the connectivity and feedback regulation of transcription initiation/elongation and alternative polyadenylation at the systems level. Taken together, integration of genomics and epigenomics information is expected to shed light on the complexity and regulation of eukaryotic transcriptomes.

Differential Protein Expression in Human Induced Pluripotent and Embryonic Stem Cells. *S. Brown-Ford[1], M. Pellitteri-Hahn[2], A. De La Forest[3], B. Halligan[2], S. Duncan[3], M. Olivier[1, 2].* 1) Dept. of Physiology, Medical College of Wisconsin, Milwaukee, WI; 2) Biotechnology Bioengineering Center, Medical College of Wisconsin, Milwaukee, WI; 3) Cell Biology, Neurobiology & Anatomy, Medical College of Wisconsin, Milwaukee, WI.

Human induced pluripotent stem cells (hiPSC) have been proposed as unique resources in the study and treatment of disease. However, many questions remain regarding how similar iPSC are to embryonic stem cells (ESC). Early characterizations using mRNA expression profiling have reported that these two cell types are almost identical. Noticeably absent from early characterizations was information on protein expression in ESC and iPSC. These questions are now being addressed. In a recent study <1% of detected proteins were expressed with two-fold difference between a human iPSC and a human ESC line, implying that iPSC and ESC are truly very similar on a cellular level. Here, we analyzed protein expression in stem cell lines derived from different individuals to assess the inter-individual and stem cell-specific differences in protein expression levels. We characterized the proteome of 3 hiPSC and 3 hESC lines using mass spectrometry. Stem cell lines were grown under standard conditions, lysed, fractionated into soluble and insoluble fractions, and analyzed using an ion-trap mass spectrometer (LTQ Orbitrap Velos). Two biological replicates and at least two technical replicates for each cell line were included in the analysis. Mass spectral data were analyzed using SEQUEST, and results from replicates were pooled. Overall, few proteins were detected at significantly different levels. On average, 2.2% of proteins were significantly different between biological replicates of the same cell line. Cell lines derived from the same individual, but independent reprogramming events showed similar differences (3.0%). Between these lines, >88% of detected proteins were shared. iPSC from genetically different individuals showed the highest amount of differential expression (5.3%). Hierarchal clustering indicated that protein expression in ESC and iPSC were more similar to each other than to a fibroblast line. Based on clustering, iPSC and ESC lines were indistinguishable. Reprogramming factors Oct3/4 and Lin28 were not significantly differentially expressed between ESC and iPSC. 22% of differentially expressed proteins between the two were histones, which has been reported in recent analyses. This analysis, for the first time, demonstrates that iPSC and ESC show highly similar protein expression, and that variability in protein expression may not be cell type specific, but determined by inter-individual and genetic differences affecting protein expression.

Understanding the molecular mechanisms underlying autism spectrum disorders using iPSC-derived neurons. *B.A. DeRosa[1, 2,3], J.M. Van Baaren[1,3], G.K. Dubey[1,3], J.M. Lee[1,3], M.L. Cuccaro[1,2,3], J.M. Vance[1,2,3], M.A. Pericak-Vance[1,2,3], D.M. Dykxhoorn[1,2,3].* 1) John P. Hussman Institute For Human Genomics; 2) Dr. John T. Macdonald Foundatioun Department of Human Genetics; 3) University of Miami Miller School of Medicine, Miami, FL 33136.

Autism spectrum disorder (ASD) is a heterogeneous, neurodevelopmental disorder characterized by incapacities in social interaction verbal and non-verbal communication and repetitive stereotypical behaviors, with recent reports estimating an average of 1 in 88 children being affected. In spite of this high prevalence, relatively little is known about the etiology of the disorder. A major constraint in ASD research has been the inaccessibility of disease-affected neural progenitors and neurons in which to study the molecular pathophysiology of ASD during neurodevelopment. A number of studies have used post-mortem brain tissue collected from individuals affected with autism. However, any findings that are identified in post-mortem ASD brain samples are likely to only represent an end point in the pathology of autism. This is because a formal diagnosis of ASD cannot be made until around 3 years of age. In order to study the processes that initiate the onset of ASD and those that have roles at various stages of neurogenesis, we have developed several induced pluripotent stem cell (iPSC) lines which were derived from the peripheral blood of individuals affected with varying degrees of autism. These ASD-specific iPSC lines are able to differentiate into neural stem cells and progenitors that give rise to electrophysiologically active cortical neurons (i.e. GABAergic and glutamatergic neurons) in a process that imitates in vivo neurodevelopment. Neurons derived from the ASD-iPSCs exhibit aberrations in morphology and proliferation compared to iPSC-derived neurons from unaffected individuals. This system provides an ideal opportunity for the use of next-generation sequencing to investigate the fundamental biological processes at play in autism through in-depth molecular profiling of ASD-affected neurons in a developmental stage and neuronal subtype-specific manner. This strategy will hopefully allow us to answer important questions about the pathophysiology of autism that could be used toward the advancement of novel therapeutics.

Whole exome sequencing in familial non-HHT Brain Arteriovenous Malformations. *N. Bendjilali[1], L. Tang[4], DE. Guo[1], R. Hernandez[6], M. Segal[5], CE. McCulloch[5], S. Inoue[3], A. Koizumi[2], WL. Young[1], L. Pawlikowska[1,4], H. Kim[1,4,5].* 1) Center for Cerebrovascular Research, Department of Anesthesia and Perioperative Care, University of California, San Francisco, CA; 2) Department of Health and Environmental Sciences, Kyoto University Graduate School of Medicine, Yoshida, Kyoto, Japan; 3) School of Pharmacy, Suzuka University of Medical Science, Suzuka, Mie, Japan; 4) Institute for Human Genetics,University of California, San Francisco, CA; 5) Department of Epidemiology and Biostatistics, University of California, San Francisco, CA; 6) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, CA.

Background: Brain arteriovenous malformations (BAVM) are rare vascular defects where arteries connect directly to veins, resulting in high-flow lesions prone to rupture. Most cases are sporadic, but BAVMs often occur patients with in Hereditary Hemorrhagic Telangiectasia (HHT), a disease caused by mutations in ALK1, ENG or SMAD4. Prior studies have suggested a genetic contribution to BAVM in familial non-HHT Japanese cases. We hypothesized that exome sequencing may identify novel, rare variants shared among these Japanese non-HHT familial BAVM cases. **Methods:** We performed exome capture and high throughput sequencing of 10 Japanese samples: 8 subjects with non-HHT BAVM (3 sibling pairs, and 2 affected from 2 different families) and 2 spouse controls. Reads were mapped to the reference human genome (UCSC hg19) with Burrows-Wheeler Aligner. Variants were called using Genome Analysis Toolkit and annotated with Annovar. For BAVM samples, we identified genes with potentially pathogenic variants (non-synonymous SNPs, insertions/deletions resulting in frameshift or amino acid change) shared within families and between at least two families. Variants present in controls (2 spousal Japanese control exomes, 73 Japanese 1000 Genomes Project samples, and 45 Japanese HapMap samples) were excluded. Only variants predicted to disrupt protein function using Polyphen-2 analysis were considered as possible candidates. **Results:** An average of 4.3Gb of mappable sequence was obtained for a target coverage of 69x per individual; 90% of all target positions achieved 10x plus coverage, and an average of 43,339 variants were called per sample. We identified 56 genes with possibly deleterious variants in at least 2 families but not in controls. No genes had variants present in all 5 families; 2 genes (CD3G and PSG4) had variants in 4 families and 9 genes had variants in 3 families. Four genes (PSG4, TTN, PCDHA8 and PCDHGA11) are in biological pathways that may be relevant to BAVM. One of the 56 genes with variants in at least 2 families lies in a previously reported linkage region on chromosome 13. **Conclusions:** Exome sequencing in 8 familial non-HHT BAVM cases identified several genes bearing candidate rare variants in cases only. More experiments are needed to validate these findings and determine the potential role of the genes identified in BAVM pathogenesis.

The Investigation of Angiotensin Converting Enzyme I/D (ACE I/D) and Plasminogen Activator Inhibitor-1(PAI-1) 4G/5G Polymorphisms in Venous Thromboembolism Patients in Turkish patients. *H. Salifoglu, H. Kaya, M. Karkucak, D. Torun, Y. Tunca.* Gulhane Military Medical Academy, Ankara, Turkey.

Venous tromboembolism(VTE) refers to trombolytic events in the venous system that are most common manifested as deep vein thromboses in the upper or lower extremity and / or pulmoner embolism.As genetic factors differs among the populations; lots of studies were done about the polymorphism related to VTE. As a result of these studies the relationship between disease development and polymorphism is not clear yet. In this study we aimed to investigate the role of Angiotensin Converting Enzyme Insertion/Deletion(ACEI/D)and Plasminogen Activator Inhibitor-1 4G/5G polymorphism in the development of disease. The study population consisted of a group of 80 VTE patients and 79 healthy subjects as a control group. Genotypes were determined by using classical polymerase chain reaction(PCR) for ACE I/D polymorphism and the PCR based on allele spesific amplification for PAI-1 4G/5G polymorphism in the development of disease. As a result ; there were no significant differences for ACE I/D and PAI-1 4G/5G polymorphism among patient and control groups($p>0.05$) These findings revealed that there is no relationship between those polymorphisms and the development of VTE, but more studies with larger group of patients and controls are needed to be done.

Organization of alphoid sequence clusters on human chromosome 21. *W. Ziccardi, C. Putonti, J. Doering.* Dept Biol, Loyola Univ Chicago, Chicago, IL.

The human genome sequence does not include the heterochromatic regions, although these sequences comprise 10–15% of the genome. We are constructing a detailed physical map of the HC21 centromere and short arm as a model for the organization of these regions. There are two types of alphoid sequences in the human genome: homogeneous higher order repeat (HOR) arrays and more ancient heterogeneous monomeric clusters, which lack any higher organization. Our prior work showed that alphoid DNA on HC21 is present in two distinct regions: D21Z1 and α21-II. The D21Z1 cluster is required for centromere function and consists of a homogeneous array of 11-mer HORs. α21-II is a region on the p arm containing putatively monomeric alphoid sequences organized as at least five distinct clusters (Mp1–Mp5) spread over some 5 Mb and dispersed among many other non-alphoid sequences. Using 21p BACs already in GenBank as well as new clones we acquired, a total of 0.5 Mb of α21-II sequence was analyzed that included representative sequence from each of the five clusters. The α21-II alphoid sequences are in fact not purely monomeric since two of the clusters have an HOR organization. While one of these (Mp3) has a highly degenerate HOR array, the other (Mp4) has a highly homogeneous organization comparable to that seen in D21Z1. The α21-II alphoid clusters are larger than comparable regions on other chromosomes and they are also more distant from the functional centromere. While the overwhelming majority of non-centromeric alphoid arrays are on the p arm of HC21, other human chromosomes have symmetry in the location of these arrays with relatively equal amounts of alphoid sequence on their q and p arms, Overall, HC21 alphoid clusters with an HOR organization are evolutionarily distinct from the monomeric arrays, and D21Z1 appears to be the most recently evolved cluster. All of the monomeric clusters are of recent evolutionary origin and appear to be of a similar age to each other. This organization is quite different from the layered structure seen on other chromosomes where the age of a non-centromeric alphoid array is related to its distance from the functional centromere, with the oldest arrays being most distal. The different type of alphoid organization on HC21p may be due to relatively frequent interchromosomal exchanges between the p arms of the acrocentric chromosomes.

A high-resolution genome-wide map of meiotic double-strand breaks in humans. *F. Pratto[1], K. Brick[1], P. Khil[1], F. Smagulova[2], G. Petukhova[2], R.D. Camerini-Otero[1].* 1) Genetics and Biochemistry Branch, National Institutes of Health, Bethesda, MD; 2) Uniformed Services University of Health Sciences, Department of Biochemistry and Molecular Biology, Bethesda, MD.

Meiotic recombination is initiated by the formation of programmed double-strand breaks (DSBs). The sites where these breaks are introduced are clustered in narrow regions called hotspots. Recent studies have determined that PRDM9, a meiosis specific histone H3 methyl-transferase, is the primary determinant of hotspot location. To date, genome-wide mapping of meiotic hotspots in humans was only possible via computational analysis of patterns of linkage disequilibrium in populations. Using LD patterns, more than 30,000 hotspots have been identified. LD-based analyses have several important caveats; they may not reflect present day crossovers, are prone to variability in recombination rate estimates and allow only for evaluation of sex-averaged and population-averaged recombination rates. In this work, we perform the first direct genome-wide mapping of meiotic recombination initiation hotspots in humans. To map hotspots we have used a sequencing-based technique that recently allowed us to generate genome-wide maps of meiotic DSBs in mouse (Khil et al. Genome Res (2012), Brick et al. Nature (2012), Smagulova et al. Nature (2011)). We found that the genome-wide distribution of human DSBs in male meiosis resembles the distribution of male specific, but not female-specific crossovers, with both male crossovers and DSBs more frequent in subtelomeric regions. This suggests that the frequency of crossovers is directly related to the frequency of DSBs and that regulation at the level of initiation is shaping the recombination landscape. Furthermore, the positions of DSB hotspots agree well with the positions of LD-based hotspots, although there are notable differences. In order to estimate inter-individual variability and the effect of different Prdm9 alleles on DSB hotspot locations, we mapped DSBs in four individuals; two were homozygous for the most common Prdm9 allele in the population (A/A) and two were heterozygous for the A allele and a closely related variant, the B allele (A/B). We found a substantial number of B allele defined hotspots and found that these hotspots are not as well correlated with LD hotspots as the A-defined hotspots. Finally, we found that DSB hotspots are enriched at breakpoints of copy number variants (disease associated or not) that arise via a homology mediated mechanism providing support for a role of programmed meiotic DSBs as the origin of unequal crossovers in humans.

Genome-wide scan of disease-inversion association. *J. Ma, C.I. Amos.* Genetics, UT MD Anderson Cancer Center, Houston, TX.

Chromosomal inversions are known to be associated with susceptibility to disease. The recent advent of paired-end sequencing approaches has made it possible to map inversions across the human genome. However, neither this sequencing-based approach nor the traditional cytogenetic approaches can easily scale to the number of samples needed for inversion-disease association tests. We have recently developed a novel approach, based on principal components analysis (PCA), for detecting and genotyping inversions from high-density single nucleotide polymorphism (SNP) array data. Inside an inversion region, recombination is usually suppressed between the inverted and non-inverted segments, which represent two distinct lineages that have been diverging for many generations and accumulating mutations independently. Locally performing PCA inside or around the inversion region will generate three clusters on the space spanned by the first two eigenvectors corresponding to the three inversion genotypes. For widely available case-control data from SNP-based genome-wide association studies (GWAS), if the markers are dense enough, our approach can be directly used to infer inversion status of all samples and thus can be used to perform association tests. If the markers are not dense enough for meaningful PCA in inversion regions due to quality control in GWAS, we can use surrogate SNPs to infer the inversion genotypes. For most of the known inversions and our predicted inversions using PCA, we found that some of the SNPs inside an inversion region are fixed in the two lineages of different orientations and thus can serve as surrogate markers. Those surrogate SNPs, for which the allele frequencies are very close to 50% in inversion heterozygotes, can be readily determined from SNP data with dense markers, such as the HapMap data. We performed genome-wide association studies by applying our approach to real GWAS data sets for known inversions given in the literature and our predicted inversions and identified a few loci associated to melanoma or lung cancer.

HOXA11 and MMP2 Gene Expressions in Women with Pelvic Organ Prolapsus. *N. Yilmaz[1], G. Ozaksit[1], Y.K. Terzi[2], S. Yilmaz[1], B. Budak[1], O. Aksakal[1], F.I. Sahin[2].* 1) Dr. ZTB Women's Health Education and Research Hospital, Ankara, Turkey; 2) Baskent University Faculty of Medicine Department of Medical Genetics, Ankara, Turkey.

Pelvic organ prolapse (POP) is a common and costly disorder that negatively impacts the quality of life in many women. Uterosacral ligaments (USLs) are supportive structures of the uterus and vagina and are often attenuated in women with POP. Mechanical reasons as well as genetic factors may play a role in POP. The HOXA genes regulate the development of the urogenital tract including uterosacral ligaments. We compared expression of HOXA11, MMP2 in USLs of women with and without POP. We compared HOXA11 and MMP2 expression in USLs of women with (n: 34) and without (n: 24) POP. Total RNA isolated from patient's (n: 34) and control's (n: 24) uterosacral ligament tissues with TriPure isolation reagent according to the manufacturer's instructions. Expression levels of HOXA11 and MMP2 were determined using semiquantitative RT-PCR in Light Cycler 480 system. Realtime ready catalog assays which are short FAM-labeled hydrolysis probe containing locked nucleic acids were used for RT-PCR reactions. Means of RNA expression of MMP2 were 1.17 ± 0.5 and 0.7± 0.3 in POP group vs control group, respectively (p= 0.003). Means of RNA expression of HOXA 11 were 2.12±1.9 and 1.79±1. 3 in POP group vs control group, respectively (p= 0.487). Although, we did not find a statistically significant difference for HOXA expression between the patient and the control groups, the difference in MMP2 expressions were statistically significant. Our results suggest that, further long term investigations with larger numbers of cases are needed to explain the genetic mechanisms underlying pelvic organ prolapsus.

Large scale whole genome and whole exome sequencing of rhesus monkeys (*Macaca mulatta*) in five primate research centers. *M. Raveendran[1], D. Rio Deiros[1], G. L. Fawcett[1,2], Z. Johnson[3], N. H. Kalin[4], R. W. Wiseman[5], B. Ferguson[6], E. Vallender[7], S. Kanthaswamy[8], D. M. Muzny[1], R. Gibbs[1,2], J. Rogers[1,2].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Yerkes National Primate Research Center, Emory University, Atlanta, GA; 4) HealthEmotions Research Institute and Dept. of Psychiatry, University of Wisconsin, Madison, WI; 5) Wisconsin National Primate Research Center, Madison, WI; 6) Oregon National Primate Research Center, Oregon Health & Science Univ., Beaverton, OR; 7) New England Primate Research Center, Harvard Medical School, Southborough, MA; 8) California National Primate Research Center, University of California-Davis, Davis, CA.

Rhesus macaques (Macaca mulatta) are important animal models for biomedical research and evolutionary analyses. Prior studies show this species has greater genetic diversity than humans, but little is known about functionally significant variants in the research population of macaques. We report preliminary efforts to characterize rhesus single nucleotide polymorphisms (SNPs) and other genetic variants through whole genome and whole exome sequencing. We are sequencing animals from five National Primate Research Centers (Yerkes, Wisconsin, Oregon, California and New England NPRCs) using Illumina Hi-Seq methods. Our full dataset will include several hundred subjects each for whole genome (30x) and whole exome sequencing. Here we report preliminary results for 5 whole genome and 8 whole exome sequences. Whole genome sequence reads were mapped to the rhesus reference genome (rhemac2) using BWA, and potential SNPs called using SAMtools mpileup. Using low-stringency coverage requirements we identified >12 million potential SNPs per individual. Pooling across animals to obtain a preliminary population-wide SNP list, we identified >30 million unique single nucleotide variants (SNVs), or one per 100 bp. Counting only SNVs observed in 2 or more individuals yields a higher confidence list of >13 million SNVs, more than in comparable studies of humans. In parallel, we are developing whole exome capture sequencing protocols to increase efficiency in discovering functional SNPs. Rhesus sequences were captured using Roche EZ Choice reagents and a custom design with exons from 18,354 high-confidence human genes. Captured rhesus reads were mapped to rhemac2, which contains 145,849 annotated UCSC exons. 95.7% of human target regions had unambiguous alignments to rhesus genome. The rhesus reads mapped to rhemac2 covered 93% of identified rhesus homologs of the human target regions at >20x coverage. This extends previous studies of the value of human reagents to capture rhesus exons. However, only 76% of bases in the 145,849 annotated rhesus exons were covered at >20x. Initial preliminary analysis of the exome data shows approximately 300 frame shift mutations and about 240 stop codon mutations. Human capture arrays provide good coverage of most of the rhesus exome but both chip design and differences between the genomes in gene content and sequence divergence reduce the ability of human arrays to interrogate the entire rhesus exome.

Whole Genome Haplotyping by Dilution, Amplification and Sequencing. *F. Kaper, S. Swamy, B. Klotzle, J. Cottrell, S. Munchel, M. Bibikova, S. Kruglyak, M. Ronaghi, M.A. Eberle, J.B. Fan.* Illumina, Inc., San Diego, CA.

Standard whole-genome genotyping technologies are unable to determine haplotypes. Several experimental methods have been described for whole-genome phasing, mostly based on separation of chromosomes or large genomic fragments. Generally these methods are expensive and labor-intensive. We have developed a method for rapid and cost-effective whole-genome haplotyping. Genomic DNA is diluted and distributed into multiple aliquots such that each aliquot receives a fraction of one haploid copy. The template in each aliquot is amplified by MDA, converted into barcoded sequencing libraries using Nextera® technology and sequenced in multiplexed pools. We first carried out a proof of concept experiment combining two male genomic DNA samples at equal ratios, resulting in a sample with diploid X-chromosomes with known haplotypes. Pools of the multiplexed sequencing libraries were subjected to targeted pull-down of a 1Mb contiguous region of the X-chromosome DMD gene. Additionally, we sequenced each undiluted male separately to confirm the haplotypes and the undiluted mixed sample to detect all heterozygous SNPs within the region. We identified 1265 heterozygous SNPs within the targeted region in the DNA mixture. Using the dilution sequencing approach, we identified individual contiguous regions within each dilution and determined the haplotypes based on the identified SNPs. These smaller haplotype segments were merged into two contiguous haplotype blocks with a mean length of ~494kb that span ~99% of the region. Genomic context rather than heterozygosity was responsible for the breakup of the region into two blocks. Comparison of the phased haplotype blocks with the haplotypes of the two individual males showed ~99% agreement. We subsequently employed the dilution-amplification strategy to haplotype the entire genome of a Yoruba male DNA sample (Corriell ID NA18506). Standard genomic sequencing to identify all heterozygous SNPs in the sample was combined with dilution-amplification based sequencing data to resolve the phase of identified heterozygous SNPs. Using this procedure we were able to phase >93% of the heterozygous SNPs from the diploid sequence data using 192 dilution-amplification reactions at ~0.4 haploid copies per aliquot. The average haplotype block size for the whole genome experiment was ~250kb with a maximum of approximately 5Mb. Therefore this strategy has successfully been applied to haplotyping of both targeted regions and the entire genome.

Mechanism and Potential Diversity of T-Cell Receptor Rearrangement from Sequence Repertoires. *A. Murugan[1], T. Mora[2], A. Walczak[3], C. Callan[1].* 1) Dept. of Physics, Princeton University, Princeton, NJ; 2) Laboratoire de physique statistique, UMR8550, CNRS, Paris, France; 3) Laboratoire de physique theorique, UMR8549, CNRS, Paris, France.

T-cell receptor (TCR) diversity is generated by VDJ recombination. In this process, germline DNA is rearranged and edited to produce a random TCR coding sequence. This editing involves random choices of the rearranged V, D and J genes, deletions of nucleotides from their ends, and the insertion of random nucleotides at the two junctions (VD and DJ). The mechanism and potential diversity of this stochastic molecular process is still not fully understood. We use deep sequencing data of TCR beta chain CDR3 repertoires in nine individuals to infer a probabilistic generative model of the VDJ rearrangement process. Since the repertoire is shaped by molecular constraints as well as selection, we focus on non-productive sequences (out-of-frame or containing a stop codon) that have not been subjected to selective forces. We find high consistency of the model between different individuals suggesting its origin in a universal molecular mechanism. The generative model characterizes the probability distributions of deletions, insertions and gene choice and the correlations between them. We find that the deletions are highly dependent on gene choice, reflecting sequence dependent nuclease activity. The insertions show a sequence bias, captured well by a di-nucleotide model. We calculate the potential diversity of TCRs and find a nucleotide sequence entropy of 47 bits (~10^14 sequences). We also find quantitative agreement between the occurrence of identical TCRs in different individuals and the predictions of the model for such recurring sequences. The generative model also serves as a baseline for signatures of selection on the repertoire. The model is inferred by maximizing likelihood of the data using an Expectation Maximization algorithm.

Expression of mouse acidic mammalian chitinase in Escherichia coli and characterization of its properties. *A. Kashimura, Y. Kida, M. Ohno, K. Ishikawa, M. Sakaguchi, F. Oyama.* Applied Chemistr, Faculty of Engineering, Kogakuin University, Hachioji, Tokyo, Japan.

Chitinase hydrolyze chitin, a polymer of N-acetyl-D-glucosamine, which is present in a wide range of organisms, including fungi, insects, and parasites. Although chitin is not present in mammals, chitinase genes were found in both human and mouse genomes. Acidic mammalian chitinase (AMCase) have been shown to be closely associated with allergic inflammation and food processing in mouse. To understand its pathophysiological roles, we expressed the mouse AMCase in E. coli as a fusion protein. We found that most of the expressed fusion protein was present in intracellular soluble fraction in E. coli with chitinolytic activity. The recombinant protein shows a distinct pH optimum at pH 2.0. Under the acidic condition, the optimal temperature was 54 oC. The recombinant AMCase binds with chitin beads and cleaves colloidal chitin and releases mainly chitobioside fragments from colloidal chitin, comparable to those of the secreted form of AMCase expressed in CHO cells or mouse stomach. This recombinant protein can be used to elucidate detailed biological functions of the mouse chitinase.

Functional analysis of mouse chitinase-like protein Ym1. *Y. Kida, M. Sakaguchi, Y. Sugahara, F. Oyama.* Dept Applied Chemistry, Kogakuin Univ, Hachioji, Tokyo 192-0015, Japan.

Chitin is a widespread environmental biopolymer of N-acetyl-D-glucosamine and provides structural rigidity to fungi, crustaceans and insects. Although chitin itself does not exist in mammals, chitinases and chitinase-like proteins (CLPs) are expressed in mouse and human. Both mammalian chitinases and CLPs belong to the family 18 of glycosyl hydrolases. CLPs are homologous to chitinases but lack the ability to degrade chitin. It is generally assumed that the lack of chitinase activity in CLPs is due to the mutation of crucial residues within the conserved catalytic domain during evolution from a common ancestor. Ym1, one of the CLPs, is expressed in mouse and induced in inflammation and pathogenesis, but its biological functions remain unknown. Ym1 is highly homologous to acidic mammalian chitinase (AMCase), but lacks chitin hydrolyzing activity. To understand the structure and function relationship of Ym1, we introduced amino acid substitutions (N136D and Q140E), in which both acidic amino acid residues are the highly conserved within chitinases. Although the mutated Ym1 possessed the identical sequence to the catalytic motif of AMCase, it remains inactive. This result indicates that lack of chitinase activity in Ym1 is not only attributed to the simple amino acid substitution in the conserved catalytic motif.

Targeted deep sequencing by Mobile Element Scanning (ME-Scan) reveals Alu insertions throughout the genome and around the world. *D.J. Witherspoon[1], W.S. Watkins[1], Y. Zhang[1,2,3], J. Xing[1,2], M.A. Batzer[4], L.B. Jorde[1].* 1) Dept. of Human Genetics, University of Utah, Salt Lake City, UT; 2) Dept. of Genetics, Rutgers, the State University of New Jersey, Piscataway, NJ; 3) Bionomics Research & Technology Center, Rutgers, the State University of New Jersey Piscataway, NJ; 4) Dept. of Biological Sciences, Louisiana State University, Baton Rouge, LA.

Mobile elements are among evolution's greatest success stories. They are ubiquitous, inhabiting virtually all genomes examined to date. In humans, retrotransposons of the Alu and LINE-1 families have reproduced so effectively and persistently that their copies make up the majority of our DNA. These genomic parasites have had a profound impact on human genetic diversity and genomic structure. Their activity continues to create novel mutations and cause genetic diseases today. Despite their pervasiveness, it remains difficult to quantitatively study their evolution, population dynamics, and impact. Mobile element insertions can only be clearly observed at the level of DNA sequence, and even that is difficult to obtain due to their repetitive nature. To address this challenge, we have improved our method of targeted high-throughput sequencing (mobile element scanning, or ME-Scan; Witherspoon et al. BMC Genomics 2010) and applied it to detect novel and polymorphic AluYb8/9 insertions in 211 individuals from 13 diverse populations: Brahmin, Mala, Madiga and tribal Irula from India; Mbuti Pygmy, Yoruba, Luhya, Alur and Hema from Africa; Italians and northern Europeans from Europe; and Japanese and Chinese from East Asia. We also scanned one 14-member family to detect retrotransposition events between parents and offspring. We indexed and pooled up to 25 individuals per library for sequencing on Illumina HiSeq and GAIIx sequencers, then used custom mapping-based computational analyses to identify known and novel Alu insertions in the data. The per-individual sensitivity of ME-Scan insertion is ~93%, and ME-Scan results are 95% concordant with Alu insertion genotypes obtained by locus-specific PCR. As expected, African populations carry more novel and rare insertions than non-African ones. Based on internal replication results, we applied conservative criteria to reduce false positive results. We detected 1543 novel Alu insertions, including many that are present in only a single individual, and identified insertions corresponding to 3086 previously-known polymorphic Alu insertion loci. Despite the large number of novel insertions, only 27 were found interrupting exons, and only 2 were in protein-coding exons. This dearth of gene-interrupting insertions is statistically significant ($p<0.001$ in both cases, compared to random distribution of novel rare insertions). This implies that natural selection is extremely intolerant of Alu insertions in exons.

Identification of *HNRNPA1* as a novel regulator of cholesterol metabolism. *C. Yu[1], E. Theusch[1], D.A. Nickerson[2], K. Lo[1], M. Kutilova[1], R.M. Krauss[1], M.W. Medina[1]*. 1) Children's Hospital Oakland Research Institute, Oakland, CA; 2) Department of Genome Sciences, University of Washington, Seattle, WA.

HMGCR encodes the rate limiting enzyme in the cholesterol biosynthesis pathway and is inhibited by statins, a class of cholesterol lowering drugs. Expression of an alternatively spliced *HMGCR* transcript lacking exon 13, *HMGCR13(-)*, has been implicated in variation in plasma LDL-cholesterol (LDL-C) and is also the single most informative molecular marker of variation in LDL-C response to statin treatment. *In silico* prediction of splicing factors that interact with rs3846662, a single nucleotide polymorphism (SNP) within *HMGCR* shown to regulate exon 13 skipping, identified a putative interaction with heterogeneous nuclear ribonucleoprotein A1 (HNRNPA1). Sterol depletion of human hepatoma cell lines reduced *HNRNPA1* transcript levels, an effect that was reversed with sterol add-back. Overexpression of HNRNPA1 increased the ratio of *HMGCR13(-)* to total *HMGCR* transcripts by both directly increasing exon 13 skipping in a rs3846662 allele-specific manner, as well as preferentially stabilizing the *HMGCR13(-)* versus the *HMGCR13(+)* transcript. Importantly, HNRNPA1 overexpression also diminished HMGCR enzyme activity, enhanced LDL-C uptake, and increased cellular APOB. Furthermore, we found that a SNP, rs1920045, associated with statin-induced *HNRNPA1* exon 8 skipping, was also correlated with *in vivo* statin response as homozygous carriers had a 7–11% smaller reduction in total cholesterol after statin treatment in subjects from the Cholesterol and Pharmacogenetics (CAP) trial (simvastatin 40mg/day, 6 weeks) and the Pravastatin Inflammation/CRP Evaluation (PRINCE) study (pravastatin 40mg/day, 24 weeks). These results suggest that sterol regulation of *HNRNPA1* modulates *HMGCR* alternative splicing in a genetically regulated manner to impact cellular cholesterol metabolism, further implicating the importance of alternative splicing as a fundamental mechanism underlying variation in both risk factors and the treatment of cardiovascular disease.

602T

Novel association of dual anti-platelet drug response with a functional variant in *PPARG*. *A.S. Fisch, J. Liu, J.P. Lewis, L.M. Yerges-Armstrong, J.R. O'Connell, B.D. Mitchell, R.B. Horenstein, N. Ambulos, K. Ryan, Q. Gibson, J. Shelton, A.R. Shuldiner.* University of Maryland School of Medicine, Baltimore, MD.

Clopidogrel and aspirin (dual anti-platelet therapy; DAPT) are widely used medications for patients with coronary artery disease to prevent myocardial infarction, especially in patients with acute coronary syndrome and following percutaneous coronary intervention. Patients' responses to DAPT are highly variable, and heritability estimates suggest that 70–80% of the variability in on-treatment platelet reactivity may have a genetic basis. Clopidogrel is a prodrug that requires activation by cytochrome P450 enzymes. Studies have shown that the common loss-of-function *CYP2C19**2 allele explains approximately 12% of the variation in on-treatment platelet reactivity and is associated with a higher incidence of cardiovascular events in DAPT-treated subjects. In search of additional variants that influence DAPT response, we genotyped 781 informative SNPs (739 SNPs with MAF>1%) (Affymetrix DMET chip) in 670 healthy individuals from the Amish Pharmacogenomics of Anti-Platelet Intervention-1 (PAPI-1) Study who received DAPT, and had pre- and post-treatment platelet reactivity measured by ex vivo light transmission aggregometry. Association of the effect of SNPs on platelet aggregation was calculated using a variance component method under an additive model simultaneously adjusting for age, sex, and relatedness. After considering multiple comparisons, we established significance at $P<6.4\times10^{-5}$, and marginal significance at $6.4\times10^{-5}<P<6.4\times10^{-4}$. We replicated the previously reported significant association between on-treatment platelet reactivity and SNPs in *CYP2C19* (*2; rs4244285) and *ABCB1* (C3435T; rs1045642). In addition, we found a novel significant association between post-DAPT therapy collagen-stimulated aggregation and the common functional Pro12Ala variant in *PPARG*, a nuclear receptor expressed in liver and other tissues that regulates transcription of multiple genes; specifically the CG genotype was associated with a greater inhibition of post-DAPT platelet aggregation (rs1801282; lag time in N=620 CC and N=26 CG, 73 sec and 111 sec, respectively; $P=2.8\times10^{-5}$). We also report a significant association between DAPT response and variants in genes involved in drug sulfation (*SULTlA2*, *SULT1A3*), and marginal significance in other drug metabolizing genes (*GSTM2*, *CYP2E1*, *CYP3A43*) and drug transporters (*ABCC1*, *ABCC3*, *ABCC8*, *SLC7A8*). Replication and functional studies will be required to further define the role of these gene variants and pathways in DAPT response.

603T

Genetic Variations associated with gemcitabine treatment outcome in Pancreatic Cancer. *L. Li[1], B. Fridley[2], G. Jenkins[2], E. Carlson[2], K. Kalari[2], G. Petersen[2], R. McWilliams[3], L. Wang[1]*. 1) Dept of Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic, Rochester, MN; 2) Dept of Health Sciences Research, Mayo Clinic, Rochester, MN; 3) Dept of Oncology, Mayo Clinic, Rochester, MN.

Background: Pancreatic cancer is a rapidly fatal disease with 5-year survival time less than 5%. Gemcitabine is first line therapy for patients with advanced pancreatic cancer for a decade. However, response rate to gemcitabine therapy varies widely. To understand and identify genetic factors that might improve efficacy and avoid toxicity of gemcitabine during pancreatic cancer therapy, we performed a genotype-phenotype association studies using DNA samples from pancreatic cancer patients treated with gemcitabine. Methods: Top 200 SNPs that were associated with gemcitabine cytotoxicity during a previous genome wide association study using 187 human lymphoblastoid cell lines were selected to determine their association with the overall survival (OS) in 397 subjects from pancreatic cancer patients treated with gemcitabine using Cox proportional hazards models. SNP interaction with gemcitabine was also analyzed. We then imputed the regions of +/− 200kb surrounding the top OS-associated SNPs using MACH 1.0 with 1000 Genome Project followed by association of these imputed SNPs with OS. Furthermore, additional 527 subjects were genotyped for top candidate SNPs using TaqMan assay, followed with association analysis when exposed to gemcitabine. Candidate genes were functionally characterized with siRNA knockdown in tumor cells. Results and Conclusions: Five top SNPs located in chromosome 1, 3, 7, 9, and 20 were identified to be associated with OS (P value less than 0.01) when exposed to gemcitabine. Imputation identified additional 103 SNPs that showed stronger associations than those 5 genotyped ones with the lowest p values = 6.47E-5. Those SNPs were mapped to 8 genes with 3 located in the introns of known genes, ARL4A, SICN, and CDH4. Replication was performed with 5 top observed SNPs plus 5 top imputed ones in 527 subjects. We found that one imputed SNP, rs4925193, in CDH4 still showed a trend in the association of OS with gemcitabine exposure (P = 0.051). Knockdown of CDH4 in pancreatic cancer cells significantly desensitized cells to gemcitabine treatment. Our genotype-phenotype association study and functional genomic study would enhance our understanding of the mechanisms involved in gemcitabine response and help us to better predict gemcitabine response in clinic.

604T

Large scale phenotyping using the 1000 Genomes Project lymphoblastoid cell line panel. *D. Spacek, M. Kaganovich, M. Snyder.* Genetics, Stanford University, Palo Alto, CA.

Understanding how differences in genotype lead to differences in phenotype is of fundamental importance to human biology. The 1000 Genomes Project has examined the genetic diversity of a large number of individuals through genome sequencing and has generated a valuable resource of EBV transformed Lymphoblastoid Cell Lines (LCLs). We have developed a high throughput approach that allows us to characterize the cellular response of LCLs to variety of pharmacologic compounds. So far we have begun to characterize the effects of methotrexate, simvastatin, and a number of other compounds on cell growth. The aim is to characterize the effect of these compounds on 1000s of cell lines. By challenging these cells with cytotoxic or cytoprotective compounds we expect to be able to discern the impact of genotypic variation on drug sensitivity. We also plan to expand this approach to the analysis of other phenotypes.

605T

The association of *SLC6A4* with antidepressant induced mania: The long and the short of it. *J.M. Biernacka[1,2], D.L. Walker[2], J. Geske[1], S. Winham[1], S. Crow[3], M. Chauhan[4], S. McElroy[5], M. Frye[2]*. 1) Dept of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Dept of Psychiatry and Psychology, Mayo Clinic, Rochester, MN; 3) University of Minnesota, Minneapolis, MN; 4) Mayo Health Systems, Austin, MN; 5) Lindner Center of Hope, Mason, Ohio.

Identifying genetic risk factors associated with antidepressant induced mania (AIM) may enable individualized treatment strategies for bipolar depression. Several studies have investigated the potential association between AIM and a length polymorphism in the promoter region of the serotonin transporter gene (*SLC6A4*), known as 5HTTLPR. We previously performed a meta-analysis of these studies, and found no significant evidence of association of the 5HTTLPR long/short variant with risk of antidepressant induced mania (Biernacka et al., 2012, J Affect Disord 136:e21-9). In the current study, we characterized AIM in a sample of 285 subjects (96 AIM+ cases, 189 AIM- controls) from the Mayo Clinic Bipolar Disorder Biobank that were genotyped for the 5HTTLPR variant as well as the rs25531 SNP in the promoter region and the intron 2 VNTR in *SLC6A4*, and evaluated association of AIM with these variants and their haplotypes. Our analysis did not provide significant evidence of association of the 5HTTLPR short allele with AIM. Moreover, inclusion of this sample in the meta-analysis did not change the conclusion of no significant association between 5HTTLPR and AIM. However, our sample provides evidence of association between the intron 2 VNTR and AIM, with the 10-repeat allele being significantly associated with reduced risk of AIM after accounting for relevant covariates including rapid cycling and presence of attention deficit hyperactivity disorder. Furthermore, a haplotype analysis suggests an association between AIM and haplotypes composed of 5HTTLPR, rs25531, and the intron 2 VNTR, with the L-A-10 haplotype being associated with reduced risk of AIM. A prior pharmacogenomics study of unipolar depression had suggested that the haplotype composed of the *SLC6A4* promoter length polymorphism and intron 2 VNTR is associated with response to antidepressants (Mrazek et al., 2009, Am J Med Genet B Neuropsychiatr Genet 150:341–51); in that study the S-A-12 haplotype was associated with lower odds of remission. Further effort into understanding the relationship between *SLC6A4* variation and response to antidepressants should evaluate the role of the intron 2 VNTR as well as other variants in *SLC6A4*, in addition to the promoter long/short variant.

606T

Interactions between polymorphisms in eicosanoid metabolism genes and vasodilator responses in humans. *L.N. Gordon[1], C.R. Lee[2], M. Pretorius[1], R.N. Schuck[2], L.H. Burch[3], D.C. Zeldin[3], S.M. Williams[1], N.J. Brown[1]*. 1) Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN; 2) University of North Carolina at Chapel Hill Chapel Hill, NC, USA; 3) National Institute of Environmental Health Sciences RTP, NC.

Endothelial-dependent vasodilation is a complex phenotype that is integral to the development of cardiovascular disease. Cytochrome P450 (CYP)-derived epoxyeicosatrienoic acid (EET) metabolites of arachidonic acid hyperpolarize vascular smooth muscle and have been shown to be potent vasodilators in preclinical models. EETs are formed by the CYP epoxygenases CYP2C8/9 and CYP2J2, and degraded by soluble epoxide hydrolase (EPHX2). Therefore, the steady state of EETs is the product of their production via CYPs balanced by their degradation via EPHX2. Consequently, we assayed 170 single nucleotide polymorphisms in 23 genes that regulate eicosanoid biosynthesis and function for associations with bradykinin-induced changes in forearm blood flow (FBF), forearm vascular resistance (FVR), and mean arterial pressure (MAP) in 67 African-American and 198 European-American subjects. Single SNP associations with these three measurements revealed no significant effects. However, given the pathway architecture involved in endothelial-dependent vasodilation, the effect of two-way SNP interactions was evaluated and numerous significant interactive effects were observed. In European-Americans, we observed significant interactive effects between polymorphisms in the ALOX5 and EPHX2 genes (rs7080474*rs7816586, β=-6.62, 95% CI -9.59 to 3.65, P=2.31×10-5), ALOX5 and CYP2J2 genes (rs7080474*rs10493270, β=12.8, 95% CI 6.82 to 18.7, P=4.15×10-5), and mitochondrial enzyme carbamoyl-phosphate synthase 1 (CPS1) and CYP2C9 genes (rs11681045*rs2253635, β=-6.85, 95% -10.1 to -3.57, P=5.83×10-5) in the FBF response to bradykinin. In African-Americans, we found a significant interactive effect between the angiotensin-converting enzyme (ACE) and CYP2C8 genes (rs4292*rs10882521, β=11.6, 95% CI 5.85 to 17.4, P=5.02×10-6) on the FVR response to bradykinin. Additionally, ten significant interactions were found in bradykinin FBF response. These interaction effects remained significant after correcting for multiple testing using FDR with q=0.10. Collectively, these findings suggest that complex interactions regulate vasodilator responses in humans, and that these effects differ by genetic ancestry.

Pharmacogenetics of schizophrenia: predicting early response to antipsychotic therapy. *M. Gupta[1], S. Jain[2], R. Kukreti[1]*. 1) Genomics & Molecular Medicine, CSIR-IGIB, New Delhi, Delhi, India; 2) Molecular Genetic Laboratory, Department of Psychiatry, NIMHANS, Bangalore, Karnataka, India.

In the post-genome era, the primary focus of pharmacogenomic studies has been to develop rational means for modifying therapeutic treatments with respect to drug and dose regimes, in order to maximize the drug efficacy and tolerability. Such studies are essential, especially for complex diseases such as schizophrenia, where long-term therapies are required and drug response is heterogeneous, following a “hit-and-trial” mode of administration in absence of a mechanism based pre-designed medication regime. In view of this fact, the present report portrays an integrative approach to identify multiple factors influencing antipsychotic drug response and build a predictive model for response to antipsychotic drugs in a south Indian population. For this study, a genetic association strategy was employed to assess polymorphisms in candidate genes from the key drug response related genes in a large, well-characterized sample of 448 antipsychotic-treated schizophrenia patients of south Indian origin, recruited from the clinical services of the National Institute of Mental Health and Neuroscience (NIMHANS), Bangalore, India. The patients were assessed for a three-month period following antipsychotic drug administration, during which they were assessed for response to antipsychotics using Clinical Global Impressions (CGI) and Positive and Negative Syndrome Scale (PANSS). Additionally, other demographic and clinical parameters were evaluated which might influence the genetic variation-drug response relationship. Using a multivariate logistic regression approach, we were able to identify a pharmacogenetic model comprising of genetic and non-genetic correlates, which had a high predictive power to discriminate between good and poor responders to antipsychotic therapy (sensitivity=75.5%, specificity=71.8%; χ2=115.13, p-value = 3.37×10-23). Our results provide credible evidence for the advantage of combined information from response-related genes and non genetic factors to form the basis of prediction tests. Predictability testing is one of the main aims of pharmacogenomic studies and this report represents an important step towards realization of this aim. These results thus underscore the need to develop an overall predictive model for antipsychotic response comprising of genotype-phenotype relationships to understand and predict the phenotypic effects of genes at the clinical level.

608T

Identification of novel polymorphisms associated with efficiency of metformin treatment in type 2 diabetes patients. *J. Klovins[1], L. Tarasova[1], L. Zarina[2], V. Pirags[2,3], OPTIMED consortium.* 1) Latvian Genome Ctr, Latviam Biomedical Ctr, Riga, Latvia; 2) Pauls Stradins Clinical University Hospital, Riga, Latvia; 3) University of Latvia, Riga, Latvia.

Many patients with type 2 diabetes (T2D) are not reaching glycemic targets by using metformin or different combinations of antidiabetic drugs, including insulin. On the other hand, intensified multidrug therapy is associated with increased risk of severe side effects and individualized selection of medication is essential. The aim of our study is to identify genetic variations associated with efficiency of metformin therapy using prospective cohort of T2D patients. 144 patients that have received metformin monotherapy were selected from OPTIMED study, a prospective clinical trial involving the treatment naive T2D patients. Treatment efficiency was estimated based on change in HbA1c levels measured 3 and 9 month after the start of the therapy. 192 tagSNPs from 15 previously reported genes influencing T2D treatment efficiency and tolerability (OCT1,2,3, MATE1,2, PMAT and others) were selected and genotyped in all patients using GoldenGate Genotyping Assay with VeraCode technology (Illumina, Inc.). We identified block of SNPs located in region between SLC22A2 -SLC22A3 genes as well as SNPs in MATE2 gene that were associated with lack of HbA1c decrease after 3 month metformin therapy. Most strongly associated SNP displayed high significance (unadjusted association test (P=9.29 e-005, OR [CI 0.95]= 4.971[2.163-11.43]). Association maintained statistical significance after Bonferroni correction and was also present when efficiency of therapy at 9 month was tested. Number of epistatic interactions was identified between the polymorphisms at OCT1-3 locus and other genes. In conclusion we have identified number of novel SNPs that may predispose to decreased metformin efficiency.

Background The association of *CETP* variation with the efficacy of statins in preventing cardiovascular (CV) events has been subject of debate. We aimed to evaluate whether common SNPs influence the efficacy of statins in modifying cholesterol levels and in preventing CV events. We focused specifically on three functional SNPs, tightly linked to the production of the *CETP* Δ9 splice variant (rs5883 and rs9930761, located in exon 9 and intron 8), or *CETP* expression levels (rs3764261, located in the promoter region). The promoter SNP was also shown to influence cholesterol levels, increasing HDL-cholesterol (HDLc), and decreasing LDL-cholesterol (LDLc).

Methods Linear regression analysis was used to investigate the relation between the three *CETP* SNPs and cholesterol levels during statin treatment. We meta-analyzed the outcomes of two studies (n=10,502) with cholesterol measures using a random-effects model. The interaction between the three SNPs and statin use on CV events was analyzed using a logistic regression model with a Statin*SNP interaction term. The results of five studies with MI outcome information available (n=16,570) were meta-analyzed using a random-effects model.

Results The promoter SNP rs3764261 significantly increased HDLc by 0.02 mmol/L per T allele (95% CI 0.02–0.03, p-value: 3.1E-09), and decreased LDLc by 0.03 mmol/L per T allele (95% CI 0.01–0.04, p-value: 0.0031) during statin use. Rs3764261 showed a nominally significant interaction with statin use (interaction OR 1.19 per T allele; 95% CI 1.01–1.40, p-value for interaction: 0.0418), but this was not significant after multiple testing correction. The SNPs influencing *CETP* splicing (rs5883 and rs9930761) did not modify statin efficacy on cholesterol levels during statin treatment or CV events.

Conclusion Using a large sample size and focusing on functional *CETP* variants, we showed a further increase of HDLc and decrease of LDLc during statin treatment for carriers of the rs3764261 T variant. This effect was accompanied by a reduced protection against MI by statins when compared to non-carriers.

Association study of inflammation-related genes and depressive disorders and antidepressant response. *M.-W. Lin[1, 2], Y.-T. Chang[3], I.-H. Lin[1], Y.-M. Bai[3].* 1) Institute of Public Health, National Yang-Ming University, Taipei, Taiwan; 2) Department of Medical Research and Education, Taipei Veterans General Hospital, Taipei, Taiwan; 3) Department of Psychiatry, Taipei Veterans General Hospital, Taipei, Taiwan.

Depressive disorder is a common and complex disease with multifactorial etiology. The illness has an annual prevalence of 7% and also has high lifetime prevalence, perhaps as high as 16%. Current antidepressant treatments, which mainly target on monoamine pathways, fail to achieve remission in more than 30% of depressive patients with multiple treatment trials. Increasing amount of evidence suggest that inflammation has an important role in the pathophysiology of depression. Many studies have shown that elevation in plasma levels of inflammatory cytokines in depressive patients, however, some studies have failed to replicate this finding. There is evidence demonstrated that plasma levels of inflammatory mediators are influenced by genetic polymorphisms. To investigate if inflammation-related genes might play some role in susceptibility to depressive disorders and also in the treatment response of antidepressants, we recruited 151 depression patients receiving 12-week antidepressant treatment and 135 normal control subjects in this prospective study. The levels of cytokine including IL-2, IL-6, CRP, soluble p-selectin, adiponectin, MCP-1, and TNF receptor 1 were assayed by enzyme-linked immunosobent assay (ELISA) kit at week 0, 4, 12. Genotypings of six single nucleotide polymorphisms on the CRP, P selectin, TNF-alpha, and TNF receptor 1 gene, respectively, were performed using the TaqMan Assay. The genotypic frequencies of SNPs between groups were compared using Chi-square test and continuous data were by t test or ANOVA. We found significant improvement of depressive symptoms after 4 week treatment of antidepressant, but the treatment effect did not last after 12 week. We also found the levels of soluble P selectin and TNF receptor 1 were increased as the period of antidepressant treatment increases, while the levels of adiponectin was significantly decreased after 4 week antidepressant treatment in depressive patients. Our study also revealed that the patients with CC+CT genotypes of the CRP rs1205 demonstrated significantly improvement in HAMD depressive score between week 4 and week 12, as well as the T allele carriers of the CRP rs1130864 showing significant higher HAMD depressive score than the carriers of C allele at week 0. Our results indicate that the CRP gene SNPs may be associated with improvement of depressive symptoms in depression patients. Further studies using larger sample size are warranted to confirm the findings of our study.

Are CYP2C9 and VKORC1 polymorphisms associated with increased bleeding or thrombosis risk among Blacks receiving warfarin anticoagulation? *F. Mili[1], T.A. Deans[2], W.C. Hooper[1], P. Weinstein[1], C. Lally[3], H. Austin[3], N. Wenger[2].* 1) Division of Blood Disorders, Centers for Disease Control & Prevention, Atlanta, GA; 2) Emory University School of Medicine, Atlanta, GA; 3) Department of Epidemiology, Emory University Rollins School of Public Health, Atlanta, GA.

Introduction: Numerous studies describing the association between complications of warfarin anticoagulation and CYP2C9 or VKORC1 single nucleotide polymorphisms (SNPs) among Whites have been published. Few studies assessing these associations have been performed among Blacks. Objectives: To investigate whether 4 CYP2C9 and 18 non-coding VKORC1 SNPs identified by re-sequencing are associated with serious bleeding or thrombosis risk among Blacks receiving warfarin anticoagulation. We conducted a small retrospective cohort study among Blacks ≥ age 18 years on warfarin for a minimum of 3 consecutive months. Participants were enrolled between February 2005 and October 2006 from an anticoagulation clinic in the metropolitan Atlanta area (n = 230, 124 men and 106 women). Results: Observed genotype frequencies for each of the variant alleles consistent with Hardy-Weinberg equilibrium comprised CYP2C9*2_C>T (4.2%), CYP2C9*3_A>C (1.9%), VK6915T>C (11%) and VK8773C>T (37%). X2 tests indicated an increased risk of bleeding complications among Blacks with CYP2C9*2 or CYP2C9*3 variant alleles vs. referent alleles [risk ratio (RR) = 4.3 (95% confidence interval (CI) 1.03–17.7; p = 0.03)], whereas the risk of thrombosis was increased but not statistically significant [RR = 2.6 (95% CI 0.29–23.7)]. A lower mean daily maintenance dose of warfarin was required among Blacks with heterozygous alleles for CYP2C9*2 vs. referent allele [4.8 (1.6) vs. 7.0 (4.5), t test p = 0.0046], as well as among those with heterozygous alleles for CYP2C9*3 [4.0 (0.82) vs. 6.9 (4.4), t test p = 0.0007] to maintain an international normalized ratio (INR) measurement within the therapeutic range. Although not statistically significant, the variant allele for either the VK6915 or the VK8773 SNPs was associated with a decreased risk of bleeding [RR = 0.72 (95% CI 0.27-1.9)], and no risk of thrombosis among Blacks. In addition, Blacks who are heterozygous for VK8773 seemed to need a higher mean daily maintenance dose of warfarin vs. those with the referent allele [7.1 (4.2) vs. 6.8 (4.7)]. Conclusions: Blacks with CYP2C9 variant alleles have an increased risk of bleeding versus those with the referent alleles. Our pilot study suggests that Blacks with novel VK6915 or VK8773 variant alleles have a lower risk of bleeding. Future research involving multiple ethnic groups and larger sample sizes is needed to define the role of genetic testing in assessing bleeding risk with warfarin anticoagulation.

Twelve Candidate Genes and Antidepressant Response in Obsessive-Compulsive Disorder. *G. Zai[1], E. Brandl[1], J. Deluce[2], J.L. Kennedy[1], M.A. Richter[2].* 1) Neurogenetics Section, CAMH, Univ Toronto, Toronto, ON, Canada; 2) Department of Psychiatry, Sunnybrook Health Science Centre, Toronto, ON, Canada.

Obsessive-compulsive disorder (OCD) is a chronic disorder with a strong genetic component. Genetic associations between OCD and several candidate genes including glutamate transporter (SLC1A1), monoamine oxidase (MAOA), glutamate receptor, ionotropic, N-methyl D-aspartate 2B (GRIN2B), serotonin 2A receptor (5HTR2A), serotonin transporter (SLC6A4), and catecholamine-O-methyl-transferase (COMT) genes have been reported albeit with inconsistent results. Pharmacogenetics represents an important alternate to investigate inter-individual genetic variation and drug response. In this preliminary study, we investigated 12 different genes including those mentioned above in addition to the disks large (drosophila) homolog-associated protein 2 (DLGAP2), myelin oligodendrocyte glycoprotein (MOG), serotonin 1B receptor (5HT1B), chromosome 9 open reading frame 68 (C9orf68), adenosine deaminase, RNA-specific, B2 (ADARB2), and oligodendrocyte lineage transcription factor 2 (OLIG2) genes. Thirty, two, six, sixteen, eleven, six, two, ten, sixteen, ten, ten, and ten single nucleotide polymorphisms (SNPs) in the DLGAP2, MOG, 5HT1B, SLC1A1, C9orf68, MAOA, ADARB2, GRIN2B, 5HTR2A, SLC6A4, OLIG2, and COMT genes respectively were genotyped in 117 individuals with OCD and retrospective response data collected on multiple serotonin reuptake inhibitor (SRI) trials. Individuals were grouped into those who improved following an adequate trial of one or more SRI(s) as compared with those who reported “minimal”, “no change”, or “worsening” in response to SRI(s) tried. Genotypes and response data were examined by exploratory analyses on a drug-by-drug and combined basis. Significant response associations were detected in DLGAP2 & paroxetine/clomipramine (P=0.008–0.042), 5HT1B & clomipramine/SRI (P=0.0003–0.045), SLC1A1 & sertraline/fluvoxamine/citalopram/SSRI/SRI (P=0.0008–0.035), C9orf68 & clomipramine/fluvoxamine/SSRI (P=0.007–0.031), MAOA & citalopram (P=0.028), GRIN2B & fluoxetine/paroxetine/fluvoxamine/citalopram/clomipramine (P=0.004–0.024), 5HTR2A & clomipramine (P=0.024), SLC6A4 & paroxetine (P=0.0006–0.010), OLIG2 & paroxetine (P=0.008), and COMT & paroxetine/sertraline/citalopram/SSRI/SRI (P=0.007–0.044). Analyses for association with response to other drug trials were negative. These results suggest that genetic variants may play an important role in SRI response to OCD. However, replication in larger and independent samples is required.

A genome-wide integrative study of microRNAs in human liver. *W. Liu[1,2], F. Innocenti[2,3], E. Gamazon[2], S. Mirkov[2], J. Ramirez[2], S. Huang[2], N. Cox[2], M. Ratain[2].* 1) Department of Medicinal Chemistry and Molecular Pharmacology, Purdue University, West Lafayette, IN; 2) Department of Medicine, The University of Chicago, Chicago, IL; 3) Institute for Pharmacogenomics & Individualized Therapy, University of North Carolina, Chapel Hill, NC.

Recent studies have illuminated the diversity of roles for microRNAs in cellular, developmental, and pathophysiological processes. Their biological consequences are actively being explored, and their functions in the initiation and progression of cancer, the regulation of cellular activity from proliferation to apoptosis, and the modulation of therapeutic response are rapidly being uncovered. The study of microRNAs in human liver tissue promises to clarify the therapeutic and diagnostic value of this important regulatory mechanism of gene expression. To this end, we conducted genome-wide profiling of microRNA expression in liver and identified hundreds of microRNAs abundantly expressed, including those significantly associated (FDR<0.05) with mRNA expression. In particular, we report here the list of Very Important Pharmacogenes (VIP Genes), comprising of genes of particular relevance for pharmacogenomics, that are under substantial microRNA regulatory effect in liver relative to genomic background. We set out to elucidate the genetic basis of microRNA expression variation in liver and mapped microRNA expression to genomic loci as miRNA expression quantitative trait loci (miR-eQTLs). We identified common single nucleotide polymorphisms (minor allele frequency >15%;) that attain genome-wide significant association ($p<10^{-11}$) with microRNA expression (based on Bonferroni adjustment for the number of SNPs and the number of expressed microRNAs tested). A comparison of eQTLs from a genome-wide transcriptome study in liver and the miR-eQTLs clarifies the role of miR-eQTLs on (mRNA) gene regulation. We found that the miR-eQTLs are significantly more likely to predict mRNA levels at a range of p-value thresholds than a random set of allele frequency matched SNPs, showing the functional effect of these loci on the transcriptome. Finally, we show that annotating SNPs reproducibly associated with complex traits from the NHGRI repository of published genome-wide association studies as well as variants from a comprehensive catalog of manually curated pharmacogenetic associations with information on microRNA expression is likely to advance our understanding of disease pathogenesis, therapeutic outcome, and other complex human phenotypes.

Protein Quantitative Trait Loci Identify Novel Proteins Predictive for Chemotherapeutic Induced Phenotypes. *A.L. Stark[2], R.J. Hause, Jr[3,4,5], L.K. Gorsic[2], N.N. Antao[2], S.S. Wong[2], D.F. Gill[3], S.H. Chung[3], S.M. Delaney[2], C.D. Brown[1,3,5], K.P. White[1,3,5], R.B. Jones[3,4,5], M.E. Dolan[2,6]*. 1) Dept Human Gen, Univ Chicago, Chicago, IL; 2) Dept of Medicine, Univ Chicago, Chicago, IL; 3) Committee on Genetics, Genomics, and Systems Biology, Univ Chicago, Chicago, IL; 4) Ben May Dept for Cancer Research, Univ Chicago, Chicago, IL; 5) Institute for Genomics and Systems Biology, Univ Chicago, Chicago, IL; 6) Committee on Clinical Pharmacology and Pharmacogenomics, Univ Chicago, Chicago, IL.

Personalized medicine aims to develop predictive markers for oncology patients at greatest risk of experiencing chemotherapeutic related toxicities and/or nonresponse. Many of the biomarkers are proteins and by identifying protein quantitative trait loci (pQTLs), genetics and genotyping can predict protein levels. Our lab has developed models that employ HapMap lymphoblastoid cell lines (LCLs) to identify chemotherapeutic susceptibility genetic variants by evaluating chemotherapeutic induced phenotypes. To identify pQTLs as well as proteins that contribute to drug-induced phenotypes, we used newly developed micro-western arrays to assay protein levels for over 400 transcription factors and core signaling proteins in 68 unrelated Yoruba derived LCLs. In order to demonstrate the utility of these protein levels, we focused on two widely used chemotherapeutics (paclitaxel and cisplatin) with two cellular phenotypes assayed (caspase 3/7 apoptosis and cell growth inhibition). These two phenotypes are negatively correlated, but varied in strength (paclitaxel r2=0.35, cisplatin r2=0.04). For each drug, we then analyzed the two phenotypes GWAS for pQTLs ($p<0.0001$) and identified a common protein implicated through different pQTLs for apoptosis and cell growth inhibition phenotypes. ZNF569 protein levels were negatively correlated with paclitaxel-induced growth inhibition ($p=0.0005$) and positively correlated with paclitaxel-induced apoptosis ($p=0.0002$). The pQTLs of ZNF569 associated with paclitaxel-induced growth inhibition and apoptosis were on different chromosomes suggesting that different regulatory architecture converges on common proteins in the related paclitaxel phenotypes. Similarly for cisplatin, SMC1A protein levels were positively correlated for growth inhibition ($p=0.004$) and negatively correlated for apoptosis ($p=0.0007$). Again, the pQTLs of SMC1A associated with cisplatin growth inhibition and apoptosis were on different chromosomes. Using siRNA, we functionally validated both ZNF569 ($p<0.002$, 0.0001) and SMC1A ($p<0.0002$, 0.001) for apoptosis and growth inhibition induced by paclitaxel and cisplatin, respectively. This work allows pharmacogenomic discovery work to move from the transcriptome to the proteome and demonstrates the cellular utility of pQTLs. A better understanding of the variation in the proteome can aid in the discovery of genetic predictors of chemotherapy toxicity and response.

615T

Functional genetic variation in *RHOA* is associated with the cholesterol-lowering effects of statin treatment. *E. Theusch[1], D. Naidoo[1], F. Bauzon[1], K. Stevens[1], L. Mangravite[2], Y.L. Kuang[1], R.M. Krauss[1], M.W. Medina[1]*. 1) Children's Hospital Oakland Research Institute (CHORI), Oakland, CA; 2) Sage Bionetworks, Seattle, WA.

Statins are drugs designed to reduce plasma LDL-cholesterol (LDL-C) levels and cardiovascular disease risk by inhibiting HMG Co-A reductase (HMGCR), the rate-limiting cholesterol biosynthesis enzyme. There is substantial inter-individual variation in statin-induced LDL-C lowering, but few genetic loci modulating statin response have been identified using candidate gene and genome-wide association studies. As an alternate approach, we used genome-wide gene expression data from human livers and sham- and statin-exposed hepatoma cell lines and lymphoblastoid cell lines (LCLs) to discover liver-expressed, statin-responsive genes that had statin-induced expression changes strongly correlated with changes in *HMGCR* expression. This filtering approach identified ras homolog family member A (*RHOA*), a gene previously shown to mediate anti-inflammatory but not cholesterol responses to statin treatment, as a candidate for future study ($r^2=0.13$, $p=7.64\times10^{-16}$ with statin-induced *HMGCR* expression changes). *RHOA* knockdown in hepatoma cell lines decreased mRNA levels of known sterol-regulated genes (*HMGCR*, *SREBF2*, and *LDLR*), increased intracellular cholesterol ester, and increased media concentrations of APOB, the major apolipoprotein on LDL particles. Using genotype data and plasma cholesterol measurements from Caucasian participants of the Cholesterol and Pharmacogenetics (CAP) simvastatin clinical trial (N=580) and the PRINCE pravastatin clinical trial (N=1307), we found that of the four common haplotypes encompassing *RHOA*, haplotype H3B was associated with reduced *in vivo* statin-induced plasma LDL-C lowering ($p=0.0149$), while haplotype H2 was associated with increased LDL-C lowering ($p=0.0349$). H3B was the only haplotype containing the minor allele of rs11716445, a SNP located in a rare *RHOA* exon (exon 2.5) identified using RNA-Seq data. Furthermore, we concluded that rs11716445 was a cis-splicing quantitative trait locus (cis-sQTL) for *RHOA* exon 2.5 because the minor allele dramatically increased the inclusion of exon 2.5 in *RHOA* transcripts from CAP LCLs, and, in rs11716445 heterozygotes, over 90% of transcripts incorporating exon 2.5 contained the minor allele. Since *RHOA* lies in a large linkage disequilibrium block, it is possible that genetic variants in other genes in the region influence statin response, but these findings suggest that functional genetic variation in *RHOA* contributes to variation in LDL-C response to statin treatment.

616T

The modulation of CYP3A4 expression by the efflux pump ABCB1 in HepG2 cells. *W. Shou[1, 2], B. Wang[2], Z. Wang[2], J. Shi[2], W. Huang[1, 2]*. 1) Rui Jin Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China; 2) Department of Genetics, Shanghai-MOST Key Laboratory of Health and Disease Genomics, Chinese National Human Genome Center, Shanghai, China.

CYP3A4, the most abundant member of Cytochrome P450 family, is involved in the metabolism of nearly 50% of drugs currently prescribed. CYP3A4 expression is strongly modulated by nuclear receptors (NR), e.g. pregnane X receptor (PXR) and Hepatocyte nuclear factor 4 alpha (HNF4α), and by exogenous or endogenous chemicals through NR-mediated induction. Many CYP3A4 modulators are also the substrates of P-glycoprotein (ABCB1), which is an important transmembrane efflux transporter. Thus, we hypothesized that ABCB1 could regulate CYP3A4 expression. To prove this hypothesis, we constructed transient and stable transfected HepG2 cells with ABCB1 expressing plasmid, and adopted small interfering RNA (SiRNA) targeting ABCB1 expression in HepG2 cells, in order to make ABCB1 overexpressing or inhibited. HepG2 cells were cotransfected with expression plasmids of nuclear receptors (PXR and HNF4α), and treated with classic CYP3A4 inducer rifampicin after transfection. Then, luciferase reporter for CYP3A4 was assayed. CYP3A4 expression was induced by rifampicin in a concentration-dependent manner. CYP3A4 reporter activity significantly decreased in ABCB1-overexpressing cells, compared to non-overexpressing cells, especially in the stable transfected cells. In addition, CYP3A4 reporter activity was significantly higher in ABCB1 inhibited cells than in negative controls, which confirmed the results in ABCB1-overexpressing cells. The two-sided results revealed that ABCB1 indirectly modulated the CYP3A4 gene expression through regulating the intracellular modulators of the CYP3A4 gene expression. Our study suggested that the efflux pump ABCB1 might be an upstream regulator of the important drug-metabolizing enzyme CYP3A4. Consequently, gene-drug and gene-gene interaction need to be carefully considered during drug metabolism.

Genetic determinants of dabigatran plasma levels and their relation to bleeding. *G. Pare[1], N.E. Eriksson[2], T. Lehr[3], S. Connolly[1], J. Eikelboom[1], M.D. Ezekowitz[4], T. Axelsson[5], S. Haertter[3], J. Oldgren[2], P. Reilly[7], A. Siegbahn[5], A-C. Syvanen[5], C. Wadelius[6], M. Wadelius[5], H. Zimdahl-Gelling[3], S. Yusuf[1], L. Wallentin[2]*. 1) Population Health Research Institute, Hamilton Health Sciences, McMaster University, Hamilton, ON, Canada; 2) Uppsala Clinical Research Center and Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 3) Boehringer Ingelheim Pharma GmbH ξ Co KG, Biberach, Germany; 4) Thomas Jefferson Medical College, Cardiovascular Research Foundation, Philadelphia, PA, USA; 5) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 6) Department of Immunology, Genetics and Pathology, Science for Life Laboratory, Uppsala University, Sweden; 7) Boehringer Ingelheim Pharma Inc., Ridgefield, CT, USA.

Background: Fixed-dose unmonitored treatment with dabigatran etexilate is effective and has a favorable safety profile in prevention of stroke in atrial fibrillation patients compared to warfarin. We hypothesized that genetic variants could contribute to inter-individual variability in blood concentrations of the active metabolite of dabigatran etexilate, and influence the safety and efficacy of dabigatran. [au0,2]Methods[xu: We successfully conducted a genome-wide association study in 2,944 RE-LY participants. Single nucleotide polymorphisms (SNP) correlated with dabigatran peak and trough concentrations were tested for an association with reported bleeding event (N= 587), major bleeding (N=101) and ischemic events (N=32).

Results: Each minor allele of the CES1 SNP rs2244613 was associated with lower trough concentrations (15% decrease per allele, 95%CI 10–19%; P=1.2 × 10-8) and a lower risk of any bleeding (OR=0.67, 95%CI 0.55–0.82; P=7 × 10-5) in dabigatran-treated participants, with a consistent but non-significant lower risk of major bleeding (OR=0.66, 95%CI 0.43–1.01). The interaction between treatment (warfarin versus all dabigatran) and carrier status was statistically significant (P=0.002) with carriers having less bleeding with dabigatran than warfarin (HR=0.59, 95%CI 0.46–0.76; P=5.2 × 10-5) in contrast to no difference in noncarriers (HR=0.96, 95%CI 0.81–1.14; P=0.65). There was no association with ischemic events. The ABCB1 SNP rs4148738 and CES1 SNP rs8192935 were associated with peak concentrations but neither was associated with bleeding or ischemic events.

Conclusions: Carriage of CES1 rs2244613 minor allele occurred in 32.8% of patients in RELY and was associated with lower dabigatran exposure. The presence of the polymorphism was associated with a lower risk of bleeding.

Crawford[1,16] on behalf of the eMERGE Network.* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Biochemistry and Molecular Biology, The Huck Institutes of the Life Sciences, Eberly College of Science, Penn State University, University Park, PA; 3) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 4) Department of Medicine, Vanderbilt University, Nashville, TN; 5) Division of Epidemiology, Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 6) Biomedical Informatics Research Center, Marshfield Clinic Research Foundation, Marshfield, WI; 7) Center for Genetic Medicine, Northwestern University, Chicago, IL; 8) Department of Medicine, Northwestern University, Chicago, IL; 9) Department of Medicine, University of Washington Medical Center, Seattle WA; 10) Office of Population Genomics, National Human Genome Research Institute, Bethesda, MD; 11) Division of Cardiovascular Diseases, Department of Medicine, Mayo Clinic, Rochester, MN; 12) Biomedical Statistics and Informatics, Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 13) Group Health Research Institute, Seattle WA; 14) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 15) Department of Pharmacology, Vanderbilt University, Nashville, TN; 16) Departments Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN.

Resistant hypertension (RH) is defined as high blood pressure (BP) that remains above treatment goals in spite of the concurrent use of at least three antihypertensive agents of different classes. Despite the increasing prevalence of RH, genetic assessments of patients with RH are limited. Large-scale DNA biobanks linked to electronic medical records (EMRs) may enable researchers to extract patients with RH to identify novel genotype-phenotype associations using existing genomic data. The first phase of the Electronic Medical Records and Genomics (eMERGE) Network was a collaboration of five EMR-linked biobanks. For each study site, GWAS were conducted for a number of common diseases and traits, including RH. Individuals of European (E)-descent or African (A)-descent were genotyped on Illumnia 660W-Quad or 1M, respectively. Electronic selection logic using billing codes, laboratory values, text queries, and medication records was used to identify RH cases and controls, which were then validated by manual review. Cases were defined by concurrent use of four or more antihypertension medication classes or concurrent use of three medication classes with elevated BP. Controls consisted of normotensives and/or hypertensives controlled on one antihypertensive medication. Single SNP tests of association using logistic regression were performed. Models were stratified by race/ethnicity and were adjusted for sex, decade of birth, and global ancestry. Among E-descent RH cases (n=1,648) and combined normotensive and controlled hypertensive controls (n=2,365), no SNP was associated with RH at genome-wide significance (p>1E-06). When E-descent cases were compared to controlled hypertensive controls (n=718) alone, the most significant association was with rs12135020 (p=1.98E-06; OR=0.61) found 8kb upstream of *CSRP1*, which is important in the development of arterial smooth muscle cells. Among cases (n=595) and combined controls (n=527) of A-descent, intergenic rs6677984 was associated with RH at genome-wide significance (p=2.37E-14; OR=0.41). We then examined whether SNPs known to influence BP or hypertension also influenced RH. Only 3/26 and 5/42 of the previously-identified SNPs examined in E- and A-descent populations, respectively, were associated with RH at p<0.05. These data suggest that some genetic variants associated with RH are independent of those known to be associated with BP and/or hypertension and highlight the utility of EMR-linked genomic data.

Genetic and clinical determinants of warfarin dose - a RE-LY genomics substudy. *N. Eriksson[1,3], L. Wallentin[1,3], L. Berglund[1], T. Axelsson[3], S. Connolly[2], M. Ezekowitz[4], J. Oldgren[1], P. Guillaume[2], P. Reilly[5], A. Siegbahn[3], A-C. Syvanaen[3], C. Wadelius[6], S. Yusuf[2], M. Wadelius[3]*. 1) Uppsala Clinical Research Center, Uppsala, Uppsala, Sweden; 2) Population Health Research Institute, Hamilton Health Sciences and McMaster University, Hamilton, ON, Canada; 3) Department Medical Sciences, Uppsala University, Uppsala, Sweden; 4) Thomas Jefferson Medical College, Cardiovascular Research Foundation; 5) Boehringer Ingelheim Pharma Inc; 6) Department Genetics and Pathology, Uppsala University, Sweden.

Purpose: The response to warfarin treatment is influenced by several genetic factors. We conducted a genome-wide association study in patients from the RE-LY study, which compared two doses of dabigatran with warfarin. We hypothesized that genetic risk factors, other than CYP2C9, VKORC1 and CYP4F2, might affect warfarin maintenance dose and percent time in therapeutic range (TTR). We also investigated the effects of VKORC1 and CYP2C9 on TTR and risk of major bleeding. Further, we investigated the performance of the International Warfarin Pharmacogenetics Consortium (IWPC) prediction model and if any additional variables (renal function, smoking, CYP4F2) might improve performance of future prediction models. **Methods:** 3,076 participants in the RE-LY genomics sub study, of which 982 were in the warfarin arm, were genotyped using the Illumina Human610-quad chip. Following quality control, 554,725 SNPs in 956 patients were available for analysis. A p-value threshold of genome-wide significance was set at 9 × 10-8. To account for possible population stratification, all genome-wide analyses were adjusted for the first four genetic principal components. TTR was calculated according to the Rosendaal method. GWAS of continuous traits was performed using linear regression. **Results:** Novel SNPs associated with warfarin dose (adjusted by clinical factors and VKORC1/CYP2C9) at a genome-wide significance level were found in the genes DDHD1 and NEDD4. We identified a SNP in the gene ASPH that was associated with TTR (-6.8 % per minor allele). During the first three months, VKORC1 rs9923231 was associated with INR outside treatment range (2.0–3.0) and CYPC29 *3 was associated with INR above 3.0. Neither CYP2C9 *2/*3 nor VKORC1 rs9923231 were associated with risk of major bleeding. The IWPC model gave an R^2 of 50.9 % and a MAE of 6.6 mg/week. The predictive value increased slightly when CYP4F2, DDHD1, NEDD4 and Creatinine Clearance (CrCl) were added to a model including the IWPC variables (added R^2 ~1 % per SNP, 0.4 % for CrCl), whereas smoking was not associated with dose. **Conclusions:** We verified the importance of VKORC1 and CYP2C9 for warfarin dose and the predictive value of the IWPC model for dose selection. We identified two novel SNPs in DDHD1 and NEDD4 affecting warfarin maintenance dose, but the incremental information provided by them and by adding Creatinine Clearance is probably limited. We also identified a SNP in ASPH associated with total TTR.

620T

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: A Genome-wide association study of quetiapine-induced weight gain derived from electronic medical records and outpatient pharmacy data. *N. Gonzaludo[1], S. Sciortino[2], L. Walter[2], N. Risch[3], P.Y. Kwok[3], C. Schaefer[2]*. 1) Dept of Bioengineering & Therapeutic Sciences, UCSF, San Francisco, CA; 2) Kaiser Permanente Northern California Division of Research, Oakland, CA; 3) Institute for Human Genetics, UCSF, San Francisco, CA.

Atypical antipsychotics are widely prescribed to treat schizophrenia, bipolar disorder, and other psychiatric conditions. Weight gain is a common side effect of many atypical antipsychotics and may contribute to the onset of diabetes and lipid disorders, along with increasing the likelihood of non-compliance. While previous studies have identified genetic factors underlying this phenotype, such studies have been limited to small sample sizes and primarily used candidate gene approaches. Since weight is commonly measured during patient visits, electronic medical records provide a means of capturing this side effect in a clinical setting across a larger and broader range of patients. As part of the Kaiser Permanente Research Program on Genes, Environment, and Health, 110,266 members have undergone genome-wide genotyping using Affymetrix Axiom technology. These subjects constitute the Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort. With data from this cohort, we are conducting a genome wide association study (GWAS) for weight gain induced by Seroquel (quetiapine), the most commonly prescribed atypical antipsychotic in the Kaiser Permanente Northern California system. Of the 110,266 subjects enrolled in the GERA cohort, 1,468 had been given at least one outpatient prescription of quetiapine in the past 10 years, with 677 patients on lower doses of quetiapine (100 mg or less daily). Of these patients, 441 had at least one weight and/or BMI measurement taken during a treatment period and at least two measurements taken up to one year prior. 48% of patients showed an increase in BMI, with a mean increase of 0.9 BMI. Of those that gained weight, 11% gained greater than 7% baseline BMI (5% over all patients). For these 441 patients, over 650K SNPs from the Axiom arrays were tested for an association with overall BMI gain using linear regression, as well as gain greater than 7% from baseline using logistic regression. Covariates for the association test included age, sex, prior atypical antipsychotic use, baseline BMI, and a diagnosis of Type 2 Diabetes. We compared our findings to known candidate genes for weight gain induced by atypical antipsychotics, including cytochrome P450 enzymes, drug targets, and energy homeostasis genes. Our study demonstrates the value of this resource for extracting robust phenotypic data and identifying genetic components underlying clinically observed drug response.

Genome wide association analysis of pain reduction in rheumatoid arthritis patients treated with anti-TNF medication. *M. Umicevic Mirkov[1], H. Scheffer[1], S. Krintel[2], S.H. Vermeulen[1, 3], J. Johansen[2], W. Kievit[4, 6], M.A.F. van de Laar[5, 6], P.C.L. van Riel[4, 6], B. Franke[1], M. Hetland[2], M.J.H. Coenen[1]*. 1) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 2) Department of Rheumatology, Copenhagen University Hospital, Glostrup, Denmark; 3) Department of Epidemiology, Biostatistics and HTA, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 4) Departments of Rheumatology, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 5) University Twente & Medisch Spectrum Twente, Enschede, Netherlands; 6) on behalf of the Dutch Rheumatoid Arthritis Monitoring registry.

Background Rheumatoid arthritis (RA) patients rate pain relief as the highest priority in treatment. Treatment strategies blocking tumor necrosis factor (anti-TNF) have proven very successful in pain reduction. Interestingly, recent research indicates that inflammation and pain pathways are important, partly independent, targets of anti-TNF. Therefore genetic factors predicting pain relief are important to personalize treatment of RA patients. **Objective** We aimed to identify genetic factors predicting pain reduction upon anti-TNF treatment in patients with RA using a genome-wide association approach. **Methods** We included 508 RA patients treated with anti-TNF agents from the Dutch Rheumatoid Arthritis Monitoring (DREAM) registry. Single nucleotide polymorphism (SNP) markers were genotyped using the Illumina HumanHap550-Duo or Human660W-Quad BeadChip. Association analysis using the Visual Analogue Pain Scale (VASpain) change 14 weeks after treatment initiation as outcome was performed on an imputed dataset under an additive genetic model with adjustment for base line VAS-pain. The top markers demonstrating association with VASpain change (p-value<10^{-3}) were selected for replication in 207 RA patients treated with anti-TNF from the Danish DANBIO registry. We performed a meta-analysis using METAL and pathway analysis using Ingenuity. **Results** 2,557,253 SNPs and 406 patients passed quality control. No findings reached the threshold for genome-wide significance (p-value≤1×10^{-8}) in the discovery cohort. Meta-analysis with the Danish sample led to the identification of three SNPs with a p-value <1×10^{-7}. These SNPs can be linked to functions that might involve pain processing in the brain and are located within or nearby *ATXN1*, a gene involved in the pathology of spinocerebellar ataxia type 1, a neurodegenerative disorder and *NRG3* which influences neuroblast proliferation, migration and differentiation. Pathway analysis, including all SNPs with a p-value<10^{-3} (n=2649) from the discovery cohort also point to the brain. The analysis shows that genes involved in neuritogenesis are overrepresented in our dataset (p=6.78×10^{-6}). In addition, six of the identified SNPs map to the α-adrenergic signaling pathway (p=6.16×10^{-4}), an important target for pain medication. **Conclusions** Significant findings will be replicated in a third patient population. Confirmed biomarkers can be used to personalize medication for the individual patient.

A Genome-Wide Association Analysis of Corticosteroid Response in Asthmatics. *Q. Duan[1], B.E. Himes[1,3], B. Schuemann[1], K.G. Tantisira[1,2], S.T. Weiss[1,3]*. 1) Channing Laboratory, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 2) Pulmonary Division, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 3) Partners Center for Personalized Genetic Medicine, Partners Health Care, Boston, MA.

Corticosteroids (CS) are the most widely used, anti-inflammatory treatment for controlling asthma, which affects approximately 300 million individuals worldwide and over 20 million Americans. However, great inter-individual variability in response to this class of drugs has been described, whereby up to 25% of patients are non-responsive. CS response is a complex trait that is partially regulated by genetic factors. In this study, the physiological response to CS is measured as a percent change in baseline FEV_1 (forced expiratory volume in one second) following 4 to 8 weeks of treatment with an inhaled CS. A genome-wide association study (GWAS) of this quantitative trait was performed in 702 non-Hispanic white asthmatic subjects from four asthma clinical trials: the Childhood Asthma Management Program (CAMP), the Leukotriene Modifier or Corticosteroid Salmeterol study (LOCCS), the Childhood Asthma Research and Education (CARE) network and the Asthma Clinical Research Network (ACRN). We used genotype data for CAMP and LOCCS from the Illumina 550K and 610K Beadarrays and imputed SNP data for ACRN and CARE (based on the 1000 Genomes Project) that had been genotyped on the Affymetrix 6.0 array. A total of 557,367 single nucleotide polymorphisms (SNPs) were tested for association with CS response using a linear regression model in PLINK with adjustments for age, sex, and height. Combined P-values were calculated using the Liptak's weighted Z method. Two of the top GWAS SNPs (P=3.17E-07 and 1.06E-05) were located in or near the *PLXDC1* gene, whose (RNA) expression has been previously correlated with asthma. Another of the top five SNPs (2.93E-06) flanks the *GALNT7* gene, the RNA expression of which has also been associated with asthma and SNPs at this locus, which regulate gene expression, have been previously associated with airway obstruction. Replication of these genetic associations is underway in white subjects from an adult asthma trial population previously ascertained by Forest Inc. In summary, this GWAS of CS response identified novel genetic loci associated with this variable drug response. Further replication analysis in independent asthma populations and functional characterization of the replicated loci is necessary to better understand the biological mechanisms underlying differential response to CS therapy. Funding sources: NHLBI R01 HL092197 and U01 HL65899.

MicroRNA-based approach expands on genome-wide association study and identifies SNPs important for response to glucocorticoids in asthma patients. *H. Im[1], E.R. Gamazon[2], D. Lenkala[2], K. Wu[2], G. Clemmer[3], S.T. Weiss[3], N.J. Cox[2], K. Tantisira[3], R.S. Huang[2]*. 1) Health Studies, University of Chicago, Chicago, Il; 2) Medicine, University of Chicago, Chicago, Il; 3) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston MA.

Our objective is to take a concerted translational effort to elucidate the genetic etiology of sensitivity to glucocorticoids (GCs), which are some of the most commonly used agents in treating inflammatory diseases. Our previous work demonstrated that by integrating gene expression into genome-wide association studies (GWASs), one can identify genetic variations that are functionally relevant to the phenotype of interest. Here we expanded this integrative genomic approach to include the use of genome-wide expression of microRNAs (miRNAs), a set of small non-coding RNAs that play an important role in diverse biological processes, and applied this approach to patients from the Childhood Asthma Management Program (CAMP), a randomized trial of asthma treatment. Utilizing a linear mixed effects model, we characterized the longitudinal phenotypic data (repeated measurement of FEV1, an indicator of lung function every 4 months for 4 years) from CAMP. The log ratio of the model-predicted FEV1 at baseline under budesonide (an inhaled GC) treatment and the observed FEV1 at baseline was used as the response phenotype of interest. Genome-wide SNP data were obtained from budesonide-treated subjects using Illumina 550K and 610K arrays. We found 12 SNPs that are associated with GC sensitivity at FDR<0.25. The most significantly associated SNP (p=2.8E-8) is also associated with the expression of 8 miRNAs, many of which have been implicated in airway function and inflammatory pathway. This study suggests that genetic variation may influence miRNA expression levels with important phenotypic effect on response to GC in asthma patients.

SLC9A9 variant as a novel biomarker of response to interferon beta: results from a pharmacogenetic study on Italian, US and French Multiple Sclerosis patients. *F. Martinelli Boneschi[1,2], F. Esposito[1,2], E. Lim[3,4], P. Brambilla[2], M. Sorosina[2], M. Romeo[1], M. Rodegher[1], N. Bohossian[5], N.A. Patsopoulos[6,7], B. Kenan[3,4], V. Martinelli[1], D. Brassat[5], G. Comi[1,2], P. De Jager[6,7]*. 1) Department of Neurology, Scientific Institute San Raffaele, Milan, Italy; 2) Laboratory of Genetics of Neurological Complex Diseases, CNS Inflammatory Unit, Institute of Experimental Neurology, Scientific Institute San Raffaele, Milan, Italy; 3) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, MA; 5) University of Toulouse, Toulouse, France; 6) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Department of Neurology, Brigham & Women's Hospital, Boston, MA; 7) Harvard Medical School, Boston, MA.

Background: Despite the broad variety of drugs approved for multiple sclerosis (MS), a large proportion of patients still experience the persistence of clinical and MRI disease activity while on treatment. The early identification of the most effective MS treatment in individuals is critical to impact the long-term outcome and to move toward a more personalized approach in MS. Objective: to identify genetic variants able to predict the response to interferon beta (IFNb). Materials and methods: A cohort of Italian relapsing-remitting (RR) MS patients treated with IFNb for at least 6 months and with a 2-year follow-up were enrolled in the study. The response to IFNb was assessed using clinical and MRI measures that correlate with disease activity. A genome-wide association study was performed to compare responders vs non-responders. The top genetic variant was replicated in three independent collections of US, Italian and French patients. Results: The rs9828519^{G} allele is associated with an increased risk of non-response to IFNb therapy in the Italian MS patients (p-value=4.43×10^8). The proportion of non-responders increases for each additional copy of the G allele that is carried, suggesting an additive effect. The same allele and the same direction of effect were confirmed in an independent collection of US MS samples (p-value=5.97×10^4). On the contrary, the genetic variant did not appear to influence the response to glatiramer acetate in the US dataset (p-value= 0.14). The same direction of effect was observed also in additional Italian and French patients, even if the results were not statistically significant within each dataset. A meta-analysis across the 4 different datasets confirmed the effect of the rs9828519 (p-value=8.39×10^7). Rs9828519 is intronic to SLC9A9, which has been recently reported to impair protein sialinization. Conclusions: Rs9828519^{G} affects the response to IFNb but not to glatiramer acetate, suggesting that this genetic variant would be a predictive marker of non-response to IFNb. Functional studies are ongoing, in order to provide further evidence of the effect of this variant on influencing the alternative splicing of the gene and to explain its effect on IFN treatment response.

Polygenic Heritability Estimates of Asthma and Treatment-Related Phenotypes. *M.J. McGeachie[1,2,3], E.A. Stahl[3,4,5], B.E. Himes[1,2,3], S.A. Pendergrass[6], M.D. Ritchie[6], R.M. Plenge[3,4,5], K.G. Tantisira[1,2,3]*. 1) Channing Laboratory, Dept of Medicine, Brigham and Women's Hospital, Boston, MA; 2) Partners Healthcare Center for Personalized Genetic Medicine, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Division of Rheumatology, Immunology and Allergy, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 5) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 6) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA.

BACKGROUND. We estimated the heritability of pharmacogenetic phenotypes related to asthma, including bronchodilator response, steroid response, airway hyperresponsiveness, and also asthma itself, using the polygenic linear mixed modeling approach of Yang et al. (2010). This method estimates the contribution of additive SNP effects to phenotype variance for genotypic data from existing asthma cohorts (ACRN, CARE, CAMP, LOCCS, LODO, and Sepracor). This method has previously been successfully applied to estimates of the genetic contribution to human height, schizophrenia, Crohn's disease, and type I diabetes, among others. RATIONALE. Our analyses address two important issues for elucidating the connection between genes and etiology of asthma through providing evidence that the heritability in asthma is due to simple additive effects of SNPs and through identifying substantial genetic components contributing to variance in bronchodilator response and airway hyperresponsiveness. METHODS. Bronchodilator response (BDR) was measured by FEV1 change before and after the administration of a bronchodilator (albuterol); where BDR was defined as the change in FEV1 as a percentage of the pre-bronchodilator FEV1. Bronchoconstriction was assessed by methacholine challenge and measured by the log provocative concentration of methacholine resulting in a 20% decrease in airway capacity, measured by FEV1 (PC20). GWAS data was available for each population. RESULTS. We obtained estimates of heritability for bronchodilator response of 28.5% (n = 1497, p = 0.043) and airway hyperresponsiveness of 51.5% (n = 1054, p = 0.064). This corresponds with previously published heritability estimates based on intraclass correlation coefficients of 40% and 67%, respectively. The asthma liability due to additive SNP effects was found to be 61.5% (n = 2633, p < 0.001), corresponding with asthma twin studies that have put the total heritability between 70% and 90%. We note that 13 recent SNPs robustly identified through asthma GWAS meta-analyses (the GABRIEL and EVE consortia) account for no more than 1% of asthma liability. CONCLUSIONS. These results indicate that a very substantial fraction of the heritability of these conditions are due to simple SNP main-effects, and that a polygenic approach can be a key tool in better identifying the combined effect of multiple variants on complex phenotypic outcomes.

626T

Web-based phenotyping yields replication of genetic associations with sensitivity to warfarin. *J.L. Mountain[1], A.K. Kiefer[1], M. Mullins[1], T.K. Acquaye[1], C.B. Marsh[2], J.A. Johnson[3], H.L. McLeod[4], J.Y. Tung[1], N. Eriksson[1], K.E. Barnholt[1].* 1) 23andMe, Inc, Mountain View, CA; 2) College of Medicine, The Ohio State University, Columbus, OH; 3) Department of Pharmacotherapy and Translational Research, University of Florida, Gainesville, FL; 4) Eshelman School of Pharmacy, University of North Carolina, Chapel Hill, NC.

Progress in pharmacogenomics research has been hampered by the cost and time required to assemble, assess, and genotype sufficiently large cohorts of patients. 23andMe's innovative research platform leverages involvement of a large and expanding cohort of over 150,000 genotyped individuals who have the option to respond to web-based questionnaires on an ongoing basis. The primary goal of this study is to develop, assess and implement web-based surveys for the rapid collection of drug response and toxicity data from thousands of individuals taking three classes of medication: warfarin, proton pump inhibitors (PPIs), and non-steroidal anti-inflammatory drugs (NSAIDs). In the first phase of this two-part study we assessed how well web-based questionnaires elucidate drug response data by comparing online self-reported data to responses obtained via semi-structured telephone interviews. Web-based surveys performed well in terms of obtaining medication response and side effects information. Test-retest reliability for most questions was high (>70%). Reporting for prescription medications taken currently proved more reliable than for medications taken in the past and for medications taken as needed. The second phase of this project is focused on validation of known associations between warfarin sensitivity and variants in the CYP2C9 and VKORC1 genes, between reactions to NSAIDs and variants in the CYP2C9 gene, and between reactions to PPIs and variants in the CYP2C19 gene. In our first analysis we examined warfarin sensitivity and CYP2C9 and VKORC1 genotypes in 1028 individuals who had taken or were taking warfarin. A test of association between reported warfarin sensitivity and sensitivity predicted on the basis of combinations of CYP2C9 (rs1057910, rs1799853) and VKORC1 (rs9923231) variants indicated borderline significance. A more detailed analysis revealed highly significant associations between self-reported dosage and rs1799853 and rs9923231, along with a near significant association with rs1057910. These initial results provide independent evidence that web-based surveys can yield drug response data of sufficiently high quality to enable highly scalable pharmacogenomics studies. The final phase of this project will leverage 23andMe's customized genotyping chip to test for novel genes associated with drug metabolism, efficacy, and toxicity. This study is funded in part by NIH grant 1R43HG005807-01.

Follow-up study of genetic risk factors for carbamazepine-induced cutaneous adverse drug reactions in Japanese population. *T. Ozeki[1], T. Mushiroda[1], A. Takahashi[2], M. Kubo[3], Y. Shirakata[4], Z. Ikezawa[5], M. Iijima[6], T. Shiohara[7], K. Hashimoto[4], Y. Nakamura[1].* 1) Research Group for Pharmacogenomics, RIKEN Center for Genomic Medicine, Yokohama, Japan; 2) Research Group for Medical Informatics, RIKEN Center for Genomic Medicine, Yokohama, Japan; 3) Research Group for Genotyping, RIKEN Center for Genomic Medicine, Yokohama, Japan; 4) Department of Dermatology, Ehime University Graduate School of Medicine, Ehime, Japan; 5) Department of Dermatology, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 6) Department of Dermatology, Showa University School of Medicine, Tokyo, Japan; 7) Department of Dermatology, Kyorin University School of Medicine, Tokyo, Japan.

An anticonvulsant, carbamazepine (CBZ), is known to show incidences of cutaneous adverse drug reactions (cADRs) including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN) and drug-induced hypersensitivity syndrome (DIHS). Previously, to identify a gene(s) susceptible to CBZ-induced cADRs, we conducted a genome-wide association study (GWAS) and following HLA typing in 61 cases and 376 patients who showed no cADRs by administration of CBZ (CBZ-tolerant controls), and found that HLA-A*31:01 was present in 60.7% (37/61) of the patients with CBZ-induced cADRs, but in only 12.5% (47/376) of the CBZ-tolerant controls (odds ratio (OR) = 10.8, 95% confidence interval (CI) = 5.9–19.6, $P = 3.64 \times 10^{-15}$). To validate the significant associations of HLA-A*31:01, we performed a replication study using an independent Japanese case-control subjects which consisted of 42 CBZ-induced cADR cases and 46 CBZ-tolerant controls. The association of HLA-A*31:01 was replicated in the second subjects ($P = 2.73 \times 10^{-6}$, OR = 10.0, 95% CI of 3.6–27.9; combined-analysis $P = 2.35 \times 10^{-23}$, OR = 11.2, 95% CI of 6.9–18.3), implying that this allele has the 62.1% sensitivity and 87.2% specificity when we apply HLA-A*31:01 as a risk predictor for CBZ-induced cADRs. We further analyzed the association of HLA-A*31:01 according to the type of cADR using the combined subjects. HLA-A*31:01 showed significant associations with DIHS ($P = 6.20 \times 10^{-15}$, OR = 14.6, 95%CI of 7.3–29.2) and SJS/TEN ($P = 2.30 \times 10^{-4}$, OR = 34.1, 95%CI of 3.9–297.2) as well as other cADRs ($P = 3.54 \times 10^{-11}$, OR = 8.2, 95%CI of 4.5–15.2), respectively. For a conditional logistic regression analysis of the GWAS data, we selected rs1633021 as the covariant with the firmest association observed in the analyzed GWAS peak of association. After the conditional analysis, there was no SNP that reached GWAS-level significant association.

Re-examination of the CATIE pharmacogenetics whole-genome dataset using a run of significiant findings approach, focus on tardive dyskinesia. *C. Zai, V. Gonçalves, A. Tiwari, G. Oh, V. de Luca, D. Mueller, J. Knight, J. Kennedy.* Dept Neurogenetics, CAMH, Toronto, ON, Canada.

Introduction: Tardive dyskinesia (TD) is a serious, potentially irreversible motor side effect that arises in patients treated long-term with typical antipsychotic medication. Over 15 years of genetic research into this debilitating condition has revealed a number of candidate genes for TD, including DRD2. A number of genome-wide association studies have been conducted recently, but none gave genome-wide significant findings. Even the most significant markers did not replicate between the two GWAS on the same data from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE). Aim: We aim to search for markers that are independent of one another within and around genes that may contribute to the risk of tardive dyskinesia. Methods: We propose to screen for runs of significant findings ($p<0.05$) in the CATIE sample using PLINK and R. After quality control and multidimensionality scaling (MDS) analysis for population stratification, we pruned the number of variants based on r-square value of 0.80. We then performed linear regression analysis on baseline total Abnormal Involuntary Movement Scale AIMS) on 385 European schizophrenia patients diagnosed with schizophrenia, including sex, age, and years of antipsychotic medication as covariates. Results: Using sliding window sizes of 10, and the criterion of a minimum of seven SNPs with $p<0.05$ within each window, we identified 76 windows of significant markers that correspond to 26 overlapping chromosomal regions for total AIMS scores. We performed 1000 permutations of the results and found only four of the permutations gave more runs that our actual AIMS data (thus $p=0.005$). A number of genes from this analysis have been implicated in ataxia (RGS6) and Bell's palsy (CSGALNACT1), suggesting that variants in these genes may contribute to part of the pathophysiology of schizophrenia and tardive dyskinesia. Discussion: This analytic approach may complement current GWAS analysis strategies in identifying novel candidate genes for complex phenotypes. We will conduct similar analysis on the individual AIMS item scores to explore whether these associations may be more specific for orofacial or limb dyskinesia.

A Bayesian Approach to Genome-Wide Genetic Association Studies with Survival Time as Outcome. *L. Chien[1], I. Chang[2], C. Hsiung[3].* 1) Institute of Statistics, National Tsing-Hua University, Hsinchu, Taiwan; 2) National Institute of Cancer Research, National Health Research Institutes, Taiwan; 3) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Taiwan.

Time to progression or overall survival is a widely used outcome variable to evaluate the treatment response in many complex disease research, including cancer. In addition to candidate gene approach, there are genome-wide association studies to look for regions in the genome that harbor genes influencing this outcome variable. Such genetic associations can be used to provide insight into relevant biological pathways or to help guide clinical care in a more personalized manner. It is well-known that clinical traits like survival time are often influenced by many variables, including epigenetic modifications, somatic mutations, genetic variants, etc.; in particular, pharmacogenomics of anticancer agents are complex because genetic variations in both host and tumor genomes are involved in determining anticancer effects of medications. It is therefore of interest to estimate the proportion of variability in the outcome variable that can be explained by the (common) SNPs in a GWAS study, in addition to looking for their associations with survival time. With these in mind, we propose a Bayesian variable selection method for survival models so that survival analysis with covariates the genotype data from a GWAS will shed light on the proportion of variance explained (PVE) by the common SNPs, the sparsity of the model and the effect size of the selected SNPs. We follow the approaches in Guan and Stephens (2011) to consider prior that uses the concept of PVE and to design MCMC algorithms for posterior inferences. Simulation studies will be provided to indicate the numerical performance of this method and compare it with single SNP analysis method. In particular, we will examine if PVE can be satisfactorily studied. Illustrations by a real dataset will be included.

***IL28B* Genotypes Associated with IFN-Induced Virologic Response in Clinical Studies Evaluating Eltrombopag Treatment in HCV-infected Patients with Low Platelet Counts.** *M. Chiano[1], L. Condreay[2], L. Briley[2], D. Pulford[1], D. Fraser[2], K. Johansson[2], D. Briley[2], E. Harris[2], S. Bhatti[1], D. Theodore[3], F. Campbell[4], S. Vasey[5], M. Arning[5], C. Spraggs[1].* 1) GlaxoSmithKline, Quantitative Sciences, Stevenage, UK; 2) GlaxoSmithKline, Quantitative Sciences, Research Triangle Park, NC, USA; 3) GlaxoSmithKline, Oncology, Research Triangle Park, NC, USA; 4) GlaxoSmithKline, Stockley Park, UK; 5) GlaxoSmithKline, Upper Providence, PA, USA.

Eltrombopag (PROMACTA™) is a thrombopoietin receptor agonist for treating thrombocytopenia in patients with chronic immune (idiopathic) thrombocytopenic purpura. We conducted two clinical studies investigating the utility of eltrombopag to increase platelet counts in thrombocytopenic patients with chronic hepatitis C virus (HCV) infections to enable initiation and maintenance of antiviral therapy with pegylated interferon alfa (2a or 2b) and ribavirin (IFN/RBV). Clinical benefit in these studies was measured by the proportion of subjects who achieved Sustained Virologic Responses (SVR). *IL28B* genotypes predict spontaneous HCV clearance and virologic response to IFN/RBV treatment. We evaluated the impact of *IL28B* variants, rs8099917 and rs12979860, in a large cohort of thrombocytopenic patients with HCV (N= 906), White (n=689) and Asian (n=217), treated with open-label eltrombopag and randomized to eltrombopag plus IFN/RBV or placebo plus IFN/RBV. Association with SVR, Rapid (RVR), and Early (EVR) Virologic Response was tested using logistic regression assuming a recessive genetic model. Overall, the proportion of subjects achieving virologic response was significantly higher in subjects receiving eltrombopag and IFN/RBV than in subjects randomized to Placebo and IFN/RBV. Markers rs12979860 and rs8099917 were each significantly associated with virologic response ($p<0.001$). The effect of rs12979860 conditional on rs8099917 remained strongly associated with virologic responses ($p<0.001$), but modelling the effect of rs8099917 conditional on rs12979860 was no longer statistically significant ($p>0.05$). The joint effect of both markers did not provide a significant improvement to the model fit. Therefore, rs12979860 provides a more parsimonious genetic predictor for virologic responses in these data. The rs12979860 `CC' genotype carriers had significantly higher virologic responses compared to subjects that carried one or no copy of this allele (response [OR, p-value]: SVR [3.6, 5.1×10^{-10}], RVR[4.0, 1.62×10^{-8}] and EVR [3.5, 1.08×10^{-12}]). The effect of IL28B genotype was stronger in white than in Asian subjects and in patients with viral genotypes known to be less responsive to IFN/RBV treatment. The distribution of IL28B genotypes was balanced across treatment groups and across ethnic subgroups, so the efficacy of eltrombopag treatment in these studies cannot be attributed to an imbalance in the distribution of the *IL28B* favourable response genotype.

Mapping the Incidentalome: Quantifying Incidental Findings Generated Through a Clinical Pharmacogenomics Project. *K.B. Brothers[2], M.J. Westbrook[1], M.F. Wright[1], S.L. Van Driest[3], T.L. McGregor[3,4], J.C. Denny[5], R.L. Zuvich[4], E.W. Clayton[1,3].* 1) Center for Biomedical Ethics and Society, Vanderbilt University, Nashville, TN; 2) Pediatrics, University of Louisville, Louisville, KY; 3) Pediatrics, Vanderbilt University, Nashville, TN; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 5) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN.

The use of multiplex genetic technologies in routine clinical care is becoming increasingly feasible. Empirical data on the numbers and types of incidental findings generated are needed so that policies and practices for their clinical use can be developed. PREDICT is an institutional program to implement prospective clinical genotyping of 34 genes to guide drug selection and dosing. Using a combination of computer and hand-based curation, we reviewed 5566 journal articles to quantify and characterize the incidental, non-pharmacogenomic genotype-phenotype associations that could be generated by this panel. We found 383 putative associations supported by at least one study demonstrating a positive association, defined as an odds ratio with a 95% confidence interval that does not cross 0. Of these, 292 are supported by at least one study showing a significantly elevated risk (odds ratio ≥2.0 or ≥0.5). Patients with certain variants in GSTM1 could carry a significant risk for over 40 phenotypes. Other patients may carry no high-risk variants for these 34 genes.

CategoryDefinitionGenotype-Phenotype Associations Replicated≥2 positive findings, 0 negative findings14No Replication Attempts1 positive finding, 0 negative findings97Mixed Findings≥1 positive findings, ≥1 negative findings272**Total383**

Some patients could receive an overwhelming number of results. Careful practices for managing incidental findings are needed.

The Coriell Personalized Medicine Collaborative Pharmacogenomics Appraisal and Evidence Scoring Sytem. *N. Gharani, M.A. Keller, C.A. Stack, T.J. Schmidlen, R.S. Kasper, J.P. Jarvis, N.P. Gerry, E.S. Gordon, M.F. Christman.* Coriell Institute for Medical Research, Camden, NJ.

The incorporation of pharmacogenomics (PGx) into drug therapy is anticipated to improve drug efficacy and reduce adverse drug reactions. However, there has been a lag in the adoption of PGx in clinical practice due, in part, to a lack of rigorous systems for translating published PGx data into standardized diagnostic tests with clear therapeutic recommendations. The Coriell Personalized Medicine Collaborative (CPMC) is a prospective observational study designed to evaluate the utility of personalized genomic information in health management. In this research context, PGx results are included based on the CPMC pharmacogenomics appraisal and evidence scoring (PhAES) system. The PhAES system is drug-centric, utilizes a multi-tiered evidence scoring procedure to define key genetic variants influencing variation in drug response, involves oversight by an external advisory committee, and presents guidelines for the translation of genetic results into anticipated drug response outcomes. The evidence score, assigned to each variant in a given gene, consists of 14 categories ranging from the strongest evidence (presence of *in vivo* clinical data for the drug under review) to the weakest (e.g. identification of the variant through a gene sequencing study with no additional *in vivo* or *in vitro* functional data). Scores less than seven indicate a defined effect on drug response or clinical outcome while those greater than eight represent a lack of sufficient evidence for an effect. Once identified, a Punnett square is used to pair the key genetic variants in all possible diploid combinations; published guidelines or empirical data are then used to present drug-specific genotype-phenotype interpretations for each of the anticipated genetic results. Key to the CPMC PhAES process is the use of an external expert advisory panel known as the Pharmacogenomics Advisory Group (PAG). The PAG evaluates PhAES results for each drug-gene pair proposed for inclusion in the CPMC study and provides an independent and expert vetting process that further validates the inclusion of each variant for use in the CPMC clinical utility study. This systematic approach for evaluating and translating published PGx data is likely to have broad utility in facilitating the adoption of PGx into clinical practice.

PharmGKB: From pharmacogenomics knowledge to clinical interpretation and implementation. *L. Gong[1], M. Whirl-Carrillo[1], J.M. Hebert[1], E.M. McDonagh[1], K. Sangkuhl[1], C.F. Thorn[1], D. Klein[1], R.B. Altman[1,2], T.E. Klein[1]*. 1) Department of Genetics, Stanford University 1501 S. California Avenue Palo Alto, California 94304; 2) Department of Bioengineering, Stanford University, Stanford, CA.

The PharmGKB is a publically available online database that provides knowledge about the impact of genetic variation on drug response. We have comprehensive catalog of genes and genetic variations that are most important for drug response (many directly linked to drug efficacy and toxicity), and have presented condensed knowledge in the forms of drug pathway diagrams and Very Important Pharmacogene (VIP gene) summaries. As the field advances, our focus has shifted towards facilitating clinical interpretation and implementation of pharmacogenomics discoveries. The recent redesign of our home page and development of specialized translational tools has enabled us to provide clinical interpretations of pharmacogenetic knowledge, including genotype-guided dosing guidelines, potentially clinically actionable gene-drug associations, FDA drug labels and genetic testing information. In addition to providing knowledge and tools that are critical for bridging the gap between bench and clinic on our website, the PharmGKB is host to several large international consortia groups who are carrying out pharmacogenetics research to answer important questions. PharmGKB also contributes to clinical implementation projects to through collaborations and participates in developing methods and tools for clinical interpretation of personal genomes. We will demonstrate available resources on PharmGKB to support clinical implementation of PGx and also discuss key success factors and challenges of our approaches in bringing the pharmacogenomics knowledge to clinic. The PharmGKB is freely available through the http://www.pharmgkb.org/ website.

Development of a scoring tool to prioritize clinical pharmacogenomic testing. *S.F. Manzi.* Gene Partnership, Children's Hospital Boston, Boston, MA.

A scoring tool was developed to assist in the process of prioritizing drug/gene pairs for clinical implementation of pharmacogenomic testing. The provision of clinical interpretation of genotype data in the electronic medical record (EMR) along with decision support at the point of ordering and dispensing is complex and requires resources to build and implement. Once the capability to provide pharmacogenomic testing with EMR decision support becomes publicized, an increasing number of requests for testing for a specific service or patient population are filed. Competing demands for IT support, balancing the needs of a single patient population for whom the information will be critical against the needs of many for whom the information will be important, providing a comprehensive test, and ensuring cost containment are some of the many factors that we incorporated into the tool. Additionally, factors such as commercial availability of the test, published knowledge base tools and guidelines and the projected utilization were also included. The tool was designed from review of the available literature and revised based upon input from our Clinical Pharmacogenomics Service Oversight committee members. We will demonstrate a use case for the tool via an example of prioritizing between TPMT genotyping for mercaptopurine use in Acute Lymphoblastic Leukemia (ALL) and *cyp2D6* genotyping for opioid drugs in acute pain management. The overall score for *TPMT* (thiopurine S-methyltransferase) genotyping was 27 points compared with a score of 20 points for *cyp2D6* (cytochrome P450, family 2, subfamily D, polypeptide 6) genotyping. The major dissenting areas included delayed toxicity (present for thiopurines, not present for opioids), overlapping toxicities with concomitant agents (present for thiopurines, not present for opioids), frequency of use (limited for thiopurines, extensive for opioids) and the commercial availability of a comprehensive test at the time of evaluation (present for *TPMT*, not present for *cyp2D6*). To our knowledge, no other decision tool designed to assist with prioritization of movement of drug/gene pair data from research to the clinical realm has been published. We will demonstrate the tool and scores relevant to our program.

Pharmacogenomic research undertaken by PharmGKB consortia groups. *E.M. McDonagh[1], M. Whirl Carrillo[1], L. Gong[1], J.M. Hebert[1], K. Sangkuhl[1], C.F. Thorn[1], D. Klein[1], R.B Altman[2], T.E. Klein[1]*. 1) Genetics Department, PharmGKB, Stanford University, Palo Alto, CA; 2) Bioengineering Department, Stanford University, Stanford, CA.

The Pharmacogenomics Knowledge Base (PharmGKB) is a comprehensive online database of associations between genetic variants and drug responses for clinicians and researchers (www.pharmgkb.org). The PharmGKB is also host to numerous international research consortia groups that are investigating important questions in the field of pharmacogenetics. The data-led consortia hosted by the PharmGKB aim to combine clinical and genotyping data from cohorts at multiple centers around the world to gain large data sets for analysis of associations between genetic variants and drug responses. The International Warfarin Pharmacogenetics Consortium - Genome Wide Association Studies (IWPC-GWAS) are combining GWAS data from different cohorts to identify novel genetic variants that are important for warfarin dosing, following work published by the IWPC combining genetic and clinical information into a warfarin-dosing algorithm. The International Tamoxifen Pharmacogenomics Consortium (ITPC) are investigating the association between CYP2D6 gene variants and efficacy and toxicity of tamoxifen, a breast cancer therapy. The International SSRI (Selective Serotonin Reuptake Inhibitors) Pharmacogenomics Consortium (ISPC) aims to identify genetic variants that affect responsiveness to SSRI antidepressant therapy. The goal of the recently formed International Clopidogrel Pharmacogenomics Consortium (ICPC) is to identify novel variants involved in clopidogrel response as well as further dissecting the role of CYP2C19 gene variants. Information and publications by the data-led consortia groups can be found at www.pharmgkb.org. PharmGKB has collaborated with the Pharmacogenomics Research Network (PGRN) to create the Clinical Pharmacogenetics Implementation Consortium (CPIC), a knowledge-based consortium of pharmacogenomic experts. CPIC publishes genotype-based drug dosing guidelines that provide guidance to clinicians who have access to preemptive genotyping results. Guideline summaries, updates and downloadable pdf files of the CPIC publications are available on PharmGKB. The consortia hosted by the PharmGKB are investigating important questions to further pharmacogenomics knowledge and contribute to the implementation of pharmacogenomics in the clinic.

636T

Effects of *CYP2C9* and *VKORC1* polymorphisms on clinical outcomes and warfarin response - focusing on personalized medicine. *P.C.J.L. Santos[1], R.A.G. Soares[1], C.M.C. Strunz[2], J.E. Krieger[1], A.C. Pereira[1]*. 1) Laboratory of Genetics and Molecular Cardiology, Heart Institute, University of Sao Paulo Medical School, Sao Paulo, SP., Brazil; 2) Clinical Laboratory, Heart Institute (InCor), University of Sao Paulo Medical School, Sao Paulo, Brazil.

Background: Warfarin therapy can be challenging because of the wide variation on inter-individual response which have been related to *CYP2C9* and *VKORC1* polymorphisms. Nowadays, a study incorporating clinical efficacy data of genotype-guided dosing algorithm has shown that warfarin pharmacogenetic would improve quality-adjusted life years gained. Aim: In this context and as an initial step towards clinical pharmacogenetic implementation, the main aim of this study was to evaluate the effects of *CYP2C9* and *VKORC1* polymorphisms on clinical outcome and warfarin response in patients from a cardiovascular center. Methods: Nine hundred thirty patients receiving warfarin therapy from Heart Institute (InCor), Sao Paulo, Brazil were selected. They were assessed for general and clinical characteristics, warfarin prescribed dosage and INR (international normalized ratio). Genotypes for the *CYP2C9*2* (430C>T, rs1799853), *CYP2C9*3* (1075A>C, rs1057910) and *VKORC1* 3673 (1639G>A, rs9923231) polymorphisms were performed. Results: Of the 930 patients (mean age 61.8±14.1), 50.5% were female, 67.0% were White, and the main indications of treatment were atrial fibrillation and heart valves. In patients who had two consecutive target INR values, warfarin dose was associated with predicted metabolic phenotypes according to *CYP2C9*2* and *CYP2C9*3* (extensive metabolizer (EM): 30.2±0.6 mg/week and intermediate or poor metabolizers (IM+PM): 26.0±0.7 mg/week; p< 0.001), and with *VKORC1* polymorphism (GG: 33.0±0.7 mg/week, GA: 26.3±0.6 mg/week, AA: 22.1±1.3; p< 0.001). Both *CYP2C9* and *VKORC1* polymorphisms were associated with the current INR value/current dose ratio. All tests were adjusted for age, gender, body mass index, and “race/color”. Patients carrying IM+PM had higher outcomes frequencies (mainly bleeding) compared to EM (30.8% and 21.6%, p= 0.003). However, no association of the *VKORC1* polymorphism with outcomes was observed. Conclusions: Our findings from a cardiovascular patient group reaffirm the influence these markers on clinical outcomes and warfarin response. In this scenario, a next step should be creating a genotype-guided dosing program selecting a contemporary control patient group to check the true cost-effectiveness of this individualized pharmacotherapy.

Performance of a biomarker risk algorithm for a primary prevention trial of Alzheimer's disease. *M.W. Lutz[1,2], D.K. Burns[1], D.G. Crenshaw[1,2], A.M. Saunders[1,2], A.D. Roses[1,2].* 1) Zinfandel Pharmaceuticals, P.O. Box 110395, Durham, NC, 27709; 2) Department of Neurology, Duke University School of Medicine, Durham, NC, 27705.

Genetic biomarkers and predictive models are increasingly being proposed for clinical trial enrichment. These models vary greatly in terms of the number of input variables, structure (algorithmic or statistical basis) and validation criteria. For prediction of the onset of mild cognitive impairment due to Alzheimer's disease, models based on genetic variants (in APOE, TOMM40), CSF-related or blood biomarkers (Aβ1-42, total tau), and imaging-related biomarkers (e.g., hippocampal atrophy measured by MRI) have been proposed. This presentation presents preliminary data on the predictive value of a biomarker risk algorithm based on age and two genetic variants: APOE genotype and TOMM40 '523 genotype. A biomarker risk algorithm has been developed to enrich a double-blind, delay-of-onset clinical trial of the efficacy of pioglitazone, a thiazolidinedione used for the treatment of Type 2 diabetes, to delay the onset of mild cognitive impairment due to Alzheimer's disease. The algorithm will be used to stratify subjects with normal cognition, as determined by a battery of neuropsychological tests, into either a high- or a low-risk group. The algorithm has been designed to allow enrichment to be applied in a reproducible manner across the ages of 68–83 years. In an independent (not used in algorithm development) cohort of 660 subjects (mean age 77 years, range 68–90 years) obtained from the Alzheimer's Neuroimaging Initiative, use of the biomarker risk algorithm was calculated to have a positive predictive value (PPV) of 79% (75–83%, 95% CI). These results compared favorably to the use of a CSF biomarker based on the combination of Aβ1-42 and total tau, which provided a PPV of 65% (53–77%, 95% CI) in a recent meta-analysis. These CSF markers were recently qualified by the European Medicines Agency for selecting patients in the context of a clinical trial. The genetic biomarker risk algorithm will be qualified for potential use as a companion prognostic biomarker at the end of the phase 3 trial when the PPV and negative predictive value (NPV) of the biomarker risk algorithm can be calculated. Use of an enrichment strategy in the context of a clinical trial allows for significant reductions in both the numbers of study subjects required and, in the case of a delay-of-onset study, trial duration.

A Study of Asthma Pharmacogenomics Using RNA-Seq. *B.E. Himes[1,2,3], R. Hu[4], P. Wagner[4], D. Chan[2], B. Klanderman[2], R.A. Panettieri Jr[5], K. Tantisira[1], S.T. Weiss[1,2], Q. Lu[4].* 1) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Partners Center for Personalized Genetic Medicine, Harvard Medical School, Boston, MA; 3) Children's Hospital Informatics Program, Boston, MA; 4) Program in Molecular and Integrative Physiological Sciences, Department of Environmental Health, Harvard School of Public Health, Boston, MA; 5) Pulmonary, Allergy and Critical Care Division, University of Pennsylvania, Philadelphia, PA.

Asthma is a chronic inflammatory airway disease with well-established heritability that affects over 300 million people around the world. The most common medications used for the treatment of asthma are β2-agonists and glucocorticosteroids, and one of the primary tissues that these drugs target in the treatment of asthma is the airway smooth muscle. RNA-Seq is a high-throughput sequencing method that provides comprehensive expression analysis, including discovery of novel genes, non-coding transcripts, and splice variants. We sought to use RNA-Seq to characterize the human airway smooth muscle (HASM) transcriptome at baseline and under three asthma treatment conditions. The Illumina TruSeq assay was used to prepare RNA-seq libraries for HASM cells from four white male donors under four conditions: 1) no treatment; 2) treatement with a β2-agonist (i.e. albuterol, 1μM for 18h); 3) treatment with a glucocorticoid (i.e. dexamethasone, 1μM for 18h); 4) simultaneous treatment with a β2-agonist and glucocorticoid. Preliminary data based on reads sequenced by an Illumina Genome Analyzer 2, aligned to the human reference hg19 using TopHat, and further analyzed using Cufflinks and CummeRbund suggest that several novel genes, including C12orf12, C16orf3, IGLJ4, KIAA1199, NUDT4, and RTN4 are involved in HASM response to asthma medications. Our results provide a transcriptomic snapshot of the effects of the most common asthma medications in HASM cells and have the potential to improve our understanding of asthma pharmacogenomics.

Genetic Moderators of Treatment Response to Methylphenidate and Guanfacine in Children and Adolescents with ADHD. *E.L. Nurmi, K.S. Mallya, F. Whelan, C.P. Laughlin, J.J. McGough, S.K. Loo, R.M. Bilder, J.T. McCracken.* Dept of Psychiatry, Univ of California at Los Angeles, Los Angeles, CA.

Background: Methylphenidate and guanfacine are effective treatments of hyperactive and inattentive symptoms associated with attention-deficit hyperactivity disorder (ADHD); however, variability in individual treatment response is substantial. We sought to determine whether genetic variation in monoamine drug targets could help explain differential treatment outcomes in a double-blind, randomized, placebo-controlled trial of dexmethylphenidate (d-MPH) and guanfacine in pediatric ADHD (n=209). Methods: Complete common variation in dopaminergic and adrenergic drug targets was tested, including dopamine (DA) receptors DRD1–5, α2-adrenergic receptor 2A (ADRA2A), and catabolic enzymes MAOA and MAOB. Single functional variants in the DA transporter (SLC3A6) and catabolic enzyme catechol-o-methyltransferase (COMT) were also genotyped. Results: In children receiving d-MPH, DRD2 and ADRA2A SNPs predicted treatment response. None of the 7 homozygotes for the minor allele of a synonymous variant (His313His, rs6275) met responder criteria, compared to an 80% response rate in 47 common allele carriers (p=0.0001). The minor (low expression) allele of the DRD2 Taq1A variant (rs1800497) was associated with an allele dosage-dependent improvement in both the d-MPH group and the d-MPH and guanfacine combined group (p=0.001). Furthermore, haplotypes of these 2 DRD2 SNPs showed differential effects on treatment response (p=0.0017). The minor allele of an ADRA2A promoter SNP (rs521674) was associated with poor d-MPH response (p=0.0004). Homozygotes for the minor alleles of functional variants in DRD1 (rs686) and DRD2 (rs2075654) predicted guanfacine response (p<0.0001). Conclusions: Common genetic variation in dopaminergic and adrenergic receptors influenced treatment response to standard ADHD drug therapies in our dataset. These results survive correction for multiple testing but warrant replication in larger samples and prospective treatment studies. Understanding pharmacogenetic moderators of ADHD treatment response such as these could improve clinical treatment matching and guide the design of future therapeutics. Supported by P50 MH077248.

Identifying genes that influence acute ethanol responsive behaviors in *Caenorhabditis elegans*. *J.T. Alaimo, A.G. Davies, J.C. Bettinger.* Pharmacology and Toxicology, Virginia Commonwealth University, Richmond, VA.

Alcohol abuse and alcohol addiction are serious and common illnesses that are strongly influenced by genetics. One factor influencing liability for alcohol dependence in humans is functional variation in genes encoding ethanol metabolism machinery, alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) (Pautassi et. al, 2010). We directly tested the effects of altering the function of these enzymes on ethanol responsive behaviors in *C. elegans*. We tested two ADH enzymes encoded by the genes *sodh-1* and *H24K24.3*, and found that loss of *sodh-1* but not *H24K24.3* caused animals to be acutely hypersensitive to ethanol's depression of locomotion. As expected, tissue ethanol concentration was increased when *sodh-1*, but not *H24K24.3* was lost. Importantly, we found that both strains develop robust acute functional tolerance (AFT) to ethanol, indicating that these enzymes are dispensable for this process. We found similar hypersensitivity to ethanol when we inactivated a subset of the worm ALDH enzymes, *alh-6* and *alh-13*. Interestingly, internal tissue ethanol concentrations in these two strains were higher than in wild type, suggesting that the lack of ALDH function causes a buildup of acetaldehyde, which can be converted by ADH into ethanol. Collectively, these data demonstrate that altered ethanol metabolism in worms results in a mild but detectable effect on ethanol response behaviors. A second risk factor for the development of alcohol dependence in humans is an individual's naive level of response to ethanol (Shuckit, 1994). The progression from initial ethanol responses to dependence is not well understood, but many studies have shown that acute ethanol administration induces changes in gene expression, which may contribute to later dependence behaviors. Our major goal is to identify genes and molecular pathways that are important in mediating ethanol responsive behaviors. We will identify ethanol responsive genes by performing a series of microarray experiments at different times and doses of ethanol exposure. Candidate genes from this analysis will be tested for their functional relevance in ethanol responses. We will test several ethanol-responsive behaviors including those measuring initial sensitivity and the development of AFT, two components of the initial level of response phenotype that is predictive of abuse liability in humans.

Characterization of Northeast Asian ADME Gene Variation via Exome Sequencing. *D.H. Hovelson[1], Z. Xue[2], S. Rashkin[1], X. Zhan[1], M.G. Ehm[2], A. Yeo[2], I.J. Jang[3], I. Ieiri[4], J.E. Lee[5], L.R. Cardon[2], S.L. Chissoe[2], G. Abecasis[1], M.R. Nelson[2]*. 1) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 2) Quantitative Sciences, GlaxoSmithKline, RTP, NC, USA and Stevanage, UK; 3) Seoul National University, Seoul, Korea; 4) Kyushu University, Fukuoka, Japan; 5) DNA Link, Inc., Seoul, Korea.

Drug response is influenced by pharmacokinetics, the availability of drug in the body. Investigating the factors that influence pharmacokinetics and selecting proper doses is a crucial part of drug development. Traditionally, early pharmacokinetic studies have been conducted in Western countries, with subsequent studies conducted in Northeast Asian countries to address the potential for population-specific effects and satisfy local regulatory requirements. Variation in genes that regulate the absorption, distribution, metabolism and excretion (ADME) of therapeutic agents can have a substantial impact on pharmacokinetic activity and may lead to variability in drug concentrations at the relevant tissue. Understanding ADME gene variation and its functional impact is important to developing safe and effective medicines administered at proper doses. There have been few systematic attempts to identify and characterize the extent of coding variation in all key ADME genes among major world-wide populations. To address this, we have integrated the exome sequence available from 19 populations from the 1000 Genomes Project and supplemented this with the exomes of 125 Korean and 125 Japanese subjects. These combined data would identify >97% of Northeast Asian coding variants with minor allele frequencies >0.5%. Average depth across the core (N=32) and extended (N=263) ADME genes for our Asian subjects is approximately 60X; for 1000 Genomes Project samples, this average depth is ~130X. We characterize a broad spectrum of variation across these genes, including single nucleotide variants, short insertion-deletion sequences and gene copy number differences. Initial analyses show an average of 1,947 non-singleton/non-doubleton SNVs in ADME gene coding regions per individual. Of these SNVs, on average, 990 are non-synonymous, 10 are nonsense, and 130 appear to be novel. We use predictive algorithms to assess the function of known and novel variants, and compare the patterns of variation across the world. The results of this study will assess the completeness of current ADME marker panels, guide the design of future pharmacokinetic studies, and hopefully improve the efficiency of getting new medicines to patients.

Drug Metabolizing Enzyme Genes and Nicotine and Cotinine Metabolism. *A.W. Bergen[1], H.S. Javitz[1], M. Michel[1], R. Krasnow[1], D. Nishita[1], C.N. Lessov-Schlaggar[2], H. Hops[3], N.J. Markward[4], S. Hall[5], T. Baker[6], D.V. Conti[7], R.F. Tyndale[8], N.L. Benowitz[9], G.E. Swan[1]*. 1) Center for Health Sciences, SRI International, Menlo Park, CA; 2) Department of Psychiatry, Washington University, St. Louis, MO; 3) Oregon Research Institute, Eugene, OR; 4) Personalized Medicine Research and Development, Medco Health Solutions, Bethesda, MD; 5) Department of Psychiatry, University of California, San Francisco, CA; 6) Department of Medicine, Center for Tobacco Research and Intervention, University of Wisconsin School of Medicine and Public Health, Madison, WI; 7) Department of Preventative Medicine, University of Southern California, Los Angeles, CA; 8) Centre for Addiction and Mental Health, and Departments of Psychiatry, Pharmacology and Toxicology, University of Toronto, Toronto, ON; 9) Departments of Bioengineering and Therapeutic Sciences and of Medicine, University of California, San Francisco, CA.

Tobacco smoking contributes to 30% of mortality in the U.S. More effective smoking cessation treatments, including treatments informed by pharmacogenetics, are needed. The Nicotine Metabolic Ratio (NMR), the ratio of two stable metabolites of nicotine, influences the number of cigarettes smoked per day, responsiveness to treatment, and tobacco carcinogen exposure. The predominant metabolic enzyme involved in nicotine and cotinine metabolism is CYP2A6. Significant additive genetic influence on nicotine and cotinine metabolism remains after accounting for *CYP2A6* common variants. Common *CYP2A6* variation accounts for ~70% of NMR variance. Pharmacogenetic analysis of the NMR may identify genes that influence the activity of CYP2A6, which is responsible for 100% of the metabolism of cotinine to 3'hydroxycotinine. We performed a pharmacogenetic study of the NMR in 220 kindreds from two West Coast metropolitan areas who received a standardized dose of deuterium-labeled nicotine and/or cotinine and from whom metabolite levels were measured using liquid chromatography-mass spectrometry. We utilized the Affymetrix DMET™ Plus Assay, which interrogates 1936 markers at 236 drug metabolizing enzyme and transporter genes. Adjusted (age, gender, BMI, smoking, hormonal status and ten principal components of population genetic variation) mean (SD) NMR values were 0.26 (0.07), plasma, in the twin dataset (N=333), and 0.29 (0.09), saliva, in the pedigree dataset (N=215), respectively. We performed hierarchical linear modeling of common DMET SNPs and adjusted NMR, followed by adjustment for correlated tests (P_{ACT}) within genes with >1 common SNP with ≥1 SNP with nominal P<0.05. We identified SNPs at 13 genes with P_{ACT}<0.05 in ≥2 transmission models in the larger twin dataset. These 13 genes include the established metabolic genes *CYP2A6* and *UGT2B7*. SNPs in 3 of 13 genes exhibit PACT<0.05 in the smaller pedigree dataset, including *CYP2A6*. We are analyzing SNPs from the two genes not previously associated with nicotine metabolism in two randomized controlled trials of smoking cessation therapy (RCTs) with NMR data. SNPs for those two genes associated with the NMR in the two RCTs will then be subsequently genotyped in an additional six RCTs, allowing us to evaluate the influence of SNPs at novel metabolic genes on smoking behaviors in eight RCTs. Funding: Collaboration Agreement between Medco Health Solutions, Affymetrix and SRI International, U01DA020830 and 1R21DA033813.

Identification of a SNP in the UGT1A1 promoter associated with increased serum bilirubin levels. *M.K. Kringen[1], A.P. Piehler[2,3], R.M. Grimholt[2], M.S. Opdal[1], K.B.F Haug[2], P. Urdal[2]*. 1) Department of Pharmacology, Oslo University Hospital, Ullevål, Oslo, Norway; 2) Department of Medical Biochemistry, Oslo University Hospital, Ullevål, Oslo, Norway; 3) Fürst Medical Laboratory, Oslo, Norway.

Background: Genetic variants are known to contribute to decreased glucuronidation activity in the liver due to decreased promoter activity of the gene encoding UDP-glucuronyltransferase 1A1 (UGT1A1). Decreased glucuronidation activity leads to increased bilirubin levels in healthy people (Gilbert's syndrome) and may cause variable responses to drugs that are metabolized by UGT1A1. In this study, we have investigated possible associations between serum bilirubin levels and seven tag-SNPs in a ~30 Kbp region upstream of the promoter of exon 1 of UGT1A1, in relation to the common TA7-repeat polymorphism (rs8175347). Methods: Buffy coat from healthy individuals with low (<17.5 μmol/L, n=150) and high (>17.5 μmol/L, n=150) bilirubin levels was obtained from the Nordic Reference Interval Project Bio-bank and Database (NOBIDA), consisting of samples from Denmark, Finland, Iceland, Norway and Sweden. DNA was extracted from 100 μl buffy coat samples and examined for common and new polymorphisms. The UGT1A1-TA7 repeat was genotyped by pyrosequencing using a PyroMark Q24, and tag-SNPs were analyzed by TaqMan® SNP Genotyping Assays on a Viia7 Real-Time PCR System. Results: Most individuals with high bilirubin levels (>17.5 μmol/L) were homozygous for the TA7-repeat (74%), while only 3% were homozygous for the TA6-repeat. However, in heterozygous TA6/TA7 individuals, both low and high levels of bilirubin were observed. By regression analysis, adjusting for age, sex and country of origin, an additional SNP (rs7564935 G>T) in the UGT1A1 promoter was found to be associated with higher bilirubin concentrations in this genotype group (P=0.02, n=114). Individuals being homozygous for the major G-allele had a mean bilirubin concentration of 18.5 μmol/L compared to 11.2 μmol/L for TT-carriers. This SNP explained about 2–3% of the bilirubin variability in TA6/TA7 individuals. Conclusions: High bilirubin levels are mainly determined by the UGT1A1-TA7 repeat. Additionally, we have identified a SNP in the UGT1A1 promoter associated with increased bilirubin concentration in TA6/TA7 heterozygous individuals. For drugs that are metabolized by UGT1A1, this SNP may predict altered drug responses in TA6/TA7-carriers.

Well-characterised cohorts and exome data: investigating antipsychotic pharmacogenomics in the South African context. *B. Drogemoller[1], D. Niehaus[2], G. Wright[1,3], B. Chiliza[2], L. Asmal[2], L. Koen[2], R. Emsley[2], L. Warnich[1]*. 1) Department of Genetics, Stellenbosch University, Stellenbosch, Western Cape, South Africa; 2) Department of Psychiatry, Stellenbosch University, Stellenbosch, Western Cape, South Africa; 3) South African Bioinformatics Institute, University of the Western Cape, Bellville, Western Cape, South Africa.

Introduction: Schizophrenia places an immense socio-economic burden on society and current treatments have substantial limitations. This burden is further heightened by poverty in low- and middle-income countries, such as South Africa. As African populations have been under-represented in genome-wide research to date, this study aims to identify unique patterns of genomic variation that may affect antipsychotic response in South African patients.

Materials and Methods: A cohort of 104 South African first episode schizophrenia patients was collected and treated for up to 3 years. This cohort is well suited to pharmacogenomic research due to the fact that patients have been carefully selected and assessed, diagnosed according to specific criteria and treated uniformly. From this cohort we have identified a subset of age, sex and ethnicity matched antipsychotic non-responders (4 unrelated individuals and 1 sib-pair) and responders (n=5) for exome sequencing. The generated exome data was subsequently analysed employing a bioinformatics pipeline, which made use of the publically-available software programs BWA, SAMtools, GATK, SeattleSeqAnnotation134 and VAAST.

Results: Analysis of the variation in the 11 schizophrenia patients revealed that >5% of the total number of SNPs detected were novel. By utilising a variety of different options in VAAST to model antipsychotic response, we identified a list of potentially damaged genes that may contribute to antipsychotic treatment response. Variation predicted to alter the resulting protein product of these genes, as well as candidate genes described in the literature/databases, was prioritised for genotyping in the entire cohort of patients.

Conclusion: This study has detected a large number of variants, a substantial portion of which remain novel, despite recent efforts to comprehensively characterise the human variome. By utilising a well-characterised cohort and identifying variation affecting patients on extreme ends of the treatment response phenotypic spectrum, we have been able to identify a unique panel of variation that may contribute to antipsychotic response. By genotyping this variation in the entire cohort, we hope to refine our results and, in so doing, improve our understanding of antipsychotic response in the South African context.

Can Genetic Variation of CES1A Predict Methylphenidate Response in ADHD Patients? *A. Cassidy[1], E. Sizer[3], D. Rutschow[1], K. Hogg[3], J. Berg[2], D. Coghill[3]*. 1) Human Genetics, Medical Research Institute, Dundee, United Kingdom; 2) Human Genetics, Medical Education Institute, Dundee, United Kingdom; 3) Division of Neuroscience, Medical Research Institute, Dundee, United Kingdom.

Carboxylesterase 1A (CES1A) is the principle metabolising enzyme for a number of drugs, including methylphenidate. There is early data to suggest that variation in CES1A can affect treatment response in patients with attention deficit hyperactivity disorder (ADHD). The existence of highly homologous isoforms of CES1A on the same chromosome creates a major challenge to identifying variation in the functional isoforms present in an individual. We aimed to develop a discriminative method using long PCR and direct sequencing to analyse the individual variation of these CES1A isoforms. Sequence analysis of a local cohort combined with review of current literature, identified typical variation between the promoter region and exon 1 of the CES1A isoforms. Using this information we have adapted a recently published long PCR method to include analysis of the functional CES1A1b, 1A1c and 1A2 minor haplotypes. Our method successfully enabled specific sequence analysis of 13.5kb of CES1A1a (the most common functional isoform), from exon 1 to intron 6. A 2-step process to further define the isoforms present was also developed. SNP haplotypes identified in the promoter region and exon 1 revealed a highly complex genotype of several functional CES1A isoforms, including a novel CES1A1 isoform, present in 1/48 alleles which may all contribute to methylphenidate response. This new understanding of the genomic structure and variation within the CES1 diplotype has allowed us to design a protocol using massively parallel sequencing in a larger-scale phenotype-genotype study of ADHD patients. This is an important step in studying the effect that the CES1 genotype has on drug metabolism.

Whole exome analysis of African American warfarin pharmacogenomics. *R. Daneshjou[1], K. Aquino-Michaels[2], B. Burkley[3], L.H. Cavallari[4], J.A. Johnson[3], N.A. Johnson[1], T.E. Klein[1], K.J. Karczewski[5], T. Langaee[3], S.R. Patel[4], M. Perera[2], H. Sagreiya[1], H. Tang[1], N. Tatonetti[5], R.B. Altman[1,5]*. 1) Genetics, Stanford University, Stanford, CA; 2) Department of Medicine, University of Chicago, Chicago, IL; 3) Department of Pharmacotherapy and Translational Research, University of Florida, Gainesville, FL; 4) Department of Pharmacy Practice, University of Illinois at Chicago, Chicago, IL; 5) Bioinformatics Training Program, Stanford University, Stanford, CA.

Warfarin, an anti-coagulant, is prescribed to over 30 million patients a year in the United States alone; however, doses can vary between patients as much as tenfold. Underdosing can lead to diminished therapeutic protection against stroke and clotting while overdosing can lead to serious adverse events such as bleeding or hemorrhaging. Currently, dosing is largely trial-and-error — physicians start with a fixed dose and calibrate doses based on coagulation tests until the target international normalized ratio (INR) is achieved. However, warfarin pharmacokinetics and pharmacodynamics are known to be affected by single nucleotide polymorphisms (SNPs) of genes involved in those pathways, such as VKORC1 or CYP2C9. While pharmacogenetic dosing algorithms such as the one produced by the International Warfarin Pharmacogenetics Consortium (IWPC) have been able to explain some of the variability seen in Caucasian patients, its accuracy falls in less studied ethnic populations such as African Americans. Recent studies have shown that genes other than VKORC1 and CYP2C9 may play an important role for warfarin dosing in African Americans. Additional new rare variants may explain this variation in warfarin response, which we explore using whole exome sequencing of 100 African American patients on warfarin with stable doses at low and high levels (<=35 mg/week and >=49 mg/week). In addition to traditional SNP-based analysis, we also use gene-based methods of analysis to bin SNPS for increased statistical power in detecting differences in high and low dose cohorts. Our work will allow for more accurate pharmacogenetic predictions in African American warfarin dosing.

Survey of rare Variants in pharmacogenes for patients with statin-induced myopathy Identified in a biorepository linked to electronic medical records. *M.T. Oetjens[1], Q. Feng[2], A.R. Ramirez[2], E. Bowton[3], T. Clark[5], D.M Roden[2,3,4], D.C. Crawford[1], R.A. Wilke[2]*. 1) Center for Human Human Genetics; 2) Department of Medicine, Division of Clinical Pharmacology; 3) Office of Personalized Medicine; 4) Department of Pharmacology,; 5) Genome Sciences Resource, Vanderbilt University, Nashville, TN.

HMG-CoA reductase inhibitors, statins, are a widely prescribed class of drugs for prevention and treatment of cardiovascular disease. Their clinical use can be limited by musculoskeletal problems ranging from mild pain (myalgias) to severe muscle damage (myopathy). Plasma levels of the non-specific muscle enzyme creatine kinase (CK) are often used to estimate severity. True myopathy (CK >10-fold upper limit of normal) occurs in ~1 of every 1000 patients exposed. We tested the hypothesis that rare variants contribute to the risk of developing statin induced myopathy in a large clinical practice-based biobank. BioVU, the biobank at Vanderbilt University is a biorepository of DNA samples linked to de-identified electronic medical records (EMRs). As of June 1, 2012, BioVU contained clinical data and DNA from 127,744 unique adults. Case finding algorithms flagged 199 potential myopathy case subjects who experienced CK elevation in the absence of an acute coronary syndrome or major trauma. Manual chart review confirmed 16 cases suitable for exome scanning. Whole exomes were captured using an Agilent SureSelect All Exon v2 38 Mb capture kit and sequenced on the Illumina HiSeq 2000. Short reads were aligned to UCSC human reference genome build hg19 using the BWA aligner with a soft-trim quality score setting (-q) of 5. The resulting BAM files were sorted, indexed and processed with GATK v1.3. Variant calling was performed on all BAM files simultaneously, and the resulting VCF file (containing variants of quality score >20) was filter flagged according to “GATK Best Practices v3.” Seven pharmacodynamic genes (HMGCR, COQ2, CPT2, EYS, RYR1, RYR2, RYR3), and eight pharmacokinetic genes (ABCB1, ABCG2, CYP3A4, CYP3A5, SLCO1B1, SLCO1B3, UGT1A1, UGT1A3) were surveyed for their total burden of rare variants unique to statin-induced myopathy patients compared with the 1000 Genomes reference population. The genetic analysis software VAAST was leveraged to determine if each identified variant was likely to alter protein structure/function. Five genes (RYR1, EYS, ABCG2, UGT1A1 and CYP34) contained one or more rare variants unique to our cases. Only RYR1 contained a rare variant deemed potentially detrimental in VAAST. Due to the rarity of statin-induced myopathy, case patients will need to be studied across institutions to determine if genetic variability in RYR1 impacts risk at the population level.

648T

Genetic Determinants of Fetal Hemoglobin Response to Hydroxyurea. *V.A. Sheehan[1], A. Sabo[1], J.R. Crosby[3], T.A. Howard[1], D.M. Muzny[1], B. Davis[3], A. Li[1], U. Nagaswamy[1], E. Boerwinkle[1,2], R.A. Gibbs[1], R.E. Ware[1,4], J.M. Flannagan[1]*. 1) Pediatric Hematology/Oncology, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas; 3) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, Texas; 4) Center for Global Health, Baylor College of Medicine, Houston, TX.

Sickle cell anemia (SCA) is the most common inherited blood disorder, affecting 1 in 400 African Americans, and causing significant morbidity and mortality. Hydroxyurea is the only FDA-approved pharmacologic treatment for SCA. The effectiveness of hydroxyurea is directly related to the level of fetal hemoglobin the drug can induce, with approximately 20% HbF needed for significant disease modification. The amount of HbF produced in response to hydroxyurea is highly variable between individuals, with induced HbF levels ranging from 5 to >30% even for compliant patients on similar dosing regimens. There is strong concordance of HbF response to hydroxyurea in sibling pairs, suggesting response is heritable, and amount of HbF produced at the maximum tolerated dose is a reliable and objective phenotype. To identify genetic modifiers of hydroxyurea induction of HbF, we performed whole exome sequencing on 50 pediatric patients who represented the extreme ends of HbF response to hydroxyurea; 26 high responders (final HbF >30% and >25% change from baseline) and 24 low responders (final HbF <20%, and <15% change from baseline). There was no significant difference in levels of baseline %HbF, gender or age between the two groups. Genomic DNA was obtained from participants in multicenter clinical trials with uniform drug administration and careful monitoring, producing the most reliable phenotypes available. Paired end libraries were constructed, and all exons in each sample captured and sequenced with 94% 20x base coverage. Low responders were compared to high responders. Although no single gene affected HbF response, univariate test results identified ten nonsynonymous polymorphisms with p-values below 1×10^{-3}. Two of the ten genes identified play a role in erythropoeisis; one in maintence of glomerular filtration, of interest as hydroxyurea is renally excreted. This initial pilot investigation examined only extreme phenotypes; these associations will be validated in a larger group using HbF as a continuous variable.

649T

Translating genetic associations to new medicines. *M.G. Ehm[1], S.L. Chissoe[1], M.R. Nelson[1], D.M. Waterworth[1], L.C. McCarthy[1], H. Tipney[1], T. Pastinen[2], M. Saleh[2], P. Gros[2], P. Agarwal[1], M. Lathrop[2], L.R. Cardon[1], J.B. Richards[2], P. Sanseau[1]*. 1) Genetics, GlaxoSmithKline, Res Triangle Park, NC & Stevenage, UK; 2) McGill University, Montreal, Quebec.

Aim: To develop methodologies and processes to efficiently translate human genetic observations into effective new therapies for disease. A key goal for drug development is to minimise drug attrition due to poor therapeutic efficacy in late stage clinical trials. There is a growing body of evidence that human genetic associations can reduce this attrition by identifying proteins causally related to human disease aetiology. Further efficiencies can be gained through genomics-based drug repositioning, wherein new indications are identified for existing drugs when their drug target is associated with a disease different from the drug's original indication. We previously reported that disease genes identified using genome-wide association studies (GWAS) are 2.7-fold enriched for established drug targets, and in some disease classes identify the majority of clinically validated drug targets. We identified 92 possible repositioning opportunities using published GWAS literature. The validation of these drug targets, through allelic expression studies, animal models and functional rare variants can provide rationale to undertake human drug trials. One example is *TNFSF11*, for which we demonstrate that the allele associated with Crohn's disease is associated with increased expression of *TNFSF11*, indicating that an antagonist of this gene's activity, such as Denosumab, may be an effective therapeutic for this condition. In a second example, variants in the melatonin receptor, *MTNR1B*, are associated with increased fasting glucose levels as well as susceptibility to type 2 diabetes (T2D). Cell model validation established that loss of MTNRM.1B function is associated with increased risk of T2D, indicating that a MTNR1B agonist, such as melatonin may be helpful in treatment of T2D. With the rapidly growing knowledge of genetic susceptibility factors for rare and common disease, and an almost complete catalog of common genetic variants, opportunities to validate new targets and reposition for existing targets are increasing. We are addressing the immediate need to identify the methods to bridge the gap between genetic associations and translation into effective medicine development programs through rapid target validation.

650T

Association of CYP3A4 and CYP3A5 genotypes with treatment-related hiperlipidemy. *L.E. Wong-Ley[1], L.E. Figuera[2], R. Ortiz-Orozco[2], M. Perez-Nuño[1], P. Aguiar-Garcia[1], F.A Ortega-Gutierrez[2], A. Nuñez-Zenteno[2]*. 1) Dept Gen, SSN-UAN, Tepic, Mexico; 2) Dept Gen, IMSS, Guadalajara, Mexico.

The usage of pravastatin as a medical treatment for hyperlipidemy and its main complication, coronary aterosclerosa disease, it is effective because it modifies the cholesterol homeostasis and it plays a very important role at the beginning and progression of the ischemic cardiopathy, the main cause of dead in our country for about four decades Some differences have been reported in the response to the treatment with pravastatin related with ethnic origin and there are differences in the frequencies of the polymorphisms that are studied, that is why we considerer a probable association between this polymorphisms and the response to the treatment. The objective the present study is to know the participation of CYP3A4 and CYP3A5 genes in the variation of pravastatin dose in Mexican population. They were included in the study 73 patients that were receiving pravastatin as part of the antilipidic treatment. All patients signed an informed consent and a questionnaire was answered. DNA was obtained from lymphocytes and followed the identification by PCR and enzymatic digestion of *2 and *3 of CYP3A5, *1B of CYP3A4 variants. A t of Student test was applied to determine doses differences between genotype groups. The genotype and allelic frequencies compared from the three referred polymorphisms between sensible and resistant groups without estimating differences that can refer to association among them and the clinical response to the treatment with pravastatin. When making the analysis of the polymorphisms of CYP3A4 and CYP3A5, between the reference group and patients with pravastatin treatment, we did not find significant statistical differences between the genotype and allelic frequencies. The genotype and allelic frequencies of the CYP3A4*1B, CYP3A5*3 and *6 polymorphisms in the patients with hyperlipidemy in the reference population, are similar to the ones of the general population. As well as the distribution of the CYP3A4*1B CYP3A5*3 and *6 polymorphisms in the reference population that agreed with the predictions of the Hardy-Weinberg Law. No main variables play an important role in the dosing of pravastatin in the studied population.

Pharmacogenetic investigation of diarrhea in pazopanib-treated patients with renal cell carcinoma. *Z. Xue[1], L. Huang[1], C.N. Sternberg[3], R.A. Figlin[4], L. McCann[1], C.F. Spraggs[1], C. Carpenter[2], L.N. Pandite[2], C. Xu[1]*. 1) Quantitative Sciences, GlaxoSmithKline, Stevenage UK, Research Triangle Park, NC, and King of Prussia, PA, USA; 2) Oncology, GlaxoSmithKline, Research Triangle Park, NC, and King of Prussia, PA, USA; 3) Department of Medical Oncology, San Camillo and Forlanini Hospitals, Rome, Italy; 4) Cedars-Sinai Medical Center, Samuel Oschin Comprehensive Cancer Institute, Los Angeles, USA.

Background: Diarrhea is a commonly observed adverse effect during pazopanib treatment. Although most diarrheal events are mild to moderate, this can be burdensome and inconvenient for patients and lead to non-compliance and possibly poor treatment outcomes. This pharmacogenetic study sought to explore the association of germline genetic factors with pazopanib-related diarrhea in patients with advanced renal cell carcinoma (RCC).

Methods: In the dataset of 397 patients from 3 clinical trials (a phase II, a phase III and its extension study) who had pharmacogenetic data, 90 (22.7%) patients experienced NCI CTCv3 AE grades ≥2 diarrhea during pazopanib treatment and were defined as `cases' in this analysis. `Controls' (n=132) were patients who did not experience diarrhea and received pazopanib for at least 42 days (median time to onset of diarrhea). Germline DNA was extracted from peripheral blood. 44 functional markers in 38 candidate genes that are involved in pazopanib metabolism, or pazopanib mode of action, or mechanism of diarrhea were investigated for association with diarrhea using logistic regression. A genome wide association study (GWAS, 1M markers) was also conducted to examine associations with diarrhea.

Results: Out of the 44 candidate functional markers analyzed, IL8 (encoding Interleukin-8) -251T/A (rs4073) and ADCY6 (encoding an enzyme catalyzing the formation of cAMP) A674S (rs3730071) showed nominally significant association with pazopanib-related diarrhea ($p<0.05$). The most significant association from the GWAS (rs6498041) was identified in the gene coding for GSG1-like protein, with a nominal p value of $p=6.4\times10^{-8}$. None of the markers were associated with diarrhea at the multiple-testing corrected significance level in either the candidate gene ($p<0.0006$) or GWAS ($p<2.5\times10^{-8}$) analyses.

Conclusions: Suggestive associations between genetic markers and diarrhea were found in pazopanib treated patients with RCC using candidate gene and GWAS analyses. Results from this exploratory genetic study may provide the foundation for further confirmatory studies to evaluate the mechanism of diarrhea in patients treated with pazopanib or other tyrosine kinase inhibitors.

652T

Multi-ethnic Glutathione S-transferase (GST) Copy Number Profiling. *S. Martis[1], R. Vijzelaar[2], J. Sload[1], H. Mei[1], L. Edelmann[1], R.J. Desnick[1], S.A. Scott[1]*. 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, New York, 10029; 2) MRC Holland, Willem Schoutenstraat 6, Amsterdam, The Netherlands.

The polymorphic glutathione S-transferases (GSTs) are a major phase II family of conjugation enzymes involved in detoxifying carcinogens and bioactivation of antineoplastic prodrugs. Of these, the most commonly studied isoenzymes are the cytosolic μ1 (GSTM1; 1p13.3), ϕ1 (GSTT1; 22q11.23), and π1 (GSTP1; 11q13.2). For example, common deletion polymorphisms in GSTM1 and GSTT1 result in reduced enzyme activity and have been implicated in several multifactorial diseases including cancer and schizophrenia. To determine the multi-ethnic frequencies of GSTM1, GSTT1 and GSTP1 copy number variants (CNVs), multiplex ligation-dependent probe amplification (MLPA) with two probes per gene was performed on over 500 DNA samples from healthy African-American, Asian, Caucasian, Hispanic, and Ashkenazi Jewish (AJ) individuals. The identified GSTM1 deletion allele frequencies were 0.561, 0.748, 0.741, 0.556 and 0.702, and the GSTT1 deletion allele frequencies were 0.561, 0.646, 0.418, 0.451 and 0.547, respectively. Selected GSTM1 and GSTT1 deletion alleles were confirmed by quantitative TaqMan® copy number assays. To determine the breakpoint regions of both GSTM1 and GSTT1 deletion CNVs, a high-resolution oligonucleotide microarray (average probe spacing of ~119 bp for GSTM1 and ~212 bp for GSTT1) was designed that interrogated 32 core pharmacogenetic genes, including the GST genes analyzed by MLPA, and array-based comparative genomic hybridization (aCGH) was performed on 46 selected multi-ethnic samples. aCGH analyses mapped the mean size of the GSTM1 deletion to ~21 kb and localized the CNV breakpoints to two directly oriented low copy repeats (LCRs; >90% similarity) resulting in full gene deletion. Similarly, the mean size of the GSTT1 deletion was ~52 kb and these narrowed breakpoints also mapped to two directly oriented LCRs with >90% similarity, indicating that common GST deletion allele formation is likely mediated by nonallelic homologous recombination. Additionally, the identified frequencies of GSTM1 and GSTT1 deletion were high in all studied populations. However, the conflicting disease and drug response association studies with GST deletions suggest that future work should focus on additional sequence and copy number variation at the GST loci.

Pharmacogenomics of cardiovascular disease treatment in subjects from the Lithuanian population. *A. Pranculis[1], I. Pepalyt[1], J. Arasimavičius[1], Z.A. Kučinskien[2], V. Kučinskas[1]*. 1) Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania; 2) Department of Physiology, Biochemistry, and Laboratory Medicine, Faculty of Medicine, Vilnius University, Vilnius, Lithuania.

Cardiovascular diseases (CVDs), which are the number one cause of death in developed countries, are caused by a combination of environmental and genetic components which also affect drug efficacy and likelihood of adverse drug reactions (ADRs). The aim of the study was to evaluate the pharmacogenomic peculiarities of the Lithuanian population according to the variants of genes associated with response to medicines used for CVD treatment and use the results to determine the course of further larger scale studies. Allele and genotype frequency distributions were compared to the results reported in Estonian, Russian, Swedish populations as well as data from other Caucasian populations reported in the NCBI database. The samples of the 96 healthy unrelated subjects from the Lithuanian population were genotyped for 770 000 SNPs using Illumina genotyping array. SNP allele and genotype frequencies within the genes associated with pharmacogenetic response to medications used for CVD treatment were calculated. Allele and genotype frequency distribution analysis according to the *VKORC1* -1639G>A showed that compared to other Caucasian populations, Lithuanian patients have a significantly lower frequency of the A allele (33%) and AA genotype (7%) and may thus require higher doses of warfarin to achieve the same therapeutic effect. *CYP2C19* c.681G>A is associated with an increased clopidogrel dose requirement. In our study group A allele frequency in the Lithuanian population was 9% and there were no AA genotype patients in our study group. When we analyzed the allele and genotype frequency distributions of the SNPs in the genes associated with response to treatment with statins a converse pattern emerged. According to the *HMGCR* SNP29 (G allele frequency <2%) people from the Lithuanian population are more sensitive to treatment with statins compared to other northern European populations. Furthermore the analysis of the SNPs in the *SLCO1B1* gene shows that due to a significantly higher frequency of c.521T>C C allele (20%) people from the Lithuanian population are more likely to develop ADRs like myopathy caused by statin treatment compared to other eastern and northern European populations. Even though these results should be replicated in a larger study group, these results indicate that patients from the Lithuanian population who were diagnosed with a CVD might benefit from the treatment with higher doses of anticoagulants and decreased doses of statin class drugs.

Systematic functional characterization of cytochrome P450 2E1 promoter variants in the Chinese Han population. *S. Qin, L. He.* Bio-X Institutes, Key Laboratory for the Genetics of Developmental and Neuropsychiatric Disorders(Ministry of Education), Shanghai Jiao Tong University, Shanghai 200030, China;.

CYP2E1 promoter polymorphisms can lead to significant interindividual differences in expression of CYP2E1. Using a database of CYP2E1 gene polymorphisims established in 2010, our study aimed to functionally characterize the single nucleotide polymorphisms (SNPs) of the promoter region and corresponding haplotypes in the Chinese Han population. 6 novel SNPs and 7 haplotypes with a frequency equal to or greater than 0.01 were constructed on a luciferase reporter system on the basis of site-directed mutagenesis. Dual luciferase reporter systems were used to analyze regulatory activity. The construct including novel SNP mutations exhibited insignificant change in luciferase activity, whereas, the activity produced by Haplo1(GTTGCTATAT), Haplo2 (CTTGCTATAT) and Haplo7 (GAGCTCACAT), containing a -333T>A polymorphism was significantly greater than for the wild type in HepG 2 cells ($p<0.05$), being 1.5-, 2.0- and 1.4- times greater respectively. These findings suggest the possibility of significant clinical prediction of adverse drug reaction and the facilitation of personalized medicine.

Influence of common polymorphisms in *ABCB1* gene on interaction between methadone and p-glycoprotein. *Y. Teng[1], C. Hung[1,2], M. Chiou[1].* 1) Department of Pharmacy, College of Pharmacy, China Medical University, Taichung, Taiwan, Republic of China; 2) Department of Pharmacy, China Medical University Hospital, Taichung, Taiwan, Republic of China.

Purpose: Drug addiction is one of the most important issues around the world. Lots of the abusers affected by acquired immune deficiency syndrome (AIDS) and need protease inhibitors for therapy. The most common treatment for opioid dependence is substitution therapy with methadone. The present study investigated whether interaction between methadone and p-glycoprotein would be influenced by common polymorphisms in *ABCB1* gene. Method: Cell lines harbored some combinations of the common polymorphisms on *ABCB1* gene were established to exam the function of p-glycoprotein. Direct sequencing was performed to confirm genotypes of the established cell lines. Effect of methadone on p-glycoprotein function was evaluated by rhodamine123 efflux assay and calcein-AM uptake assay in different genotypes of cells. Fluorescence microscopy assay was also conducted. Results: The expression of p-glycoprotein in different cell lines was confirmed by real-time RT-PCR. Common polymorphisms in *ABCB1* gene did not affect mRNA expression. The function of p-glycoprotein was confirmed by comparisons of intracellular accumulation of rhodamine123 between the parental cells and p-glycoprotein-carrying cells. The inhibition effect of methadone on p-glycoprotein function was demonstrated both in rhodamine123 efflux assay and calcein-AM uptake assay. Treatment of 1 μM methadone significantly inhibited rhodamine123 efflux and increased intracellular calcein fluorescence (both $p<0.001$). Cells carrying different p-glycoprotein genotypes showed distinguished effect from the cells carrying wild-type p-glycoprotein. Conclusion: Due to the inhibition effect of methadone on p-glycoprotein, the concentration of protease inhibitor may be increased. Patients with different *ABCB1* genotypes may experience different drug-drug interaction. These results may be helpful in the future clinical practice.

Genetic regulation of circulating glycine concentration in the Finnish population. *J. Kettunen[1], T. Tukiainen[1], M. Ala-Korpela[2], J. Eriksson[3], O. Raitakari[4], MR. Järvelin[5], T. Lehtimäki[6], V. Salomaa[7], M. Perola[7], A. Palotie[1,8], S. Ripatti[1,8].* 1) Institute for Molecular Medicine Finland, FIMM, Helsinki, Finland; 2) Computational Medicine, Institute of Clinical Medicine, University of Oulu, Oulu, Finland; 3) Unit of Chronic Disease Epidemiology and Prevention, National Institute for Health and Welfare, Helsinki, Finland; 4) Research Centre of Applied and Preventive Cardiovascular Medicine, University of Turku, Turku, Finland; 5) Department of Epidemiology and Biostatistics, Imperial College London, London, UK; 6) Department of Clinical Chemistry, University of Tampere and Tampere University Hospital, Tampere, Finland; 7) Department of Chronic Disease Prevention, National Institute for Health and Welfare, Helsinki, Finland; 8) Human Genetics, Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, UK.

Glycine is an amino acid which acts as an inhibitory neurotransmitter in the central nervous system but is also required as a co-agonist along with glutamate for NMDA receptor which controls synaptic plasticity and memory. The level of glycine in the spinocerebral fluid and blood is regulated by the glycine cleavage enzyme complex through degradation of glycine by decarboxylation. All four key enzymes of the cleavage system have been linked with non-ketotic hyperglycinemia [OMIM 605899], a recessive Mendelian disease where the patients have severe neurological phenotypes including seizures, profound mental retardation, episodes of delirium, chorea, and vertical gaze palsy during febrile illness or progressive spastic diplegia, optic atrophy and others symptoms with varying severity. Most patients with this disease have defects in the glycine decarboxylase (*GLDC*) gene in chromosome 9. Here, we present genome wide association study for serum glycine levels using 1000 genomes imputation panel where we replicate a known glycine association in chromosome 2 (rs1047891, $p = 5.7*10^{-167}$) and present a new genome wide significant non-synonymous variant (rs143119940, Val735Leu) in the *GLDC*-gene which is associated with the blood glycine levels ($p = 3.4*10^{-11}$, MAF = 0.03) in 9238 population based samples unselected for neurological traits. This variant showed lower enzyme activity by 19% in a previous functional study and thus may contribute to the milder forms of non-ketotic hyperglycinemia where the disease variants have not yet often been identified or other diseases of central nervous system.

Functional and physical interaction of the mitochondrial electron transport chain and fatty acid oxidation and its disruption in fatty acid oxidation deficient animals. *J. Vockley[1], Y. Wang[1], E. Goetzman[1], J. Palmfeldt[2], N. Gregersen[2].* 1) Pediatrics, University of Pittsburgh School of Medicine, Pittsburgh, PA; 2) Aaruhus University School of Medicine, Aarhus, Denmark.

We have recently shown that many of the functions of fatty acid oxidation (FAO) are contained in a multifunctional fatty acid oxidation complex and that this complex is physically and functionally associated with the electron transport chain (ETC) supercomplexes. In the present study, we have used blue native gel electrophoresis (BNGE) and mass spectrometry (MS) to isolate ETC complexes from heart mitochondria form a long chain acyl-CoA dehydrogenase (LCAD) deficient mouse and characterized ETC and FAO function induced by the FAO deficiency. Compared to wild type animals, complexes I, II, III, and V activity were reduced in LCAD deficient animals. Complex II activity was affected the most with a reduction to 20% of normal. A bridging assay that measures flow of electrons from FAO to ETC was reduced by ~90% when palmitoyl-CoA was used as substrate as compared to a 50% reduction in FAO alone. Activity with octanoyl-CoA was unchanged. Accumulation of reactive oxygen species related to complex I function was markedly increased in LCAD (-/-) mice compared to wild type, indicating loss of integrity of this complex. Mass spec analysis identified at least 8 FAO proteins that co-localize with respiratory chain supercomplexes and to a lesser extent with isolated complex I in mitochondrial extracts from wild type mice. These included the gene products of *HADHA, HADHB, HADH, ACAA2, VLCAD, CPT2, CPT1B, ECHS1* and *ACSL2.* BNGE showed disruption or decreased stability of the formation of ETC supercomplexes in LCAD(-/-) mice, and mass spec analysis confirmed that all supecomplex subunits were reduced at least 50% compare to wild type. In addition, the FAO proteins were predominantly associated with isolated complex I. Protein cross linking studies revealed that the mitochondrial trifunctional protein (an NAD dependent enzyme encoded by the HADHA, HADHB genes) directly interacted with the 75 kDa subunit of ETC complex I that contains the NADH binding domain for this complex. Our results confirm our previous description of a multifunctional mitochondrial energy complex that encompasses both the ETC and FAO in a way that promotes metabolic channeling for energy production. Secondary disruption of this complex in the face of primary FAO defects is likely to play a role in the pathogenesis of this heterogeneous group of disorders.

658T

Dysregulation of central nervous system sphingolipid metabolism as a unifying mechanism for neuro-cognitive manifestations of Gaucher disease and HIV infection. *A.F. Elias[1,3], N.J. Haughey[2], K. Mackey[3], T. Pitman[4], A.W. Thomas[5], S. Wakefield[4], S.P. Yang[4].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD., Select a Country; 2) Department of Neurology, Richard T. Johnson Division of Neuroimmunology, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Ryan White HIV/AIDS Clinic at Partnership Health Center, Missoula, MT; 4) Department of Medical Genetics, Shodair Children's Hospital, Helena, MT; 5) Montana Cancer Center at St. Patrick Hospital, Missoula, MT.

Gaucher disease (GD) is caused by the inherited deficiency of lysosomal glucocerebrosidase resulting in the accumulation of sphingolipids. Three major phenotypes of GD have been described based on the absence (type 1) or presence (types 2 and 3) of central nervous system (CNS) involvement. Particularly, type 3 GD is a chronically progressive neuronopathic form with variable age of onset. The molecular basis of the neurological manifestations in GD is not well understood. Cytotoxic sphingolipids such as glucosylceramide and glucosylsphingosine accumulate in the CNS in patients with GD types 2 and 3, but not in type 1, and may be involved in neuronal cell death. Similarly, abnormal cerebrospinal fluid (CSF) sphingolipid content has been associated with memory impairment in patients infected with the human immunodeficiency virus (HIV), and the accumulation of cytotoxic ceramide has been implicated in the pathogenesis of HIV-associated neurocognitive disorders (HAND). Here, we present the unusual case of a 35-year-old patient with HIV infection and GD. Shortly after HIV diagnosis in 2007, highly active antiretroviral therapy (HAART) was initiated and resulted in consistent virological suppression. An evaluation for hepatosplenomegaly, thrombocytopenia and anemia led to the diagnosis of GD type 1 in 2011. Soon after, he started enzyme replacement therapy (ERT). Moderate hematological and visceral and mild bone involvement were present at diagnosis. However, neuro-cognitive impairment affecting several areas of function as well as subtle signs of CNS involvement including dysphagia were subsequently noted. HAND would be an unexpected complication of HIV given the short time since infection and effective treatment with HAART. Likewise, course and pattern of organ manifestations would be atypical for type 1 GD. We postulate that his neurological complications result from the convergent effects of GD and HIV on sphingolipid metabolism in the CNS leading to a more severe phenotype similar to type 3 GD. This hypothesis is presented in the context of clinical data including ophthalmological, audiological, radiological and neuro-cognitive studies as well as sphingolipid content in CSF and genotypic correlation. Therapeutic consequences including the combination of ERT with substrate reduction therapy are discussed. A unifying role for sphingolipids in the pathogenesis of neurodegeneration makes GD a potential model for other neurodegenerative disorders.

Autism Spectrum Disorders Functioning Levels and Metabolic Alterations. *N. Arciniegas[1,2], N. Linares[1], M. Cabrera-Rios[4], S. Carlo[1,3].* 1) Instituto Filius, University of Puerto Rico, Rio Piedras, PR; 2) Dept Pediatrics, Hosp La Concepcion, San German, PR; 3) Molecular Medicine Dept, Hosp La Concepcion, San German, PR; 4) Bio Ie Lab, University of Puerto Rico, Mayaguez, PR.

Autism Spectrum Disorder (ASD) is a neurodevelopment disorder characterized by poor socialization skills, communication problems, and repetitive behavior. The diagnosis can be apparent during the early months of age but is usually more visible between the ages of two and three years old. It has been hypothesized that the condition is the result of a neurological disorder that affects normal brain function which alters information processing in the brain. As of now ASD is divided in 5 different diagnoses that include: Autism, PDD-NOS, Asperger syndrome, Rett syndrome and Children Disintegrative disorder. This classification will change in the DSM-V. Several etiologies had been implicated in the diagnosis of autism including metabolic, genetic and neurologic. A pilot project was designed to evaluate the possibility of presence of metabolic alterations in patients with ASD and speech delay. The study consisted of 12 patients: 3 with autism, 3 with PDD-NOS, 3 with Asperger and 3 with speech delay and sensory integration problems. Laboratory evaluation consisted of Urine Organic Acids, Plasma Amino Acids, Lactate, Pyruvate, Carnitine and Acylcarnitine profiles, Karyotype and EEG. Results showed elevation in the lactate to pyruvate ratio in one hundred per cent of patients. Usually, an L: P ratio >25 is considered increased and suggestive of a respiratory chain dysfunction at the mitochondrial level. One patient with autism had an abnormal EEG without clinical manifestations. Four patients showed elevated Free to Total carnitine ratios. All karyotypes, urine organic acids, plasma amino acids were normal and three patients had elevated glutarylcarnitine (C5DC). As previously suggested we conclude that there is mitochondrial etiology implicated in ASD and other related disorders.

Creatine transporter deficiency: novel mutations and functional studies. *O. Ardon[1,2], X. Yin[2], N. Longo[1,2], A. Shilon-Hadass[3], G. Gabis[3], C. Hoffman[3], M. Tzadok[3], G. Heimer[3], S. Sadan[3], B. Ben-Zeev[3], Y. Anikster[3]*. 1) R & D, ARUP, Salt Lake City, UT; 2) Division of Medical Genetics, Dept of Pediatrics, University of Utah, Salt Lake City, UT; 3) Edmond and Lily Safra Children's hospital and Sackler Faculty of Medicine, TAU, Sheba Medical Center, Israel.

X-Linked cerebral creatine deficiency (MIM 300036) is caused by deficiency of the creatine transporter encoded by the SLC6A8 gene. This disorder is characterized by mental retardation, delays in language and speech, autistic-like behavior, seizures in about 50% of cases, and in some cases mid-facial hypoplasia and short stature in hemizygous males. Here we report the first two patients with this condition from Israel. Both were evaluated for global developmental delays and language apraxia. Borderline microcephaly was noted in one of them. Their non-verbal communication was better than other areas and they had no autistic symptoms. Diagnosis was prompted by brain MRI/MRS evaluations which revealed normal white matter distribution, but absence of the creatine peak in both patients. Biochemical testing indicated normal plasma levels of creatine and guanidinoacetate, but an increased urine creatine/creatinine ratio of 2.9 in both patients (normal values are 0.006 to 1.2). The diagnosis was confirmed by demonstrating the absence of [14]C-creatine transport in fibroblasts. Molecular studies indicated that the first patient is hemizygous for a single nucleotide change substituting a single amino acid (c.619 C>T (exon 3) p.R207W). Expression studies in HeLa cells confirmed the causative role of the R207W substitution. The second patient had a single base insertion (c.1254+1insA) at a splicing site in the intron-exon junction of exon 8. This sequence variant is being evaluated as disease causing variant by mRNA processing studies in fibroblasts. These two patients are the first reported cases of creatine transporter deficiency in Israel, and are both in Jewish families of Sephardi origin.

661F

Mice deficient for Succinyl-CoA Synthetase exhibit functionally significant mtDNA depletion and are a model for mitochondrial disease. *T. Donti[1], M. Ge[1], K. Eldin[2], B. Graham[1]*. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Over the past few years, mitochondrial DNA (mtDNA) depletion has been implicated in several mitochondrial diseases. Mutations in subunits of Succinyl-CoA Ligase (Synthetase), a component of the citric acid cycle, have been associated with mitochondrial encephalomyopathy and mitochondrial DNA depletion. In humans, mutations in SUCLA2, encoding the ADP-specific beta subunit, and SUCLG1, encoding the alpha subunit, have been identified as causes of mitochondrial disease with mtDNA depletion. The goal of this project is to develop model systems of Sucinyl-CoA Ligase deficiency to study disease pathogenesis and biology of mtDNA maintenance. A gene trap allele of Sucla2 (Sucla2SAβgeo) has been isolated in mouse embryonic stem (ES) cells and used to generate transgenic animals. Sucla2SAβgeo homozygotes exhibit recessive lethality with most mutants dying late in gestation (e18.5). Rare stillborn homozygote pups exhibit significantly elevated levels of methylmalonic acid (MMA) and varying degrees of mtDNA depletion. Histological analysis of mutant placenta reveals increased mineralization and mutant embryos are approximately 25% smaller than wild type littermates. Mutant placenta and embryonic (e17.5) brain, heart and muscle show varying degrees of mtDNA depletion (20–60%), while there is no appreciable mtDNA depletion in mutant liver. Mouse embryonic fibroblasts (MEFs) derived from e12.5 embryos show a 50% reduction in mtDNA content after five passages for mutant compared to wild type. The mtDNA depletion in MEFs and mutant tissues is functionally significant as indicated by reduced steady state levels of COXI by western and by respiratory chain deficiencies. Ongoing and future studies include performing complementation experiments in cells to determine the structural requirements of Sucla2 for mtDNA maintenance as well as expression of affinity-tagged Sucla2 in mutant MEFs to identify interacting proteins by pulldown and mass spectrometry. This mouse model of Succinyl-CoA ligase deficiency and mtDNA depletion will provide insights into the pathogenesis of mitochondrial diseases with mtDNA depletion and into the biology of mtDNA maintenance as well as facilitate the exploration of novel therapeutic strategies.

662T

Role of Medium Chain Acyl-CoA Dehydrogenase in the Metabolism of Sodium Phenylbutyrate. *K. Kormanik[1,2], H. Kang[1,2], D. Cuebas[3], B. Scharschmidt[4], J. Vockley[1,2], A-W. Mohsen[1]*. 1) Department of Pediatrics, University of Pittsburgh School of Medicine, Pittsburgh, 15224; 2) Department of Human Genetics, University of Pittsburgh, Graduate School of Public Health, Pittsburgh, PA 15213; 3) Department of Chemistry, Missouri State University, Springfield, MO 65897; 4) Hyperion Therapeutics, South San Francisco, CA 94080.

Background: Sodium phenylbutyrate is primarily used to treat urea cycle disorders. Following conversion to phenylbutyryl-CoA ester, it is postulated to undergo one round of β-oxidation to give phenylacetyl-CoA and acetyl-CoA. The former is hydrolyzed to the drug active form phenylacetate. Molecular modeling suggests that medium chain acyl-CoA dehydrogenase (MCAD), a key enzyme in straight chain fatty acid β-oxidation, could utilize phenylbutyryl-CoA as substrate. *Methods*: Phenylbutyryl-CoA was synthesized using mixed anhydride method. Recombinant human MCAD was purified to essential homogeneity using our standard technique. To test the ability of MCAD to bind the phenylbutyryl-CoA, the ester was titrated under anaerobic conditions into the purified MCAD and changes in MCAD flavin spectrum were observed. MCAD enzyme activity using phenylbutyryl-CoA as substrate was tested using the ETF (electron transfer flavoprotein) fluorescence reduction assay. To confirm that MCAD is the enzyme primarily responsible for the β-oxidation of phenylbutyryl-CoA in vivo, extracts of normal and MCAD-deficient lymphoblast cells were tested for their ability to reduce ETF in the presence of the ester. *Results*: Phenylbutyryl-CoA induced a decrease of the MCAD flavin absorbance at 447 nm and an increase at 570 nm. These changes are similar to those induced by octanoyl-CoA, its bona fide substrate, and unique to the development of the charge transfer ternary complex. The calculated apparent binding constant (Kd app) for these substrates was 2.16 μM and 0.12 μM, respectively. ETF was reduced by MCAD in the presence of phenylbutyryl-CoA. The MCAD catalytic efficiency and the Km for phenylbutyryl-CoA were 0.2 mM-1.sec-1 and 5.3 μM compared to 4.0 mM-1.sec-1 and 2.8 μM for octanoyl-CoA. While ETF fluorescence reduction activity was detected in extracts of normal cells, it was undetectable in extracts of cells deficient in MCAD. *Conclusions*: Phenylbutyryl-CoA binding to MCAD was confirmed with the observed generation of the charge transfer complex as well as the ability of this ternary complex to transfer the reducing equivalents to ETF and release the enoyl-CoA product. The results are consistent with MCAD playing a key role in phenylbutyrate metabolism. With the drug being investigated for other uses in >30 different trials, its metabolism and mode of action must be carefully investigated in patients with partial or complete MCAD deficiency.

Common dysfunctional variants of *ABCG2* decrease extra-renal urate excretion and cause hyperuricemia. *H. Matsuo[1], T. Takada[2], A. Nakayama[1], T. Shimizu[3], H. Kasuga[2], H. Nakashima[4], T. Nakamura[5], Y. Takada[6], Y. Kawamura[1], Y. Utsumi[1], H. Ogata[1], M. Nakamura[7], Y. Sakurai[4], T. Hosoya[8], N. Shinomiya[1], H. Suzuki[2], K. Ichida[7,8]*. 1) Dept Integrative Physiol, National Defense Med College, Tokorozawa, Japan; 2) Dept Pharm, Univ Tokyo Hosp, Tokyo Japan; 3) Midorigaoka Hosp, Takatsuki, Japan; 4) Dept Prev Med Publ Health, National Defense Med College, Tokorozawa, Japan; 5) Lab Math, National Defense Med College, Tokorozawa, Japan; 6) Central Res Institute, National Defense Med College, Tokorozawa, Japan; 7) Dept Pathophysiol, Tokyo Univ Pharm Life Sci, Tokyo, Japan; 8) Dept Intern Med, Jikei Univ School Med, Tokyo, Japan.

ATP-binding cassette transporter, sub-family G, member 2 (ABCG2, also known as BCRP) is identified as a high-capacity urate exporter and its dysfunction has an association with serum uric acid (SUA) levels and gout/hyperuricemia risk. Hyperuricemia causes gout and kidney stones, and accelerates development of chronic kidney disease. Generally, hyperuricemia has been classified into urate "overproduction type," "underexcretion type," and "combined type" based on only renal urate excretion, without considering extra-renal pathway such as gut excretion. Here we show that decreased extra-renal urate excretion caused by common dysfunctional variants of *ABCG2* is a novel common mechanism of hyperuricemia. Clinical parameters for urate handling including urinary urate excretion (UUE) were examined in 644 Japanese male outpatients with hyperuricemia. The severity of their ABCG2 dysfunction was estimated by genotype combination of two common *ABCG2* variants, nonfunctional Q126X (rs72552713) and half-functional Q141K (rs2231142). Contrary to the general understanding that ABCG2 dysfunction leads to decreased renal urate excretion, UUE was significantly increased by ABCG2 dysfunction (P=3.60×10^{-10}). Mild, moderate and severe ABCG2 dysfunctions significantly raised the risk of "overproduction" hyperuricemia including overproduction type and combined type, conferring risk ratios of 1.36 (95% confidence interval [CI] 1.09–1.71; P=4.55×10^{-3}), 1.66 (95% CI 1.32–2.10; P=8.58×10^{-6}) and 2.35 (95% CI 1.86–2.97; P=3.32×10^{-7}), respectively. In *Abcg2*-knockout mice treated with uricase inhibitor, oxonate, SUA and renal urate excretion were increased, while intestinal urate excretion was decreased, compared to those of wild-type mice. Together with high ABCG2 expression in extra-renal tissues, these results suggest that common dysfunctional variants of *ABCG2* decrease extra-renal urate excretion, especially in intestines, and cause hyperuricemia. This novel mechanism would have been mistaken for urate "overproduction." Thus, "overproduction type" in the current concept of hyperuricemia should be renamed "renal overload type," which is caused by two different mechanisms, "extra-renal urate underexcretion" and genuine "urate overproduction." This new concept will lead to a more accurate diagnosis and more effective therapeutic strategy for hyperuricemia and gout.

664T

Exploring the phenotype of MMACHC deficiency (*cblC*) in zebrafish with morpholinos and zinc finger nuclease targeted mutagenesis. *J.L. Sloan[1], K. Bishop[2], T.L. Blake[2], R.J. Chandler[1], B.P. Brooks[3], R. Sood[2], C.P. Venditti[1]*. 1) Organic Acid Research Section, Genetics and Molecular Biology Branch, National Human Genome Research Institute, Bethesda, MD; 2) Zebrafish Core Facility, Genetics and Molecular Biology Branch, National Human Genome Research Institute, Bethesda, MD; 3) Ophthalmic Genetics and Visual Function Branch, National Eye Institute, Bethesda, MD.

Cobalamin C deficiency (*cblC*) features a combined impairment of the cobalamin dependent enzymes, methionine synthase and methylmalonyl-CoA mutase. It is caused by mutations in the *MMACHC* gene, which encodes an enzyme that is suspected to participate in cobalamin decyanation and intracellular trafficking. The clinical spectrum of *cblC* is wide and patients can have developmental abnormalities, such as congenital microcephaly, heart defects and intrauterine growth retardation (IUGR). To examine the underlying pathophysiology of this disorder, we have studied the phenotype in zebrafish using two approaches. FITC-tagged morpholinos targeting the cognate ATG and an exonic junction were designed and used to knockdown zebrafish *MMACHC*. Morphants began to display defects at 24 hours, including brain necrosis and diminished movement when compared to controls. The morphants had delayed hatching and were significantly smaller in size, had less blood, smaller heads and eyes, and were neurologically impaired compared to controls. By 96 hours, injected fish displayed pericardial edema. Both morpholinos produced a similar phenotype, which was dose-dependent. The same phenotype was observed in the p53$^{-/-}$ fish, suggesting it is not due to off-target effects. Further investigation using transgenic fish expressing GFP in the CNS revealed underdeveloped brains and absent Rohon-Beard neurons. Additionally, histologic examination revealed a fatty liver and abnormalities in the retina. Metabolic analysis of extracts derived from the morphants showed increased methylmalonic acid (MMA) and cystathionine, and MMA was increased in fish incubated with the precursor, propionic acid (PA). Furthermore, the mutant fish were sensitive to PA, such that they died earlier than the mutant fish not incubated with PA. To extend our morpholino studies, a zinc finger nuclease targeted to *MMACHC* was engineered and an allelic series was created: p.V31fsX78, p.H43PfsX21, p.L44HinsM. We are in the process of breeding and phenotyping these mutant lines. The model presented here is the first animal model of *cblC* and faithfully replicates some of the more severe findings observed in humans. Furthermore, it demonstrates the utility of zebrafish to easily examine aspects of metabolic diseases that will be difficult to study in other organisms, such as embryonic manifestations, and should facilitate the exploration of the underlying pathophysiological mechanisms and testing of new therapies for *cblC*.

Comparative study of gene expression profiling of skin fibroblasts of Leigh syndrome French Canadian subjects and controls. *J. Tardif, C. Laprise, LSFC Consortium.* Université du Québec à Chicoutimi, Chicoutimi, Québec, Canada.

Background: Leigh syndrome French Canadian (LSFC) is a neurodegenerative disorder caused by a mutation in the leucine-rich pentatricopeptide repeat containing (LRPPRC) gene which is implicated in the stability and the handling of mature mRNAs. This mutation leads to a cell specific decrease in cytochrome c oxydase (COX)(complex IV of the respiratory chain), namely 90% in liver and brain and 50% in muscle, fibroblasts, and kidney. The clinical manifestations are hypotonia, developmental delay, chronic well-compensated metabolic acidosis and high mortality before five years old due to frequent of episodes of severe acidosis often leading to coma. LSFC has a carrier rate of 1/23 in the Saguenay-Lac-Saint-Jean region, due to a founder effect. The goal of this study was to determine and compare the gene expression profile of LSFC and control subjects. Methods: Fibroblasts were isolated from skin biopsies of 12 LSFC subjects and 12 control subjects in the LSFC Consortium Biobank that were age and sex paired. RNA was extracted using QIAGEN RNeasy mini kits and genomic expression analysis was performed using Affymetrix Genechip Hgu133plus2 microarrays. A robust multiarray analysis (RMA) normalization, a “batch effects” correction, and a Smyth's moderated t test were used to select differentially expressed genes (p value < 0.05 and absolute fold change ≥ 1.5) (Affy, Limma, and ComBat libraries (R 2.14.1). Findings: Forty-nine differentially expressed genes were identified and classified into seven biological categories. From those genes, eight are involved in energy production and electron respiratory chain whereas five are involved in lipid and glucose metabolism. Differences in the expression of six genes (ACSS3, ND4, ND6, NDUFA4L2, ANGPTL4 and HES1) in these two categories were validated using real-time PCR. Among those genes, NADH dehydrogenase [ubiquinone] 1 alpha subcomplex, 4-like 2 (NDUFA4L2) is of particularly interest in LSFC. NDUFA4L2 is a hypoxia-induced gene, which reduces mitochondrial oxygen consumption through inhibition of complex I activity. This, in turn, limits the production of intracellular reactive oxygen species that would otherwise occur under conditions of low oxygen. Relevance: These findings suggest that the over-expression of NDUFA4L2 may be a compensatory mechanism involved in the survival of LSFC cells and advances our understanding of LSFC. Further studies should permit a better understanding of the role of NDUFA4L2 in LSFC pathology.

***SUCLG1* Mutations Causing Mitochondrial Depletion Syndrome With Congenital Anomalies.** *H.C. Andersson[1,2], M. Landsverk[3], T. Yeh[2], D. Cejas[2], D. Singh[2], L.J. Wong[3].* 1) Hayward Genetics Center, Tulane Univ Med Ctr, New Orleans, LA; 2) Dept Pediatrics, Tulane Univ Med Ctr, New Orleans, LA; 3) Dept. Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

A newborn with congenital anomalies (cleft lip/palate, ectopic left kidney and severe ductal-dependent coarctation of aorta) developed marked and unremitting lactic acidosis on day of life 1 while hemodynamically stable with good blood perfusion. Urine organic acids showed massive lactic acid, small amount of methylmalonic acidemia and 3-hydroxypropionic acid. Serum pyruvate was low (0.1mg/dl) and lactate:pyruvate ratio (>40) was markedly elevated. Muscle biopsy demonstrated markedly decreased complex I and IV and normal pyruvate dehydrogenase complex (CIDEM, Case Western). Muscle mtDNA was markedly depleted (27% of control). Sequencing analysis of SUCLG1 showed homozygous c.749A>G(p.E250G) mutation previously reported to have caused infantile mitochondrial DNA (mtDNA) depletion syndrome. Causes of primary lactic acidosis due to mtDNA depletion are not typically considered to cause congenital anomalies but two prior reports have described three patients with SUCLG1 mutations and mitochondrial depletion with congenital anomalies similar to ours. Rivera et al (Mitochondrion 10:362, 2010) described one male with brain cysts, horseshoe kidney and hypospadius and one female with interrupted aortic arch who both had SUCLG1-related mtDNA depletion syndrome. Randolph et al (MGM 102:149, 2011) describe a Mexican female with craniofacial dysmorphisms and R single palmar crease with c.280-1A>G mutation in SUCLG1. We propose that the phenotype of mtDNA depletion caused by SUCLG1 mutations should be expanded to include congenital anomalies. Physicians evaluating infants with lactic acidosis and congenital anomalies should consider the mtDNA depletion syndrome.

A mouse model of mitochondrial complex I deficiency exhibits progressive cardiac disease and seizures. *W.J. Craigen[1,2,3], T. Donti[1], Y.C. Lai[2], S. Ather[3], X. Wehrens[3], B.H. Graham[1].* 1) Molecular & Human Genetics, Baylor Col Med, Houston, TX; 2) Pediatrics, Baylor Col Med, Houston, TX; 3) Molecular Physiology and Biophysics, Baylor Col Med, Houston, TX.

Mitochondria are essential for many fundamental cellular processes, including energy production, ROS metabolism, Ca2+ homeostasis, and apoptosis. Dysfunctional mitochondria frequently result in multi-organ disease that can include neuronal, endocrine, cardiac and skeletal muscle pathology. Mitochondrial complex I is composed of approximately 45 subunits and is the most common abnormality in mitochondrial respiratory chain disease. NADH:ubiquinone oxidoreductase iron-sulfur protein 4 (NDUFS4) is one of the nonenzymatic, nuclear-encoded subunits of complex I that is essential for assembly. Mutations in NDUFS4 cause complex I deficiency and a Leigh-like phenotype in humans that typically results in death within 3–16 months of birth. A gene trap allele of *Ndufs4* (*Ndufs4*$^{SA\beta geo}$) has been used to generate transgenic animals. Although *Ndufs4* mRNA is reduced to 5% of wildtype levels, *Ndufs4*$^{SA\beta geo}$ homozygotes are viable and exhibit a significant partial deficiency of complex I (20–30% of control activity), as well as a less pronounced partial deficiency of Complex III. Unlike other previously reported mouse strains lacking NDUFS4, *Ndufs4*$^{SA\beta geo}$ mice do not die prematurely, but exhibit increased sensitivity to kainate-induced seizures and impaired cardiac function, with a conduction abnormality, bradycardia, and diminished contractile function. Mouse embryonic fibroblasts obtained from the homozygous mutants exhibit decreased cellular respiration that is corrected by treatment with vitamin E. This mouse model will provide insights into the pathogenesis of mitochondrial complex I diseases as well as facilitate the exploration of novel therapeutic strategies.

Enzyme Function Affected by Mutations in the Sucrase-Isomaltase Gene. *J. Huang, Z. Wu, S. Uhrich, C.R. Scott.* Department of Pediatrics, University of Washington, Seattle, WA. 98195-6320.

Congenital sucrase-isomaltase deficiency (CSID) is a rare, autosomal recessive disease, caused by mutations in the sucrase-isomaltase (SI) gene. The SI gene provides instructions for producing the enzyme sucrase-isomaltase. This enzyme is found in the small intestine and is responsible for breaking down sucrose and maltose into their simple sugar components. These simple sugars are then absorbed by the small intestine. Mutations that cause this condition alter the structure, disrupt the production, impair the function of sucrase-isomaltase and prevent the enzyme from digesting sucrose and isomaltose. The SI gene consists of 48 exons and encodes 1827 amino acids; amino acids from 1 to 1007 form the isomaltase domain, whereas from 1008 to 1827 form the sucrase domain. We have examined thirty-three CSID patients worldwide by sequencing the entire SI gene coding region, and found one nucleotide deletion, one presumed splicing error and 30 missense variations. Among all missense variations, 6 of them change the genetic code into a chain termination codon and 24 of them result in amino acid substitutions. Based on current knowledge, either the nucleotide deletion, splicing error or translation termination will obviously bring major transformation of the enzyme structure and lead to complete loss of enzyme function. We focused our study on the 24 amino acid variations. Applying available softwares, we predict how these variations affect enzyme SI activity. The result shows: (1) At least seven variations F15V, A231T, Q930R, I1111V, L1239L, M1523I and S1802T are expected to have no effect or only mild effect on enzyme function; we coincidentally found 5 of the seven have been listed in SNP database (http://genome.ucsc.edu) correspondingly; (2) Of the remaining 17 variations, the following 10 variations P348L, V577G, L741P, F875S, W931R, G1073D, C1531Y, R1544C, T1606I and F1745C are likely involved in abnormal folding that severely damages enzyme SI function; the mutations V577G, G1073D and F1745C have the highest frequencies in CSID patients.

Hyperammonemia and urea cycle homeostasis in methylmalonic acidemia. *R.J. Chandler[1], H. Morizono[2], P.J. McGuire[3], C.P. Venditti[1].* 1) Genetics and Molecular Biology Branch, National Human Genome Research Institute, National Institutes Health, Bethesda, MD; 2) Research Center for Genetic Medicine, Children's National Medical Center, Washington DC; 3) Genetic Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Methylmalonic Acidemia (MMA) is an autosomal recessive disorder of metabolism caused by a deficiency in the mitochondrial enzyme methylmalonyl-CoA mutase. MMA patients can experience life-threatening metabolic instability with intermittent bouts of hyperammonemia; the mechanism(s) underlying the pathology of these episodes are not well understood. Presently, the inhibition of N-acetylglutamate synthetase (NAGS) by propionyl-CoA, a metabolite elevated in MMA, is thought to indirectly decrease carbamoyl phosphate synthetase 1 (CPS1) activity and cause hyperammonemia in the patients. To investigate possible mechanism(s) of pathology, we performed proteomic analysis of liver extracts from a mouse model of MMA using two-dimensional fluorescence difference in-gel electrophoresis (DIGE) and a quantitative analysis using iTRAQ labeling and tandem mass spectrometry. Proteomic results from the liver of MMA mice revealed decreased levels of the urea cycle (UC) enzymes Cps1, ornithine transcarbamylase (Otc), argininosuccinate synthetase 1 (Ass1), argininosuccinate lyase and arginase compared to controls. The mRNA levels of *Nags* and *Otc*, but not other UC enzymes, were significant reduced in the livers of the MMA mice. To extend these observations, livers from six metabolically stable MMA patients were studied. Immunoblots of patient liver extracts showed normal levels of CPS1, OTC and decreased levels of ASS1. However, the specific activity of CPS1 and OTC were increased in patient livers relative to controls, indicating activation at the enzyme level. Since deficiencies in the urea cycle enzymes cause hyperammonemia, we hypothesize that increased metabolic stress disrupts the normal homeostasis of the UC and contributes to the intermittent hyperammonemia observed in MMA.

Propionic acidemia: Is there a decreased in tricarboxylic acid cycle enzyme functions? *K. Chapman, A. Markowitz-Shulman, G. Cunningham, J. Cabrera-Luque, M. Summar.* Genetics and Metabolism, Children's National Medical Center, Washington, DC.

Background: Propionic acidemia (PA, OMIM #606054) is an organic acidemia caused by dysfunction of propionyl CoA carboxylase leading to accumulation of propionic acid and decrease of down-stream intermediates including the tricarboxylic acid cycle (TCA) intermediate, succinyl CoA. Objectives: Thus, TCA cycle function can be decreased in PA explaining, in part, the decreased energy phenotype seen in patients. Design/Methods: Lymphoblastoid cell lines (LCLs) derived from presumably healthy controls and PA patients were grown in low glucose (about 9 mg/dL) and normal conditions (about 120 mg/dL) for 1 or 3 days and the levels of OGDH and FH were semiquantified by Western blotting. Results: Our studies demonstrate that total protein levels do not change under low glucose conditions compared to regular growth conditions for lymphoblastoid cell lines from individuals with PA. In addition the level of the TCA cycle enzyme, oxoglutarate dehydrogenase (OGDH) as measured semi-quantitatively by Western blot when cells are grown in low glucose conditions as compared to typical conditions is unchanged. Unlike OGDH, fumarate hydratase (FH) levels are increased in low glucose conditions compared to typical conditions after one day. Despite increases in total protein between days one and three, fumarate hydratase amounts are decreased day 3 compared to day 1. Conclusions: Cells from PA individuals are programmed, on the short term, to bypass the site of their decreased intermediate (succinyl CoA) by increasing protein distal to the block (FH), while leaving protein levels proximal to the block (OGDH) less affected.

671F

Cap Myopathy - A Distinct Form of Congenital Myopathy. *S.J. Piteau[1], G. Smith[1], S. Ludwin[2], J. MacKenzie[1].* 1) Pediatrics, Queen's University, Kingston, Ontario, Canada; 2) Pathology, Queen's University, Kingston, Ontario, Canada.

Cap myopathy is a congenital myopathy charaterized by cap structures located at the the periphery of the muscle fiber. Cap structures consist of disarranged thin filaments with enlarged Z discs. We describe a case of cap myopathy in a 7 year old boy and contrast it with 16 other cases identified in the literature. Our case presented at birth with hypotonia and weakness, and he subsequently developed respiratory failure in infancy requiring biPAP at night. He is ambulatory but has increasing fatigue requiring a wheelchair by mid-afternoon. His initial biopsy at 3 months of age showed fiber type disproportion with Type 1 atrophy; a repeat muscle biopsy at 6 years of age was consistent of cap myopathy. Sequencing for the TMP2 gene revealed no mutation. Mutation analysis for the TMP3, ACTA1, and TNNT1 genes is being considered. The clinical presentation and natural history of cap myopathy is variable exhibiting some phenotypic overlap with nemaline myopathy. Our patient has a more severe phenotype than the majority of reported cap myopathy cases in the literature. Our case supports the identification of cap myopathy as a distinct form of congenital myopathy and further elucidates some of the features of this disease.

We defined MEGDEL syndrome as 3-MethylGlutaconic Aciduria with impaired oxidative phosphorylation, Deafness, Encephalopathy, Leigh-like MRI, progressive spasticity and dystonia. Whole exome/Sanger sequencing identified 17 mutations in SERAC1, a gene of unknown function in 18 patients from 16 families. Upon the similarity of MEGDEL and Barth syndrome and the presence of a lipase domain in SERAC1 we performed phospholipid analysis. This revealed abnormal phosphatidylglycerol acyl chain composition, altered cardiolipin subspecies and low bis(monoacylglycero)phosphate levels in patients fibroblasts. As firmly established in Barth syndrome, cardiolipin alterations lead to oxidative phosphorylation dysfunction. Low bis(-monoacylglycero)phosphate levels are known to accumulate intracellular cholesterol, which was confirmed by abnormal filipin staining in patients fibroblasts. SERAC1 was further shown to be localized at the interface between endoplasmatic reticulum and mitochondria, in the mitochondria associated membrane (MAM) fraction, important for the exchange of phospholipids. Complementation of patient fibroblast with wild-type human SERAC1 by lentiviral infection led to a normalization of the phosphatidylglycerol acyl chain composition, linking SERAC1 mutations to the compromised phosphatidylglycerol remodeling. SERAC1 is crucial for both mitochondrial function and intracellular cholesterol trafficking. Our data identify SERAC1 as key player in phosphatidylglycerol remodeling as well as first enzyme in the as yet unknown bis(monoacylglycero)phosphate biosynthetic pathway.

673F

Somatic cell diagnostic studies may miss some patients with mutations in *MMAA* and *MMAB*, genes responsible for isolated methylmalonic aciduria. *L. Dempsey Nunez[1], M.L. Illson[1], J. Kent[2], Q. Huang[2], A. Brebner[1], D. Watkins[1], B.M. Gilfix[3], C. Wittwer[2], D.S. Rosenblatt[1,3].* 1) Human Genetics, McGill University, Montreal, Qc, Canada; 2) Department of Pathology, University of Utah Medical Center, Salt Lake City, Utah; 3) Department of Medicine, McGill University, Montreal, Quebec, Canada.

The gene products of MMAA and MMAB are required for the intracellular metabolism of cobalamin (Cbl). Mutations in these genes lead to the cblA and cblB class of disorders that are characterized by isolated methylmalonic aciduria. We have been concerned that somatic cell methods of diagnosis may miss patients with mild cellular phenotypes. A high resolution melting analysis (HRMA) assay was developed to rapidly scan the coding exons and flanking intronic regions of the MMAA and MMAB genes for variants. DNA from 96 unaffected reference individuals, 42 patients with complementation confirmed cblB, 72 patients with complementation confirmed cblA, and 181 patients with elevated isolated methylmalonic acid, who could not be diagnosed using complementation analysis, were scanned by HRMA. Suspected variants were confirmed using Sanger sequencing. In the cblA cohort, HRMA correctly identified all previously known mutations as well as an additional 22 variants, 10 of which had not been previously reported. Novel variants included one duplication (C.551dupG, p.C187LfsX3), one deletion (c.387delC, p.Y129YfsX13), one splice site mutation (c.440-2A>G, splice site), 4 missense mutations (c.748G>A, p.E520K; c.820G>A, p.G274S; c.627G>T, p.R209S; c.826A>G, p.K276E), and 3 nonsense mutations (c.960G>A, p.W320X; c.1075C>T, p.E359X; c.1084C>T, p.Q362X). All novel variants, listed below, affect highly conserved residues and are predicted to be damaging. In the cblB cohort, HRMA correctly identified all of the previously reported mutations as well as 9 additional variants, one of which was novel (c.12C>A, p.C4X). Scanning of MMAA in the 181 undiagnosed samples revealed a single novel heterozygous missense change (c.821G>A, p.G274D). Scanning of MMAB in the same samples identified 8 variants in 6 samples. Five of these variants were previously characterized as mutations, while 3 were novel missense variants (c.185C>T, p.T62M; c.398C>T, p.S133F; c.394T>C, p.C132R). The identification of 2 individuals among the undiagnosed samples with compound heterozygous variants in the MMAB gene suggests the existence of an unrecognized atypical MMA phenotype for cblB. This mild phenotype was not detected through somatic cell studies, and demonstrates the need for additional diagnostic approaches such as HRMA to screen clinical samples from patients with isolated MMA.

674T

The clinical spectrum of combined malonic and methylmalonic aciduria, a defect in the intramitochondrial fatty-acid-biosynthesis pathway. *I. Manoli[1], J.L. Sloan[1], J.J. Johnston[2], L. Peller[2], J.C. Sapp[2], L.G. Biesecker[2], C.P. Venditti[1].* 1) Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD; 2) Genetic Disease Research Branch, NHGRI, NIH, Bethesda, MD.

We have identified acyl-CoA synthetase family member 3 (*ACSF3*) as the gene encoding a malonyl- and methylmalonyl-CoA synthetase residing in the mitochondrial matrix. ACSF3 deficiency causes a form of combined malonic and methylmalonic aciduria/acidemia (CMAMMA). In these patients, methylmalonic acid predominates and malonyl-CoA decarboxylase activity is normal. *ACSF3* mutations occur with a minor allele frequency of 0.005 in ~5,950 control individuals, predicting that CMAMMA has a population incidence of ~1:40,000. To further delineate the phenotypes associated with this enzymopathy, we evaluated fifteen subjects, 1.5–64 years of age, with CMAMMA. Seven subjects were diagnosed in adulthood with neurological or psychiatric manifestations (seizures, memory problems, psychiatric disease and/or cognitive decline, peripheral sensory neuropathy and optic nerve atrophy), after exclusion of vitamin B12 deficiency and other more common diagnoses. Three subjects presented during childhood with symptoms suggestive of an intermediary metabolic disorder (coma, ketoacidosis, hypoglycemia, failure to thrive, elevated transaminases), while the five others had more general findings including microcephaly, dystonia, axial hypotonia, muscle weakness, seizures, mild dysmorphic features, autism and global developmental delay. Three out of ten apparently unaffected siblings were diagnosed with CMAMMA after the index case was ascertained in each family. Missense mutations and one in-frame deletion were located in highly conserved acyl-CoA synthetase motifs, while none of the patients carried two nonsense mutations. One mutation, p.R558W, was present in 13/30 alleles. In one subject only one mutation was identified. In another, no damaging mutations were detected; however fibroblasts from this subject showed increased methylmalonic acid secretion following *in vitro* stimulation. Given the predicted population incidence, it is likely that many patients with ACSF3 deficiency remain undiagnosed. Furthermore, the variable clinical phenotypes observed in the patient cohort mandates the consideration of alternative diagnoses in addition to CMAMMA. The generation of an *ACSF3* mouse model will be required to understand the pathogenic role of mutations and to define disease pathophysiology.

675F

Neurochemical profiles in children with inborn errors of metabolism determined by in vivo 1H-magnetic resonance spectroscopy. *W. Al-Hertani[1], E. Mason[1], T. Tam[1], B. Schmitt[3], S. Blaser[2], H. Branson[2], A. Schulze[1].* 1) Division of Clinical and Metabolic Genetics, Hosp Sick Children, Univ Toronto, Toronto, ON, Canada; 2) Division of Diagnostic Imaging, Hosp Sick Children, Univ Toronto, Toronto, ON, Canada; 3) Dept of Radiology, Med Univ Vienna, Vienna, Austria.

Background: Proton Magnetic Resonance Spectroscopy (1H-MRS) is a useful, non-invasive tool for in vivo assessment of biochemical profiles in the human brain. However, our knowledge about the metabolites and neurochemical profiles in metabolic disease is limited. **Objective:** Quantitative description of neurochemical profiles in children with inborn errors of metabolism (IEM). **Methods:** Retrospective quantitative data analysis from children with 42 different diagnoses of IEM, including i.e. Organic Acidurias (16 patients), Remethylation defects (7), Urea Cycle defects (7), Storage disorders (43) and OXPHOS defects (7), and comparison with age-matched normative data from 2,275 children. MRS data were obtained from basal ganglia (BG) and periventricular white matter (PVW), by the point resolved spectroscopy sequence (PRESS) method: TR = 2000 ms, TE = 35/144 ms, NEX = 128. Post-processing of data and analysis was performed using LCmodel software. **Results:** A number of abnormal neurochemical profiles were identified including low total choline in MMA, Arginase deficiency, MTHFR deficiency and SSADH deficiency, low total creatine in Citrullinemia, Arginase deficiency, and Krabbe, and high Inositol in Citrullinemia and NCL. Observed changes can be related to the pathophysiology of the disease or to the treatment. **Conclusions:** Quantitative neurochemical profiling applying normative data will add to the understanding of the pathophysiology of IEM and will be a useful tool for treatment monitoring.

Analyzing Functional Phenotypes in Fibroblasts from Patients with Clinically-Diagnosed Mitochondrial Disease. *B. Graham[1], T. Donti[1], A. Bessee[2], W. Craigen[1,3], P. Bonnen[1,2].* 1) Dept Molecular & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor Col Medicine, Houston, TX; 3) Dept Pediatrics, Baylor Col Medicine, Houston, TX.

Mitochondria are intracellular organelles that are essential for many cellular functions including oxidative phosphorylation and energy metabolism. The mitochondrial proteome is derived from two genomes: the nuclear genome and the mitochondrial DNA (mtDNA). Mutations in either mtDNA encoded or nuclear encoded genes cause mitochondrial disease. Fibroblast cell lines derived from patients with clinically-suspected mitochondrial disease provide a convenient resource for research studies, but the perceived low sensitivity of this cell type for displaying abnormal mitochondrial phenotypes has limited their diagnostic use. For this study, a collection of primary fibroblast cell lines from at least 16 unrelated patients with clinically-diagnosed mitochondrial disease but no molecular diagnosis was subjected to a battery of assays for mitochondrial function. Tests include assays for cellular respiration, electron transport chain (ETC) activities, relative changes in mitochondrial membrane potential (MMP), increased reactive oxygen species (ROS), changes in mtDNA copy number, and abnormal mitochondrial morphology. To date, 7 out of 16 (44%) patient cell lines exhibit abnormalities in ETC activities and/or mtDNA content compared to controls with other assays pending. A battery of functional assays in fibroblasts offers the promise of increased diagnostic sensitivity and can ultimately be used to functionally screen candidate disease genes identified from whole exome studies.

Clinical Molecular Laboratory Analysis of the Genes of Fatty Acid Oxidation. *M.T. Hardison, M. Landsverk, L. Wong.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Fatty acid oxidation (FAO) is integral in maintaining normal mitochondrial homeostasis and vital to the function of the electron transport chain and subsequent production of adenosine tri-phosphate (ATP). Deficiencies in genes involved in FAO are autosomal recessive disorders that result in a decreased ability to oxidize fatty acids, thereby signifying metabolic dysfunction. Early detection by newborn screening (NBS) through the measure of acylcarnitines using tandem mass spectrometry has increased the number of patients identified with FAO deficiencies through the identification of milder phenotypes. However, acylcarnitine profiles alone cannot confirm a diagnosis; activated mitochondrial fatty acid oxidation during catabolism can lead to false positives. In addition, mutations in these genes can result in phenotypes that overlap with other disorders. Additional tests such as mutation analysis of a suspected gene are often necessary to confirm a proper diagnosis. We analyzed all individuals submitted to our laboratory for clinical molecular testing of genes involved in FAO: ACADM (MCAD), ACADVL (VLCAD), HADHA (LCHAD), HADHB, LCAD, SLC25A20 (CACT), ETFA, ETFB, ETFDH, CPT1A, CPT1B, and CPT2 from January 2007 to December 2011. More than 2135 samples were reviewed with phenotypes ranging from positive newborn screen results to rhabdomyolysis to hypoglycemia. 184 patients were identified with at least two known mutations, either apparently homozygous or in a compound heterozygous state. Additionally, 381 patients were identified to carry a single known mutation and are carriers of FAO diseases. Finally, a total of 164 patients with novel variants were identified in 8 of the 12 genes investigated. Due to the large number of unclassified variants in each of these genes, frequent review of the literature is required to interpret sequencing data of FAO patients. Since the clinical presentation of FAO disorders can be very heterogeneous, this group of genes should be considered in patients with muscle myopathy or rhabdomyolysis. For example, one of the patients in our cohort presented with recurrent rhabdomyolysis and was initially tested for McArdle disease (Glycogen Storage Disease type V) when in fact, she was compound heterozygous for two CPT2 mutations. We are currently developing a next generation sequencing panel consisting of all of the FAO genes that will be a useful tool in the analysis of patients with suspected FAO disorders.

Fabry Disease: Molecular analysis of GLA in females with no family history. *D. Doheny[1], I. Nazarenko[1], J. Kim[1], R. Dobrovolny[1,2], R. Desnick[1].* 1) Dept Gen and Genomic Scienc, Mount Sinai Sch Med, New York, NY; 2) Institute of Inherited Metabolic Disorders Ke Karlovu 2, Praha 2, Czech Republic.

Fabry disease (FD) is an X-linked lysosomal storage disorder due to deficiency of the lysosomal enzyme, α-galactosidase A, resulting in progressive accumulation of globotrioasylceramide (GL-3) and related glycosphingolipids in plasma and tissue lysosomes throughout the body. Classically affected males (<1% α-Gal A activity) present in childhood with acroparesthesias, angiokeratomas, corneal/lenticular opacities, hypohidrosis, and, with advancing age, renal failure and cerebrovascular and cardiovascular complications leading to early demise, whereas later-onset variants with residual α-Gal A activity present in later life with cardiac and/or renal disease without the classic childhood manifestations. Manifestations in heterozygotes (hets) of both the classic and variant forms of FD are variable due to Lyonization and often non-specific. Diagnosis of FD in males with either phenotype is reliably made by demonstrating markedly deficient α-Gal A enzyme activity. In female hets, enzymatic diagnosis can be problematic as their α-Gal A activities are variable, 50% being normal. Thus, accurate diagnosis of hets requires GLA gene analysis, beit targeted analysis of known family GLA mutation or sequencing. Due to symptom variability in hets, females are often presented for FD testing without FD-specific symptoms or family history of FD. We present our experience in FD testing of such females. Routine FD testing, both enzymatic assay and DNA analysis, was performed in a CLIA-approved laboratory. Dosage analysis to detect large GLA deletions/duplications was performed as previously reported (Dobrovolny et al, Hum Genet 2010). Among 317 females with no family history of FD, enzyme assay was performed on 280, sequencing on 193 of which 64 (33%) were found to have a GLA mutation. Based on review of clinical information of those without a mutation (N=129), dosage analysis was performed on 36, identifying three (8%) with large GLA deletions. Extensive review of medical records and clinical information revealed differences in frequency of FD-specific symptoms between those females with and without a GLA mutation, specifically corneal findings and renal morphology, whereas incidence of other FD-related but non-specific symptoms were similar. These findings suggest that corneal findings and renal morphology are primary indicators for FD testing in females without a family history of FD; such clinical findings should be differentiated from phenocopies.

Maple syrup urine disease due to a new point mutation at BCKDHB in Iranian family. *M. Hamid[1], G.R Shariati[2,3], A.H Saberi[2,3], M. Mohammadi[2].* 1) Pasteur Institute of Iran, Tehran, Iran; 2) Narges Medical Genetics & PND Laboratory, No. 18, East Mihan Ave, Kianpars, Ahvaz, Iran; 3) Department of Medical Genetic, Faculty of Medicine, Ahvaz Jundishapur University of Medical Sciences, Ahvaz, Iran.

Maple syrup urine disease (MSUD) is a rare autosomal recessive disorder of branched-chain amino acid (BCAA) metabolism caused by the defective function of branched-chain a-ketoacid dehydrogenase complex (BCKD). The disease-causing mutations have already been described in BCKDHA, BCKDHB and DBT. In this study, we report a couple who first presented to our clinic from south of Iran with Arab ethnic origin. Mutation analysis confirmed that this couple, who were first cousins were heterozygous for a novel mutation, p.E330K (GAG>AAG) mutation in exon 9 at BCKDHB gene. This finding, potentially facilitate prenatal diagnosis during subsequent pregnancy and carrier detection. In addition, this mutation expands the mutation spectrum of this disease.

680T

Peanut Consumption Increases Levels of Plasma Very Long Chain Fatty Acids in Humans. *C.T. Lam[1,5], D.A. Wong[1], S.D. Cederbaum[1,2,3], B. Lim[4], Y. Qu[4].* 1) Department of Pediatrics, University of California Los Angeles, Los Angeles, CA; 2) Department of Psychiatry, University of California Los Angeles, Los Angeles, CA; 3) Department of Human Genetics, University of California Los Angeles, Los Angeles, CA; 4) Department of Genetic Testing, Kaiser Permanente Southern California, Los Angeles, CA; 5) Medical Genetics Branch, NHGRI, National Institutes of Health, Bethesda, MD.

Peanut consumption has been suspected of raising plasma levels of C26:0 and C26:0/C22:0 to levels indistinguishable from that found in patients with peroxisomal disorders, such as X-linked adrenoleukodystrophy. However, this occasionally observed phenomenon has not been systematically studied or documented in humans. The objective of this study is to determine if peanut consumption in the form of peanut butter will significantly elevate plasma levels of very long chain fatty acids into the range that would raise concern for a peroxisomal disorder in humans. We enrolled six subjects in a prospective, IRB-approved protocol where plasma very long chain fatty acids were measured before and after consumption of four tablespoons of peanut butter. We found that peanut butter consumption did significantly elevate plasma C26:0 and C26:0/C22:0 to levels indistinguishable from those seen in patients with peroxisomal disorders. C26:0 level exceeded upper normal limit reaching peak values within 3 to 4 hours after peanut butter consumption in all 6 subjects. The C26:0/C22:0 ratio also exceeded the upper normal limit in all 6 subjects and reached the peak value within 3 to 4 hours in 5 out of 6 subjects. Twelve hours after peanut butter consumption, levels of C26:0 and C26:0/C22:0 ratio returned back to the normal range in all 6 subjects. When comparing peak versus baseline mean very long chain fatty acid levels and their related ratios, a statistically significant difference was observed for C26:0 ($p<0.0032$) and C26:0/C22:0 ratio ($p<0.0001$). Although the means are significantly different between baseline and peak values for C22:0 ($p<0.0116$) and C24:0 ($p<0.0107$), the levels of C22:0 and C24:0 in two subjects never exceeded the upper normal limit. Of note, in our study, the participants were allowed to resume a regular diet with the exception of avoiding foods containing peanut oil, olive oil, corn oil, mustard oil, and Lorenzo's oil, and none of the levels of C26:0 or C26:0/C22:0 significantly increased with other food consumption during the study period. Thus we conclude that the consumption of peanuts is a definite cause of elevations of very long chain fatty acids and needs to be taken into account when interpreting these laboratory values. Additionally, this study suggests that dietary causes of elevations in very long chain fatty acids maybe specific to peanuts and foods known to be high in C26:0 content instead of food in general.

Diagnostic Testing for Multiple Treatable Metabolic Neurodegenerative Disorders by Next Generation Sequencing. *S. van Koningsbruggen[1], O.R. Mook[1], G. Visser[2], M.A. Haagmans[1], R.C. Hennekam[3], G.S. Salomons[4], P. Verwaijen[5], H.R. Waterham[6], F.A. Wijburg[3], M.M. Mannens[1].* 1) Clinical Genetics, University of Amsterdam, Academic Medical Center, Amsterdam, The Netherlands; 2) Department of Metabolic Diseases, Wilhelmina Children's Hospital Utrecht, University Medical Center Utrecht, Utrecht, The Netherlands; 3) Department of Pediatrics, University of Amsterdam, Academic Medical Center, Amsterdam, The Netherlands; 4) Metabolic Unit, Department of Clinical Chemistry, VU University Medical Center, Amsterdam, The Netherlands; 5) Actelion Pharmaceuticals Nederland B.V. Woerden, The Netherlands; 6) Lab. Genetic Metabolic Diseases, University of Amsterdam, Academic Medical Center, Amsterdam, The Netherlands.

The group of Metabolic Neurodegenerative disorders is comprised of a wide variety of disorders, caused by mutations in different genes. Most of these disorders are progressively degenerative and characterized by non-specific symptoms such as mental retardation and epilepsy, which can seriously hamper the diagnosis of patients. Because a subset of the disorders is (partially) treatable, this group of patients would greatly benefit from an early and accurate diagnosis. We have set up a diagnostic assay using Next Generation Sequencing in which we can screen in parallel for multiple genes involved in 50 treatable metabolic neurodegenerative disorders. We have developed a capture array to enrich all coding exons and the flanking intronic regions of 60 involved genes. These sequences are subsequently run on the Roche 454 GS-FLX sequencer and analysed using the Roche mapper software followed by a homemade analysis pipeline. We complement this platform with Sanger sequencing of the homopolymer regions and the low coverage regions such as some of the high GC rich first exons. Using this combined approach, we are now able to obtain and analyse the complete coding sequence and flanking regions of 60 genes within a turnaround time of 2 months. Our diagnostic test for 50 disorders, that can be difficult to discriminate, will allow a much faster diagnosis, which is essential in these treatable progressive disorders. Results of the first series of patients are presently pending. This study was supported by a grant from Actelion Pharmaceuticals Nederland BV.

682T

Prevalence of *GNE* p.M712T and Hereditary Inclusion Body Myopathy (HIBM) in Sangesar Population of Northern Iran. *H. Khademian[1, 2], R. Carbajo[1, 3], E. Mehravar[2], L. Sandoval[1, 4], J. Garcia-Figueroa[1, 4], Z. Khokher[1, 3], D. No[1, 3], Y. Valles-Ayoub[1], D. Darvish[1].* 1) HIBM Research Group, Reseda, CA; 2) Sangesar Charity Organization for HIBM, Sangesar, Semnan, Iran; 3) California State University Northridge, Northridge, CA, USA; 4) Los Angeles Mission College, Sylmar, CA, USA.

GNE myopathy or Hereditary inclusion body myopathy (HIBM) is an ultra-rare severely disabling autosomal recessive adult onset muscle disease which affects roughly 1–3 individuals per million worldwide. Genetically, HIBM is caused by mutations in the glucosamine (UDP-N-acetyl)-2-epimerase/N-acetylmannosamine kinase gene (*GNE*), resulting in diminished enzyme function and reduced sialic acid biosynthesis. A founder variant *GNE* p.M712T was first described in patients of Iranian and Middle-Eastern descent living outside of Iran. Asymptomatic heterozygote or carrier frequency has been reported as high as 1 in 11 within the Persian-Jewish community residing in Los Angeles, California. To investigate the prevalence of the p.M712T variant in Iran, we studied 792 random samples in Sangesar (Mahdishahr) in Northern Iran. DNA samples were obtained by buccal swab, and genotyping was performed by melting curve analysis. The results included 31/792 (3.91%) heterozygous carriers and 5 (0.31%) homozygotes for *GNE* p.M712T. All 5 homozygous individuals, age 30–64 years, were already symptomatic at the start of the study. In addition, 7 of the wild type samples had HIBM-like symptoms; interesting results were found after sequencing the entire *GNE* gene. Our findings suggest that the prevalence of *GNE* p.M712T is higher in the Sangesar population, comprised mostly of Muslim and Bahai descendants, compared to the general world population. Additional studies are warranted to further elucidate the prevalence of the *GNE* p.M712T allele within various sub-populations of Iran.

683F

Clinical application of massively parallel sequencing for molecular diagnosis of genetically heterogeneous Glycogen Storage Diseases. *J. Wang[1], H. Cui[1], NC. Lee[2], WL. Hwu[2], YH. Chien[2], WJ. Craigen[1], LC. Wong[1], VW. Zhang[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, United States; 2) Department of Pediatrics and Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan.

Glycogen storage diseases (GSDs) are a group of inherited genetic disorders of glycogen synthesis or catabolism that can involve multiple organ systems, including skeletal muscle and the liver. Early diagnosis with proper treatment can greatly improve the quality of life, reduce organ damage, and extend patient's life span. Due to the genetic heterogeneity and limited availability of invasive biopsy for enzyme studies, the definitive diagnosis of GSDs is based on sequence analysis of selected potentially causative genes, which is costly and time consuming, often leading to delayed diagnosis. We developed the next generation sequencing (NGS) based approach by simultaneous capture of 16 genes currently known to cause both muscle and liver forms of GSDs: GYS2, GYS1, G6PC, SLC37A4, GAA, AGL, GBE1, PYGM, PYGL, PFKM, PHKA2, PHKB, PHKG2, PHKA1, PGAM2, and PGM1, followed by massively parallel sequencing (MPS). All nucleotides in the coding regions of 16 genes have been enriched with sufficient coverage in an unbiased manner. A total of 7 samples with known mutations were validated. All disease causing mutations were identified correctly. The mutations include single nucleotide substitution, small deletions and insertion/duplications. The results showed 100% sensitivity and specificity compared to Sanger sequencing. In addition, a total of 17 DNA samples from unrelated individuals with clinical and/or enzymatic findings suggestive of GSD but without identified mutations were analyzed. Deleterious mutations or novel variants in various GSD genes were detected in 11 patients (11/17=65%) and therefore confirmed the diagnosis. Most importantly, the uniform deep coverage of all coding sequence regions allows the detection of large deletions involving single or multiple exons. Homozygous or hemizygous deletions were identified in 3 patients by a lack of coverage in the targeted regions. Heterozygous exonic deletion can also be detected by analyzing the sequence reads using computational programs. Our data underscore the importance and clinical utility of MPS-based analysis in the molecular diagnosis of a defined disorder that may be caused by defects in multiple genes. The high throughput MPS strategy to simultaneously analyze all the genes responsible for liver and muscle forms of GSD greatly improves the diagnosis of GSD in a cost and time efficient manner.

Findings from the ZOOM genetic screening study of Niemann-Pick disease type C in adults with neurological and psychiatric signs. *P. Bauer[1], D.J. Balding[2], H.H. Klünemann[3], D. Linden[4], D. Ory[5], M. Pineda[6], J. Priller[7], F. Sedel[8], A. Muller[9], H. Chadha-Boreham[9], R. Welford[9], D.S. Strasser[9], J.E. Wraith[10], M.C. Patterson[11]*. 1) Dept Medical Genetics, University of Tuebingen, Tuebingen, Germany; 2) Institute of Genetics, University College London, UK; 3) Regensburg University Clinic for Psychiatry and Psychotherapy, Regensburg, Germany; 4) Psychological Medicine and Neurology, Cardiff University, UK; 5) Washington School of Medicine, St. Louis, Missouri, USA; 6) Hospital Sant Joan de Déu, Barcelona, Spain; 7) Neuropsychiatry, Charité-Universitätsmedizin, Berlin, Germany; 8) Pitié Salpêtrière Hospital, Paris, France; 9) Actelion Pharmaceuticals Ltd, Allschwil, Switzerland; 10) Manchester Academic Health Science Centre, St Mary's Hospital, Manchester, UK; 11) Mayo Clinic, Rochester, MN, USA.

Niemann-Pick disease type C (NP-C) is a rare, autosomal-recessive, fatal progressive neurological disease caused by mutations in either the *NPC1* gene (in 95% of cases) or the *NPC2* gene. Late-onset cases of NP-C (at ≥15 years of age) are being recognised with increasing frequency. Psychiatric manifestations are prevalent among adult patients. The ZOOM study was designed to evaluate the frequency and phenotypes of NP-C in adult patients with neurological and psychiatric symptoms. Consecutive patients aged ≥18 years with psychosis and/or early-onset progressive cognitive decline combined with neurological and/or visceral symptoms were recruited from psychiatric and neurological reference centres. Diagnostic testing for NP-C involved *NPC1* and *NPC2* exonic gene sequencing and multiplex ligation-dependent probe amplification (MLPA) analysis. When available, results of filipin staining were collected. Plasma oxysterol (cholestane-3β,5α,6β-triol) and other metabolites are also being investigated as potential biomarkers for NP-C. *NPC1* and *NPC2* gene sequencing was completed in 250/256 enrolled patients from 30 centres in the EU and USA (median [range] age 38 [18–90] years). Three patients had a confirmed diagnosis of NP-C: two based on gene sequencing alone (known causal disease mutations) and one based on gene sequencing and positive filipin staining. The latter patient had one known causal disease mutation and one unclassified variant in the *NPC1* gene. All three NP-C positive patients had early-onset cognitive decline with or without psychosis combined with characteristic neurological symptoms of NP-C. A further 12 patients displayed either single mutant NP-C alleles (8 with *NPC1* mutations and 3 with *NPC2* mutations) or a known causal disease mutation and an unclassified *NPC1* allele variant (n=1). All 12 of these patients had either psychosis (n=9), early-onset progressive cognitive decline (n=1) or both (n=2), and 9 of them also had neurological symptoms. Overall, the NP-C carrier frequency in this patient sample was higher than in the general population. Further analyses are currently ongoing to investigate whether the combination of clinical manifestations, genetic analysis and filipin staining (when available), associated with measurement of oxysterol and other metabolite levels, could help to improve the diagnosis of NP-C in this patient population.

Detection of mucopolysacchariduria in dried-urine filter paper samples: an useful technique for regions where transportation of liquid samples is challenging. *R. Giugliani[1,2,3], F. Bender[1,2,3], G. Marasca[1,2], R. Guidobono[1,2], J. De Mari[1,2], M. Burin[1,2,3], G. Civallero[1,3]*. 1) Dep Genetics / Med Genet Serv, HCPA/UFRGS, Porto Alegre, RS, Brazil; 2) MPS Brazil Network, Porto Alegre, RS, Brazil; 3) INAGEMP - Brazilian National Institute of Population Medical Genetics, Porto Alegre, RS, Brazil.

The mucopolysaccharidoses (MPS) are caused by storage of glycosaminoglycans (GAGs) and other complex molecules in tissues, among other pathogenic mechanisms. New therapies are available or are in development for these pathologies, and early diagnosis seems to be important for the therapy outcomes. Almost all patients have increased levels of GAGs in urine. However, test of urine may be challenging as transportation of liquid urine samples in appropriate conditions for long distances, especially across international borders, could be difficult. Objectives: To standardize and validate a method for collection and analysis of GAGs levels in urine spotted in filter paper. Methods: Random urine samples were collected from untreated MPS patients and from controls. To part of the control samples it was added chondroitin sulphate in different concentrations. An aliquot of the urine sample was refrigerated at 4°C while another aliquot was impregnated in the filter paper. The assay of GAGs in liquid urine or in DUFP samples was performed according to the method of De Jong et al, 1992, with slight modifications. Specifically for DUFP samples, 15 paper circles of 6.0 mm diameter were diluted in 1.1 ml of distillated water and incubated overnight at 4°C. After incubation, 125 ul of this solution were used for the assay of GAGs and 50 ul for creatinine determination. Non-parametric tests were used to measure differences between creatinine and GAGs assay in urine and DUFPs, and differences between GAGs concentrations in normal and affected subjects. Results: Concentrations of creatinine and GAGs in liquid urine and on their corresponding DUFP samples from normal subjects were analyzed. No statistically differences were found in these assays ($p<0.05$). Added chondroitin sulfate was similarly recovered from liquid urine or DUFP samples. Concentrations of GAGs in urine or DUFP from normal controls and MPS patients showed similar discrimination between groups. Concentration of GAGs in MPS patients never overlapped with that of normal controls. Our results showed no differences in the concentration of GAGs between liquid and dried samples. Untreated patients with MPS and normal controls were well discriminated using any of the samples. Conclusion: the assay of GAGs in dried-urine filter paper samples is a helpful method for the identification of patients with MPS, and that its incorporation in reference laboratories should be considered.

686T

Analysis of non-reducing ends (NRE) of glycosaminoglycans for the diagnosis and monitoring of therapy in mucopolysaccharidoses type I and type II. *T. Yuzyuk[1], E. Schwarz[2], J. Brown[4], B. Crawford[4], M. Pasquali[1,2,3]*. 1) Department of Pathology, University of Utah Health Sciences Center, Salt Lake City, UT; 2) ARUP Institute for Clinical and Experimental Pathology ®, Salt Lake City, UT; 3) ARUP Laboratories Inc., Salt Lake City, UT; 4) Zacharon Pharmaceuticals Inc., San Diego, CA.

Mucopolysaccharidoses Type I and Type II (MPS I and MPS II) are lysosomal storage disorders caused by deficiency of alpha-L-iduronidase and Iduronate-2-sulfatase, respectively. The deficiency of these enzymes impairs the degradation of glycosaminoglycans (GAGs), with accumulation of dermatan and heparan sulfate. Both disorders affect multiple organs and, in some cases, the central nervous system. Enzyme replacement therapy is available for both conditions and better biomarkers are necessary for monitoring treatment. Traditional methods analyze intact GAGs and cannot distinguish between the two mucopolysaccharidoses and provide only limited specificity to monitor response to treatment. GAGs are degraded in the lysosome from their non-reducing ends and deficiency of an enzyme causes the accumulation of a modified sugar in this position specific for each disorder. The Sensi-Pro® Non-Reducing End (NRE) assay can identify and quantify (by UPLC-MS/MS) the non-reducing ends of the accumulated GAGs after digestion with enzymes specific for each GAG. Here we show that this NRE assay distinguished the GAGs accumulated in patients with MPS I and MPS II: the NREs of heparan and dermatan sulfate accumulated in these two mucopolysaccharidoses differed in mass to charge ratio and/or in retention time. Normal controls had no accumulation of these species. In addition to NREs, this method generates fragments corresponding to internal disaccharides that could be used as a measure of total GAGs. Our results show that analysis of GAGs by analysis of NREs can identify biomarkers specific for each mucopolysaccharidosis and allow the simultaneous measurements of total GAGs. These biomarkers can greatly increase our ability to diagnose and monitor response to treatment in patients with mucopolysaccharidoses.

Rare, bizarre, and complex illnesses with unusual medical events in patients should be a signal to trigger a mitochondrial work-up: clinical decision tree for mitochondrial disorder work up is provided. *A. Perszyk.* Pediatric Multispecialty Ctr, Univ Florida, Jacksonville, FL.

Mitochondria produce energy for all the cell's processes. When a sudden or acute event occur these changes might first sign of cellular malfunctioning. The more an event is rare, bizarre, unexpected one should be keen to study that patient more fully to ascertain the reason. Complex illnesses involve multiple organ systems. Any unusual medical event, sudden change or unexpected illness may have a more hidden etiology then the most obvious or apparent explanation. In patients with any such events, the clinician should begin a mitochondrial work-up. Decision tree for assistance in suspecting mitochondrial disorders is presented. These are the reasons for genetics consultation that lead to an eventual diagnosis of an energy pathway defect or inborn error of metabolism in either mitochondrial oxidative phosphorylation, Krebs cycle defect, or a fatty acid oxidation defect. Any complex medical disease can mimic mitochondrial disorders. Secondary mitochondrial disturbance and disease progression can be the basis of additional interventions that can benefit patient health and may in some instances reverse recent decline in patient health. Mitochondrial diseases must be diligently sought and work up for these must be done before concluding that the symptoms in question are not mitochondrial in origin. The hospitalist and office practitioner should be keen to do a mitochondrial metabolic work-up for previously healthy patients that have sudden episodes of mental status changes, ataxia, unexplained weakness, hearing loss or idiopathic thrombocytopenia. We have made diagnoses in patients that first presented with cardiac arrhythmia, electromechanical dissociation, enlarged kidneys, renal tubular acidosis, ascites without hepatomegaly. Recurrent fevers, recurrent aspiration pneumonia, osteopenia and recurrent fractures, depression, anorexia nervosa, and cyclic vomiting syndrome. Severe seizure disorder, central apnea, lactic acidosis, neurocognitive decline and patient referral to hospice end-of-life care. Mitochondrial disorders can be misdiagnosed as polyneuropathy, HLH, abnormal CPK, post-anesthetic complications with respiratory insufficiency or rhabdomyolysis, fasting induced hypoglycemia, recurrent rhabdomyolysis, and epileptic neurodegeneration. Interventions have improved outcomes in our patients, but the key is to know when to first suspect that a mitochondrial disorder may be present.

688T

Clinical re-sequencing of 450 genes to diagnose mitochondrial disorders: Results from the first 119 patients. *J. DaRe[1], V. Vasta[2], T. Tran[2], J. Penn[1], L. Susswein[1], J. Booker[1], S. Hahn[2,3].* 1) Transgenomic, Inc., New Haven, CT; 2) Seattle Children's Hospital Research Institute, Seattle, WA; 3) University of Washington, School of Medicine, Seattle, WA.

The diagnosis of mitochondrial disorders (MD) is very challenging as they are clinically and genetically heterogeneous. We recently implemented a clinical next-generation sequencing (NGS) test to diagnose MD targeting over 450 nuclear genes. The genes were categorized into four groups; (1) encoding entire subunits of the mitochondrial respiratory chain complex (RCC), assembly factors; (2) mitochondrial DNA transcription/translation and biogenesis factors; (3) other enzymes and carrier proteins;(4) genes causing secondary mitochondrial dysfunction or presenting with similar phenotypes. After removing variants with a relatively high minor allele frequency in our cohort or public databases, an average of 7 variants per patient was thought to be potentially pathogenic. Most of these were unpublished, single heterozygous variants of unknown significance in genes with autosomal recessive (AR) disease inheritance, resulting in possible carrier status for the corresponding disease. In a total of 64 (54%) cases, we identified variants considered to be possibly disease-causing, with 11 cases involving genes with AR inheritance, 38 cases with autosomal dominant (AD) inheritance, 4 cases with X-linked inheritance, 8 cases with positive findings in both AR, AD, and/or XL disease genes, and 3 cases in genes that have both AR and AD disease inheritance. Subsequent parental testing decreased the number of cases with plausibly causative mutations cases to 47 (39%), though incomplete penetrance or differences in expression remain possible. Of note, we found only 3 cases with variants in category 1 (RCC subunits/assembly factors). Most variants were in category 4 genes. These include OTC (urea cycle disorder), sulfite oxidase deficiency, and Fabry disease, spastic paraplegia, spinocerebellar ataxia, CLN6 (neuronal ceroid lipofuscinosis), and UBE3A (Angelman syndrome). The genes that we found the second most variants in were category 2, possibly indicating that mutations in these genes may be more prevalent in primary mitochondrial disease than mutations in RCC subunits or assembly factors. Some cases had positive findings in multiple genes, indicating that complex clinical phenotypes may be caused by oligogenic mutations. While NGS shows promise for diagnosing suspected MD patients, the challenges remain high as the underlying genetic heterogeneity may be greater than suspected and defining the significance of variants detected requires additional studies.

689F

Insulin Resistance: Development of a clinical assay for *INSR* mutation detection. *M. Procter[1], O. Ardon[1], A. Carey[1], H. Amiri[1], N. Longo[1,2], R. Mao[1,2].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) University of Utah Department of Pathology, Salt Lake City, UT.

Background : Insulin resistance is a pathological condition decreasing insulin's ability to lower blood sugar levels. In response to insulin resistance, the pancreas tries to compensate by increasing insulin secretion. Over time, pancreatic beta cells fail and are unable to synthesize/secrete the needed insulin. When this happens, hyperglycemia and diabetes result. Insulin resistance can be localized at a pre-receptor, receptor and post-receptor levels. The insulin receptor is a transmembrane receptor activated by insulin and encoded by a single gene (*INSR*) with alternate splicing resulting in 2 isoforms. *INSR* is located on the short arm of chromosome 19 and composed of 22 exons. Mutations in *INSR* cause rare insulin resistant syndromes, the most severe of which are Donohue Syndrome (leprechaunism) and Rabson-Mendenhall Syndrome, both of which result in growth restrictions, dysmorphic features, altered glucose homeostasis, and early demise, Donohue patients by age 1 year and Rabson-Mendenhall patients up to 17 years. Both conditions are inherited as autosomal recessive traits. Mutations in *INSR* are also implicated in familial hyperinsulinemic hypoglycemia type 5 (HHF5) as well as having a possible role in diabetes type 2. **Methods:** PCR amplification of the 22 coding exons of the *INSR* gene was performed using M13-tailed primers. Bidirectional DNA sequencing was performed with BigDye Terminator chemistry and M13 primers and the product was analyzed on the ABI 3100 genetic analyzer. Data analysis was performed using Mutation Surveyor software comparing the sequence to a reference INSR sequence (Genebank NC_000019). In order to validate a clinical assay for *INSR* sequencing, we sequenced 11 samples. Eight of the 11 samples were from a collaborator who had already sequenced them. Four of these 8 samples were from individuals known to carry mutations in the INSR gene while the other 4 of 8 were shown to be normal by sequencing in their lab. The remaining 3 of 11 samples were from unaffected individuals. **Results:** We found 100% correlation for samples which had previously been sequenced and no mutations in normal individuals. The majority of the mutations we found caused premature coding termination. **Discussion:** Donohue Syndrome and Rabson-Mendenhall Syndrome are very rare and difficult to diagnose. Current diagnosis is currently made based on clinical criteria. ARUP now offers a sequencing assay to identify INSR mutations causing these disorders.

690T

Comparative transcriptome profiles in Gaucher disease mice treated with Imiglucerase (imig) or Velaglucerase Alfa (vela). *N. Dasgupta[1], Y-H. Xu[1,2], S. Oh[1,2], Y. Sun[1,2], L. Jia[3], S. Barnes[1], M. Keddache[1,2], GA. Grabowski[1,2].* 1) The Division of Human Genetics, Cincinnati Children's Hospital Research Foundation, Cincinnati, OH 45229-3039; 2) Department of Pediatrics, University of Cincinnati College of Medicine Cincinnati, OH 45229; 3) Advanced Biomedical Computing Center SAIC-Frederick Frederick National Laboratory for Cancer Research NIH Main campus bldg.37, Bethesda, MD 20892.

Gaucher disease (GD) type 1, a lysosomal storage disease, is caused by the defective activity of acid beta-glucosidase (GCase). Intravenous infusion of purified recombinant GCases reverses many disease manifestations in affected GD patients. Two approved treatments, imig and vela, are structurally and functionally similar GCases, but differ at amino acid 495 [H (imig) and R (vela, the natural aa)]. Both drugs are mannose terminated, but vela has more mannoses in its oligosaccharide side chains. The mode of action of the two drugs was evaluated by direct comparison of transcriptome expression profiles in the visceral organs of D409V/null (9V/null) GD mice treated with either imig or vela. The genome-wide transcriptomes were performed in parallel with the Affymetrix Array and Illumina RNA seq platforms. Analyses revealed high tissue-specific correlation between the two drugs. Differences between the two were identified with secondary analyses, i.e., Anova and DESeq, to identify the differentially expressed (DE) genes. RNA-seq identified 290 (spleen), 78 (liver), and 11 (Lung) DE genes from imig-treated vs. vela-treated 9V/null mice (cutoff ±1.5 fold change, FDR= 0.05). With identical RNA samples, Affy mouse arrays showed 97 (spleen) and 1 (liver) DE genes. Additionally, 47 (spleen) DE genes overlapped with the two methods. There were 243 or 50 unique genes identified by RNA-seq or Affy array, respectively. RNA-seq detected 3 times more genes than Affy array, indicating a greater dynamic range of RNA-seq. Cell division/proliferation, hematopoietic system/development, and inflammatory response/macrophage regulation were the top functional groups (p ~e03 to e06). The gene interactions networks derived from the top functional groups in the spleen focused on: 1) down-regulation of erythroid proliferation/development genes including Gata1 and 2) up-regulation of cytokine/macrophage genes. Both networks showed ~50% of DE genes from imig or vela treatment overlapped with the DE genes in the untreated 9V/null vs. shame-treated WT mice, suggesting partial correction in the spleen. Unexpectedly, this direct comparative study uncovered different molecular pathophysiologic processes in the imig- vs. vela-treated mice even though these drugs had nearly identical therapeutic efficacy by histopathologic and glycosphingolipid analyses.

691F

Enzyme replacement therapy started at birth improves outcome in difficult-to-treat organs in mucopolysaccharidosis I mice. *G. Baldo, F. Mayer, B. Martinelli, F. Meyer, P. de Oliveira, A. Tavares, L. Meurer, T. de Carvalho, U. Matte, R. Giugliani.* Hospital de Clinicas de Porto Alegre, Porto Alegre, Rio Grande do Sul, Brazil.

Mucopolysaccharidosys type I (MPS I) is a disorder characterized by deficiency of the lysosomal hydrolase alpha-L-iduronidase (IDUA) and storage of undegraded glycosaminoglycans (GAG) heparan sulphate and dermatan sulphate. Since we previously observed that in patients with MPS, the storage of undegraded GAG occurs from birth, in the present study we aimed to compare normal, untreated MPS I mice, and MPS I mice treated with Laronidase (1.2 mg/kg every 2 weeks) started from birth (ERT-neo) or from 2 months of age (ERT-ad). All animals were sacrificed at 6 months for analysis. GAG levels were measured and both treatments were equally effective in normalizing them in the viscera (liver, lungs, kidney, heart and testis), but had no detectable effect on the joint. Heart function was accessed by echocardiography, and parameters such as ejection fraction and fractional area change also improved with both treatments. On the other hand, mice treated from birth presented better outcomes in the difficult-to-treat aortas and heart valves, who were thickened in MPS I mice. Surprisingly, both groups had improvements in behavior tests, and normalization of GAG levels in the brain. IDUA injection resulted in detectable levels in the brain tissue 1 hour after administration, suggesting that the enzyme crossed the blood-brain-barrier. ERT-ad mice developed significantly more anti-IDUA-IgG antibodies, and mice that didn't develop antibodies had better performances in behavior tests, indicating that development of antibodies may reduce enzyme bioavailability. Our results suggest that ERT started from birth leads to better outcomes in the aorta and heart valves, as well as a reduction in antibody levels. Some poor vascularized organs, such as the joints, had partial or no benefit and ancillary therapies might be needed for patients. The results presented here support the idea that ERT started from birth leads to better treatment outcomes and should be considered whenever possible, a observation that gains relevance as newborn screening programs are being considered for the treatable LSDs.

692T

Long-term bone mineral density response to enzyme replacement therapy in a retrospective pediatric cohort of Gaucher patients. *B. Bembi[1], G. Ciana[1], L. Deroma[1], A.M. Franzil[2], A. Dardis[1].* 1) Regional Coordinator Centre for Rare Diseases, University Hospital “Santa Maria della Misericordia”, Udine, Italy; 2) Pediatric Department, Ospedale degli Infermi, Biella, Italy.

Osteopenia is described as a relevant sign of bone involvement in Gaucher disease (GD) both in pediatric and adult patients. Furthermore, abnormal bone metabolism is considered to play a role in growth and pubertal delay. To analyze the long-term effect of enzyme replacement therapy (ERT) on bone mineral density (BMD), a retrospective observational study was conducted in a cohort of 18 GD pediatric patients (13 males, 5 females; median age 9.2 years). They received biweekly infusions of 20–60 IU/kg of alglucerase/imiglucerase. Clinical, laboratory and imaging parameters were evaluated every 2 years. According to the International Society of Clinical Densitometry guidelines, a Z-score≤-2.0 was considered pathological. Nine patients (group P0) began ERT during infancy and nine (group P1) during puberty. At baseline, in three patients (16.6 %; 1P0, 2P1) Z-score was≤-2.0 (range -2.47 to -2.25). In patient P0 it normalized after 2 years, while in the 2P1 patients (splenectomised siblings) it persisted abnormal. The remaining 15 patients (83.4 %) always presented a normal value. In group P0, Z-score improved in infancy but showed a significant decrease during puberty, on the contrary it constantly improved in group P1. Furthermore, at baseline group P0 showed a higher median Z-score than group P1: 0.79 (0.38; 1.50) and -1.61 (-2.25; -1.56) respectively. The use of correct BMD standards to interpret bone loss during pediatric age suggests a limited significance of bone loss in these patients. Moreover, the persistence of residual disease activity may affect normal bone growth during puberty in GD populations.

693F

Evaluation of long-term enzyme replacement therapy for children with Fabry disease. *A.M. Hebert[1], T. Taber[1], L. Lacbawan[1], M. Banikazemi[1,2], O. Goker-Alpan[1].* 1) LSD Research and Treatment Unit, O&O Alpan LLC, Fairfax, VA; 2) Comprehensive Center for Lysosomal Storage Disorders, Columbia University Medical Center, New York, NY.

Fabry disease is an X-linked disorder caused by the deficiency of the lysososomal enzyme α-galactosidase-A (a-GalA), and it affects multiple organs including kidneys, heart, eye, and nervous system. There are two recombinant α-GalA preparations for enzyme replacement therapy (ERT), agalsidase alfa (Replagal) and beta (Fabrazyme), but only Fabrazyme gained FDA approval in 2001. Short-term studies in adults indicate limited efficacy of ERT in treating major complications, but reports on the efficacy of ERT in preventing Fabry disease related complications in pediatric population are not available. We report the course of Fabry disease in 12 children (3 male, 8 female; age range: 7–16 years), diagnosed after ERT became available. In this cohort, the median age of onset of Fabry disease symptoms was 6 years (range: 3–9 yrs). All but one was diagnosed during family screening, and three were symptom free at the time of diagnosis. The mutations included c.G146C, c.G680A, c.718-719delAA, c. G730A, c.C748T, and c.G982C. There were 4 sib-pairs, including one set of twins. The most common presenting symptom was neuronopathic pain (7/12), with GI disturbance as the second most common complaint (4/12). The majority (10/12) have received ERT for a mean duration of 28 months (range: 3–94 months). ERT has been well tolerated in all but one male who developed significant infusion-related reactions. Renal assessments have included eGFR (10/12), and urinary protein excretion (4/12). eGFR ranged between 103.0–372.2 ml/min/1.73, and mean total urinary protein was 51 mg/24 hr/m2 (range: 31.2–74.5). Additionally, two females had proteinuria/microabuminuria. Among cardiac assessments, echocardiography was normal (10/10), and sinus bradycardia was recorded in 3 of 10, one female had non-sustained SVT. On ERT, almost all, including two male patients, remained symptom free, while pain was controlled successfully with adjunct pharmacotherapy. Previous reports indicate major morbidity among children with Fabry disease; however, this cohort shows better control of symptoms. This data also suggests that ERT for treatment of Fabry disease is well tolerated and can improve symptoms in the pediatric population, although further study is essential for long-term outcomes.

694T

Combined Therapy in a Patient with Gaucher Type III. *J. Navarrete, P. Galindo, R. Delgado, A. Limon.* Dept Gen, Hosp Sur PEMEX, Mexico City, Mexico.

Female patient 6 years old with Gaucher Disease TypeIII first seen at 2 years old with hepatosplenomegaly, anemia and thrombocytopenia, bone marrow aspiration was done and hematology made the diagnosis of Gaucher disease. Enzyme activity was done in leukocytes finding an activity of beta glucosidase of 0.9Umol/L/h and DNA analysis was done finding the mutation 1448C or L444P homozygous. ERT with imiglucerase 120 mgs/kg was started every other week since she was 3 years old. AFter 6 months of treatment her blood values were normal and her bone crises disappear. Two years later there was a shortage of the enzyme and the patient was without treatment during 3 months, the patient restarted with thrombocytopenia, anemia and bone crises. Oral substrate reduction therapy was given to the patient 100 mgs every day. The blood values became normal after one month of therapy. Three months later we had the enzyme back and we restarted imiglucerase 120 mgs/kg and continued with oral therapy 100 mgs everyday. We present the clinical, hematological outcome of the patient. We think that in some cases combined therapy can work for some patients with LSD's.

Biochemical Characterization of Myelin Abnormalities in the Corpus Callosum in MPS I Dogs. *S-H. Kan[1], S.Q. Le[1], J.K. Yee[1], M. Guzman[2], N.M. Ellinwood[3], P.I. Dickson[1].* 1) Department of Pediatrics, LA Biomedical Research Institute, Torrance, CA; 2) Department of Pathology, St. Louis University, St. Louis, MO, USA; 3) Department of Animal Science, Iowa State University, Ames, IA, USA.

Mucopolysaccharidosis type I (MPS I) is a lysosomal storage disease that leads to neurological deficits. Brain magnetic resonance imaging frequently shows abnormalities in white matter suggestive of demyelination. Our neuroimaging and ultrastructural studies in the corpus callosum of the MPS I dog also suggest that abnormal myelin may contribute to white matter disease.

We isolated the genu and splenium of the corpus callosum from MPS I dogs (n=4, ~25 months) and unaffected carrier dogs (n=4, 19–30 months). We performed real-time reverse-transcriptase polymerase chain reaction (RT-PCR) for the myelin related genes, including *MBP*, *PLP1*, *MOG, MAG* and *MOBP*, etc. To study the development of myelin in younger dogs, we also evaluated 2 dogs at age 4 months, and 4 dogs at age 6 months. RT-PCR results were further confirmed in protein expression level by western blots and immunohistochemistry. Oligodendrocytes were studied by immunohistochemistry using marker O4. Myelin was purified from 4 adult MPS I-affected and 4 carrier dogs by sucrose gradient centrifugation, and the fatty acid composition was analyzed by GC/MS.

The expression of myelin-related genes PLP1 and MBP was slightly reduced in the affected animals, and the diminished expression of these genes appeared as early as 4 months of age. Western blot from purified myelin fractions confirmed reduction of MBP in affected MPS I dogs. Additional studies are underway.

Biochemical studies in the MPS I dog model show myelin abnormalities in the corpus callosum. These findings suggest that abnormal myelin may play a role in white matter disease in patients with MPS I.

Enzyme replacement therapy in a Gaucher type 3 patient: report of a paradigmatic case. *F. Vairo[1,2], A.D. Dornelles[1], S.D. Mittelstadt[1], M. Wilke[1], D. Doneda[1], C.B.O Netto[1], I.V.D. Schwartz[1,3].* 1) Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Brazil; 2) Post Graduate Program in Genetics and Molecular Biology, Universidade Federal do Rio Grande do Sul, Brazil; 3) Genetics Department, Universidade Federal do Rio Grande do Sul, Brazil.

Introduction: There are three recombinant enzymes available for the treatment of Gaucher disease (GD): imiglucerase, alfavelaglucerase and taliglucerase alfa. Case report: A male GD type 3 patient, 14 years old, genotype p.L444P/L444, diagnosed at 2 years old. He had been treated with imiglucerase for 9 years since the diagnosis. In 2008, however, he presented a severe adverse reaction to imiglucerase, characterized by cough, laryngeal stridor and periorbital edema. The infusions were suspended for 3 months when imiglucerase was restarted with pre-medication and a slower infusion rate. After 5 months, he presented a new adverse reaction with vomiting, tachypnea, cough and periorbital edema. Intradermal testing confirmed IgE-mediated reaction but serological tests were negative. After 2 years and 10 months with no specific treatment and a significant worsening of the clinical picture, taliglucerase alfa was prescribed, with pre-medication and a slower infusion rate. At the first infusion he presented moderate adverse reaction (skin rash, sweating, headache and vomiting), and the infusions were suspended. After two months, alfavelaglucerase was initiated uneventfully. He maintains day-hospital infusions without premedication and shows improvement of clinical and laboratory parameters. Conclusion: This is the first report of the use of alfavelaglucerase in patients with GD type 3. The use of recombinant enzymes is safe for the majority of GD patients but severe reactions may occur. Premedication and slower infusion rate reduce the incidence of adverse reactions but may not solve the problem. This case report further demonstrates the different safety profile among all the recombinant enzymes available for the treatment of GD.

697F

Alteration in liver TGFβ expression and signaling in MPS I canines and the effect of enzyme replacement therapy. *M. Vera, S.Q. Le, S.H. Kan, P.I. Dickson.* Department of Pediatrics, Division of Medical Genetics, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA.

Mucopolysaccharidosis I (MPS I) is a lysosomal storage disease caused by deficiency of α-L-iduronidase enzyme activity leading to impaired degradation of extracellular matrix glycosaminoglycans (GAG) such as heparan sulfate. Enzyme replacement therapy (ERT) with recombinant human α-L-iduronidase (rhIDU) successfully reduces lysosomal GAG storage in MPS I canines and human patients; however, in the canine model anti-rhIDU IgG antibodies develop and reduce the therapeutic efficacy of ERT. Interactions between the extracellular matrix (ECM) and cytokines such as transforming growth factor beta (TGFβ) are likely to be important in modulating the signaling events required to establish immune tolerance to ERT and prevent anti-rhIDU antibody formation. Our research hypothesis is that the ECM alterations in MPS I affect the distribution and bioavailability of TGFβ in the tissues of affected canines and that this altered distribution normalizes with the effect of ERT on the ECM. TGFβ is secreted in the form of a latent complex that is sequestered in the extracellular matrix by indirect noncovalent association with heparan sulfate. In this work we compared the distribution and signaling activity of TGFβ in the liver and spleen of untreated MPS I canines and MPS I canines treated with intravenous rhIDU ERT. We performed immunohistochemistry with primary antibodies against TGFβ, and the lymphocyte markers CD3 (T cells) and CD79a (B cells) and found that untreated MPS I canine livers had increased staining with all markers compared to normal canines, and that this effect was reduced with ERT. We performed Western blot analysis of liver tissue with primary antibodies against TGFβ and the signaling intermediate SMAD2 and found that precursor TGFβ expression was reduced in untreated compared to treated MPS I canines, while SMAD2 phosphorylation was increased in treated compared to untreated animals. These preliminary data suggest that a non-specific inflammatory response occurs in the liver of untreated MPS I canines and that ERT may reduce this inflammation.

Korean experience with Citrin Deficiency. *B.H. Lee[1,2], Y.M. Kim[1], G.H. Kim[2], K.M. Kim[1], H.W. Yoo[1,2].* 1) Pediatrics, Asan Med Ctr, Seoul, South Korea; 2) Medical Genetics Center, Asan Med Ctr, Seoul, South Korea.

Two phenotypes can occur by citrin deficiency, neonatal intrahepatic cholestasis by citrin deficiency (NICCD; OMIM #605814) and adult-onset type II citrullinemia (CTLN2; OMIM #603471), and some patients with NICCD develop CTLN2 in their later lives. More cases continue to be identified in Korea as well. This study evaluated the clinical and molecular genetic characteristics of 24 Korean patients with citrin deficiency. Thirteen patients were male and 11 patients were females. Eighteen patients manifestated as NICCD, whereas six patients as CTLN2. Prolonged neonatal jaundice was noted in 83.3% of the patients with NICCD. Two patients with NICCD were identified by neonatal screening. Hyperammonemic encephalopathy was accompanied in 5 patients with CTLN2. Atypical manifestations such as severe coagulopathy (1 pt), dyslipidemia (2 pts), and peripheral neuropathy (1 pt) were also noted. At initial evaluation, most patients showed abnormal serum liver enzyme levels (89.4 %), hyperammonemia (77.8 %), and hypoproteinemia (77.8 %). All the patients had citrullinemia (350.9 ± 313.9 umol/L; nl, 1–46 umol/L), normo/hyper-argininemia (116.6 ± 68.0 umol/L; nl, 10–140 umol/L), and increased threonine to serine ratios (3.7 ± 2.9; nl, <1.1 umol/L). Methioninemia and galactosemia were observed in 11 and 4 cases, respectively. SLC25A13 mutations were identified in all patients. Five common mutations, IVS16ins3kb (115 alleles, 32.6 %), 851del4 (12, 26.1 %), IVS11+1G>A (8, 17.4%), IVS13+1G>A (2, 4.3 %), and S225X (3, 6.5 %), comprises 87 % of all the mutations. Prolonged jaundice in 6 pts with NICCD was spontaneously resolved by 3 to 7 months of age. Fatty liver or dyslipidemia were noted in 11 patients (84.6%). Recurrent episodes of hyperammonemic encephalopathy, liver cirrhosis and death were noted in 4, 2, and 1 pts with CTLN2, respectively. Liver transplantation was done in 2 pt with CTLN2. None with NICCD progressed to CTLN2 until 3.1 (0.2–8.6) years of age. In conclusion, typical presenting phenotypes and biochemical findings can be used as the hallmarks for the diagnosis of citrin deficiency. Genetic screening for 5 common mutations in SLC25A13 can be recommended for the Korean patients with citrin deficiency for the rapid diagnosis. Considering the poor clinical course of CTLN2, long-term follow-up evaluation for the patients with NICCD is crucial, and more efforts are needed to diagnose the patients with CTLN2 at early stage.

Molecular diagnosis in mitochondrial respiratory chain deficiency using exome sequencing. *R. Kopajtich[1], T.B. Haack[1,2], B. Haberberger[1,2], K. Danhauser[1,2], J.A. Mayr[4], W. Sperl[4], U. Ahting[5], G.F. Hoffmann[6], M. Tesarova[7], E. Frisch[3], M. Schülke[3], I. Wittig[8], P. Freisinger[9], D. Ghezzi[10], M. Zeviani[10], A. Rötig[11], E. Graf[1], T.M. Strom[1,2], T. Meitinger[1,2], H. Prokisch[1,2].* 1) Helmholtz Zentrum München, Munich, Germany; 2) Technical University Munich, Munich, Germany; 3) Charité University Medical Center, Berlin, Germany; 4) Paracelsus Medical University Salzburg, Salzburg, Austria; 5) Städtisches Klinikum München, Munich, Germany; 6) University Hospital Heidelberg, Heidelberg, Germany; 7) Charles University in Prague and General University Hospital in Prague, Prague, Czech Republic; 8) Goethe-Universität Frankfurt, Frankfurt, Germany; 9) Community Hospital Reutlingen, Reutlingen, Germany; 10) Neurological Institute Besta, Milano, Italy; 11) INSERM, Paris, France.

Advances in sequencing technologies offer the prospect to reduce the uncertainty and length of the diagnostic journey toward a molecular diagnosis for mitochondrial disorders. Sequencing the entire coding sequence of the human genome (exome sequencing) enables the investigation of about 18,000 genes in parallel and is especially promising in genetic and clinically heterogeneous disorders. We applied exome sequencing in combination with stepwise filtering of gene variants combined with functional complementation experiments. For this study 41 unrelated individuals were chosen who display juvenile-onset mitochondrial disorders without pathogenic variants in the mtDNA. Exome sequencing data were filtered using three different criteria: (i) the presence of mutations in known disease causing genes; (ii) mutations in candidate genes that match the biochemical and clinical phenotype; (iii) mutations in genes that code for mitochondrial proteins. In 14/41 cases we identified mutations in known disease-causing genes (BOLA3, NDUFS8, NDUFS3, MTFMT, TRMU, C8orf38, C20orf7, FOXRED1, NUBPL, GFM1) five of which have only recently been shown to be associated with mitochondrial disorders. In 9/41 cases, the exome sequencing approach led to the identification of mutations in novel genes (ACAD9, MTO1, AGK, NDUFB3, EARS2). The pathogenic character of the identified variants could be confirmed by functional complementation experiments in five of them. In 12/41 cases no obvious disease-causing mutations could be identified. Currently we investigate prioritized rare variants in genes which function in the mitochondrial transcription and translation process. In parallel to the functional studies we analyzed novel candidate genes in a collection of 600 DNA samples from patients with mitochondrial respiratory chain deficiencies. We conclude that in a research setting NGS is a promising method for the diagnostic workup of patients suffering from metabolic diseases. We aim to implement exome sequencing as a standard diagnostic procedure. Since for most patients with mitochondrial disorder there is no clear phenotype-genotype correlation, exome sequencing is prioritized over multiple rounds of single gene sequencing. In addition, unbiased genome-wide analysis allows the identification of new disease genes thereby extending our understanding of the underlying pathomechanisms.

Occurrence of lysosomal storage disorders in children with hepatomegaly or hepatosplenomegaly: An institutional experience. *M. Mistri[1], C. Ankeleshwaria[1], A. Bavdekar[2], M. Kamate[3], C. Datar[4], F. Sheth[1], J. Sheth[1].* 1) Biochemical and Molecular Genetics, FRIGE's Institute of Human Genetics, Ahmedabad, Satellite, India; 2) K.E.M. Hospital, 489, Rasta peth, Sardar Mudliar road, Pune- 411011, India; 3) K.L.E.S. Dr. Prabhakar Kore Hospital & Medical Research Centre, Nehru Nagar, Belgaum, Karnataka,India; 4) Sahyadri Medical Genetics and Tissue Engineering Facility, 170/01 Barve Memorial Complex, J.M. Road, Pune- 411005.

Nine hundred and sixty eight subjects were referred from January 2001 to April 2012 for various LSDs. There major presenting clinical sign and symptoms were enlarged liver and/or spleen, regression of milestone, neurodegeneration, cherry red spot, coarse facial features, skeletal abnormalities, hypotonia, seizures, burning sensations and corneal clouding. From these, 236 patients with the signs of hepatomegaly and/or hepatosplenomegaly were investigated for LSDs such as glycolipids and lipids storage disorders, mucopolysaccharidosis, Pompe disease, Sialic acid disorder, galactosialidosis and I -cell disease. Of these, 110 (46.6%) were found to be affected with different LSDs and remaining 126 (53.4%) were found to be normal for afore mentioned LSDs. Among the affected, Gaucher was confirmed in 48 (20.3%) cases followed by NPD-A/B in 17 (7.2%), mucopolysaccharidosis in 18 (7.6 %), GM-1 gangliosidosis in 14 (5.9 %), Sandhoff in 5 (2.1 %), I-cell disease in 4 (1.7%), Galactosialidosis in 2(0.84%) and Pompe in 1(0.42 %). Patients clinically suspected for Gaucher and NPD-A/B were screened for plasma chitotriosidase(ChT), which act as screening marker for these disease and found markedly elevated (2,000–85,496 nmol/ml/hr). Of 48 patients of Gaucher, 39 (81.25%) had elevated chitotriosidase (4,274–85,496 nmol/ml/hr), 1(2.0%) with undetectable chitotriosidase, 2(4.0%) with normal chitotriosidase and in 6 (12.5 %) chitotriosidase was not carried out. From 17 patients of NPD-A/B, 12(70.5%) had elevated chitotriosidase (2,675–19,236nmol/ml/hr), 1(5.8%) had undetectable chitotriosidase, 2(11.8%) had normal chitotriosidase and in 2 (11.8%) chitotriosidase was not carried out. This study demonstrates that nearly 47% of children with hepatosplenomegaly and developmental delay have a high probability of LSDs and should be screened for LSDs and confirmative enzyme study needs to be carried out for future pregnancies and for therapeutic options.

701F

Exome sequencing reveals that mutations in the genes encoding aminoacyl tRNA synthetases (ARS) cause a variety of clinical syndromes. *M.T. Geraghty[1], M.J.M. Nowaczyk[2], P. Humphreys[1], J. Schwartzentruber[3], C.L. Beaulieu[1], A. Smith[4], L. Huang[4], J. Majewski[3], D.E. Bulman[1,4], K.M. Boycott[1] FORGE Consortiom.* 1) Children's Hosp Eastern Ontario, University of Ottawa, Ottawa, Ontario; 2) McMaster University Medical Center, Hamilton, Ontario; 3) McGill University and Genome Quebec Innovation Center, Montreal, Quebec; 4) Ottawa Hospital Research Institute, University of Ottawa, Ottawa, Ontario, Canada.

ARS are ubiquitously expressed essential enzymes required for cytosolic and mitochondrial protein translation. To date there have been few reports of deficiencies of these enzymes causing human disease. Using exome sequencing we identified mutations in genes encoding members of the ARS family in several patients with a variety of clinical presentations. Patient 1, a 12 year old female presented with exercise intolerance, left ventricular noncompaction without cardiac dysfunction and elevated lactate and alanine. Numerous investigations including muscle histology and respiratory chain analysis were normal. Compound heterozygote mutations in the gene encoding Glycine ARS (*GARS*) were found using exome sequencing. Mutations in this gene have previously been reported as causing the autosomal dominant neuropathies CMT2D and dSMA-V. Patients 2 and 3 are male and female siblings who presented in infancy with microcephaly, cortical blindness, developmental delays and a seizure disorder. Brain MRI revealed cerebral white matter and callosal hypoplasia in both. Chromosome microarray and metabolic studies were normal. Exome sequencing identified the same two compound heterozygous mutations in both children in the gene encoding the Lysine ARS (*KARS*). Autosomal recessive mutations in this gene have been reported in a patient with intermediate CMT, developmental delay, dysmorphic features and vestibular Schwannoma. Patients 4 and 5 are a brother sister pair who presented with microcephaly and mild developmental delays associated with spasticity and arreflexia. Additionally the older brother had hepatomegaly with macronodular cirrhosis and pulmonary cysts. Exome sequencing revealed the same two mutations in both siblings in *YARS* (Tyrosine ARS). Mutations in this gene have been described in dominant intermediate CMT. These cases expand the phenotype associated with deficiencies of ARS and illustrate that defects in tRNA metabolism represent an emerging class of human disease.

Novel mutations in the PC gene in patients with type B pyruvate carboxylase deficiency. *E. Oestergaard[1], M. Duno[1], LB. Møller[2], HS. Kalkanoglu-Sivri[3], A. Dursun[3], D. Aliefendioglu[4], H. Leth[5], M. Dahl[6], E. Christensen[1], F. Wibrand[1]*. 1) Clinical Genetics, Copenhagen University Hospital, Copenhagen, Denmark; 2) Center of Applied Human Molecular Genetics, Kennedy Center, Glostrup, Denmark; 3) Department of Pediatrics, Section of Nutrition & Metabolism, Hacettepe University Faculty of Medicine, Ankara, Turkey; 4) Department of Pediatrics, School of Medicine, Kirikkale University, Kirikkale, Turkey; 5) Department of Pediatrics, Roskilde University Hospital, Roskilde, Denmark; 6) Department of Pediatrics, Odense University Hospital, Odense, Denmark.

We have investigated seven patients with the type B form of pyruvate carboxylase (PC) deficiency. Mutation analysis revealed eight mutations, all novel. In a patient with exon skipping on cDNA analysis, we identified a homozygous mutation located in a potential branch point sequence, the first possible branch point mutation in PC. Two patients were homozygous for missense mutations (with normal protein amounts on western blot analysis), and two patients were homozygous for nonsense mutations. In addition, a duplication of one base pair was found in a patient who also harboured a splice site mutation. Another splice site mutation led to the activation of a cryptic splice site, shown by cDNA analysis. All patients reported until now with at least one missense mutation have had the milder type A form of PC deficiency. We thus report for the first time two patients with homozygous missense mutations with the severe type B deficiency, clinically indistinguishable from other patients with type B form of PC deficiency. The mutations found here are novel; it is noteworthy that four Turkish patients did not have any mutations in common, despite the rarity of PC deficiency. There is thus no evidence for recurrent mutations in the Turkish or other populations.

703F

Bioinformatics and Genotypic evaluation of the IDUA gene and protein in MPS I patients diagnosed in Colombia, Ecuador and Perú. *H. Velasco[1], J. Gonzalez[2], T. Pineda[3]*. 1) Genetic Institute, National University, Bogota Cundinamar, Colombia, MD, MSc; 2) Associate Professor, School of Science, Department of Computational Biology, Pontificia Universidad Javeriana, Bogota Colombia, MSc, PhD; 3) Genetic Institute, National University, Bogota Cundinamar, Colombia, MD.

Mucopolysaccharidosis Type I (MPSI) is an autosomal recessive disorder classified into the “rare diseases” with an incidence of 1:100.000–300.000. Mutations in the IDUA gene lead to deficiency in the enzyme α - L -Iduronidase, which is involved in the breakdown of dermatan and heparan sulphates. These compounds will accumulate in the lysosome and will affect many tissues, including neuronal tissue. Since the isolation and characterization of the IDUA gene by Scott et al in 1992, it has been possible to use molecular tools for MPSI diagnosis. Colombia, Ecuador and Peru lacked a molecular methodology for diagnosis and genetic evaluation of this disorder and there was a total ignorance about the mutational profile of the MPSI in our patients. The aim of this study was to analyze genotypic and with bioinformatics tools the mutations found in the 14 MPSI patients from Colombia, Ecuador and Peru. Of the 15 patients analyzed (13 with severe phenotype and one intermediate), the most common mutation found was W402X with a frequency of 42.8%. 6 patients presented 7 novel mutations, which is a high novel mutational rate in our population (33%). In addition to the experimental findings, we proceeded in the first instance to the bioinformatics validation of the novel mutations found in our populations and then to the creation and validation of a bioinformatics model of the IDUA protein for the analysis of 3 novel missense mutations (Y625C, P385L, R621L) where it was found that all of them are potentially pathogenic and some alter the RMSD and ASA values, therefore they are able to disturb the tridimensional structure of the protein and the IDUA accessibility to the substrates. This is the first study in Colombian, Ecuadorian and Peruvian about the mutational behavior of IDUA gene in MPSI patients where we propose the “COLOMBIA” bioinformatics model for subsequent studies of mutations in IDUA. These results will allow a better understanding about the behavior of the gene and the enzyme providing better approaches in the management of the MPSI.

704T

A founder mutation causing a severe methylenetetrahydrofolate reductase deficiency in Bukharian Jews. *S. Ben-Shachar[1], T. Zvi[1], A. Rolfs[2,3], A. B. Klobus[3], Y. Yaron[1,4], A. Bar-Shira[1], A. Orr-Urtreger[1,4]*. 1) Genetic Institute, Tel Aviv Sourasky Med Ctr, Tel-Aviv, Israel; 2) Albrecht-Kossel-Institute for Neuroregeneration, Medical Faculty, University of Rostock, Rostock, Germany; 3) Centogene GmbH, The Rare Disease Company, Rostock, Germany; 4) Sackler Faculty of Medicine, Tel-Aviv University, Tel Aviv, Israel.

Methylenetetrahydrofolate reductase (MTHFR) deficiency (MIM #236250) is an autosomal recessive disorder caused by mutations in *MTHFR* gene with a well characterized biochemical and clinical presentation. We have diagnosed MTHFR deficiency in two children, each from an unrelated non-consanguineous Jewish family of Bukharian origin. In both children *MTHFR* gene sequencing detected a homozygous c.474A>T (p.G158G) mutation in exon 3. As this mutation creates a potential donor splice site (GT), we tested its splicing effect and detected an abnormal transcript which includes the entire intron 3 of the gene and inserts an early termination codon. We have subsequently tested 196 healthy unrelated Jewish individuals of Bukharian origin and detected 5 carriers for this mutation (carrier frequency: 1:39). We conclude that c.474A>T is a pathogenic founder mutation, prevalent among Jews of Bukharian ancestry. Given the disease severity and the frequency of this allele, we recommend that screening for this mutation is offered to individuals of Bukharian origin, in order to facilitate prenatal or preimplantation diagnosis.

705F

Somatic cell and molecular studies on an atypical patient with combined homocystinuria and methylmalonic aciduria (*cblC*). *A. Brebner[1], C. Ficicioglu[2], D. Watkins[1], T. Pastinen[1,3], D.S. Rosenblatt[1]*. 1) Department of Human Genetics, McGill University, Montreal, Quebec; 2) Children's Hospital of Philadelphia, Philadelphia, PA; 3) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec.

The *cblC* complementation group, caused by mutations in the *MMACHC* gene, is the most common inborn error of vitamin B_{12} (cobalamin) metabolism with over 500 cases known. We describe a patient who came to medical attention at 59 years of age because of squamous cell carcinoma of the tonsil. A metabolic analysis unexpectedly revealed elevated serum methylmalonic acid (MMA) and homocysteine. His serum vitamin B_{12} level was not low. The excretion of metabolites corrected with vitamin B_{12} supplementation. Commercial sequencing of the *MMACHC* gene showed only one novel heterozygous missense mutation, c.158T>C (p.L53P). Somatic cell studies using cultured fibroblasts showed decreased incorporation of both [^{14}C]propionate and [^{14}C]methyltetrahydrofolate into cellular macromolecules, demonstrating abnormalities in the function of both cobalamin-dependent enzymes, methylmalonyl CoA mutase and methionine synthase. Cells from the patient also had decreased synthesis of both adenosylcobalamin and methylcobalamin. Somatic cell complementation confirmed the diagnosis of *cblC*. Genomic DNA and RNA were isolated from patient fibroblasts. RNA was converted to cDNA using reverse transcriptase. Mutations in the *MMACHC* gene were searched for using PCR and Sanger sequencing. Sequencing of the genomic DNA confirmed the presence of the heterozygous c.158T>C (p.L53P) missense mutation. This mutation is at a conserved residue and predicted to be possibly damaging by Polyphen. The c.158T>C mutation was seen in a separate *cblC* patient in compound heterozygosity. This supports its role as a causal mutation in *cblC*. Sequencing of the cDNA identified the c.158T>C mutation in apparent hemizygosity. To date, no second mutation has been identified that could be causing the absence of one allele at the mRNA level. No mutations were found in a putative promoter site (1.8kb upstream the ATG start site) as well as 5' and 3' untranslated regions. These results suggest that the second mutation may be located in a non-coding region of the *MMACHC* gene, and that this mutation is responsible for eliminating expression of one allele.

Exome sequencing reveals a homozygous *ABCD4* mutation in an adolescent with hyperpigmentation, ischemia, hyperhomocysteinemia, and methylmalonic aciduria. *J.C. Kim[1], A. Brebner[1], N.C. Lee[2], W.L. Hwu[2], Y.H. Chien[2], S. Fahiminiya[3], J. Majewski[1,3], D. Watkins[1], D.S. Rosenblatt[1]*. 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Department of Pediatrics and Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 3) McGill University and Genome Québec Innovation Centre, Montreal, Canada.

The proband, a 14-year-old boy, was noted to have hyperpigmentation and gray hair at the age of 4 years. At age 7 years, he had a transient ischemic attack with left limping gait for 1–2 months. MRI/MRAI of the brain revealed decreased flow in the left middle cerebral artery (M2) region. Hyperhomocysteinemia (71.47 μM, reference range 3.4–15.6 μM) with methylmalonic aciduria and low serum vitamin B_{12} (cobalamin) level (152 pg/ml; reference range 179–1132 pg/ml) were noted, suggesting an inborn error of cobalamin metabolism. The incorporations of both [^{14}C]propionate and [^{14}C]methyltetrahydrofolate in cultured fibroblasts were within reference ranges and too high to allow for complementation analysis. However, there was decreased synthesis of both adenosylcobalamin and methylcobalamin and accumulation of unmetabolized cyanocobalamin. Size exclusion chromatography showed that 8–9% of the patient's cobalamin was enzyme bound (reference >50%). Exome sequencing of the patient's genomic DNA demonstrated that he was homozygous for a novel missense mutation (c.423C>G, p.N141K) in the *ABCD4* gene, indicating that the patient falls into the *cblJ* class of inborn error of cobalamin metabolism. We have recently discovered that the *cblJ* and *cblF* defects are phenocopies, and that both result in the failure of cobalamin to exit the lysosome. The c.423C>G mutation affects an asparagine residue that is conserved to zebra fish. It was predicted to be probably damaging by the mutation prediction software Polyphen-2. Segregation analysis showed that the patient's father, mother, aunt and two unaffected siblings were heterozygous carriers of the c.423C>G mutation. Clinically the proband appears to be less severely affected than other reported *cblF* and *cblJ* patients. At the cellular level, high propionate and methyltetrahydrofolate incorporation precluded complementation analysis. Accumulation of unmetabolized cyanocobalamin was less marked than in other *cblF* and *cblJ* patients, the synthesis of adenosylcobalamin and methylcobalamin was greater, and more cobalamin was bound to enzymes. These findings suggest that the c.423C>G mutation is less damaging than previously reported *ABCD4* mutations and that the range of biochemical and clinical phenotypes of inborn errors of cobalamin are broader than previously recognized.

707F

Molecular characterization of the GALK1 gene in Filipino patients with Non-Classical Galactosemia. *C.L.T. Silao[1,2], K.N. Hernandez[1], D.M. Canson[1], S.C. Estrada[1,2]*. 1) Inst of Human Genetics, Manila, Philippines; 2) Dept of Pediatrics, University of the Philippines College of Medicine-Philippine General Hospital, Manila, Philippines.

Introduction Galactosemia is an autosomal recessive disorder resulting from a deficiency in one of the three enzymes (galactokinase, epimerase, or galactose-1-phosphateuridyltransferase) responsible for the metabolism of galactose. Galactokinase (GALK) deficiency is characterized by elevation of blood galactose concentration and diminished galactose-1-phosphate resulting in the production of galactitol. Unlike galactose-1-phosphateuridyltransferase deficiency, GALK deficiency patients do not present with severe manifestations in infancy. Clinical manifestations are relatively mild and include neonatal and childhood cataracts, as a result of accumulation in the lens of galactitol, without hepatocellular dysfunction. The disorder is caused by mutations in the GALK1 gene, located in chromosome 17q24. GALK deficiency has an unknown incidence in the general population but is probably less than 1 in 100,000. No study has been done, so far, to determine the molecular characteristics of GALK1 in Filipino patients with GALK deficiency. Methodology The study included six (10) unrelated Filipino non-classical galactosemia patients detected by the Philippine Newborn Screening Program from 1998 to 2012. To investigate the molecular defects of the GALK1 gene, polymerase chain reaction with subsequent direct sequencing were performed on genomic DNA extracted from dried bloodspots or from peripheral blood of the patients using the Qiagen QIAamp DNA Blood Mini/Midi Kit (Qiagen, SantaClara, CA). Results and Discussion Three novel missense mutations in the GALK1 gene (p.G65S, p.G136R, and p.E284K) were identified. Two patients were found to be homozygous for p.E284K while three were homozygous for p.G136R. Two patients were compound heterozygotes for different mutations (p.G65S/p.G136R and p.G136R/p.R256W). Two patients were identified as heterozygotes for the previously reported c.-22 T>C promoter region mutation, one of whom is the p.G136R/p.R256W heterozygote mentioned above. One patient was found to be heterozygous for an unreported intronic mutation (IVS2 -14 G>A). Conclusion The present results provide information regarding the GALK1 mutations that occur in affected Filipinos and further emphasize the heterogeneity of Galactosemia at the molecular level.

708T

Exome sequencing reveals a frequent Moroccan founder mutation in SLC19A3 as a new cause of early-childhood fatal Leigh syndrome. *H. Smeets[1,2], M. Gerards[1,2], R. Kamps[1,2], I. Boesten[1], E. Jongen[1], B. de Koning[1], K. Schoonderwoerd[3], A. Sefiani[4], I. Ratbi[4], W. Coppieters[5], L. Karim[5], I. de Coo[6], B. van den Bosch[1]*. 1) Unit Clinical Genomics, Dept Clinical Genetics, Maastricht UMC, Maastricht, Netherlands; 2) Research Schools GROW and CARIM, Maastricht UMC, Maastricht, Netherlands; 3) Dept of Clinical Genetics, Erasmus MC, Rotterdam, Netherlands; 4) Centre de Génomique Humaine, Université Mohammed V Souissi, Rabat, Morocco; 5) GIGA, Université de Liège, Liège, Belgium; 6) Dept of Neurology, Erasmus MC, Rotterdam, Netherlands.

Leigh syndrome is an early onset, often fatal progressive neurodegenerative disorder caused by mutations in the mitochondrial or nuclear DNA. Until now mutations in more than 35 genes have been have been reported to cause Leigh syndrome, indicating an extreme genetic heterogeneity for this disorder, but still only explaining part of the cases. The possibility of whole exome screening enables not only mutation detection in known candidate genes, but also the identification of new genes associated with Leigh syndrome in small families and isolated cases. Exome sequencing was combined with homozygosity mapping to identify the genetic defect in a Moroccan family with fatal Leigh syndrome in early childhood and typical MRI abnormalities. We detected a homozygous nonsense mutation in the thiamine transporter SLC19A3 (p.Ser7Ter) leading to nonsense mediated decay. Seventeen additional patients with Leigh syndrome were screened for mutations in SLC19A3. Two unrelated patients, both from Moroccan origin and one from consanguineous parents, were homozygous for the same p.Ser7Ter mutation. One of these patients showed the same MRI abnormalities as the patients from the first family. Although unrelated, all patients came from the same area in North-Morocco. Marker analysis of the region surrounding the mutation revealed the same rare haplotype on 5 chromosomes and half the haplotype on the sixth, confirming a founder effect. Strikingly, the only patient in the second family treated with biotine had a much better life expectancy. Our data shows that SLC19A3 is a new candidate for mutation screening in patients with Leigh syndrome, who might benefit from high doses of biotine and/or thiamine. Especially Moroccan Leigh patients should be tested for the c.20C>A founder mutation in SLC19A3.

709F

SATB2 Acts as an Activator of the UPF3B Gene. *P. Leoyklang[1,2,3], K. Suphapeetiporn[2,3], C. Srichomthong[2,3], S. Tongkobpetch[2,3], H. Dorward[4], A.R. Cullinane[4], M. Huizing[4], W.A. Gahl[4], V. Shotelersuk[2,3]*. 1) 1Biomedical Science Program, Faculty of Graduate School, Chulalongkorn University, Bangkok, Thailand; 2) 2The Center of Excellence for Medical Genetics, Department of Pediatrics, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; 3) 3Excellence Center for Medical Genetics, King Chulalongkorn Memorial Hospital, Thai Red Cross, Bangkok, Thailand; 4) Medical Genetics Branch, NHGRI (NIH), Bethesda, MD.

Two syndromic cognitive impairment disorders have very similar craniofacial dysmorphisms. One is caused by a heterozygous nonsense mutation of SATB2, a transcription regulator, and the other by heterozygous mutations leading to premature stop codons in UPF3B, encoding a member of the nonsense-mediated mRNA decay complex. We hypothesized that the products of these two causative genes functioned in the same pathway. Here, we demonstrated that the SATB2 nonsense mutation identified in our patient led to a truncated protein that localized to the nucleus, formed a dimer with the wild-type SATB2 and interfered with its normal activity. This suggested that the SATB2 nonsense mutation had a dominant negative effect leading to more severe clinical manifestations, compared to patients with SATB2 haploinsufficiency. We also showed that the patient's leukocytes had significantly decreased UPF3B mRNA compared to controls. A chromatin immunoprecipitation assay demonstrated that the SATB2 protein bound to the promoter of the UPF3B gene. A luciferase reporter assay revealed that recombinant SATB2 protein significantly activated gene transcription using the UPF3B promoter. These findings indicate that SATB2 acts as an activator of the UPF3B gene through binding to its promoter. This study emphasizes the benefit of linking disorders with similar clinical phenotypes to elucidate previously unrecognized mechanisms of interaction.

Low bone strength is a manifestation of phenylketonuria in mice and is attenuated by a glycomacropeptide-based diet. *R. D. Blank[1, 2], P. Solverson[3], S. G. Murali[3], S. J. Litscher[1, 2], D. M. Ney[3]*. 1) Medicine/Endocrinology, Univ of Wisconsin School of Medicine & Public Health, Madison, WI; 2) GRECC, William S. Middleton Veterans Hospital, Madison, WI; 3) Nutritional Sciences, Univ of Wisconsin, Madison, WI.

Purpose: Phenylketonuria (PKU), caused by phenylalanine (phe) hydroxylase loss of function mutations, requires a low-phe diet plus amino acid (AA) formula to prevent cognitive impairment. Skeletal fragility is a poorly understood chronic complication of PKU. Glycomacropeptide (GMP), a low-phe protein isolated from cheese whey, provides a palatable alternative to AA formula. We sought to determine the impact of the PKU genotype and dietary protein source on bone biomechanics.

Methods: Wild type (WT; $Pah^{+/+}$) and PKU ($Pah^{enu2/enu2}$) mice on a C57BL/6J background were fed high-phe casein, low-phe AA, and low-phe GMP diets between 3 to 23 weeks of age. Following euthanasia, femur biomechanics were assessed by 3-point bending and femoral diaphyseal structure was determined. Femoral *ex vivo* bone mineral density (BMD) and bone mineral content (BMC) were assessed by dual-enengy x-ray absorptiometry (DXA). Sixteen whole bone parameters were used to perform prinicipal component analysis. Data were analyzed by 3-way ANOVA with genotype, sex, and diet as the main factors.

Findings: Regardless of diet and sex, PKU femora were more brittle, as manifested by lower post-yield displacement, weaker, as manifested by lower energy and yield and maximal loads, and showed reduced BMD and BMC compared with WT femora. Regardless of genotype and sex, the AA diet reduced femoral cross-sectional area with a consequent reduction of maximal load compared with the GMP diet. Four principal components accounted for 87% of the phenotype variance and confirmed the genotype and diet effects.

Conclusions: Skeletal fragility, as reflected in brittle and weak femora, is an inherent feature of PKU in mice. This PKU bone phenotype is attenuated by a GMP-based rather than an AA-based diet.

711F

Natural History Study of Patients with Hereditary Inclusion Body Myopathy (HIBM). *J.K. De Dios[1], J. Shrader[2], G. Joe[2], C. Ciccone[1], A. Mankodi[3], J. Dastgir[3], C. Bonnemann[3], M. Bevans[2], D. Draper[1], J. McKew[4], M. Huizing[1], W.A. Gahl[1], N. Carrillo-Carrasco[4]*. 1) Medical Genetics Branch (MGB), National Human Genome Research Institute (NHGRI), National Institutes of Health (NIH), Bethesda, MD; 2) Clinical Center, NIH, Bethesda, MD; 3) National Institute of Neurological Disorders and Stroke (NINDS), NIH, Bethesda, MD; 4) Therapeutics for Rare and Neglected Diseases (TRND), National Center for Advancing Translational Sciences (NCATS), NIH, Bethesda, MD.

Background: HIBM, a rare disorder characterized by progressive muscle weakness, is caused by *GNE* mutations, impairing sialic acid biosynthesis. Weakness, apparent in early adulthood, progresses slowly from distal to proximal, first in lower and subsequently in upper extremities, with relative sparing of the quadriceps. There is no therapy available and patients eventually require a wheelchair. **Methods**: We have evaluated 17 patients (age range, 28 to 58 years) in a prospective, longitudinal, single-center study of HIBM (CT.gov: NCT01417533) to define the natural history, genotype-phenotype correlations, prognostic factors, associated manifestations and potential biomarkers and outcome measures. **Results**: The mean age of presentation was 27 years with a mean diagnostic delay of 10 years (range: 2–19 years). Initial manifestations included falls, gait disturbance, foot drop, and overuse-related hand weakness (n=1). Various genotypes were seen, the most common being homozygous p.M712T (n=3). Decreased mean predicted ankle dorsiflexion (9 %), grip (34%) and knee extension (69%) strength were seen. Grip strength deficits emerged around 7.5 years after onset of first symptoms. The 6-minute walk was 68% of mean predicted distance and directly correlated with Activities-specific Balance Confidence Scale Scores. Less strength for selected muscle groups was also related to less balance confidence and longer duration of disease. MRI of lower extremities showed atrophy of muscles with relative sparing of the quadriceps. Prolonged QTc (n=1) and asymptomatic cardiomyopathy (n=1) were seen, but their association to HIBM remains unclear. CPK levels ranged from 161–1152 and decreased with progression of the disease. Mild elevation of ALT (n=2) and hypoalbuminemia (n=12) were seen; all patients had normal renal function tests. **Conclusions**: The characteristic presentation may be modified by muscle overuse. More data are needed to establish genotype/phenotype correlations, but variability among siblings suggests involvement of other factors. Muscle strength and volume decreased with progression and correlated with functional measures and balance confidence. The heart was the only other organ involved as previously reported (Chai et al 2011). Planning clinical trials for potential therapies (ManNAc and sialic acid) is complicated by diagnostic delays and lack of natural history data. Selection of appropriate biomarkers and clinical outcome measures is under evaluation.

712T

Hepatic carnitine palmitoyltransferase 1A deficiency: Adulthood complications and a Durango, Mexico founder mutation. *N. M. Gallant[1,2], N. Vatanavicharn[1,3], D. Salazar[4], W. R. Wilcox[1,2]*. 1) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Department of Pediatrics, UCLA School of Medicine, Los Angeles, CA; 3) Division of Medical Genetics, Department of Pediatrics, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand; 4) Biochemical Genetics Laboratory, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

Background: Hepatic carnitine palmitoyltransferase (CPT1A) deficiency is a rare disorder of mitochondrial long-chain fatty acid transport typically presenting with sudden episodes of hypoketotic hypoglycemia, liver dysfunction and hepatic encephalopathy during times of fasting or illness. Scant information is known about complications in adulthood and long-term outcome. Methods: We report four patients in three families with CPT1A deficiency and complications not described previously. Molecular sequence analysis of CPT1A and haplotype analysis were performed. Results: Novel clinical and radiographic findings included intrahepatic cholestasis, recurrent pancreatitis, and abnormal brain MRI with T2-hyperintensity in the bilateral basal ganglia and brainstem. Two patients had persistent renal tubular acidosis in spite of therapy with MCT oil. Three patients from two unrelated families were of Durango, Mexican descent. Molecular sequence analysis of CPT1A showed homozygosity for a common disease-causing variant (Q100X), and all shared the same haplotype on chromosome 11q13 from D11S4155-6 to D11S4095-15a. Conclusions: We describe four patients with CPT1A and novel clinical and radiographic findings. We speculate that these new findings may be due in part to a toxic effect of long-chain fatty acids or their acyl-CoA esters in the brain, liver, pancreas and kidney. Two unrelated families from Durango, Mexico share a common haplotype on chromosome 11q13, suggesting their common CPT1A disease-causing variant Q100X to be a founder mutation.

713F

Basis of immune dysregulation in Gaucher disease. *C. Martin[1], L. Kozhaya[2], T. Taber[1], D. Unutmaz[2], O. Goker-Alpan[1]*. 1) LSD Research and Treatment Unit, Center for Clinical Trials, O & O Alpan, Fairfax, VA; 2) New York University School of Medicine, Department of Microbiology, New York, NY.

Gaucher disease (GD), the inherited deficiency of the lysosomal enzyme glucocerebrosidase, is the most common Lysosomal Storage Disorder. Activated lipid engorged macrophages are the hallmark for GD. Although the mechanisms for macrophage activation in GD is unclear, there is clinical evidence of immune dysregulation, and a non-specific inflammatory response, characterized with poor wound healing, frequent infections, and predisposition to cancers, are frequently encountered in patients with GD. The basis of immune dysregulation was explored in patients with Gaucher disease. Under an IRB approved protocol, 14 subjects (4M: 10F), (age range 34–56) were evaluated and immune profiling analysis were performed and results were compared to healthy controls. The proportion CD14+ monocytes, CD4+ lymphoid dendritic cells and CD1d-restricted NKT cells were greatly reduced in GD patients ($p < 0.05$). In addition, while the total NK cell numbers were reduced, the proportion of NK cells displayed more activated/differentiated phenotype. There was also a profound decrease in naïve T cells. Clinically, these findings correlated with the disease burden and response to enzyme replacement therapy. Elucidating the link between immunological dysregulation in Gaucher disease will not only provide insights into novel functions of this lysosomal enzyme, but also further our understanding of the pathways that establish the cross talk between immune cells.

714T

Longitudinal Change in Brain Volumes and Cognitive Function in MPS IIIA. *I. Nestrasil[1], K. Delaney[1], B. Yund[1], A. Ahmed[1], K. Rudser[1], V. Kovac[1], P. Haslett[2], C. Richard[2], C. Whitley[1], E. Shapiro[1]*. 1) University of Minnesota, Minneapolis, MN; 2) Shire HGT.

Background: MPS IIIA (Sanfilippo syndrome type A) is primarily a neurological disease. Quantitative MRI and neurocognitive function may provide understanding of the disease and provide information about rate of decline. In an ongoing study of the natural history of this disease (NCT01047306), we previously reported that baseline cognition is significantly associated with age and grey matter volumes. Goals: To present longitudinal data in MPS IIIA patients and to estimate the rate of decline in both cognition and MRI over 12 months. Methods: Longitudinal cognitive and quantitative MRI data were collected from 24 children with documented Sanfilippo syndrome type A. Volumetric analysis by automated segmentation, and developmental quotient (DQ) and age equivalent scores by cognitive assessment were obtained. Results: For a subset of 19 patients with classic disease diagnosed before age six, all but one participant showed no development past a ceiling of 28 months. Younger patients continued to show slow development until 28 months; those over two showed no growth or decline in skills. For patients diagnosed after age six, patterns were variable. Decrements in developmental quotients were associated with the age of the child such that younger children showed steeper declines than older children. Gray matter volumes were similarly associated with age with larger decrements in volumes in younger children. When the two were associated a robust correlation was found between developmental quotient and total gray matter volume ($r = 0.86$. $p < .01$) Conclusions: Loss of grey matter volume is the primary MRI pattern linked to decline in cognitive function in MPS IIIA patients. We have demonstrated that both Developmental Quotient and Gray Matter Volume are markers of disease progression in MPS IIIA, and that they are closely associated. We have also shown that MPS IIIA patients usually do not exceed a ceiling of development at 28 months age equivalent.

715F

Is the Profile of Medical Signs and Symptoms Associated with Specific Genotype in Mucopolysaccharidosis Type I? *A. Ahmed, R. Cooksley, C. Whitley, E. Shapiro.* Department of Pediatrics, University of Minnesota, Minneapolis, MN.

Mucopolysaccharidosis Type I or MPS I is an autosomal recessive lysosomal disorder due to deficiency or absent of the enzyme alpha-L-iduronidase. Over 100 mutations have been identified on the IDUA gene located on chromosome 4p16.3. MPS I affects almost all organ systems of the body. Previous research has focused on the correspondence of mutation with severity of disease. In this study, our goal is to determine the association of mutation (nonsense, missense, splice site and deletions/insertions) with the profile of organ system involvement. Methods: Medical history data and genotype were collected on 26 severe and 14 attenuated MPS I participants as part of a NIH supported longitudinal study. Medical history included skeletal, cardiorespiratory, somatic, vision, hearing, neurological, and cognitive status. For severe patients, all but one had hematopoietic cell transplant; for attenuated patients, all were on enzyme replacement therapy. Data were analyzed to determine the probability of specific organ system involvement in particular mutation types. Results: In the severe group, 18 had two nonsense mutations and 6 had abnormalities of either splice site or a deletion; 2 had one nonsense and one missense mutation. In the attenuated group, 8 were nonsense/missense, and the remaining 6 had combinations of splice site/missense/deletions. All patients had skeletal and most had cardiac abnormalities. Most had corneal opacities but they varied in severity; multiple episodes of otitis media/with tube placement were common but not universal. Frequency of surgeries was higher in nonsense mutations. The probability of cognitive impairment was higher for the nonsense mutations. Probabilities of organ involvement for each type of mutation will be reported. We conclude that examining the probability of specific organ system involvement in particular mutation types can contribute important data for understanding the development of signs and symptoms in MPS I.

716T

Prevalence of Fabry disease in patients with chronic pain. *C. Goizet[1,2], V. Dousset[3], M. Cadenne[3], E. Maurat[2], S. François[2], C. Blanchard[2], P. Poulizac[4], S. Tabuteau[4], C. Hubert[5], S. Laborde[3], P. Casenave[6], X. Ferrer[2,6], G. Solé[2,6], I. Coupry[2], F. Bauduer[2,7], T. Levade[8], D. Lacombe[1,2]*. 1) Medical Genetics, CHU Pellegrin, Bordeaux, France; 2) Université Bordeaux Segalen, Laboratoire Maladies Rares: Génétique et Métabolisme (MRGM), EA4576, Bordeaux, France; 3) CHU Bordeaux, Hopital Pellegrin, Pôle des Neurosciences Cliniques, Centre Douleurs Chroniques, Bordeaux, France; 4) CHU de Bordeaux, Direction de la Recherche clinique et de l'Innovation, Talence, France; 5) Université Bordeaux Segalen, Plateforme Génome Transcriptome, Centre de Génomique Fonctionnelle de Bordeaux, 33076 Bordeaux, France; 6) CHU Bordeaux, Groupe Hospitalier Sud, Service de Neurologie, Pôle des Neurosciences Cliniques, Pessac, France; 7) Centre hospitalier de la Côte Basque, Service d'Hématologie, Bayonne, France; 8) CHU Toulouse, Laboratoire de Biochimie Métabolique, Toulouse, France.

Fabry disease (FD) is an X-linked recessive lysosomal disease caused by α-galactosidase A (α-gal) deficiency related to a deleterious mutation in the GLA gene, causing progressive glycosphingolipid storage in various organ systems. Chronic pain is classically considered as a frequent and early feature. To our knowledge, despite several studies of FD's prevalence in various populations with organ deficiencies that may occur in the course of the disease, there are no reports about the prevalence of FD in patients with chronic pain of undetermined causes. The objective of this study was to determine FD prevalence, as assessed by alpha-gal activity and genetic tests, in patients suffering from chronic pain of undetermined causes. We included 119 consecutive patients with such a diagnosis followed by the Centre of Chronic Pain in our University Hospital. Male patients underwent biochemical analyses to evaluate peripheral α-gal activity in leucocytes, although a search for GLA mutations was directly performed in female patients. Of 119 consecutive screened subjects (81 females, 38 males), all enzymatic assays were normal but one previously unknown GLA mutation p.Arg363His was found in a 62-year-old woman affected by asthenia since several years and presenting with a 2-years history of distal chronic pain in the limbs. Evaluation for additional features of FD in this patient is in progress. This is the first study reporting FD prevalence in a consecutive cohort of patients with chronic pain of undetermined causes. We found a relatively high prevalence among the included patients. These findings need to be confirmed in a larger cohort of patients in order to determine whether a systematic screening for FD is indicated in all patients with chronic pain, since it is a treatable genetic disorder.

717F

Infantile onset severe phenotype of cblG disorder in a patient and abnormal neurotransmitter metabolites. *R. Jobling[1,2], S. Hewson[1,2], S. Mercimek- Mahmutoglu[1,2]*. 1) The Hospital for Sick Children, Toronto, Canada; 2) University of Toronto, Toronto, Canada.

Cobalamin G disorder (*cbl*G) is an autosomal recessive inborn error of cobalamin metabolism caused by mutations in the *MTR* gene, encoding methionine synthase. It is characterized by developmental delay, seizures, hyperhomocysteinemia, hypomethioninemia and low intracellular methylcobalamin.

Case report: This is an 11-month-old girl, first child of consanguineous Somali parents, who presented with developmental regression and microcephaly at age 3 months. Her condition progressed to central hypotonia and epileptic encephalopathy at age 5 months. She had total a homocysteine of 100 μmol/L (reference: 0.5–11 μmol/L) and methionine of 9 μmol/L (reference: 15–21 μmol/L) with normal methylmalonic acid in urine. She was started on intramuscular hydroxycobalamin 1 mg/day, oral betaine 250 mg/kg/day and folic acid (5 mg/day). Total homocysteine decreased to 28 μmol/L within 6 days of therapy. The synthesis of methylcobalamin was low in cultured skin fibroblasts by complementation analysis, confirming cblG disorder. She was homozygous for a known intronic mutation (IVS-166 A>G) in the MTR gene. CSF neurotransmitter analysis showed low levels of 5 -methyltetrahydrofolate (MeTHF) (28 nmol/L; reference:40–240), homovanillic acid (245 nmol/L; reference:450–1132) and 5 -hydroxyindolacetic acid (109 nmol/L; reference:179–711).

Discussion: This patient presented with a severe phenotype of cblG disorder. The intronic mutation identified has been previously described as a null-type mutation in two siblings with severe neonatal onset in compound heterozygous state. To our knowledge, this is the first patient with cblG disorder in whom low levels of neurotransmitters and cerebral folate have been found.These abnormalities are of particular interest given the known neurological and psychiatric manifestations of this condition. The findings in this case are a potential source of new insight into the pathophysiology of *cbl*G.

718T

Abnormal central tegmental tract signal in a patient with mild glycogen storage disease type 1a (GSD1a). *D.L. Renaud[1, 3], S.T. Janousek[2], D.K. Freese[3], W.F. Schwenk[3].* 1) Div Child/Adolescent Neurology, Mayo Clinic, Rochester, MN; 2) Noran Neurological Clinic Minneapolis, MN; 3) Department of Pediatrics, Mayo Clinic Rochester, MN.

Case Report A 15 month old boy, born to non-consanguineous parents, presented for evaluation of spells. His development and neurological examination were normal. He had hypoglycemia as a newborn. No subsequent episodes of hypoglycemia were documented. His EEG was normal. The MRI revealed abnormal signal in the central tegmental tracts bilaterally. Evaluation in the Neurometabolic Clinic revealed an elevated uric acid of 11.1 (2.4–5.4) and lactic acid at 7.8 (normal <3.2). Hyperlipidemia was present. The ALT was increased at 479. Neutropenia was absent. Urine organic acids revealed 3-methylglutaconic acid and 3-methylglutaric acid. An abdominal ultrasound demonstrated marked hepatomegaly with normal hepatic echogenicity. Kidneys were mildly enlarged. The biochemical and clinical profile were suggestive of GSD1a despite the limited history of hypoglycemia. Enzyme analysis of glucose-6-phosphatase activity in liver revealed a significantly decreased (0.9 micromole/min/gram tissue) but not absent enzyme activity (normal 3.50 +/− 0.8). Sequencing revealed a homozygous mutation, c.648G>T, which results in the creation of a new splice donor site in exon 5 and premature translation termination. Conclusions Central tegmental tract abnormalities have been described in patients with disorders of amino acid, organic acid and tetrahydrobiopterin metabolism. GSD1a should be added to the differential diagnosis of this MRI finding.

719F

Mild clinical and atypical somatic cell findings in a *cblF* patient detected by expanded newborn screening. *D. Rosenblatt[1], A. Brebner[1], I.R. Miousse[1], J.C. Kim[1], M.T. Geraghty[2], D. Watkins[1], C. Armour[3].* 1) Department of Human Genetics, McGill University, Montreal, Quebec; 2) Department of Pediatrics, Children's Hospital of Eastern Ontario and University of Ottawa, Ottawa, Ontario; 3) Medical Genetics Unit, Department of Pediatrics, Queens University, Kingston, Ontario.

A full term female infant came to medical attention following a positive newborn screen due to a borderline elevation of C3 and an increased ratio of C3:C2. The family history was unremarkable and she was of mixed European Caucasian descent. At the time of ascertainment, she was clinically well, with unremarkable physical exam. Follow-up testing at age 12 days demonstrated a continued elevation of C3 at 2.55 (reference value < 0.65), with increased excretion of methylmalonic acid (MMA), without methylcitric acid. The total serum homocysteine was elevated (39 μmol/L, reference range: 4–15μmol/L). The hemoglobin and MCV values were within reference limits. The serum cobalamin level was low (62 pmol/L, reference range 165–740 pmol/L). The urinary quantitative MMA level was 54mmol/mole creatinine (reference upper limit: 6.6mmol/mole creatinine). The infant responded first to cyanocobalamin and then to hydroxycobalamin (1mg every 2 weeks) and all values normalized. At 2.5 years of age she remains healthy and developing appropriately. Somatic cell studies using cultured fibroblasts studies showed that incorporation of [^{14}C]-propionate into cellular macromolecules was at the lower end of the reference range but too high to allow for complementation analysis. The incorporation [^{14}C]-methyltetrahydrofolate was well within the reference range. Fibroblasts from the patient showed decreased synthesis of both adenosylcobalamin and methylcobalamin and an excess of the labelled substrate, cyanocobalamin. Mutation analysis of *LMBRD1* revealed one copy of the common c.1056delG (p.L352fsX18) and one copy of a splice mutation c.1339–1G>T (p.T447fsX33) leading to a cDNA product lacking exon 14 (Miousse IR et al. Mol Genet Metab 102:505–507, 2011). Thus, expanded newborn screening has detected a *cblF* patient with a mild clinical phenotype and atypical cellular findings. Molecular analysis of the candidate gene allowed for the correct diagnosis and prompt therapy likely prevented any permanent neurological or physical sequelae.

720T

Fumarase deficiency. Expanding the phenotype. *K. Siriwardena[1], W. Al-Hertani[1], J. Kronick[1], D. Chitayat[1,2].* 1) The Hospital for sick Children, Department of Pediatrics, 1)Division of Clinical and Metabolic Genetics, University of Toronto, Ontario,Canada; 2) Mount Sinai Hospital, Department of Obstetrics and Gynecology, 2The Prenatal Diagnosis and Medical Genetics Program,; University of Toronto, Toronto, Ontario, Canada.

Fumarase is the enzyme that converts fumarate to malate in the Krebs cycle. The enzyme is encoded by the FH gene mapped to chromosome 1q42.1and deficiency of fumarase activity causes a rare autosomal recessive condition known as fumaric aciduria, or fumarase deficiency that is associated with severe neurological impairment and seizures. We report on a 24-month-old male, born to non-consanguineous parents with a non contributory family history who presented at 8 months of age with global developmental delay, failure to thrive, microcephaly, dystonia, chorea, intractable epilepsy, osteopenia and facial dysmorphism. Brain MRI showed delayed myelination with diffuse T2 hyperintensity in the supratentorial white matter with normal MRS. Urine organic acid analyses showed markedly increased excretion of fumaric acid, leading to the diagnosis of fumarase deficiency. DNA analysis revealed compound heterozygotic novel variants in the fumarate hydratase (FH) gene. Results of patient's enzyme analysis and parental DNA analysis are pending. There are less than 50 cases of Fumarase deficiency reported worldwide. This case report expands on the phenotype described for this disease. Inactivation of fumarate hydratase (FH) drives a metabolic shift to anaerobic glycolysis in the absence of hypoxia in FH-deficient kidney tumors and cell lines from patients with hereditary leiomyomatosis renal cell cancer (HLRCC), resulting in decreased levels of AMP-activated kinase (AMPK) and p53 tumor suppressor. Further studies are required to find if parents of patients with fumarase deficiency are at increased risk for developing hereditary leiomyomatosis renal cell cancer (HLRCC).

721F

Renal Growth in Isolated Methylmalonic Acidemia (MMA). *P. Kruszka, I. Manoli, J. Sloan, C.P. Venditti.* Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD.

OBJECTIVES: A major complication of methylmalonic acidemia (MMA) is the development of tubulointerstitial nephritis and renal failure. The effect of MMA on kidney size has not been studied. This study examines kidney size variation with age and other measureable predictors and develops a kidney length nomogram. DESIGN: Renal ultrasounds, anthropometric measurements, and laboratory evaluations including serum creatinine (Cr), serum and urine methylmalonic acid, and cystatin C were conducted on 50 non-transplanted patients (ages 2.2 to 36.3 years) with enzymatic and mutation confirmed MMA. The patients were followed prospectively from 2004 to 2011, with some patients imaged sequentially, yielding 84 total ultrasounds. MMA patients were compared to a control group of 209 patients aged 0 to 19 years using the paired t-test. Linear and multiple regression analysis were used to study relationships between renal length and other clinical variables. RESULTS: Comparisons with age-matched controls showed a significant difference in renal length ($p < 0.05$) for most age groups. The regression equation for the control group was renal length (cm) = 6.79 + 0.22 * age (years) for children older than 1 year and for our study patients was 6.80 + 0.09 * age (years); $p < 0.001$ for both the constant and β_{age} coefficient ($R^2 = 0.399$). The most highly correlated single predictor model for MMA patients used height instead of age ($R^2 = 0.490$). When serum Cr values were in the normal range (Cr < 1.3), the most predictive multiple regression model found height, age, and serum methylmalonic acid (MMA_S) to be the optimal independent variables ($R^2 = 0.720$). Cystatin C was comparable to MMA_S in the multiple regression model and correlated closely with Cr and MMA_S (Pearson correlation coefficients = 0.7901 and 0.7684, respectively). Urine methylmalonic acid concentration was not a significant predictor of renal length when controlling for age, height and Cr ($p = 0.849$). CONCLUSIONS: Renal length in MMA patients is significantly decreased compared to normal controls and predicted by a multiple regression model that uses the clinical variables of height, age, and MMA_S when Cr is in normal range. In addition to generating a clinically useful nomogram, our results capture a marker of the natural history of MMA renal disease. The use of a simple index such as renal length will contribute to the study of therapeutic interventions designed to target the kidney in this population.

Plasmalogen deficiency in the Pex7 hypomorphic mouse, a model of Rhizomelic Chondrodysplasia Punctata, causes neonatal lethality associated with late lung maturational defects. *N. Braverman[1], X. He[1], S. Jiralerspong[1], G. Nimmo[1], Y. Chen[1], J. Hacia[2], A. Moser[3], W. Cui[1].* 1) Dept Human Gen & Pediatrics, McGill Univ, MCH Res Inst, Montreal, PQ, Canada; 2) Dept Biochemistry & Molecular Biology, Univ Southern California, Los Angeles, CA, USA; 3) Dept Neurogenetics, Kennedy Kreiger Institute, Baltimore, MD, USA.

The biological functions of plasmalogens (PLs), a specialized class of membrane glycerophospholipids, are largely unknown. Cell-based studies implicate roles in oxidant protection, inflammatory responses, vesicle formation and signal transduction. PLs are also integral components of surfactant. Inherited defects of PL synthesis cause rhizomelic chondrodysplasia punctata (RCDP), a heterogeneous disorder commonly due to defects in the peroxisome transporter, PEX7. The clinical features of RCDP include growth and developmental retardation, cataracts and skeletal dysplasia. Patients suffer chronic respiratory compromise that ultimately causes death. To investigate PL functions, we generated hypomorphic Pex7 mouse models that survived on a mixed 129/C57Bl6 background, but died within a few days of life on a C57Bl6 background. Morphometric studies showed that death was associated with increased saccular wall tissue and decreased air spaces, indicating a delay, or arrest, in alveolarization. In addition, we found increased numbers of terminal bronchiole epithelial cells (Clara cells) and alveolar type II epithelial cells, as well as increased lipid peroxidation protein adducts. We suggest that (1) PL deficiency may affect cell signaling in late lung maturation and independently, also promote oxidant damage, (2) tissue effects of PL deficiency may be modified by strain background and, (3) PL deficiency contributes to the chronic lung disease observed in RCDP patients.

Phenylketonuria and defective metabolism of tetrahydrobiopterin. *A. Al-Aqeel.* Department of Pediatrics, Riyadh Military Hospital, Stem Cell Therapy program, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia.

Variant forms of hyperphenylalaninemia result from abnormalities of tetrahydrobipterin (BH4) cofactor synthesis. BH4 is an essential cofactor not only for phenylalanine hydroxylase, but also for tyrosine and two tryptophan hydroxylases, three nitric oxide synthases, and glyceryl-ether monooxygenase. Defective activity of tyrosine and tryptophan hydroxylases explains the neurological deterioration in patients with BH4 deficiency with progressive mental and physical retardation, central hypotonia and peripheral spasticity, seizures and microcephaly Five separate genetic conditions affect BH4 synthesis or regeneration: deficiency of GTP cyclohydrolase I, 6-pyruvoyl tetrahydropterin synthase (6-PTS), sepiapterin reductase, dihydropteridine reductase (DHPR) and pterin-4alpha-carbinolamine dehydratase. Only the latter of these conditions is relatively benign and is associated with transient hyperphenylalaninemia, however the clinical manifestations of the other disorders are quite similar. All these conditions can be identified in newborns by an elevated phenylalanine, with the exception of sepiapterin reductase and the dominant form of GTP cyclohydrolase I deficiency that results in biopterin deficiency/insufficiency only in the brain. Diagnosis relies on the measurement of pterin metabolites in urine, dihydropteridine reductase in blood spots, neurotransmitters and pterins in the CSF and on the demonstration of reduced enzyme activity (red blood cells or fibroblasts) or causative mutations in the relative genes. In Saudi Arabia newborn screening metabolic disorders was started in 2005 with overall incidence of 1:900, with an incidence of PKU cases of 1:4000. Deficiency of 6-PTS is the most common of the defects in biopterin metabolism, with almost 50% of all cases of PKU detected on newborn screening 6-PTS gene is an 8Kb span with 6 exons, with over 40 mutations reported. Four unique mutations are reported in Saudi Arabia, one of which with 23 base pairs deletions. In conclusion 6-PTS deficiency PKU is common in Saudi Arabia with novel mutations.

724T

Two Cases of Neonatal Onset Type II Citrullinemia Diagnosed by Urine Organic Acids Based Newborn Screening. *Y. Watanabe[1, 2], K. Tashiro[1], K. Aoki[1], T. Inokuchi[1], Y. Seki[2], T. Yanagi[2], T. Mizuochi[2], J. Okada[2], M. Yoshino[2], T. Matsuishi[1, 2].* 1) Research Institute of GC/MS, Kurume University, Kurume, Japan; 2) Dept. Pediatrics, Kurume University, Kurume, Japan.

Background: Citrullinemia type II caused by citrine deficiency, can manifest in newborns as neonatal intrahepatic cholestasis (neonatal intrahepatic cholestasis caused by citrin deficiency: NICCD). Citrin is encoded by SLC24A13 and is a mitochondrial membrane protein consisting of the aspartate-glutamate carrier. Citrin deficiency is an autosomal recessive disorder with the higher incidence in far eastern Asian countries. Citrin deficiency is recognized as one of the common genetic causes of neonatal intrahepatic cholestasis as are galactosemia and tyrosinemia type1. Symptoms associated with NICCD including intrahepatic cholestasis, liver dysfunction due to hepatic fibrosis and fatty infiltrations generally resolve within one year with appropriate treatment. However, some infants require liver transplantation. Majority of patients with citrin deficiency present with high blood citrullin levels in newborn screening (NBS). A pilot study of urinary organic acid based NBS has been conducted since 1996 in the southwest area (Kyushu Island) of Japan. Two cases of NICCD were missed by blood amino acid based NBS by tandem mass spectrometry, but they were identified by urine organic acid based NBS. Patients and Methods: Case 1 was a 2784g, term male infant. Blood and urine specimens were collected on age 4 days for NBS. A high urine 4-hydroxyphenyllactic acid (4OH-PLA) was noted. Blood based NBS was unremarkable. Case 2 was an 1808g, 33 weeks, preterm male infant born by caesarian section. High 4OH-PLA and 4OH-phenylpyruvic acid (4OH-PPA) levels were noted in urine specimens collected on age 18 days. A high blood galactose was noted on age 21 days although blood based NBS on age 5 days was unremarkable. Conclusions: Because of the high incidence, particularly in the far eastern Asian countries, citrin deficiency is an important genetic condition for NBS. Biochemical analytes including blood ammonia, serum amino acids including citrulline, arginine, methionine, phenylalanine, tyrosine, and threonine, as well as serum pancreatic secretory trypsin inhibitor, serum alfa-feto-protein, and galactose have been reported to be elevated in patients with citrin deficiency. Although high levels of urine 4OH-PLA and 4OH-PPA are known to be non-specific findings and often seen in patients with hepatic dysfunction of many different etiologies, they might serve as useful early biomarkers for citrin deficiency in the newborn period.

Translational research in newborn screening: implementation of a consensus data set for the long-term follow-up of patients to improve scientific understanding and optimize health outcomes. *S. Berry[1], K. Hassell[2], A. Brower[3], Joint Committee of the NBSTRN Clinical Centers Workgroup and NCC/RC Long-Term Follow-Up Workgroup.* 1) Dept Pediatrics, Univ Minnesota, Minneapolis, MN; 2) University of Colorado, Aurora, CO, 80045, USA; 3) American College of Medical Genetics, Bethesda, MD, 20814.

Background: The goal of translational research in newborn screening is to accelerate the implementation of new discoveries into public health programs and routine medical practice. Innovations in analytical technologies and the development of novel therapies and management approaches trigger validation activities across the spectrum of the screening, diagnosis, treatment and long-term follow-up. While analytical validation takes place within the state-based newborn screening programs and quality control programs are in place, clinical validation occurs in the course patient care in specialty centers and there is no mechanism to collect, aggregate and analyze information. We report on an innovative effort to implement a system to capture health information across the lifespan for newborn screen identified patients. Methods: A consensus data set developed through the efforts of the Joint Committee, described above, and accompanying informatics tools developed by the NBSTRN, were implemented within the context of two research projects. The aims of the first research project was to further understanding of the natural history of metabolic conditions included in routine newborn screening efforts, while the objective of the second study was to develop and pilot a novel newborn screening technology and therapeutic intervention for a condition that is not included in newborn screening. The structure and goals of the two projects were different but both utilized the same consensus set of data elements to understand the natural history and impact of newborn screening on diverse conditions. In addition, each project implemented disease specific data elements. Results: A consensus common data set of approximately 170 elements for use across all disorders, and individual disease specific data sets with a range between 300 and 600 individual elements were implemented in two ongoing research studies. Data capture, aggregation and analysis occurred within the context of routine clinical care and included data derived from public health screening. Conclusions: The implementation of a consensus data set for the long-term follow-up of newborns facilitates the translation of new discoveries into clinical practice to improve health outcomes and further scientific understanding. The use of this approach in ongoing research studies serves a model for future initiatives as genomic technologies begin to be applied to disease screening and management across the lifespan.

Newborn screening for infantile Pompe disease: Report of a pilot study in National Center for Child Health and Development. *M. Kosuga, K. Kida, N. Fuji, T. Okuyama.* Department of Clinical Laboratory Medicine, National Center for Child Health and Development, Tokyo, Japan.

Newborn screening (NBS) for Pompe disease has been initiated in several countries and regions, and is reportedly successful. However, the comparatively high frequency of pseudodeficiency allele makes NBS for Pompe disease complicated in Japanese population. We have demonstrated our modified screening procedure was able to distinguish pseudodeficiency individuals from Pompe disease patients. Based on this research, we have started a pilot study of NBS for infantile Pompe disease in our hospital and reported the result of this study. Healthy newborns born from Jan. to May in 2011 in National Center for Child Health and Development were screened. Informed consent was obtained from all newborn's family members. Dried blood spot (DBS) samples were obtained from newborns in 3–5 days after deliver. Samples with 30% of the normal GAA activity mean, % inhibition 60%, and NAG/GAA ratio 30 were considered as 1st screening positive.361(Male: 185, Female: 176) neonates were screened in this pilot study. 15 neonates were found with less than 30% of normal GAA activity level. 14 of 15 newborns were diagnosed as pseudodeficiency with the result of gene analysis. The frequency of pseudodeficiency was 3.9%. One newborn was underwent the measurement of GAA activity in lymphocytes and GAA gene analysis. This newborn was diagnosed as normal healthy individual in the end. Specificity of the pilot study was 95.8%.

727F

The identification of infants with Fabry, Pompe, and Mucopolysaccharidosis-I from newborn blood spots. *C.R. Scott[1], S. Elliott[1,2], N. Buroker[1], L.I. Thomas[1], M. Glass[2], F. Turecek[3], M.H. Gelb[3].* 1) Dept Pediatrics, 356320, Univ Washington Sch Med, Seattle, WA; 2) Washington State Dept of Health Newborn Screening Laboratory, Shoreline, WA; 3) Dept Chemistry, Univ Washington, Seattle, WA.

Can infants with lysosomal storage diseases (LSDs) be identified from newborn blood spots? With an appropriate buffer, substrates and internal standards, quantitation of the enzymes responsible for Fabry, Pompe, and MPS-I can be simultaneously assayed and quantitated by MS/MS. Here we report the results from screening 100,000 samples obtained from newborns. A stipulation of IRB was that screening be performed on anonymized samples. From the 100,000 samples, we identified infants with low enzyme activity, and confirmation was performed by mutation analysis of DNA isolated from a 3.2-mm blood spot.

For Fabry, a total of 16 samples were identified with low enzyme activity. Eight males were confirmed to have mutations consistent with Fabry. Thus, the prevalence for Fabry is ~1/6,800 males. The method has a positive predictive value (PPV) of 0.5 and a false positive rate (FPR) of ~1/14,000.

For Pompe, 17 infants were identified with low activity. Four were confirmed to have nucleotide changes consistent with clinical Pompe. All were of "late-onset" phenotype. Of the remaining 13 samples, four were heterozygote/wt, three were heterozygote/pseudo def, six were pseudo def/wt. The prevalence for Pompe was ~1/28,000, with a PPV = 0.24 and FPR = ~1/8,600.

Nine samples were identified with low activity for α-iduronidase. Three had mutations consistent with the diagnosis of MPS-I. One was homozygous for a null-mutation (Hurler), two were consistent with an "attenuated" phenotype. Of the six unaffected samples, one was a heterozygote/wt, two were poor punches, and three were wt/wt. The prevalence for MPS-I was ~1/35,500, with a PPV = 0.33 and FPR = ~1/15,000

The prevalences of these LSDs is 2–6x greater than reports from clinical studies. The MS/MS assay is effective for measuring multiple enzymes with a low false-positive rate. The assay can be performed by any screening laboratory that is interested in expanding their repertoire for the detection of genetic disease.

Support: NICHD #HHSN2672006 and Genzyme Corp.

728T

Bare lymphocyte syndrome type III, a novel mutation in *RFXAP* and failure to identify with newborn screening for severe combined immunodeficiency. *L. Randolph[1], J. Chase[2], M. Aguilera[3], J. Siles[4], J. Church[5].* 1) Division of Medical Genetics, Children's Hospital Los Angeles and Keck School of Medicine, University of Southern California, Los Angeles, CA; 2) Division of General Pediatrics, Children's Hospital Los Angeles and Keck School of Medicine, University of Southern California; 3) Molecular Biology Center GENETAQ, Málaga, Spain; 4) Molecular Biology Center GENETAQ; 5) Division of Clinical Immunology and Allergy, Children's Hospital Los Angeles and Keck School of Medicine, University of Southern California.

Newborn screening (NBS) for severe combined immunodeficiency (SCID) is performed by measuring T-cell receptor excision circles (TREC), episomal products of T-cell maturation in the thymus, from dried blood spots obtained at birth. However, there are genetic forms of SCID that theoretically would not be diagnosed by this method. Our patient was 14 months of age at the time immune deficiency was suspected. The son of second cousins, he had FTT, global DD and multiple atypical respiratory infections (e.g. rhinovirus pneumonia) and B. pertussis pneumonia, despite having been properly immunized. Serum IgG, IgA, and IgM were undetectable. Flow cytometry revealed T- and B-lymphocytosis but a reversed CD4/CD8 ratio. His T-cells responded in vitro to non-specific mitogens but not to tetanus or candida antigens. Retrospective review of his NBS TREC result was normal. Single nucleotide polymorphism (SNP) chromosomal microarray was initially performed because of DD. It showed a deletion on 5p15.2 including the catenin delta 2 (*CTNND2*) gene, which predicts moderate to severe mental retardation. Loss of heterozygosity was also noted in several areas, including a region encoding the regulatory factor X-associated protein (*RFXAP*) gene in 13q13.3. Mutations in this gene cause bare lymphocyte syndrome (BLS) types II and III. This form of SCID results from the lack of expression of MHC II (BLS II) or MHC I and II (BLS III). Further investigation of our patient demonstrated that his lymphocytes lack expression of HLA A, B and C (MHC I) and HLA DP, DQ and DR, resulting in a diagnosis of BLS III SCID. *RFXAP* was sequenced, and a novel homozygous mutation was identified: c.323T>A in exon 1, a nonsense variant predicted to lead to a premature stop codon. **Summary**: Lack of MHC expression profoundly impairs antigen-specific T- and B-cell functions. Thymus production of mature T-cells is normal in BLS III; this results in a form of SCID that will not be identified by current NBS testing. SNP arrays can be useful in identifying candidate genes in complex disorders such as these.

729F

Standard value of urine HVA/VMA ratio in the early neonatal period to screen for Menkes disease. *M. Yagi, N. Kusunoki, T. Lee, H. Awano, T. Yokota, A. Miwa, A. Shibata, I. Morioka, Y. Takeshima, K. Iijima.* Dept Pediatrics, Kobe Univ Graduate Sch Med, Kobe, Hyogo, Japan.

[Background] Menkes disease (MD) is a lethal, X-linked recessive disorder of copper metabolism dominated by neurodegenerative symptoms and connective tissue disturbance. Early treatment with parenteral copper-histidine has been shown to improve clinical outcomes. However, early detection is difficult because clinical abnormalities are subtle in early neonatal period. Previously, it was reported that decreased activity of dopamine β-hydroxylase, a copper-dependent enzyme, leads to increased urine homovanillic acid/vanillylmandelic acid (HVA/VMA) ratio in MD patients, and the urine HVA/VMA ratio (cut-off value:4.0) is a useful screening method for MD [Matsuo et al. *J Inherit Metab Dis.* 2005]. However, there is no data of urine HVA/VMA ratio in neonates. **[Purpose]** To examine the standard value of urine HVA/VMA ratio in early neonatal period. **[Methods]** Concentration of urine HVA and VMA from 54 neonates with a gestational age from 32 to 41 weeks at 1 or 4 days of age were measured by high-performance liquid chromatography. **[Results & Discussion]** Among all samples, HVA concentrations ranged from 5.0 to 245.1μg/mg creatinine (mean ± SD=26.4 ± 43.0), VMA concentrations ranged from 3.9 to 23.7μg/mg creatinine (mean ± SD= 7.34 ± 2.93), and HVA/VMA ratios ranged from 0.725 to 29.1(mean ± SD= 3.35 ± 4.28). Three samples had extremely high HVA/VMA ratios; 9.21, 17.7 and 29.1. All of three were collected from the cases treated with catecholamine on their collection date. The treatment with catecholamine influences HVA and VMA measurements. Among 51 samples except the three with catecholamine treatment, HVA/VMA ratios ranged from 0.725 to 4.66 (mean ± SD=2.45 ± 0.75). These values were similar to previously reported urine HVA/VMA ratios at 6 months of age which was used as a control data to determine the cut-off value. These data suggest that the urine HVA/VMA ratio can be an effective screening method for MD in early neonatal period as well.

Correlation of phenylalanine concentration with neuropsychiatric symptom scores in phenylketonuria patients. *T. Morgan, N. Owen, A. Bawcom, G. Wey, L. Ashford, J. Phillips.* Pediatrics, Medical Genetics, Vanderbilt Univ Sch Med, Nashville, TN.

Background. In Phenylketonuria (PKU), the central nervous system may be adversely affected by accumulation of the toxic precursor (Phe) as well as a deficit of the product (Tyr), which is a precursor for Dopa and Dopamine. Lifetime Phe:Tyr ratio (PTR) correlates with executive cognitive function in PKU patients, but less is known about the relationship between PTR and neuropsychiatric symptoms such as anxiety, depression, and attention deficit-hyperactivity disorder (ADHD). Thus, we hypothesized that amino acid concentrations, which are more convenient than lifetime measures, may reflect current neuropsychiatric status. To test this hypothesis we determined the correlation between concomitant neuropsychiatric symptom scores and Phe, Tyr, and PTR in PKU patients. Methods. Subjects were enrolled in an observational, single-site, pilot study nested within a multi-center, double-blind, placebo-controlled, randomized trial (PKU-016) to evaluate the safety and efficacy of sapropterin hydrochloride (Kuvan®) for neuropsychiatric symptoms in patients with PKU. Subjects had PKU with stable diets and medication intakes. Baseline and serial fasting amino acid levels, dietary histories, and neuopsychiatric testing using HAM-A, HAM-D, and ADHD standardized testing scales were obtained. Symptom scores were summed across all tests, and correlations with PTR, Phe and Tyr were tested for two-tailed statistical significance by the Spearman rank-sum correlation coefficient. Results. Eleven pediatric and adult subjects were enrolled at the Vanderbilt study site. Mean sum of scores (HAM-A, HAM-D, ADHD RS/ASRS) was 35.1 ± 16.5 (standard deviation). There was a correlation ($r = 0.66$; $P = 0.026$) between spot PTR and total sum of scores. Phe concentration had a similar correlation ($r = 0.67$; $P = 0.02$), but Tyr concentration was not correlated ($r = 0.22$; $P = 0.52$). Discussion. Despite the modest sample size of our pilot study, we found a strong, statistically significant correlation between neuropsychiatric symptoms in stable PKU patients and spot PTR and Phe but not Tyr concentrations. A larger, multi-site study is needed to determine optimal, clinically relevant, PTR and Phe cutoffs at which neuropsychiatric testing is warranted. In addition, the extent to which neuropsychiatric scores track with PTR and Phe over time, as well as the efficacy of sapropterin hydrochloride for optimizing PTR, Phe, and neuropsychiatric scores, should be determined.

731F

A rare disease - simple treatment: Sepiapterin Reductase Deficiency with a novel mutation. *I.M. Zamir, B. Ben-Zeev, A. Mimouni-Bloch, S. Msilaty-Gross, Y. Anikster.* The Edmond and Lily Safra Children's Hospital and Sackler Faculty of Medicine, Tel Aviv University, Tel Hashomer, Israel.

Sepiapterin Reductase catalyzes the last step in the biosynthesis of Tetrahydrobiopterin (BH_4), which is important in the metabolism of phenylalanine, catecholamines and serotonin. SPR deficiency patients were described as having a Dopa-responsive dystonia, progressive psychomotor retardation, hypersomnia and microcephaly, with the classic triad of oculogyric crises, paroxysmal stiffening and hypotonia and an autosomal recessive inheritance pattern. No Hyperphenylalaninemia is noted, which makes this condition difficult to recognize with regular newborn screening. The rational for therapy is substituting with L-Dopa and 5-Hydroxytryptophan. We report a 20-month-old Russian origin girl that presented with marked global developmental delay and oculogyric crises. She is the first born of unrelated healthy parents. Her weight was 8kg at age 17 months. Upon examination the patient exhibited head lag with opisthotonus and oculogyri crises during crying, weakness of neck and back with spastic quadriparesis, no eye contact was maintained and cogwheel rigidity in all limbs was present with positive Babinski's sign. Imaging was normal. Extensive workup revealed increased Sepiapterin and Biopterin levels, low levels of Dihydropteridine Reductase, with no Hyperphenylalaninemia. CSF levels of 5-Hydroxyindolacetic acid (5-HIAA), Homovanillic acid (HVA) and L-Dopa were all markedly reduced. Sepiapterin Reductase Deficiency was diagnosed. The patient was started on LevoDopa titrated up to 40 mg/d, 5-Hydroxytryptophan 8 mg/kg/week and Folinic Acid 15 mg/d. Great improvement was noted with higher levels of arousal and absence of opisthotonus and oculogyri crises, markedly improved tonus, reflexes and speech with movement in all limbs. Subsequent *SPR* gene sequencing revealed that the patient is a compound heterozygote for 2 mutations: 1) c.448A>G/N (p.R150G) in exon 2 - was carried by the mother and was previously described in Dopa-responsive SPR deficiency patients; 2) A novel mutation - c.26–36dup/N (p.T13CfsX4) in exon 1 - was carried by the father. We describe a patient with the classic manifestations of SPR deficiency, with a novel mutation in the *SPR* gene. It is of utmost importance to diagnose this potentially treatable condition early as there is a good chance of normal development when promptly treated.

A Phase 2a Study to Investigate the Effects of a Single Dose of Migalastat HCl, a Pharmacological Chaperone, on alpha-Gal A Activity in Subjects with Fabry Disease. *F.K. Johnson[1], P.N. Mudd Jr.[2], S. Sitaraman[3], R. Winkler[3], J. Flanagan[4], R. Khanna[4], K.J. Valenzano[4], D.J. Lockhart[4], P. Boudes[3] On Behalf of Study AT1001–013 Principal Investigators.* 1) Clinical Pharmacology and Pharmacokinetics, Amicus Therapeutics, Cranbury, NJ; 2) Clinical Pharmacology, Glaxo Smith-Kline, Research Triangle Park, NC; 3) Clinical Research, Amicus Therapeutics, Cranbury, NJ; 4) In Vivo Pharmacology, Amicus Therapeutics, Cranbury, NJ.

Fabry disease is an X-linked glycosphingolipid metabolism disorder caused by mutations in the GLA gene which results in a deficiency in lysosomal enzyme alpha-galactosidase A (alpha-Gal A). Migalastat HCl (AT1001, GR181413A) is a pharmacological chaperone that binds and stabilizes mutant and wild-type forms of alpha-Gal A. In preclinical studies, co-administration of migalastat HCl with gene-activated or recombinant human alpha-Gal A (generically known as enzyme replacement therapies (ERTs), agalsidase alfa and beta, respectively) to rodents resulted in greater increases in skin, heart, kidney, and plasma alpha-Gal A activity than seen with agalsidase alone. Co-administration with migalastat HCl also resulted in greater reductions in tissue globotriaosylceramide (GL 3) in a Fabry mouse model. Study AT1001–013 (NCT # 01196871) is a Phase 2a study to evaluate the safety and pharmacokinetic (PK) effects of oral administration of migalastat HCl two hours prior to initiation of intravenous infusion of agalsidase alfa or beta in male patients with Fabry disease. The primary objective of the study is to characterize the effects of a single administration of 150 mg or 450 mg migalastat HCl on alpha-Gal A activity in plasma, skin, and peripheral blood mononuclear cells (PBMCs). This is an open-label, single-dose, fixed-sequence study in two sequential stages. Stage 1 is comprised of 3 periods: algalsidase alfa or beta ERT alone, 150 mg migalastat HCl followed by initiation of ERT, then 150 mg migalastat HCl alone. Stage 2 is comprised of 2 periods: ERT alone, then 450 mg migalastat HCl followed by initiation of ERT. A minimum 14-day interval separates each treatment period. Results for alpha-Gal A activity and total alpha-Gal A protein in plasma, skin, and PBMCs, and plasma migalastat PK will be presented at the meeting.

A novel drug target site for medium chain acyl-CoA dehydrogenase deficiency: Implications for future drug therapy. *H. Kang[1], J. Vockley[1,2], A-W. Mohsen[2].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Pediatrics, University of Pittsburgh, Pittsburgh, PA.

Medium chain acyl-CoA dehydrogenase deficiency (MCADD) is one of the most common biochemical genetic disorders in the US. Patients are asymptomatic at birth but are at risk for episodes of life threatening metabolic decompensation. Episodes first occur between 3 and 24 months of age in association with physiological stress. Mortality rate during an acute crisis in undiagnosed patients can be as high as 20%. With newborn screening, MCADD can now be identified pre-symptomatically, nearly eliminating mortality. However, treatment requires lifelong dietary monitoring, and significant morbidity still occurs due to hospitalizations for IV glucose therapy. A medication capable of relieving the metabolic block would be of great benefit. A single point mutation in the ACADM gene (A985G) substituting K304 with a glutamate, has been identified in 90% of the alleles in deficient patients. This amino acid change in turn leads to impaired folding and/or stability of MCAD. Substrate binding to MCAD K304E mutant has previously been shown to improve thermal stability of the protein. To improve the MCAD K304E mutant stability and activity, we explored the possibility that other ligands can confer similar protective effect. The electron transfer flavoprotein (ETF), the second substrate/electron acceptor, binds to the MCAD:CoA ester ternary complex to complete the α,β-dehydrogenation reaction with concomitant release of the enoyl-CoA product. X-ray structure of the MCAD:ETF complex published data was used to examine ETF docking site and its pharmacophore characteristics was confirmed. Different 12-mer peptides were synthesized based on the structure of the ETF docking peptide. To test whether these peptides can influence enzyme activity, the purified recombinant MCAD K304E mutant protein was coincubated with these peptides and enzyme assays were performed at different temperatures. The presence of wild type peptide, ETF βR191-βK202, has shown improved MCAD mutant activity at higher temperatures. A derivative of the WT peptide, DP193, showed better improvement (~2.5°C) of the MCAD mutant activity with increasing temperatures, compared to WT peptide. CD spectroscopy protein melting assays confirmed a shift of the Tm of 4°C with coincubation of DP193 peptide and MCAD mutant protein. This suggests that ETF docking site can be targeted for MCADD drug design using a structural based approach and that peptide 193 can be used as a scaffold for fragment based drug design approach.

Immune Response against Enzyme Replacement Therapy (ERT) Alters Enzyme Distribution in Mucopolysaccharidosis I Mice. *S. Le, S-H. Kan, M. Vera, P. Dicskon.* Dept Med Gen, LA Biomed Harbor-UCLA, Torrance, CA.

Mucopolysaccharidosis type I (MPS I) is an inherited and progressive lysosomal storage disease. Enzyme replacement therapy (ERT) with recombinant human alpha-L-iduronidase (rhIDU) is available, but studies in MPS I dogs suggest that anti-iduronidase antibodies may reduce the effectiveness of treatment.

This study aimed to characterize the tissue and cellular distribution of rhIDU in naïve and sensitized MPS I (*Idua*$^{-/-}$) mice. *Idua*$^{-/-}$ mice (n=13)were sensitized to rhIDU by weekly exposure to the antigen via tail-vein injection from 4 to 15 weeks of age. At week 16, a single dose of rhIDU labeled with the near-infrared fluorophore AlexaFluor 680 (AF680-IDU) was administered to the sensitized mice and 6 MPS I mice that were naïve to rhIDU. *In vivo* and *ex vivo* AF680-IDU distribution was quantified using a CRi Maestro EX fluorescent small animal imager.

Three of the sensitized mice died prior to the completion of the experiment, apparently from infusion reactions. Of the ten surviving sensitized mice, five had anti-iduronidase IgG antibody titers ranging from 3 to 30 OD units/ml and were designated “high-titer,” while five had titers <1 OD units/ml and were designated “low-titer”. Incubation of MPS I fibroblasts with serum from 4 high-titer mice let to an approximate 40% reduction in rhIDU uptake compared with antibody-free serum.

We observed a difference in the distribution of AF680-IDU to all organs in high-titer vs. naïve MPS I mice. We evaluated distribution in organs with high reticuloendothelial (RE) content (liver, spleen, thymus) and organs with low RE content (lung, kidney, heart, brain). We found that the sensitized, high-titer mice had an average fluorescence intensity that was ~33–45% lower in high RE organs and ~33–70% lower in low RE organs compared to naïve mice. This difference reached statistical significance for the heart and liver (p=0.015). Studies of the effect of the immune response against rhIDU on cellular and sub-cellular distribution are underway. Experiments in MPS I mice confirm findings in dogs that anti-iduronidase antibodies may alter the distribution of rhIDU.

Hepatic gene transfer of TFEB results in clearance of mutant alpha-1-antitrypsin. *N. Pastore[1], P. Piccolo[1], F. Annunziata[1], R.M. Sepe[1], F. Vetrini[2], D. Palmer[2], P. Ng[2], K. Blomenkamp[3], J. Teckman[3], A. Ballabio[1,2,4,5], N. Brunetti-Pierri[1,5].* 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 3) Department of Pediatrics, Washington University School of Medicine, St. Louis Children's Hospital, St. Louis, MO, USA; 4) Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, Houston, TX, USA; 5) Department of Pediatrics, Federico II University, Naples, Italy.

Alpha-1-antitrypsin deficiency caused by missense mutation (lysine for glutamate at amino acid position 342) altering protein folding is the most common genetic cause of liver disease in children. The only curative treatment currently available is liver transplantation. Transcription factor EB (TFEB) is a master regulatory gene affecting the number and function of lysosomes and autophagy. In the present study, we have investigated efficiency of hepatic gene transfer of TFEB at increasing clearance of mutant hepatotoxic alpha-1-antitrypsin (ATZ). We injected a helper-dependent adenoviral (HDAd) vector expressing the TFEB under the control of a liver-specific promoter (HDAd-TFEB) in the PiZ mouse model, a transgenic mouse expressing the human ATZ gene and recapitulating the features of liver disease observed in humans. Three-month old PiZ mice were injected intravenously with HDAd-TFEB at the dose of 1x10e13 vp/kg or, as controls, with the same dose of a HDAd vector expressing the unrelated alpha-fetoprotein (AFP) gene under the control of the same expression cassette (HDAd-AFP) or saline. Compared to saline or HDAd-AFP, mice injected with HDAd-TFEB showed a dramatic reduction in hepatic ATZ accumulation, as demonstrated by marked reduction of periodic acid-Schiff (PAS) staining and ATZ-containing globules. Moreover, a marked, statistically significant decrease in both ATZ monomer and polymer was observed in HDAd-TFEB injected mouse livers as compared to either saline or HDAd-AFP injected control mice, thus indicating that TFEB hepatic expression enhances disposal of both insoluble and soluble hepatic ATZ. TFEB gene transfer resulted in an increase of hepatic LC3, a marker of autophagic activity, and increased ATZ degradation by autophagolysosomes. Taken together, these results demonstrate that hepatic gene transfer of TFEB reduces accumulation of ATZ by enhancement of autophagy. In addition, we showed a reduction of hepatocyte apoptosis and hepatic fibrosis, which are key features of the hepatic disease of AAT deficiency, in HDAd-TFEB injected mice. In summary, we showed that TFEB-mediated hepatocyte expression results in clearance of ATZ, improvement of the liver phenotype and therefore, is an attractive gene-based strategy for the treatment of alpha-1-antitrypsin deficiency hepatic disease.

Neuronal differentiation of induced pluripotent stem cells from Gaucher disease fibroblasts. *J.B. Florer[1], C.N. Mayhew[2,3], Y. Sun[1,3], G.A. Grabowski[1,3].* 1) Division of Human Genetics, Cincinnati Children's Hospital Research Foundation, Cincinnati, OH; 2) Division of Developmental Biology, Cincinnati Children's Hospital research Foundation, Cincinnati, OH; 3) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati OH.

Gaucher disease (GD) is caused by inherited deficiencies of acid β-glucosidase (GCase). Two major GD variants have been delineated: Type 1 is the nonneuropathic, and types 2 and 3 are the acute and subacute neuronopathic variants. Parkinson's disease and synucleinopathies have been linked to GD. To understand the pathogenesis of the neuronopathic involvement in GD and to generate patient specific pluripotent stem cells for potential treatment, induced pluripotent stem cells (iPSC) were derived from fibroblasts of a GD patient carrying mutation L444P/P425R and an unaffected individual. The iPSCs were differentiated to neural cell types using a neural aggregate method. Populations of the induced neural cells expressed nestin and sox2, indicating generation of neural progenitor cells (NPC). The NPCs were grown on polyornithine/laminin coated plates in defined media with bFGF and were maintained for more than 14 passages. The differentiation of neurons from NPCs was carried out by replacing the bFGF with FGF8 and SHH. The derived cells exhibited neuronal morphology with extended neurites and expressed neuron markers Map2 and Tuj1. A subset of cells stained positive for tyrosine hydroxylase indicating generation of dopaminergic neurons. GCase activity was deficient in fibroblasts, iPSCs and NPCs derived from the GD patient. The glucosylceramide species profiles were specific to each cell type in GD and the control. There were increased amounts of glucosylceramide in the GD fibroblasts, and increased glucosylsphingosine in the GD fibroblasts and GD derived NPC and neurons. Similar cell culture systems are being developed using our GD mouse models. The results demonstrated that iPSC-derived NPCs, neurons, and striatal neurons from various GD human and mouse fibroblasts were viable, which indicates the cell non-autonomous nature of neuronal death in the CNS variants of Gaucher disease.

737F

Resveratrol and bezafibrate both dramatically induce transcription of aspartoacylase - a potential new treatment for Canavan Disease? *B.S. Andresen[1], T.K. Doktor[1], J.O. Sass[2,3], J. Bastin[4], F. Djouadi[4], T.J. Corydon[5], E. Christensen[6], A.M. Lund[6], H.S. Andersen[1].* 1) Dept Biochem & Molec Biol, Univ Southern Denmark, Odense M, Denmark; 2) Department of Clinical Chemistry and Biochemistry, Kinderspital Zürich, Zürich, Switzerland; 3) Universitätsklinikum Freiburg, Germany; 4) INSERM U747, Univ Paris Descartes, France; 5) Dept. of Biomedicine, Aarhus University, Aarhus, Denmark; 6) Dept Clin. Genet., Rigshospitalet, Copenhagen, Denmark.

Bezafibrate (BZF) and Resveratrol (RSV) are potent modulators of gene expression, and are currently being tested as drugs for treatment of fatty acid oxidation defects. The rationale being that BZF or RSV may increase expression sufficiently to alleviate disease manifestation in patients who have missense mutations with some residual enzyme activity. We employed Next Generation Sequencing of RNA (RNA-seq) from fibroblasts stimulated with RSV or BZF to shed light on their global effects on gene expression. Interestingly, aspartoacylase (ASPA) is dramatically up-regulated by both treatments. We validated this by QPCR including other cell types. The effect of RSV could be partly antagonized by sirtinol, indicating Sirt-1 involvement. Moreover, RNA-seq and QPCR/PCR validation revealed RSV and BZF mediated induction of transcription factors with binding sites in the ASPA promoter and up-regulation of proteins important for myelin synthesis and function. Aspartoacylase is important for myelin synthesis in the brain and mutations in ASPA cause Canavan Disease (CD). RSV stimulation of fibroblasts from CD patients with different missense mutations showed dramatic increase (5–10x) in ASPA transcription. We are currently exploring the stimulatory effects of RSV and BZF on ASPA expression further in order to elucidate their potential as drugs for treatment of Canavan Disease.

The ingestion of a high protein diet during gestation magnifies the *in vivo* production of metabolites in MMA mice *in utero*. *D. Brown[1, 2], J. Senac[1], J. Sloan[1], I. Manoli[1], C. Venditti[1]*. 1) National Institutes of Health, Bethesda, MD; 2) Washington Hospital Center, Washington, DC.

Objective: To use a mouse model of methylmalonic acidemia (MMA) to show that dietary manipulation during gestation can have an effect on an affected fetus. Introduction: There are several reports of prenatal treatment with vitamin B12 when the fetus has been affected with MMA. However, there have been no studies to examine the effects of maternal diet on the developing fetus. Because both MMA patients and Mut -/- mice display increased methylmalonic acid in utero, we hypothesized that excess of branched chain amino acids during development could stimulate the production of abnormal metabolites and potentially modify the disease phenotype. Materials/Methods: Mut +/− were bred for timed mating studies. Daily plug checks were performed. The mice were assigned to either a regular mouse diet (20% by weight) or a high protein mouse diet (70% by weight). On embryonic day 19, the pregnant females were sacrificed and the feti genotyped. Methylmalonic acid was measured in the amniotic fluid and plasma, and the liver and kidneys were fixed for histochemical studies. Results: On embryonic day 19, Mut -/- pups had methylmalonic acid levels averaged 306 micromolar (N=3) when the mother was fed regular chow whereas the average methylmalonic acid concentration was 468 micromolar (N=2) when the mother ingested a high protein diet. Maternal serum MMA levels were 3.6 and 6.8 micromolar respectively. Conclusions: A trend of higher MMA levels was seen in fetuses exposed to a high protein diet in utero than exposed to a regular diet. With simple dietary manipulation, serum levels of MMA were increased suggesting that maternal diet can accentuate metabolic abnormalities in an affected fetus. These results suggest that prenatal dietary treatment can be important to improving the outcomes of patients with MMA.

Danshen Extract regulates energy metabolism by activating the AMPK-SIRT1-PGC-1α. *Y.H. Cho[1], C.R. Ku[1], H. Lee[1], E.J. Lee[1,2]*. 1) Endocrinology, Brain Korea 21 Project for Medical Science, Institute of Endocrine Research, and Severance Integrative Research Institute for Cerebral & Cardiovascular Disease, Yonsei University College of Medicine, Seoul, South Korea; 2) Endocrinology, Northwestern University Feinberg School of Medicine, Chicago, IL USA.

Danshen, dried root of Salvia miltiorrhiza, is one kind of traditional Chinese medicine that has many effects on metabolic diseases. However, the mechanisms by which Danshen extract (DE) functions as a metabolic regulator remain largely unknown. Here we demonstrate that DE regulates energy homeostasis in brown adipocytes through activation of AMP-activated protein kinase (AMPK) and Sirt 1, resulting in mitochondrial biogenesis function. Furthermore, oral administration of DE to rodents exerts AMPK-Sirt1-PGC-1α levels in hypothalamus and contributes to body weight. AMPK phosphorylation and Sirt1 activation levels were increased by DE treatment in brown adipocytes as well as in hypothalamus, resulting activation of its down stream target, peroxisome proliferator-activated receptor-γcoactivator-1α (PGC-1α). Activation of AMPK and Sirt1by DE in brown adipocytes enhanced mitochondrial biogenesis by induction of key metabolic regulator, PGC-1α. The activation of these key metabolic sensors results in enhancement of uncoupling protein 1(UCP-1), known as thermogenin, accounting for the beneficial metabolic effects of DE. These results indicate that DE regulates energy expenditure through an AMPK-Sirt1-PGC-1α-dependent mechanism in adipocytes and hypothalamus.

Protocols for sick day management and emergency interventions for mitochondrial disorder patients are important for family education, treatment and support. *M. Fredrich, A. Perszyk.* UF, Jacksonville, FL.

Treatment protocols are an important and useful clinical tool for the care of patients with complex medical disorders. Mitochondrial disorders are often unique and individual patient characteristics must be learned by patient and family and by the team of nurses and doctors caring for them. Differentiating signs and symptoms into several steps can help a family manage at home, and know when to call or come in for acute management of the symptoms. We have been building individual protocols for our mitochondrial disorder patients. We find that careful review of systems (ROS) can be helpful at finding patterns and individualize patient treatments. This checklist helps to educate the patient and family about the range of their symptoms and provide a more consistent approach to terminology. We have begun using a checklist and reporting system to help with patient checkup. This helps to review the range of clinical signs and symptoms that are relevant to the particular patient and family. Illustrated in this presentation is our clinical checklist, dietary plan, medications, and patient specific concerns that help the process of learning individual patient characteristics. This greatly facilitates the treatment steps that work for the family at home and in the emergency department and hospital settings.

741F

High Fat Diet Paradoxically Improves Cold Survival in a Mouse Model of Medium-Chain Acyl-coA Dehydrogenase Deficiency. *S.E. McCandless[1], L. Rice[1], C.L. Hoppel[2]*. 1) Department of Genetics, Case Western Reserve University, Cleveland, OH; 2) Center for MItochondrial Diseases, Case Western Reserve University, Cleveland, OH.

Background: The natural history of medium-chain acyl-coA dehydrogenase (MCAD) deficiency has been significantly altered by early diagnosis through newborn screening leading to prompt initiation of therapy. Unfortunately, it is not clear which component of the treatment plan is required for improved outcome. Some clinical centers use a fat reduced diet, which can minimize excretion of metabolites of fatty acid oxidation (FAO), but has not been clearly shown in a clinical or experimental setting to be necessary for improved outcomes. **Objective:** We set out to use the mouse model of mcad deficiency (generated by P. Wood and further refined by us) as a tool to investigate the clinical and biochemical consequences of human MCAD deficiency and to evaluate the effect of a high fat diet on survival during cold challenge at 4° C for 4 hours. **Methods:** The original mouse strain was created on a mixed 129 and C57/B6 background. We have backcrossed from this mixed background >10 generations to produce additional strains with the mcad deficient allele on "pure" B6 (B6 $^{mcad-/-}$) and AJ (AJ $^{mcad-/-}$) backgrounds. Clinical investigations included 4 hour cold challenge (4 hours at 4°C after a 24 hour fast) with the primary outcome measurement of survival (as defined by spontaneous respiration and rectal tempature of >19° C). **Results:** In the 4 hour cold challenge, eating a regular diet, B6 $^{mcad-/-}$ and AJ $^{mcad-/-}$ had much worse survival than wild type littermates (14% vs. 71% and 14% vs. 100%, respectively, n=7 for all groups) and shorter time to death (p<.02) as defined by rectal temperature <19° C. After eating a high fat diet, B6 $^{mcad-/-}$ littermates (n=16 high fat diet) all survived the same cold challenge at 10 weeks post-gestation (p=.0001 compared to regular diet, n=7), regardless of whether the high fat diet began in the mother during gestation or at the time of weaning. Similarly, AJ $^{mcad-/-}$ fed a high fat diet (n=8) had markedly improved survival compared to the regular diet (n=7), with 87.5% vs 14% surviving (p=.02). **Conclusions:** Preliminary studies with two pure background strains of *mcad* deficient mice show evidence of markedly improved tolerance to cold challenge in animals fed a high fat diet compared to those fed normal mouse chow, which is relatively low in fat. Additional studies are underway to explore the possible mechanism for this finding and to identify biomarkers that might be used to look for a similar response in humans.

742T

Sapropterin Treatment for Toddlers with PKU. *N.L. Pallone.* Canadian PKU & Allied Disorders Inc., Toronto, ON, Canada.

Treating PKU Toddlers with sapropterin is still relatively rare, especially in Canada and Europe, and yet this age group can perhaps benefit most from this drug treatment, due to the sensitivity to high or unstable blood-phe levels of the rapidly developing brain. This case report looks at one particular patient (RP) on sapropterin from 20 months to 48 months of age. Information including genotype, phenotype, blood phe levels and stability of levels prior to using sapropterin and during drug treatment is analyzed. This case report will also look at why treatment was initiated when RP was in good metabolic control on dietary treatment alone, and what points should be considered when assessing clinical responsiveness to sapropterin. We will look at what factors can help determine which patients will respond to sapropterin treatment, and why it is important to move forward with this treatment for this young age group of PKU patients. Sapropterin treatment in this patient clearly lowered levels and reduced deviations of levels. An added benefit has been an increased phe tolerance which allows for more natural protein and a better chance of diet adherence once RP becomes a teen and adult. The author will also touch upon the concerns of caregivers in regards to funding criteria of sapropterin specifically as it relates to the risks of normalizing a phe-restricted diet, and how to avoid those risks.

Ubiquinol preparations are numerous and selection of appropriate mitochondrial supplement requires careful scrutiny by family and doctor. *N. Franklin, A. Perszyk.* UF-Jax, Med. Genetics, Jacksonville, FL.

Ubiquinol and Ubiquinone are two related compounds felt to be beneficial when supplemented in the diets of patients with mitochondrial pathway defects. Ubiquinol is widely available in different formulations with a variety of biochemical, and health-related marketing claims. We reviewed over 100 commercially available Ubiquinol products. Product claims, ingredients and manufacturer supplied information were compared with cost per 100mg. Some product formulations appeared more deserving of consideration due to claims of enhanced mitochondrial functioning, patient compliance, and potential measurable health benefits. Selection of ingredients can be especially relevant to certain patients with absorption issues, or dietary fat restrictions. Our findings uncovered significant disparities in the price of the items sold. The price ranged from $0.12 to $3.12 per 100mg. Out of pocket costs for supportive treatments of mitochondrial disorders can be considerable for a family on a budget. The average consumer and physician would benefit greatly from this information to assist them in determining appropriate product selection. We feel that this compilation of data warrants additional investigations into true product efficacy. Well designed physiological studies relating to the duration of action, timing, dosing and frequency of Ubiquinol products for patients with mitochondrial disorders needs further investigation before a more coherent understanding of intra-cellular Ubiquinol benefits can be assessed.

744T

The role of N-acetylcysteine in treating mitochondrial liver disease. *AK. Niemi, GM. Enns.* Dept of Pediatrics, Division of Medical Genetics, Stanford University, Stanford, CA.

Mitochondrial diseases are often multisystem disorders that can present as liver failure or have nonspecific liver dysfunction as part of the phenotype. They are characterized by increased oxidative stress due to respiratory chain dysfunction and production reactive oxygen species (ROS). Treatment includes antioxidants aiming at decreasing the production of ROS or reducing them to a non-reactive form. Glutathione (GSH) is a major cellular antioxidant protecting cells from free radical damage. Acetaminophen overdose is characterized by elevated transaminases and liver synthetic dysfunction. GSH depletion as the cause of acetaminophen-induced liver failure is well established (Heard 2008, Hinson et al. 2010). The standard treatment is N-acetylcysteine (NAC), which prevents liver injury by restoring hepatic GSH. We describe two patients with a mitochondrial disorder with elevated transaminases and liver dysfunction that improved after treatment with NAC. Patient 1 is a 5-yo girl with mitochondrial DNA deletion syndrome characterized by failure to thrive, bone marrow failure, short stature, exocrine pancreatic insufficiency and panhypopituitarism. At age 5y she was hospitalized due to urinary tract infection and was noted to have elevated AST 500 u/L, ALT 400 u/L and INR 1.4. Extensive viral studies were negative. A week after admission oral NAC was started (150mg/kg/d). Within 24h AST, ALT and INR started improving and normalized in a week. Patient 2 is a 4-yo girl who initially presented with neonatal lactic acidosis, hyperammonemia and elevated transaminases and has had frequent hospitalizations with similar findings. Urine organic acids show abnormal elevations of lactate, fumarate, and malate. An extensive workup has not revealed a diagnosis. She has remained on a mitochondrial antioxidant cocktail because her condition worsens upon weaning these cofactors. At age 3y she had fever, cough and a nasopharyngeal swab positive for influenza A. Transaminases were higher than during other hospitalizations (AST~2,000 u/L, ALT~1,600 u/L), INR was 2.6. NAC was started and within 3 days AST, ALT and INR normalized. Both patients have remained on NAC. Mitochondrial patients have low GSH levels compared to controls (Atkuri et al. 2009) and thus their tissues, including liver, may be more sensitive to any cellular stress that depletes GSH. Therefore, NAC may be a therapeutic intervention worth considering in patients with mitochondrial dysfunction and liver disease.

Phase 3 Study of Migalastat HCl for Fabry Disease: Stage 1 Results. *K. Nicholls[1], C. Feliciani[2], S. Shankar[3], F. Ezgu[4], S.G. Janmohamed[5], S.M. Laing[5], R. Schroyer[6], A.C. Bragat[7], S. Sitaraman[7], V. Sniukiene[7], R.E. Winkler[7], P. Boudes[7].* 1) Royal Melbourne Hospital, Parkville Au, Victoria, Australia; 2) Policlinico Universitario Agostino Gemelli, Roma, Italy; 3) Emory University, Atlanta, GA, USA; 4) Gazi University, Ankara, Turkey; 5) GlaxoSmithKline, Stockley Park, UK; 6) GlaxoSmithKline,Renaissance, PA, USA; 7) Amicus Therapeutics, 1 Cedarbrook Drive, Cranbury, NJ 08512.

Background: Fabry Disease (FD) is a rare X-linked deficiency in the lysosomal enzyme α galactosidase A (α-Gal A). While FD is typically more severe in homozygous males, heterozygous females are also often symptomatic. If untreated, many patients will develop serious end organ complications of kidney failure, cardiac arrhythmias, and/or stroke. There is an unmet need for oral therapies for FD, for which the only currently available treatments are intravenous Enzyme Replacement Therapies (ERT). Migalastat HCl (AT1001/GR181413A) is an investigational pharmacological chaperone that binds to the active site of α-Gal A and increases enzyme stability and trafficking to the lysosome, where it can metabolize its predominant substrate (globotriaosylceramide, GL-3). The relatively slow progression of FD would require prolonged studies to evaluate the effect of therapy on clinical outcomes. Reduction of GL-3 deposition in kidney has previously been used as an indicator of a clinically meaningful impact of therapy on the pathophysiology of FD. Methods: Stage 1 of Study AT1001–011/NCT 00925301 is a 6-month, double-blind, randomized, placebo controlled evaluation of the efficacy and safety of oral migalastat HCl in male and female patients who were treatment-naive or off ERT for at least the preceding 6 months. The study population was enriched by requiring that patients had urine GL-3 levels at least 4 times above upper limit of normal and also had a mutation predicted to be amenable to migalastat HCl, as determined by an in vitro cell-based assay. Patients were stratified by gender and randomized 1:1 to receive either placebo or migalastat HCl 150 mg every other day. The primary objective after 6 months of treatment was to evaluate the effect of migalastat HCl on clearance of kidney GL-3, as assessed by quantitative histological scoring of GL-3 inclusions in peritubular capillary cells (PTCs). Patients were considered responders when they had at least a 50% reduction from baseline to Month 6 in the average number of GL-3 inclusions per PTC. A key secondary endpoint was the effect of migalastat HCl on the percent change from baseline to Month 6 in urine GL-3. Results: Enrollment for this study has been completed (67 patients randomized). Efficacy and safety results after 6 months of double-blind treatment will be summarized.

746T

Differential risk for Parkinson disease in males and females with Gaucher disease. *D. Elstein[1], R. Alcalay[2], T. Dinur[1], G. Altarescu[1], E. Ben-Chetrit[1], A. Zimran[1].* 1) Gaucher Clinic, Shaare Zedek Medical Ctr, Jerusalem, Israel; 2) Department of Neurology, Columbia University Medical Center, New-York, NY, USA.

Background: Male gender is a risk factor in idiopathic Parkinson's Disease (PD), but not in many forms of genetic PD (e.g., LRRK2, PARKIN). Whether gender plays a role in PD risk among Gaucher disease (GD) patients is unknown. Objective: To examine the role of gender in PD penetrance among Type-1 GD patients. Methods: Medical files of patients >18 years of age between 1990–2010 were reviewed for PD signs or clinical diagnosis by a neurologist. Available patients with suspected parkinsonism underwent an additional neurological examination by a movement disorders specialist. Kaplan Meier survival curves were used to estimate age-specific risk for PD among males and females. Age-specific risk for PD was compared between males and females using Cox Hazard ratio model. Results: 510 type 1 GD adults (233 males; 45.7%) had records reviewed. 12 patients with suspected parkinsonism were identified; 11 were confirmed by a movement disorder specialist, using UK PD Brain Bank Criteria for PD (2.2%). PD diagnosis was associated with male gender (81.8% versus 44.9% male, p= 0.027) and older age (mean age, GD/PD=62.8, GD non-PD=47.1, p=0.004). Age-specific risk for PD was higher in males compared to females (p=0.039, Cox Hazard ratio model). At age 65 the cumulative risk for PD among GD among males 7.7% and among females was 1.5%. Conclusion: As opposed to other genetic forms of PD, male gender is a significant risk factor for PD among GD patients.

Potential cluster of MPS IV A in Northeast Brazil. *F. Kubaski[1,2], A.C. Brusius-Facchin[1,2], P.F.V. Medeiros[3], C.S.E. Gondim[3], R. Giugliani[1,2,4], S. Leistner-Segal[1,2].* 1) Medical Genetics Service, Hospital de Clinicas de Porto Alegre, Porto Alegre, RS, Brazil; 2) Postgraduate Program in Clinical Sciences, UFRGS, Porto Alegre, RS, Brazil; 3) Federal University of Campina Grande, Hospital Alcides Carneiro, Campina Grande, PB, Brazil; 4) Department of Genetics, UFRGS, Porto Alegre, RS, Brazil.

Mucopolysaccharidosis IV A (MPS IV A) or Morquio syndrome type A is an autosomal recessive inborn error of metabolism caused by deficiency of lysosomal enzyme N-acetylgalactosamine-6-sulfate sulfatase (GALNS), which results in storage of keratan sulfate and chondroitin-6-sulfate. MPS IV A is a rare disorder, and precise epidemiologic data in Latin America and Brazil are scarce. Surprisingly, in a specific region of Northeast Brazil, in the state of Paraíba (PB), 7 index cases were diagnosed with MPS IV A. Objectives: Our aim was to characterize the genotype of these patients, through GALNS gene analysis. Methods: We have developed a protocol to identify GALNS common mutations by ARMS-PCR. Five common mutations found in previous studies performed in Brazilian patients (p.S341R, p.L307P, p.N164T, p.G139S, p.G116S) were analyzed for patients included in the MPS BRAZIL NETWORK protocol. Results: These 5 mutations were found in 10 out of 26 MPS IV A patients previously diagnosed by enzyme assay, including 4 patients from PB. The p.S341R mutation was found in homozygosis in 2 patients and in heterozygosis in one patient. One patient was negative for the presence of this mutation. For further 3 patients from this region we tested only for the presence of the p.S341R mutation and the results were 1 homozygous, 1 heterozygous and 1 negative. Thus, for a total of 7 patients from PB we have an allele frequency of 50% for this specific mutation. Conclusions: These 5 mutations can be considered common in Brazilian patients once they were found in 38 % of our cases. This number justifies a strategy based on initial screening for these 5 recurrent mutations in our population. The identification of heterozygous individuals within these families will be important for genetic counseling and for estimating the disease prevalence in this region. Further studies to identify the origin of this mutation, including haplotype and segregation analyses are in progress, and will be evaluated in conjunction with epidemiological data. The presence of a specific mutation for MPS in a cluster was already observed in MPS VI in another area of Northeast Brazil. In this area, a comprehensive population medical genetics approach was implemented to prevent and treat early MPS VI, including training of health agents, education to the community, genetic counseling and targeted newborn screening. A similar approach is under consideration for MPS IV A in this potencial cluster.

748T

Persistent Thrombocytopenia in Type I Gaucher Disease : evaluation and management. *H. Rosenbaum.* HEMATOLOGY, RAMBAM MEDICAL CAMPUS, HAIFA, Israel.

Backgound: Type I Gaucher disease (GD) the non-neuronopathic form is characterized by hepatosplenomegaly, pancytopenia and skeletal complications due to the accumulation of glucocerebroside in macrophages. Thrombocytopenia is usually related to hypersplenism and/or infiltration of bone marrow by the lipid-laden macrophages namely Gaucher cells. Enzyme replacement therapy (ERT) restores the hemoglobin and platelet count in treated GD patients within 12–24 months of treatment. In GD patients, including ERT treated, with persistent low platelet counts other etiological factors should be considered including immune thrombocytopenia(ITP),and concomitant hematological malignancies or metastatic bone marrow by other neoplastic disease. Goals: delineate guidelines and alogarithm for the evaluation of persistent thrombocytopenia and bleeding phenomena in GD. Focus on the approach to treatment especially new modalities including immunomodulation by steroids (high dose Dexamethason) IVIG and Rituximab. Discuss dosage of ERT and switch to other ERT in persistent thrombocytopenia. Emphasize whether steroid therapy is feasible in GD. Debate on the role of thrombopoeitin receptor analogue and splenectomy in patients with ITP and GD. Report successful procedure of splenic artery embolisation which might replace splenectomy in GD pthrombocytopenic patients.This ambulatory therapy might be useful in cases of urgent need to raise platelet counts prior to surgery. Methods: report and discuss cases of GD and thrombocytopenia and summarize the evaluation measures and new therapy strategies.

749F

Chemotactic factors critical for increased immunological cell invasion in Gaucher disease mice. *M.K. Pandey[1, 2], N.A. Jabre[1], G.A. Grabowski[1,2].* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH 45229, USA; 2) Department of Pediatrics, University of Cincinnati, College of Medicine, Cincinnati, Ohio 45229, USA.

Gaucher disease results from mutations in *GBA1* that cause functional disruption of the encoded lysosomal enzyme, acid β-glucosidase (β-D-glucosyl-N-acylsphingosine glucohydrolase, EC 4.2.1.25; GCase). The consequent excess accumulation of glucosylceramide (GC) and glucosylsphingosine (GS) in lysosomes is central to the disease pathogenesis with classical involvement of macrophage (MΦ) lineage cells of visceral organs, bone, or brain. Several studies have implicated the increased secretion of chemokines and increased infiltration of variety of immunological cells, e.g., T lymphocytes, B lymphocytes, MΦs, dendritic cells (DCs), and neutrophils (PMNs) in Gaucher disease. Trafficking of immunological cells to the sites of inflammation requires the presence of chemokines. Although increases of different immunological cells and several chemokines are known in Gaucher disease, the mechanisms and specific molecules involved in causing the increased influx of immunological cells in this disease is unclear. Increased levels of I-309, MCP-5, CXCL2, CXCL-9, CXCL-10, CXCL-11, CXCL-13, and their corresponding leukocytes i.e., MOs (monocytes), MΦs, DCs, PMNs, T, and B cells have been identified in the circulation of 9V/null Gaucher disease mice. 9V/null sera was shown to attract different immunological cells was shown by in vitro chemotaxis in Boyden chambers and by flow cytometery. Enhanced chemotaxis of 9V/null lung, spleen, liver, and bone marrow derived immunological cells, i.e., MΦs ($CD11b^+$ $F480^+$), PMNs ($Gr1^{high}$ $CD11b^+$), DCs ($CD11c^+$ $CD11b^+$), T lymphocytes ($CD3^+$ $TCR\beta^+$), and B lymphocytes ($B220^+$ $CD19^+$) into 9V/null sera supports above chemotactic factors as responsible for increased infiltration of leukocytes in Gaucher disease.

Systematic Screening for treatable inborn errors of metabolism in intellectual disability patients: First Study Results. *S. Stockler[1], R. Salvarinova[1], G. Horvath[1], Y. Lillquist[1], H. Vallance[2], S. Sinclair[2], M. Lafek[1], T. Murphy[2], A. Lehman[4], M. Patel[4], M. Demos[3], M. Connolly[3], C. van Karnebeek[1], TIDE-BC, Treatable Intellectual Disability Endeavor in British Columbia, Vancouver, Canada.* 1) Biochemical Diseases, Dept Pediatrics, BC Children's Hosp, Vancouver, BC, Canada; 2) Biochemical Genetics Laboratory, BC Children's ospital, Vancouver, BC, Canada; 3) Pediatric Neurology, BC Children's Hospital, Vancouver, BC, Canada; 4) Medical Genetics, BC Children's & Women's Hospital, Vancouver, BC, Canada.

Background: Current recommendations to investigate genetic causes of intellectual disability (ID) are based on frequencies of single conditions and yield of tests rather than availability of causal therapy. Early recognition of treatable inborn errors of metabolism (IEM) is crucial for minimizing brain damage and reducing of health-care costs. **Methods & Results:** Our literature review identified 81 IEM, presenting predominantly with ID and amenable to causal therapy. Although evidence is limited, therapies are often effective, safe, accessible. We translated this knowledge into a diagnostic protocol: The 1st tier comprises metabolic screening tests in blood (plasma amino-acids, homocysteine) and urine (creatine metabolites, glycosaminoglycans, oligosaccharides, organic acids, purines/pyrimidines), with potential to identify 62% of treatable IDs. The second tier focuses on remaining disorders, requiring `single test per disease' approach. A freely available App (www.treatable-id.org) supports the protocol. During first 6 months 130 patients were enrolled in a funded study implementing the protocol;a confirmed diagnosis was established in 25% (5 treatable IEM), probable in 17% (4 treatable IEM). We will present the indvidual diagnoses (treatable IEMS) in more detail. **Conclusions:** Our preliminary results indicate that treatable IEM constitute etiology in 4–7% of all ID patients evaluated in tertiary care centres, and account for a considerable proprotion of all diagnoses 16%). Our novel approach may well improve outcomes and convince colleagues/ policymakers to change practice and care for individuals with ID.

A novel homozygous mutation in EARS2 causing a fatal multisystem infantile disease. *A. Pyle[1], B. Talim[2], H. Griffin[1], H. Topaloglu[2], M. Santibanez-Koref[1], P.F. Chinnery[1], R. Horvath[1]*. 1) Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, United Kingdom; 2) Department of Pediatrics, Hacettepe University, Ankara, Turkey.

Mitochondrial disorders are clinical phenotypes, usually a result of mitochondrial dysfunction, caused by mutations in either mitochondrial DNA (mtDNA) or nuclear-encoded (nDNA) mitochondrial genes. The majority of these gene defects manifest as histological and biochemical abnormalities in affected tissues. Clinical phenotypes are typically early-onset, severe and often fatal, implying the importance of efficient mitochondrial translation from birth. mtDNA-related disorders are well defined and the analysis of mtDNA is standardized. More recently, research focus has shifted to nuclear genes and a number of new mutations have been identified in genes involved in mitochondrial protein synthesis. The resulting multiple-respiratory complex disorders are heterogeneous and poorly defined at the molecular level. We present a patient, the third child of consanguineous Turkish parents with severe infantile multisystem disease, involving the brain and liver. The proband died at 3 months of age of necrotising bronchopneumonia. Biochemical and histochemical analysis of skeletal muscle identified a severe, combined, deficiency of respiratory chain complexes I and IV. Subsequent mtDNA analysis excluded mtDNA depletion, deletions or point mutations in affected tissue. Common nDNA causes of mitochondrial dysfunction, including nuclear encoded mitochondrial elongation factors or ribosomal factors were also excluded. Through a combination of homozygosity mapping and whole exome sequencing we identified a homozygous missense mutation in mitochondrial glutamyl-tRNA synthetase (EARS2). Pathogenicity was confirmed by familial segregation and exclusion in ethnically matched controls. Nuclear-mitochondrial disorders are characterised by disturbed mitochondrial translation and EARS2 is the newest member of this gene family. We have shown that in addition to central nervous system involvement, some patients develop a progressive and fatal course in infancy and therefore our case widens the clinical spectrum of EARS2 mutations.

752T

Novel phenotype associated with *OPA* mutations? *M. Tesarova[1], V. Stranecky[2], H. Kratochvilova[1], Z. Hajkova[1], J. Sladkova[1], J. Spacilova[1], H. Hansikova[1], T. Honzik[1], H. Hartmannova[2], L. Noskova[2], L. Piherova[2], E. Lalonde[3], J. Majewski[3], S. Kmoch[2], J. Zeman[1]*. 1) Department of Pediatrics and Adolescent Medicine, Charles Univesrity in Prague and General University Hospital in Prague, Prague 2, Czech Republic; 2) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Prague, Czech Republic; 3) Department of Human Genetics, McGill University Health Centre, Montreal, Quebec, Canada.

Mutations in *OPA1* gene, encoding a dynamin-like mitochondrial GTPase indispensable for mitochondrial network structure and morphology, were found to be responsible for autosomal dominant optic atrophy (ADOA). Moreover *OPA1* mutations may be responsible for a continuum of phenotypes ranging from mild disorders affecting only the optic nerve to severe and multi-systemic diseases. In Caucasian non-consanguineous family, 3 boys were born with lactic acidosis, a severe muscle hypotonia, breathing and breastfeeding difficulties. Patient 1 (P1) died on day 9 with early metabolic lactate acidosis. In his younger brothers (P2, P3), central hypotonic syndrome was present (2nd month of life). Severe vision and hearing impairment developed at 4 months followed by hypertrophic cardiomyopathy. Brain atrophy was found by MRI in P2 at 4 month of age. In P3, brain atrophy and Leigh syndrome were observed at autopsy. P2 died at the age of 10 months, P3 died at the age of 12,5 months. Metabolic examination revealed lactic acidosis with increased excretion of Krebs cycle intermediates and 3-methylglutaconic acid (only P3). In isolated muscle mitochondria of P2 and P3, mild decrease in activity of complex II+III, complex IV and PDHc were observed. Mutation in mtDNA and *TMEM70, TAZ, SCO2, SCO1* were excluded by direct sequencing in P3. Genome-wide copy number analysis was unremarkable. Subsequently, whole-exome sequencing in P2 and P3 revealed heterozygous mutations: c.1062_1064delAGA (p.E354del, novel mutation) inherited form father and c.1768C>T (p.R590W) inherited from mother in *OPA1* as the most probable candidates. Steady-state levels of OPA1 isoforms were significantly decreased in muscle, heart and frontal core of patient 3 with profound reduction of short isoforms. In cultured skin fibroblasts of P2, P3, and their parents, OPA1 isoform levels were decreased in both patients' and father's sample. More pronounced reduction of short OPA1 isoforms (S3, S4, S5) was observed in patients compared to parents. Moreover, mitochondrial network was more fragmented in patients' fibroblasts compare to parental samples. Nevertheless, RCC activities were in reference range. To conclude, whole-exome sequencing revealed possibly pathogenic mutations in *OPA1* gene. Despite ongoing analyses to confirm *OPA1* mutation as cause of the disease, symptoms described in our patients may enlarge phenotypic variability associated with OPA1. *Supported by RVO-VFN64165/2012 and IGA NT 13114-4/2012.*

Evaluating pain, negative mood, and resilience in patients affected by Fabry disease. *A. M. Lelis[1], R. Duran[1], L. Beckman[1], J. Garbanati[1], W. Wilcox[2], J. Mirocha[2]*. 1) Alliant International University, 1000 S. Fremont, Alhambra, CA; 2) Cedars-Sinai Medical Center, 8700 Beverly Blvd, Los Angeles, CA 90048.

The purpose of the current study was to evaluate pain, negative mood, and resilience in individuals diagnosed with Fabry disease. Fabry disease (FD) is a rare, hereditary condition in which psychosocial correlates of pain experience have been severely understudied. A total of 75 men and women with FD were recruited from Cedars-Sinai Fabry Center in Los Angeles, California. This study utilized a variety of instruments, including: a demographic questionnaire, Brief Pain Inventory, Resilience Scale, Beck Depression Inventory-II, and Beck Anxiety Inventory. The results indicate that pain intensity is positively correlated with depression and anxiety, while pain intensity is negatively correlated with resilience. The results also show that pain frequency acts as a moderator between resilience and depression. While there were no statistically significant differences between men and women with FD, there were clinically important differences in the depression scale between the sexes. The clinical implications of this study are discussed. Specifically, resilience appears to be a key factor in successful adaptation to FD. Clinicians should focus their attention on resilience skills and training rather than solely trying to assess and medicate depression, anxiety, and pain. Future studies in the FD population are needed to investigate the effect of resilience training on the ability to manage stress and decrease experience of pain, depression, and anxiety.

Comparison of the differentiation potential of human mesenchymal stem cells and several animal species. *F. Piryaei[1], M. Ramezani[2], M. Kadivar[3], F. Piryaei[4]*. 1) Dept. of Biology, Faculty of Science, Payame Noor University, Center of Tehran,, Tehran, Iran; 2) Dept. of Biology, Faculty of Science, Islamic Azad University, Ashtian Branch, Ashtian, Iran; 3) Dept. of Biochemistry, Pasteur Institute of Iran, Tehran, Iran; 4) Dept. of Medical Genetics, National Institute of Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran.

Considering the increasing use of mesenchymal stem cells isolated from various sources in the clinic, the basic studies needed to evaluate proliferation, differentiation and other biological characteristics of them done. In the present study, efficiency and power differentiation in five different categories mesenchymal stem cells are compared with each other. Bone marrow mesenchymal stem cells from rabbits, rats, C57 mice, chicken and mesenchymal stem cells derived from human knee synovium tissue were cultured with a density of 5000 cells/cm2 in 12-chamber dishes. After the cells reached the appropriate level of growth, specific differentiation inducers were added. 21 days later, differentiation of all stem cells to adipocyte, osteocyte and chondrocyte were evaluated and compared using specific staining methods. Our results indicated that all five mesenchymal stem cells were able to differentiate into osteocyte, adipocyte and chondrocyte. Moreover, the highest potentials for differentiation to adipocyte and osteocyte and chondrocyte were seen in mesenchymal stem cells derived from chicken bone marrow and human synovium, respectively. In this study, differences in the differentiation potential of mesenchymal stem cells isolated from different tissues and species were observed that could be caused by small differences in their environment in vivo. Understanding these differences can lead to more effective use of these cells in the clinic.

Bone marrow derived cells as a stable source of sialic acid for mice with GNE myopathy. *MC. Malicdan[1,3], K. Momma[2], F. Funato[3], YK. Hayashi[3], I. Nonaka[1], M. Huizing[1], W. Gahl[1,4], CF. Boerkoel[1], I. Nishino[3], S. Noguchi[3]*. 1) MGB, NHGRI, National Institutes of Health, Bethesda, MD, USA; 2) Department of Neuromuscular Research, Natiional Institute of Neuroscience, NCNP, Tokyo, Japan; 3) Department of Neurology, National Defense Medical College, Saitama, Japan; 4) Office of the Clinical Director, NHGRI, NIH, Bethesda, MD, USA.

GNE myopathy, previously known as distal myopathy with rimmed vacuoles (DMRV), or hereditary inclusion body myopathy (hIBM), is an autosomal recessive myopathy characterized by progressive weakness and atrophy involving the distal muscles, and myofiber vacuolation and degeneration. GNE myopathy is secondary to mutations in the GNE gene, which encodes the bifunctional enzyme which catalyzes the first two crucial steps in sialic acid biosynthesis. We and others have shown that hyposialylation is one of the key players in disease pathomechanism. This notion is supported by our recent publications showing that the myopathic phenotype in the existing DMRV/hIBM mouse was prevented by giving exogenous oral sialic acid metabolites or modified ManNAc conjugates. Despite these promising results, designing an oral therapeutic regimen is often challenged by the the extremely rapid excretion of orally administered sialic acids that potentially requires frequent or almost continuous dosing. In this study, we established allogenic bone marrow transplantation (BMT) as a choice for therapy.Bone marrow cells were isolated from CAG-GFP expressing mice and injected intravenously to 30 weeks old DMRV mice after a single dose of sublethal irradiation. Chimerism and cell surface sialylation of peripheral leukocytes after RBC lysis was assessed four weeks after cell transplantation and monthly thereafter. Results show that there was a clear increment in cell surface sialylation and correlated with chimerism. GFP-positive donor cells were seen to engraft into skeletal muscles and other organs of DMRV/hIBM mice. DMRV/hIBM mice subjected to BMT had a marked improvement in lifespan and motor performance. Analysis of muscle contractile properties and pathology revealed an improvement in muscle phenotype. Evaluation of specific glycoproteins in the muscle demonstrated a recovery of cellular sialylation. GNE activity and sialic acid levels in several organs revealed a remarkable increase as compared to non-treated mutant mice. Our results provide a proof of concept for the utility of cell based therapies in DMRV/hIBM, and that hematopoetic cells can be a good source of sialic acid production. We envision that with this strategy, GNE myopathy patients can have a lasting supply of sialic acid that may benefit them towards disease recovery.

Lysine Restricted Diet as Novel Therapy for Pyridoxine Dependent Epilepsy: First Observational Study. *C. van Karnebeek[1,5], H. Hartmann[2], S. Jaggawantru[3,5], J.P. Collet[3,5], B. Plecko[4], S. Stockler[1,5], Pyridoxine Dependent Epilepsy Consortium.* 1) Biochemical Diseases, BC Children's Hospital, University of British Columbia, Vancouver CA; 2) Clinic for Liver, Kidney & Metabolic Diseases, Hannover Medical School, Hannover, DE; 3) Dept of Pediatrics, BC Children's Hospital, University of British Columbia, Vancouver CA; 4) Neurology Dept, Zurich University Hospital, Zurich, CH; 5) TIDE-BC (Treatable Intellectual Disabiliy Endeavour in British Columbia), BC Children's Hospital, Vancouver CA.

Background: Pyridoxine Dependent Epilepsy classically presents as a neonatal onset epileptic encephalopathy. This cerebral organic aciduria is caused by deficiency of antiquitin (ATQ) (alpha-aminoadipic semialdehyde dehydrogenase, ALDH7A1), an enzyme facilitating lysine catabolism. Despite adequate seizure control with pyridoxine in most cases, neurodevelopmental outcome is poor with 75% of patients suffering developmental / cognitive deficits. **Objective:** To evaluate effects of dietary lysine restriction as add-on therapy on biochemical parameters, seizure control and neurodevelopmental outcomes in patients with molecularly confirmed ATQ deficiency. **Methods:** An observational was performed; 5 patients with confirmed ATQ deficiency were started at age 11mos-11yrs on lysine restriction 50–60mg/kg/day and regular monitoring and outcome assessments during a 12–24mos period. **Results:** The diet was well tolerated; good compliance, no reports of adverse-events. Observed reduction of plasma pipecolic acid on diet was 44–81percent; of pre-treatment level; for urine AASA 57–87percent. (Subjective) Improvements of neurodevelopment, behavior and seizure control are reported. **Conclusions**: Our observational study suggests a positive effect of lysine restriction on relevant outcomes in ATQ deficiency (evidence level 4). The PDE consortium (www.pde-online.org)has initiated further research using novel trial methodologies to generate natural history data and more solid therapeutic evidence, before burdensome dietary therapy becomes mainstay treatment.

757W

High-fat diet rescues lethality of homozygous knock-in R155H mice with VCP-Associated Disease. *K.J. Llewellyn, A. Nalbandian, C. Nguyen, V.E. Kimonis.* Department of Pediatrics, Division of Genetics and Metabolism, 2501 Hewitt Hall, University of California-Irvine, Irvine, CA 92697, USA.

Hereditary inclusion body myopathy, Paget's disease of bone and frontotemporal dementia (IBMPFD), is a rare, progressive and fatal disease caused by mutations in the VCP gene. The most common feature of this disease is the myopathy (IBM), which is present in 90% of individuals with an onset of 30–40 years of age. The progressive muscle weakness can often progress to respiratory failure or cardiomyopathy and cardiac failure that can result in death at 40–60 years of age. The Paget's disease of bone (PDB) aspect is observed in 50% of individuals with an onset in their 30–40s. Frontotemporal dementia (FTD) is observed in 30% of patients with a later onset of 50–60 years of age. ALS is seen in 10% of patients and recently VCP was shown to be the cause of 2% of isolated familial ALS. Studies of patients' myoblasts and the heterozygous knock-in mouse carrying the common VCP R155H/+ mutation, developed in our lab, have placed VCP at the intersection of the ubiquitin-proteasome signaling and autophagy pathways, both mechanisms being considered responsible for the intracellular protein degradation and abnormal pathology seen in muscle and brain. We have recently created a double dominant homozygote mouse (VCPR155H/R155H) that has a more rapid and severe muscle, brain and spinal cord pathology, with most surviving no more than 21 days. Feeding pregnant heterozygous dams a diet with 2.6% increased fat, high in polyunsaturated fatty acids, especially linoleic acid (18:2) and oleic acid (18:1) however results in a dramatic improvement in the survival of their homozygous offspring, who on average can now live up to 10 months. These mice still weigh less than their wild-type litter mates and are significantly weaker as demonstrated by grip strength analysis however, Preliminary histological studies have shown improvement in the muscle pathogenesis in these homozygotes at 3 weeks compared to homozygote's on a normal diet as observed by IHC, western blot and CT-scans. Our hypothesis is that linoleic acid in the fat diet is critical for the embryological neurodevelopment of the mouse. We are currently investigating the optimum diet that completely rescues the lethal phenotype. This discovery provides the opportunity to develop a promising therapeutic strategy for patients with VCP and related diseases.

Serin diet relieves symptoms of Hereditary Sensory and Autonomous Neuropathy type 1A caused by a c.992 C>T, p.(Ser331Phe), mutation in SPTLC1. *B. Rautenstrauss[1,2], E. Wilichowski[3], E. Holinski-Feder[1], T. Hornemann[4]*. 1) Medizinisch Genetisches Zentrum, Munich, Germany; 2) Ludwig-Maximilians-Unverisity, Friedrich-Baur-Institute, Munich, Germany; 3) Georg-August-University, Goettingen, Germany; 4) University Zurich, Zurich, Switzerland.

Hereditary sensory and autonomic neuropathies (HSAN) are a genetically and clinically heterogeneous group of disorders associated with sensory dysfunction. HSAN1 is a dominantly inherited sensorimotor axonal neuropathy. The patient has 3 healthy siblings and healthy parents. Symptoms: Coinciding with the start of ambulation motor disabilities; generalized hypotrophy; reduced walking distance; unstable gait; multiple falls; no mental retardation; MRI studies of the brain were normal; reduced pain sensitivity: recurrent traumatic and thermal injuries of feet, knees and hands; disturbed wound healing; ulcerated fingertips; unnoticed fracture of a metatarsal bone; at the age of 9 years: bilateral lensectomy due to juvenile cataract; cataract surgery: repetitive ulcerations of the cornea, poor healing tendency; complete retinal detachment (right eye); nerve biopsy: marked wasting of myelinated fibres, axonal damage; axonal motor and sensory neuropathy. Finally a de novo c.992 C>T, p.(Ser331Phe), mutation in the SPTLC1 gene was identified. This mutation turns the sphingolipid synthesis to neurotoxic lipids in this patient as well as in cell cultures. A serin diet (400mg/kg bodyweight) developed in an animal model (SPTLC1 mutation p. (Cys133Trp)) resulted after 3 months in an overall improvement: ameliorated growth of nails and hair; wounds of the skin show faster healing; gain of weight; coughassist could be reduced to only one treatment during the winter period; sweating is reconstituted; ability to an extended period of upright standing. This HSAN patient is an excellent example for effective translational medicine and the first individual in Germany receiving a causal treatment for a Hereditary Sensory and Autonomous Neuropathy.

759W

Pilot trial of high-dose carnitine supplementation in young, non-dysmorphic males with autism spectrum disorders (ASDs). *R. Goin-Kochel[1], F. Scaglia[2], C. Schaaf[2], D. Dang[2], A. Laakman[1], K. Nowell[3], A. Beaudet[2]*. 1) Pediatrics, Baylor Col Medicine, Houston, TX; 2) Molecular & Human Genetics, Baylor Col Medicine, Houston, TX; 3) Educational Psychology, Univ of Houston, Houston, TX.

Mutations in the trimethyllysine hydroxylase epsilon (*TMLHE*) gene cause an inborn error of carnitine metabolism that may be relevant in ASDs (Celestino-Soper, et al., 2012). This discovery led us to hypothesize that neuronal carnitine deficiency associated with low dietary intake, impaired transport, or defective synthesis of carnitine is a risk factor for ASDs, especially in non-dysmorphic males, and that carnitine supplementation may prevent or reverse symptoms of ASDs in this subgroup. We are conducting an open-label pilot trial of the behavioral effects of high-dose carnitine supplementation in such boys. Five males with ASDs (μ age = 6.1y, *SD* = 1.4) were recruited through the Simons Simplex Collection and Autism Treatment Network at Baylor College of Medicine. One child had a *TMLHE* deletion, and all had confirmed ASDs per scores on the *Autism Diagnostic Interview—Revised* (ADI-R) and the *Autism Diagnostic Observation Schedule* (ADOS). Levels of free carnitine in plasma were in the normal range pre-treatment, except for a slightly low level of 23.4 μM in one boy with a history of low plasma carnitine; levels of plasma carnitine rose in all patients on therapy by an average of 50%. Parent-reported behavioral data were gathered on children at 3 time points during an 8-week supplementation period; study clinicians also performed pre- and post-treatment behavioral assessments. Participants began oral supplementation with carnitine at 200mg/kg divided in 3 daily doses. If well tolerated after 1 week, the dose was increased to 400mg/kg per day up to a maximum daily dose of 6g per day. Dosage was reduced in cases where side effects (e.g., fishy odor, diarrhea) became difficult for the family to tolerate. Results indicated average improvements on: the *Aberrant Behavior Checklist* (39%), *Autism Impact Measure—Frequency Scale 1* (20%) and *Frequency Scale 2* (26%), and the *Social Communication Questionnaire—Current* (28%). For the 4 participants with complete post-test data, clinicians observed (a) few-to-no improvements on the ADOS and (b) mild improvements on the *Global Clinical Impression* scale. Evidence for benefit was greatest in the 7 yo with *TMLHE* deficiency and the 4 yo with a history of low plasma carnitine. These data suggest that some children with ASDs may show mild to modest behavioral improvements with carnitine supplementation. However, a larger, double-blinded, placebo-controlled study is necessary to eliminate possible response biases.

RESULTS OF THE PHASE II MULTICENTER, SINGLE ARM, PHASE II CONTROLLED TRIAL `IEDAT-01'. *L. Chessa[1], V. Leuzzi[2], A. Plebani[3], R. Micheli[3], A.R. Soresina[3], I. Quinti[2], D. D'Agnano[3], C. Bozzao[1], P. Lulli[1], M. Magnani[4]*. 1) U.O.D. Medical Genetics, Hosp S Andrea, Via di Grottarossa 1035, I-00166 Roma, Italy; 2) Department of Child Neurology and Psychiatry, Sapienza University, Via dei Sabelli, Roma, Italy; 3) Department of Pediatrics, University of Brescia, Brescia, Italy; 4) Department of Biomolecular Sciences, University of Urbino "Carlo Bo", Via Saffi 2, I-61029 Urbino (PU), Italy.

A six months multicenter single arm phase II controlled trial entitled IEDAT-01 (Evaluation of Effects of Intra-Erythrocyte Dexamethasone Sodium Phosphate on Neurological Symptoms in Ataxia-Teleangiectasia Patients) has been recently performed in Italy. Primary objective of the trial was to evaluate the improvement in central nervous system symptoms measured by International Co-operative Ataxia Rating Scale (ICARS) in patients with Ataxia Teleangiectasia (AT) during a 6 months period of ERY-DEX treatment (dexamethasone sodium phosphate ex vivo encapsulated into human autologous erythrocytes). The ICARS parameters: posture, kinetics, speech and oculomotion were evaluated at time points 1 (enrollment), 4 (after three months of ERY-DEX treatment) and 7 (at the end of ERY-DEX therapy). Secondary objectives were to evaluate the effect of ERY-DEX on: 1) treatment-Emergent Adverse Events, 2) the global health status of the patient, 3) adaptive behavior measured by the Vineland Adaptive Behavior Scale (VABS), and 4) special laboratory parameters. A total number of 22 AT patients (11 females and 11 males, age range 4–18 yrs) were enrolled, following strict inclusion/exclusion criteria; four of them did not complete the trial, one for no compliance and three for low level CD4+ lymphocytes. The trial was completed without notification of major adverse events. The patients perceived the treatment as very positive and after the end of the trial most of them requested to the local Ethical Committees the compassionate use and were authorized to continue the ERY-DEX therapy. The patients who completed the trial can be subdivided in responders (11 of 18; 7 females and 4 males) and non-responders (1female and 6 males). The responders show a diminution of ICARS scores ranging from 6 and 17 points, the non-responders a variation of ICARS scores ranging from 3 and -6. The best neurologic results of the therapy were obtained on kinetic scores; on the contrary, evaluation of posture and oculomotion seems to provide lower improvements. In conclusion, the condition of responders seems to correlate with the loading dosage of ERY-DEX and with the sex of patients, while it is independent on the type of mutation, age and clinical status. New incoming trials would help to ameliorate the treatment and to elucidate the biological bases of responder/non responder condition.

Generation and characterisation of FRDA mouse model cell lines. *C. Sandi, S. Al-Mahdawi, V. Ezzatizadeh, S. Virmouni, M. Sandi, M. Pook.* School of Health Sciences and Social Care, Brunel University, Middlesex, UB8 3PH United Kingdom.

Friedreich ataxia (FRDA) is an inherited autosomal recessive neurodegenerative disorder caused by a GAA trinucleotide repeat expansion mutation within the first intron of the FXN gene. Normal individuals have 5 to 30 GAA repeats, whereas affected individuals have from approximately 70 to more than 1,000 GAA triplets. In addition to progressive neurological disability, FRDA is associated with cardiomyopathy and an increased risk of diabetes mellitus. Currently there is no effective therapy for FRDA, which is perhaps due to the lack of an effective system to test potential drugs. To understand the pathological consequences and to find a potential therapy for FRDA, in vitro and/or in vivo model systems are considered to be essential. We have generated GAA repeat expansion mutation-based FRDA mouse models that exhibit GAA repeat instability, epigenetic changes and progressive mild pathology, representative of FRDA. Using these mouse models, we have established novel cell culture systems, including FRDA mouse primary fibroblasts and neural stem cells (NSCs) for the investigation of FRDA molecular disease mechanisms and in vitro therapeutic testing. Experiments are also under way to differentiate the NSCs to obtain cultures of differentiated neural cells. The FRDA mouse primary fibroblasts have shown less tolerance to both hydrogen peroxide and FAC/BSO-induced oxidative stress compared to control mouse fibroblasts. The frataxin expression levels in FRDA mouse derived fibroblasts are also significantly decreased compared to control fibroblasts. Furthermore, we have found reduced gene expression levels of antioxidant genes, such as Cat, Sod2, Gpx1, and mismatch repair (MMR) genes, such as Msh2, Msh3, Msh6 and Pms2. We are currently investigating the level of expression of these genes in NSCs and differentiated neural cells. In summary, we have generated FRDA mouse fibroblasts and neural cell lines that will be a valuable resource to further understand FRDA pathogenesis and therapy.

Non-penetrance in RP17? An investigation into the molecular mechanisms underlying retinitis pigmentosa 17 with the view to developing novel gene-based therapies. *A. Pandor, S. Prince, R. Ramesar.* Human Genetics, University of Cape Town, Observatory, Western Cape, South Africa.

Retinitis pigmentosa (RP) is a highly heterogeneous form of inherited blindness that affects more than 1.3 million individuals worldwide. The RP17 form of the disease is caused by an arginine to tryptophan (R14W) mutation in the signal sequence of carbonic anhydrase IV (CAIV). In an effort to elucidate the molecular mechanisms underlying RP17, three cell types were transfected with the wild type (WT) and the R14W mutant form of the protein. We show using immunocytochemistry that unlike transfected WT CAIV which is transported to the plasma membrane of transfected COS-7 and HT-1080 cells, R14W mutant CAIV is retained in the endoplasmic reticulum when transfected into the same cell type. Further analyses of these cells by western blotting reveal that whereas the WT CAIV is processed to its mature form in both these cell lines, significant levels of the R14W mutant protein remain in its immature form. Importantly, flow cytometry experiments demonstrate that compared to WT CAIV protein, expression of specifically the R14W CAIV results in an S and G2/M cell cycle block, followed by apoptosis. Interestingly, when the above experiments were repeated in the human embryonic kidney cell line, HEK-293, strikingly different results were obtained. These cells were unaffected by the expression of the R14W mutant CAIV and were able to process the mutant and WT protein equally effectively. These findings regarding cell type specificity were used as a basis to explore methods of therapy for RP17. In particular, allele-specific small hairpin RNA was used to silence expression of R14W mutant CAIV, and to rescue cells from undergoing cell cycle arrest and apoptosis. A study of specific chaperones involved in protein folding, as well as gene and protein expression studies (microarray and mass spectrometry analysis), were also carried out to determine which proteins that were expressed in HEK-293 cells play a part in the ability to fold, process and transport R14W mutant CAIV. The results of this study have important implications for our understanding of the RP17 phenotype, and in investigating gene and protein therapy for the prevention and treatment of RP17.

Pharmacological Evaluation of a CNP Analogue for the Treatment of Achondroplasia. *F. Lorget[1], N. Kaci[2], J. Peng[1], C. Benoist-Lasselin[2], E. Mugniery[2], T. Oppeneer[1], D. Wendt[1], S. Bullens[1], S. Bunting[1], L. Tsuruda[1], C. O'Neill[1], F. Di Rocco[2], A. Munnich[2], L. Legeai-Mallet[2].* 1) BioMarin, Novato, CA; 2) Inserm U781, Paris Descartes Unversity, Necker hospital.

Achondroplasia (ACH), the most common form of dwarfism, is caused by a gain of function mutation in the fibroblast growth factor receptor 3 gene (FGFR3). The C-type natriuretic peptide (CNP) antagonizes FGFR3 downstream signaling by inhibiting the mitogen-activated protein kinase (MAPK) pathway. The use of CNP as a therapeutic agent for ACH is impracticable due to its short half-life. Here, we are presenting an update on the pharmacological activity of BMN 111, a novel CNP analogue with an extended plasma half-life allowing once daily subcutaneous (SC) administration. In ACH growth plate chondrocytes, we demonstrated that BMN 111 decreased MAPK pathway activation but did not affect STAT pathway activation. In Fgfr3Y367C/+ mice mimicking ACH, daily SC administration of BMN 111 led to the attenuation of the dwarfism phenotype. With 20 days of daily SC dosing of BMN 111 (800 μg/kg) beginning at seven days of age, we observed a significant increase in the axial and appendicular skeleton length with improvements in ACH related clinical features including flattening of the skull, reduced inverted crossbite and straightening of the tibias and femurs. The growth plate defect (reduced height of the pre-hypertrophic/hypertrophic zones and lack of columnar arrangement) was corrected along with the normalization of the size and shape of the proliferative and hypertrophic chondrocytes. A rescue of the height and architecture of the different zones of the growth plate was observed. The height of the proliferative zone was increased; the replicating chondrocytes were organized into columns parallel to the long axis of the bone. In the hypertrophic zone, the terminally differentiated chondrocytes recovered a columnar alignment. These data support further development of BMN 111 for the treatment for ACH and hypochondroplasia (HCH).

Role of vitamin D in osteoarthritis knee: A six month double blind, randomized, placebo control trial. *S. R. Nath, D. Sanghi, S. Raj, K. Baghel, A. Mishra.* Orthopaedic Surgery, KG Medical College, CSM Medical University, Lucknow, UP, India.

Background: Inadequate sunlight exposure and lower serum levels of 25(OH)D appears to be associated with an increased risk for progression of OA knee.This study was planned to assess the effect of vitamin D on the progression of disease. Methods: A six month, double blind, randomized and placebo controlled trial of vitamin D, in vitamin D insufficient OA knee subjects (serum 25(OH)D levels <50 nmol/L) was conducted. 150 subjects of primary OA knee were subjected to personal interview to determine their vitamin D intake and the daily sunlight exposure in hours. Serum levels of calcium, phosphorus, alkaline phosphatase and 25(OH) D were measured to determine their vitamin D profile. We identified 64 vitamin D insufficient subjects out of 150 primary OA knee patients. These were randomized by random allocation table for intervention. In cases a bolus dose of calciferol in 60,000 IU/day for 10 days followed by 6,000 IU/month for six months was administered and in controls a placebo in the same schedules and durations was given. Primary outcome measures were clinical WOMAC scores and VAS for knee pain. Secondary outcome measures were radiological features and KL grades. The serum levels of vitamin D were assessed by using Enzyme Linked Immunosorbent Assay (ELISA) and calcium/phosphorus/alkaline phosphatase by UV end point method. Results: There was no significant baseline difference of age, sex, analgesic frequency, dietary vitamin D intake, serum levels of vitamin D, calcium, phosphorus and alkaline phosphatase and in clinical and radiological scores between the cases and controls. BMI (25.96 vs 25.65, p=0.75) and pain (10.94 vs 10.64, p=0.66) was higher in the placebo group although difference was not statistically significant. There was no significant difference in radiological features and KL grades from baseline and at 6 months in both the groups. At six month, both the groups had an improvement in WOMAC and VAS pain scores but vitamin D showed benefit over placebo from baseline (p<0.01); for WOMAC physical function vitamin D group showed significant improvement over placebo which remained same as their baseline levels. Conclusions: Although a long term study is being recommended to establish radiological progression, if any, this short term randomized placebo control trial yields a beneficial effect of vitamin D in pain and physical function in KOA. Vitamin D intake was beneficial in symptomatic improvement of KOA.

Use of the amniotic fluid transcriptome to identify novel antenatal treatments for fetuses affected with Down syndrome. *F. Guedj[1], L. Massingham[1], K. Johnson[1], U. Tantravahi[2], D. Bianchi[1].* 1) Mother Inftant Research Institute, Tufts Medical Center, Boston, Massachusetts, USA; 2) Women and Infants Hospital Department of Pathology Providence, Rhode Island, USA.

Background: Using cell-free fetal RNA obtained from amniotic fluid supernatant, we previously identified statistically significant gene expression differences in second trimester fetuses with Down syndrome (DS) compared to euploid gestational age matched controls (PNAS 2009;106: 9425). Oxidative stress was identified as a major functional abnormality in DS fetuses. Here we applied Connectivity Map data (www.broadinstitute.org/cmap) to suggest small molecules that might “treat” the transcriptome alterations displayed by aneuploid fetuses. **Methods:** We evaluated the protective effect of the top three antioxidant molecules identified by the Connectivity Map: apigenin, celastrol and dimethyloxalylglycine (DMOG) on amniocytes obtained from euploid fetuses (n=5) and fetuses with a known diagnosis of DS (n=4). Cells were cultured and incubated in the absence or presence of different concentrations of antioxidants for three consecutive days before experimental assessment. Preliminary experiments focused on identifying optimal non-toxic concentrations of each molecule. The COMET assay, a fluorescent single cell electrophoresis test, was used as an objective measure of oxidative stress through the measurement of DNA in the comet tail. **Results:** We initially determined the most suitable antioxidant non-toxic concentrations for apigenin, celastrol and DMOG to be 1–4 μM, 50–200 nM and 50–100 μM, respectively. Analysis of 200–300 cells/cell line/condition revealed that: 1) Amniocytes from DS fetuses have higher oxidative stress (% DNA in tail = 14.12 ± 5.17 %) compared to euploid (% DNA in tail = 5.13 ± 2.50 %) (p<0.001). 2) Treatment of DS amniocytes with increasing concentrations of apigenin (1, 2 and 4 μM) significantly reduced the % of DNA in the comet tail by 52.35 % (p<0.05), 64.2 % (p<0.001) and 80.6 % (p<0.0001) respectively. **Conclusions:** These in vitro studies provide proof of principle that amniotic fluid transcriptome data can be used to suggest molecules for fetal treatment in aneuploidy. The results show that apigenin significantly reduced the oxidative stress observed in amniocytes from fetuses with DS. This antioxidant effect is now being evaluated for celastrol and DMOG using the same experimental approach. These molecules will be administered in vivo in wild-type pregnant mice carrying Ts1Cje pups to test the hypothesis that antenatal treatment of oxidative stress improves neurocognition in DS.

Treatment of basal cell carcinomas with a hedgehog pathway inhibitor vismodegib in Basal Cell Nevus Syndrome. *A. Treherne[1,2], S. Bale[3], W. Chen[4], J.R. Toro[5]*. 1) Dermatology Department, Veterans Affairs Medical Center, Washington, DC; 2) Dermatology Department, Howard University College of Medicine, Washington, D.C; 3) GeneDx Gaithersburg, M.D; 4) Pathology Department, Veterans Affairs Medical Center, Washington, D.C; 5) Genetic Epidemiology Branch, Division of Cancer Epidemiology and Genetics, NCI, Bethesda, M.D.

A 52-year-old caucasian man with a history of basal cell nevus syndrome (BCNS) presented for evaluation and treatment of new skin lesions. He has a history of multiple basal cell carcinomas (BCC) with the first one appearing on the corner of his right eye at age 19 followed by 100s of BCCs distributed over his trunk and extremities. Previous treatments (excision, Mohs surgery, currettage and electrodessication, cryotherapy, 5-aminolevulinic acid photodynamic therapy, imiquimod and 5-fluorouracil) only provided temporary relief followed with the development of numerous new BCCs. Patient reported a history of a seizure four years ago with transient loss of consciousness and bladder control. He denied history of visual changes, jaw pain, swelling or cysts. Dermatologic examination revealed frontal bossing, milia like-papules on his eyelids, 2–3 mm erythematous palmo-plantar pits, more than 100 erythematous to pearly papules and plaques scattered over the face, neck, trunk and upper extremities, and a 1 cm firm dermal nodule on the right vertex of the scalp. Dermoid cysts at the web space of fingers were not noted. MRI without and with IV contrast of the brain showed, no evidence of a primary neoplasm, calcification of the falx cerebri or agenesis of the corpus callosum. Microscopic examination of lesional skin from the scalp and various skin sites revealed BCCs. Genetic counseling was performed. Genetic testing using targeted CGH array analysis with exon-level resolution showed a duplication of exon 3 of the PTCH 1 gene confirming the diagnosis of BCNS. The patient was started on vismodegib (erivedge) 150 mg orally once daily. Three months after initiation of therapy with vismodegib, no new BCCs and decrease in size of BCCs by 51–59% percent on his left bicep and left upper jaw were noted. He denied common side effects reported associated with vismodegib including muscle spasms, alopecia, dysgeusia, weight loss, fatigue, nausea, diarrhea, decreased appetite, constipation, arthralgias, vomiting, and ageusia. He was advised to use condoms with spermicide, during sexual intercourse with female partner while taking vismodegib and for at least 2 months after the last dose. In addition, patient was recommended not to donate blood or blood products while taking vismodegib and for at least 7 months after the last dose. To date follow-up response to treatment will be presented.

TGFβ signaling exerts dimorphic effects on aortic aneurysm formation and progression in Marfan syndrome. *L. Carta[1], J.R. Cook[1], M. del Solar[1], E. Chiu[1], N. Clayton[2], C. Nelson[2], B. Wentworth[2], F. Ramirez[1]*. 1) Pharmacology and Systems Therapeutics, Mount Sinai School of Medicine, New York, NY; 2) Genzyme Corporation, Framingham, MA.

TGFβ antagonism, using either the pan-TGFβ neutralizing antibody (TGFβNab) 1D11 or the angiotensin type I receptor (AT1r) blocker Losartan, has been shown to prevent formation of thoracic aortic aneurysm (TAA) in $Fbn1^{C1039G/+}$ mice, an animal model of MFS featuring non-lethal TAA progression. By contrast, Losartan treatment has been reported to delay TAA dissection and rupture in $Fbn1^{mgR/mgR}$ mice, which recapitulate the lethal phenotype of early onset, progressively severe MFS. Our ongoing investigations have confirmed this last finding by showing aortic growth normalization but significant medial degeneration in $Fbn1^{mgR/mgR}$ mice that are also deficient for the AT1 receptor. We furthermore found that neonatal administration of the TGFβNab 1D11 promotes TAA dissection and rupture in $Fbn1^{mgR/mgR}$ mice earlier than in untreated mutant mice, and that 1D11 administration after completion of postnatal vessel growth extends the average survival of $Fbn1^{mgR/mgR}$ mice to the same extent as Losartan treatment. These findings are therefore consistent with the notion that TGFβ signaling plays a protective role during early TAA formation and that factors other than promiscuous TGFβ activity trigger the onset of aortic disease in MFS. This view also implies that anti-TGFβ therapy, albeit effective in blunting aortic growth during adulthood, may be counterproductive in treating young MFS patients.

768W

Safety of Velaglucerase Alafa in Type 1 Gaucher Disease Patients with Anti-Imiglucerase Antibodies. *O. Goker-Alpan[1], GM. Pastores[2], B. Rosenbloom[3], J. Ibrahim[4], GM. Cohn[5], D. Zahrieh[5], PK. Mistry[6]*. 1) Lysosomal Disorders Research and Treatment Unit, Center for Clinical Trials, O&O Alpan, Fairfax, VA; 2) New York University School of Medicine, New York, NY; 3) Tower Hematology Oncology, Beverly Hills, CA; 4) St Joseph's Children's Hospital, Paterson, NJ; 5) Shire HGT, Lexington, MA; 6) Yale University School of Medicine, New Haven, CT.

PURPOSE To assess the safety of velaglucerase alfa in type 1 Gaucher disease (GD1) patients with anti-imiglucerase antibodies at baseline (BL) in the multicenter treatment protocol HGT-GCB-058 (which gave patients the option of velaglucerase alfa treatment during imiglucerase supply disruptions). METHODS Treatment-naïve patients received 60 U/kg velaglucerase alfa every other week (EOW); patients transitioning from imiglucerase (switch) received the same dose of velaglucerase alfa as their prior imiglucerase dose (15–60 U/kg EOW). Study participation ended upon transition to commercial therapy. Patients were tested for anti-imiglucerase and anti-velaglucerase alfa antibodies at BL and anti-velaglucerase alfa antibodies at 13, 25, 37, 51 weeks. Treatment-emergent adverse events (AE) were monitored. RESULTS 37/211 patients enrolled in HGT-GCB-058 were positive for anti-imiglucerase antibodies at BL (all switch patients; median age/range: 59/9–79 years; 17 females; 6 splenectomized). The median (lower-upper quartile) exposure time to velaglucerase alfa was 22.1 weeks (14.1–28.1). 13/37 experienced ≥1 AE (most mild or moderate in severity), 8 experienced ≥1 drug-related AE (mild-moderate), 6 experienced ≥1 infusion-related AE (mild), and 1 discontinued due to blood pressure increase (mild). 12/37 anti-imiglucerase antibody-positive patients were also anti-velaglucerase alfa antibody positive (cross-reactive) at BL: 1 subsequently tested negative for anti-velaglucerase alfa antibodies during the study (no reported AE), 2 discontinued before the first in-study antibody assessment (no reported AE), and 9 remained positive for both antibodies during the study. Only 1 patient developed treatment-emergent anti-velaglucerase alfa antibodies; he was anti-imiglucerase antibody positive at BL (no reported AE). Of the 10/37 patients who had positive in-study anti-velaglucerase alfa antibody tests, 4 experienced ≥1 AE (mild-moderate), 3 experienced ≥1 drug-related AE (mild-moderate) and 2 experienced ≥1 infusion-related AE (mild); none discontinued due to an AE. No antibody-positive patient experienced a serious AE. 1 patient positive for both antibodies at BL and who remained anti-velaglucerase alfa antibody positive throughout was also IgE positive for both antibodies. No hypersensitivity reactions were reported. CONCLUSIONS Velaglucerase alfa was generally well tolerated in GD1 patients with BL anti-imiglucerase antibodies who transitioned from imiglucerase.

Safety and Tolerability of Velaglucerase Alfa Enzyme Replacement Therapy in Patients Aaged ≥65 Years with Type 1 Gaucher Disease: A Multicenter, Open Label Trial. *J. Ibrahim[1], GM. Pastores[2], B. Rosenbloom[3], O. Goker-Alpan[4], GM. Cohn[5], D. Zahrieh[5], PK. Mistry[6].* 1) Genetics Division, St Joseph's Regional Med Ctr, Paterson, NJ; 2) New York University School of Medicine, New York, NY; 3) Tower Hematology Oncology, Beverly Hills, CA; 4) LSD Research and Treatment Unit, Springfield, VA; 5) Shire HGT, Lexington, MA; 6) Yale University School of Medicine, New Haven, CT.

PURPOSE The most common lysosomal storage disorder is Type 1 Gaucher disease (GD1), an inherited deficiency of lysosomal glucocerebrosidase. The FDA approved a treatment protocol in 2009 to offer velaglucerase alfa to GD1 patients affected by the imiglucerase supply disruption. The objective of the treatment protocol was to observe the safety of velaglucerase alfa in GD1 patients ≥ 2 years of age, treatment-naive or switched from imiglucerase, with no prior anaphylactic reaction to enzyme replacement therapy. METHODS This was a subset analysis of safety data in an elderly population being switched from prior imiglucerase therapy from the US multicenter treatment protocol. Switch patients received the same dose as their prior imiglucerase regimen (15–60 U/kg every other week [EOW]). RESULTS 52 of 211 patients who initiated velaglucerase alfa were ≥65 years of age. In this older subgroup, the median age was 68.5 (range, 65–89) years, 26 (50%) were women, 21 (40.4%) were splenectomized, and all had been switched from imiglucerase treatment. At baseline, the median hemoglobin concentration was 13.2 g/dL (range, 10.4–16.6 g/dL; n=51) and the median platelet count was 161.0 × 109/L (range, 47.0–474.0 × 109/L; n=49). Patients could discontinue the protocol when commercial therapy was available to them; median treatment duration was 197 (range, 1–475) days. 23 (44.4%) patients experienced ≥1 adverse events (AEs). Drug-related AEs were observed in 6 (11.5%) patients. A total of 3 serious AEs (cerebrovascular accident, diverticulitis, and bacterial peritonitis) were reported in 2 (3.8%) patients; all were considered unrelated to study drug. 5 severe AEs were reported in 3 (5.8%) patients (cerebrovascular accident; upper abdominal pain and leukopenia; diverticulitis and bacterial peritonitis); all were considered unrelated to study drug and all affected patients continued treatment with no change in dose. A mild infusion-related AE (blood pressure increase) caused study discontinuation in 1 (1.9%) patient. Mean hemoglobin and platelet levels remained stable throughout treatment. CONCLUSIONS These previously treated GD1 patients ≥65 years old were successfully transitioned to velaglucerase alfa, which was generally well tolerated and had a safety profile consistent with that reported previously in children and younger adults.

770W

A Double Blind, Placebo Controlled Trial of Minocycline in Children with Fragile X Syndrome. *R. Hagerman[1], M.J. Leigh[1], D.V. Nguyen[2], T.I. Winarni[3], S. Rivera[4], a. schneider[1], t. chechi[5], d. hessl[6].* 1) Dept Pediatrics, MIND Inst, Univ California Davis Med Ctr, Sacramento, CA; 2) Department of Biostatistics UC Davis, Davis, California; 3) Diponogoro University, Samarang, Java, Indonesia; 4) Department of Psychology, Center for MIND and Brain, UC Davis, Davis California; 5) MIND Institute, UC Davis Medical Center, Sacramento California; 6) Department of Psychiatry, MIND institute, UC Davis Medical Center, Sacramento California.

Background: Fragile X syndrome (FXS) is the most common inherited cause of intellectual disability and the most common known single gene cause of autism. Minocycline has been found to decrease levels of matrix metalloproteinase 9 and normalized synaptic connections and behavior in the knockout mouse model of FXS. Objective/Hypothesis: To determine the efficacy and tolerability of minocycline as a targeted treatment for children and adolescents with FXS. Design/Methods: Randomized, double-blind, placebo-controlled, crossover trial lasting for 6 months. Patients (n=55, 87.3% male, 78% white) were recruited from a sample of individuals with FXS, ages 3.5 to 16 years of age, mean age 9.0+/-3.5 years. Outcome measures including the Clinical Global Impressions-Improvement (CGI-I) scale, Visual Analogue Scale (VAS) for behaviors, and the Aberrant Behavior Checklist (ABC) were administered at baseline, 3 months and 6 months. Results: Sixty-nine subjects were screened and 66 were randomized into two treatment arms. Fifty-five subjects (83.3%) completed at least the first period and 48 (72.7%) completed the full 6 month trial. Intention-to-treat analysis demonstrated statistically greater improvements in CGI-I after treatment with minocycline compared to placebo (2.49 ±0.13, 2.97 ±0.13, respectively, p 0.0173) and greater improvement in anxiety and mood-related behaviors on the VAS (minocycline 5.26 cm ±0.46 cm, placebo 4.05 cm±0.46cm; p 0.0488). No significant treatment effects were seen in the secondary outcome measures. Side effects were not significantly different during the minocycline and placebo treatment periods, with the most common side effect being gastrointestinal problems such as loose stools. No serious adverse events occurred during minocycline treatment. Five out of 26 participants (23.8%) had positive ANA levels post treatment, but baseline values were not available and patients were asymptomatic. Conclusions: Treatment with minocycline for three months in children and adolescents with FXS resulted in greater global improvement. Treatment for three months appears safe; however, longer trials are indicated to further assess benefits, side effects, and factors associated with a clinical response to minocycline.

Enhancing suppression of nonsense mutations in Duchenne muscular dystrophy. *P.S. Lai, R. Elangovan, S.K.H. Tay, P.S. Low.* Dept Pediatrics, National Univ Singapore, Singapore, Singapore.

Translational readthrough of premature stop codons (PTCs) arising from pathogenic nonsense mutations represents a potential approach for therapy in recessive genetic disorders. Compounds such as aminoglycosides have been shown to restore full length proteins through suppression of PTCs but they are commonly associated with severe side effects of toxicity or if used at subtoxic doses, result in reduced suppression of PTCs. We report a study demonstrating that co-administration of an adjunct compound can increase aminoglycoside-induced readthroughs of PTCs using a mammalian HEK293T cell model transfected with reporter constructs carrying three types of stop codons cloned from Duchenne muscular dystrophy patients. Readthroughs were assayed using the Dual Luciferase Reporter Assay System. Statistical analysis was carried out using independent group T-test and two-tailed ANOVA T-test. Comparative studies using five different aminoglycoside compounds (gentamycin, paramomycin, tobramycin, amikacin, ribostamycin) at concentrations ranging from 0.5–10 μg/ml show highest readthroughs induced by ribostamcyin (41%). Interestingly, the latter is a 3-ring compound in contrast to the rest and could have a structural advantage in more effective binding to the 30s ribosomal sub-unit during readthrough induction. Paramomycin and tobramycin was not as effective as gentamicin and amikacin, with highest readthroughs between 6.18 to 13.38%. As expected, there was a difference in readthrough susceptibility among the three codons: UAG>UAA>UGA. Co-treatment with a polyanion, poly-L-aspartic acid (PAA) led to 25% increase in readthrough levels after 24 hours. PAA was observed to be effective when used at a ratio of 1:10 of the concentration of each aminoglycoside. Our data also shows a time-lag for optimal effect of PAA with the increase in readthrough being even more significant on Day 5 (120 hours) after treatment. The maximum increase achieved was 49% for ribostamycin. The results suggest that PAA could be used to reduce the dose of aminoglycosides required to achieve clinically therapeutic threshold levels of readthoughs and attenuate the effects of toxicity commonly associated with long-term use of these compounds. The ability of PAA to enhance suppression of the PTCs is likely due to its binding with cationic aminglycosides to form intracellular complexes resulting in higher cytoplasmic levels of aminoglcosides accessible for ribosome binding and mediating readthroughs.

Long-term safety of migalastat HCl in patients with Fabry disease. *D.P. Germain[1], R. Giugliani[2], G.M. Pastores[3], K. Nicholls[4], S. Shankar[5], R. Schiffmann[6], D. Hughes[7], A.B. Mehta[7], S. Waldek[8], A. Jovanovic[8], K. Benistan[1], J.K. Simosky[9], V. Sniukiene[9], R. Winkler[9], P.F. Boudes[9]*. 1) Division of Medical Genetics, University of Versailles, Garches, France; 2) Med Genet Serv/HCPA, Dep Genetics/UFRGS and INAGEMP, Porto Alegre, RS, Brazil; 3) New York University, New York, NY; 4) Royal Melbourne Hospital, Parkville, Australia; 5) Emory University, Atlanta, GA; 6) Baylor Research Institute, Dallas, TX; 7) Royal Free Hospital, London, UK; 8) Salford Royal Hospital, Manchester, UK; 9) Amicus Therapeutics, Cranbury, NJ, USA.

Background: Fabry disease (FD) results from an inborn error of glycosphingolipid metabolism in which α-galactosidase A (α Gal A) deficiency leads to accumulation of its substrates, primarily globotriaosylceramide (GL-3). While FD is an X-linked lysosomal storage disorder, both males and heterozygous females are affected. If untreated, many patients will develop serious end-organ complications of kidney failure, cardiac arrhythmias, and/or stroke. Methods: The safety of oral migalastat (AT1001/GR181413A) has been evaluated in Study FAB-CL-205 (NCT00526071), an ongoing, open-label, uncontrolled study in 23 patients with FD who completed a preceding phase 2 study. The study primary objective was to evaluate the long-term safety and tolerability of migalastat. Initial patients (15/23) received 150 mg every other day (QOD). All patients participated in a dose escalation period (DEP), in which they received migalastat 250 mg for 3 days on/4 days off for 2 months before escalating to a dose of 500 mg for 3 days on/4 days off. As the 500 mg dose regimen had no clear additional benefit in increasing α Gal A activity or decreasing urine GL-3, the dose was returned to 150 mg QOD. Data is presented up to a cut-off date of April 2012. Results: The enrolled subjects (14 males, 9 females) had a median age of 42 years. Median treatment duration, including the preceding study, was 5 years (medians: 1.4 years at 500 mg, 1.7 years at 150 mg QOD post-DEP). There were no deaths. Seven patients reported 22 serious adverse events (SAEs), all unrelated to migalastat. Treatment was prematurely discontinued by 6 patients: 1 male for SAEs unrelated to treatment (ventricular fibrillation and stroke); 1 female for withdrawal of consent, and 4 males for lack of response (3/4 with a non-amenable mutation, as defined retrospectively by an in vitro cell-based assay). Two patients had a dose reduction from 500 mg migalastat due to AEs (Patient 1 reported muscle twitching; Patient 2 reported confusion, dizzy episode, intention tremor, arthralgia, and myalgia). All 23 patients reported at least one treatment emergent adverse event (TEAE) and 12 patients reported 35 TEAEs considered related to treatment. The most common TEAEs were arthralgia (9 subjects), fatigue (8), back pain (7), and pain in extremity (6). Conclusion: Migalastat doses of 250 mg 3 days on/4 days off and 150 mg QOD were well tolerated. The dose of 150 mg QOD is being used in phase 3 studies.

Eliglustat, an Investigational Oral Therapy for Gaucher Disease Type 1 (GD1): Phase 2 Results After 4 Years of Treatment. *M.J. Peterschmitt[1], E. Lukina[2], N. Watman[3], M. Dragosky[4], G.M. Pastores[5], E. Avila Arreguin[6], H. Rosenbaum[7], A. Zimran[8], E. Sysoeva[2], R. Aguzzi[1], L.H. Ross[1], A.C. Puga[1]*. 1) Genzyme, a Sanofi company, Cambridge, MA; 2) Hematology Research Center, Moscow, Russia; 3) Hospital Ramos Mejia, Buenos Aires, Argentina; 4) IMAI-Research, Buenos Aires, Argentina; 5) New York University, New York, NY; 6) Instituto Mexicano del Seguro Social Hospital de Especialidades, Col. La Raza, Mexico; 7) Rambam Medical Center, Haifa, Israel; 8) Sha'are Zedek Medical Center, Jerusalem, Israel.

Background: In Gaucher disease type 1 (GD1), deficient acid β-glucosidase activity causes glucosylceramide accumulation primarily in tissue macrophages (Gaucher cells), resulting in multisystemic manifestations (thrombocytopenia, anemia, hepatosplenomegaly, bone disease). A variable clinical course and progression led to the development of therapeutic goals for disease manifestations (Pastores, 2004). Eliglustat, a potent and specific inhibitor of glucosylceramide synthase, is under development as an oral substrate reduction therapy for GD1. **Aim**: Report long-term efficacy and safety results. **Methods**: This ongoing, open-label, uncontrolled, multicenter Phase 2 clinical trial enrolled 26 adults with GD1 who had splenomegaly with thrombocytopenia and/or anemia and were not on treatment for the previous 12 months. Efficacy outcomes, assessed periodically, included changes from baseline in hemoglobin, platelets, spleen and liver volumes, skeletal manifestations, biomarker levels and achievement of therapeutic goals. **Results**: Nineteen patients completed 4 years of eliglustat treatment; no patient discontinued in the last 2 years. After 4 years, mean hemoglobin level and platelet count increased 2.3±1.5 g/dL (11.3±1.5 g/dL to 13.6±1.2 g/dL) and 95% (68,700±21,200/mm^3 to 125,400±51,100/mm^3), respectively; mean spleen and liver volumes (multiples of normal, MN) decreased 63% (17.3±9.5 to 6.1±3.4 MN) and 28% (1.7±0.4 MN to 1.2±0.3 MN), respectively. All patients met ≥3 of 4 long-term therapeutic goals (spleen, 100% of patients; liver, 94%; hemoglobin, 100%; platelets, 50%). Median chitotriosidase and CCL-18 each decreased 82%; plasma GL-1 and GM3 normalized. Mean lumbar spine bone mineral density increased 0.8 T-score (-1.6±1.1 to -0.88±1.3), with the greatest increases in patients with osteoporosis at baseline. Femur dark marrow, believed to reflect Gaucher cell infiltration into bone marrow, was reduced or stable in 17/18 patients. No bone crises were reported. Eliglustat was well-tolerated. Most adverse events (AEs) were mild and unrelated to treatment. Ten drug-related AEs, all mild, occurred in 8 patients. No new serious AEs were reported in any patient between 3 and 4 years of treatment. **Conclusions**: Eliglustat continues to show promising efficacy and safety, with clinically meaningful improvements across disease parameters. Results from 2 controlled Phase 3 trials in untreated and enzyme replacement therapy maintenance patients will be available in 2013.

Ammonia (NH3) Control in Children Ages 2 Months through 5 Years with Urea Cycle Disorders (UCDs); Comparison of Sodium Phenylbutyrate and Glycerol Phenylbutyrate. *W. Smith[1], G. Diaz[2], U. Lichter-Konecki[3], S.A. Berry[4], C.O. Harding[5], S.E. McCandless[6], C. LeMons[7], K. K Dickinson[8], D. Coakley[8], T. Moors[8], M. Mokhtarani[8], B.F. Scharschmidt[8], B. Lee[9].* 1) Dept Pediatrics, Div Gen, Maine Med Ctr, Portland, ME; 2) Mount Sinai School of Medicine, Department of Genetics and Genomic Sciences, Department of Pediatrics, 1428 Madison Avenue, New York, NY 10029; 3) Children's National Medical Center, Division of Genetics and Metabolism, 111 Michigan Avenue NW #1950, Washington, DC 20010; 4) University of Minnesota, 420 Delaware St. SE, MMC 75, Minneapolis, MN 55455; 5) Oregon Health Sciences University, 3181 SW Sam Jackson Park Road, A036/B198, Mailcode L103, Portland, OR 97239; 6) Case Western Reserve University, 11100 Euclid Avenue, Cleveland, OH 44106; 7) National Urea Cycle Disorders Foundation, 75 South Grand Avenue, Pasadena, CA 91105; 8) Hyperion Therapeutics, 601 Gateway Blvd, Suite 200, South San Francisco, CA 94080; 9) Baylor Baylor College of Medicine, One Baylor Plaza, Room R814, Houston, TX 77030.

Ammonia and pharmacokinetic (PK) profiles were examined in a study of glycerol phenylbutyrate (GPB or HPN-100), an investigational drug being developed for UCDs, vs. sodium phenylbutyrate (NaPBA) in children with UCDs. Design This was an open label switch-over study of UCD patients ages 29 days to under 6 yrs on a stable dose of NaPBA powder. On Day 1 patients underwent a 24-hr (0, 8, 12 and 24 hr) sample collection on NaPBA, were switched to a PBA-equimolar dose of GPB, underwent another 24-hr sampling on Day 10 and were offered enrollment in a 12-month extension study with GPB treatment. Plasma and urine samples were assayed for ammonia and drug metabolites. Patients/parents completed questionnaires regarding signs and symptoms associated with NaPBA use or UCD at the time of enrollment and again after treatment with GPB. Results. 15 patients (8 ASL, 3 ASS, 3 OTC, 1 ARG) ages 2 mo to 5 years were enrolled. Patients received a mean NaPBA dose of 5.27g/day (353 mg/kg/d; range 55.6, 583.9 mg/kg/d) and switched to a mean GPB dose of 5.16 g/day or 346.26 g/kg/d; range 61.1, 578.1 mg/kg/d). Plasma ammonia values were lower on GPB treatment at all time points and assessed as AUC0-24 (ratio of GPB/NaPBA means 0.79; 95% CI 0.593–1.055; p 0.03 Wilcoxon signed-rank test; 0.07 t-test) or peak ammonia values (39.39 vs. 52.74 μmol/L; p 0.14). The upper 95% confidence interval of 1.055 was less than the predefined margin of 1.25 achieving non-inferiority. Six patients experienced AEs on GPB; all mild with no SAEs, discontinuations, or significant lab changes. Eleven of 15 patients enrolled in the switch over reported 35 symptoms associated with NaPBA use or UCD on Day 1 (e.g. body odor, protein intolerance, lethargy, vomiting, refusal to eat, abdominal pain). Twenty-three of these 35 symptoms either had improved or resolved on treatment with GPB by Day 10, particularly body odor and recurrent vomiting. Mean systemic exposure (AUC0-24) of PBA, PAA and PAGN following GPB administration were similar to NaPBA. Urinary PAGN concentration and PAGN/creatinine ratio varied less over 24 hours and were greater with GPB treatment. All 15 patients enrolled in the 12-month safety extension study, along with an additional 8 patients who did not participate in the switch over part. Conclusions. GPB results in more evenly distributed urinary output of PAGN over 24 hours and offers ammonia control which is at least as good as that observed with NaPBA in young children with UCD.

A comprehensive genetic and functional analysis of a large cohort of patients with Kabuki syndrome: suggestions for therapy. *L. Micale[1], C. Fusco[1], B. Augello[1], M.N. Loviglio[1,2], C. Maffeo[1], M.T. Pellico[1], L. Zelante[1], G. Merla[1].* 1) IRCCS, Casa Sollievo della Sofferenza, San Giovanni Rotondo, Foggia, Italy; 2) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland.

Kabuki syndrome (KS) is a multiple congenital anomalies syndrome characterized by a peculiar face and varying degrees of mental retardation with mutations in the histone methyl transferase MLL2 as the underlying cause. MLL2 is involved in embryogenesis and development, acting as transcriptional activators of multiple genes. Recently three KS individuals with partial and complete deletion of KDM6A gene, encoding a histone demethylase interacting with MLL2, were reported. We performed sequence analysis of all 54 exons of the MLL2 gene in 250 individuals with KS, identifying causative MLL2 mutations in approximately 75 % of them. In line with other reports, the majority of them carry protein truncating mutations (nonsense or frameshift). Splice site mutations were also detected and some of them characterized. MLL2 mutation-negative KS patients were subsequently tested for exon (s) deletions/duplications in KDM6A and MLL2 genes, but no causative variants were found. These data indicate that MLL2 mutation is the main cause of KS and that genomic rearrangements of MLL2 and KDM6A are extremely rare in KS, substantiating its genetic heterogeneity and the search for additional causative gene(s). Moreover we investigated the functional consequences of some MLL2 mutations. We found that a number of MLL2 nonsense mutations result in mRNA degradation through the nonsense-mediated mRNA decay, leading to protein haploinsufficiency in KS-lymphoblastoid cell lines (KS-LCLs). Further we measured by qPCR the mRNA levels of MLL2 targeted HOX genes in KS-LCL, detecting a significant reduction of their expression level compared to control cells. These data support the hypothesis that the KS may benefit from a read-through therapy aimed to restore the physiologically levels of MLL2 protein. Therefore we are performing a proof-of-principle study on a selected number of KS-LCLs with MLL2 nonsense mutations by using specific compounds that mediate translational read-through of nonsense mutations and thereby stimulate the expression of full-length functional proteins. An overview of our recent insights in molecular and functional features of KS will be presented.

Differential effects of ramipril and losartan therapy on phenotype in mice model for Marfan syndrome. *B.L. Lima, G.P. Cardozo, G.R. Fernandes, L.V. Pereira.* Dept Gen, Inst de Biociencias - USP, São Paulo, Brazil.

The Marfan syndrome (MFS) is an autosomal dominant disease of connective tissue, which affects 1 in 5,000 individuals. The main clinical manifestations include aneurysms and aortic disruption, excessive growth of bones, scoliosis and thoracic deformities. Mutations in the FBN1 gene, which encodes the fibrillin-1 protein, were genetically linked to the MFS, classifying this disease in the fibrilinopathies group. The complex pathogenesis of MFS also involves changes in TGFβ signaling, increased matrix metalloproteinase (MMP) expression, tissue fragmentation, and abnormal matrix-cell interactions. During the last years, therapeutic strategies, based on the use of drugs, have been studied in animal models and patients with MFS. Among these drugs we find Losartan, an antagonist of AT1, which may restore the vascular and pulmonary phenotype in animal models. Clinical trials involving patients with MFS revealed that, even with the patients presenting improvements in vascular alterations, the results are far from those seen in animal models. The hypothesis is that the dose given to patients is not sufficient to reproduce the effects observed in animals, which received very high drug dose. During the year of 2011 our group compared the effect of Ramipril, an ACE inhibitor, with the effects of Losartan, on the phenotypic manifestations of SMF in the murine model mg$\Delta^{loxPneo}$. The treatment with Ramipril was realized with doses equivalent to those already used in humans (5 mg/kg). At 6 months, animals treated with Ramipril, showed an increase of approximately 35% in the Fbn1 gene transcription, and a similar improvement in pulmonary and vascular manifestations, when compared with animals treated with Losartan. However, these animals also presented an impressive improvement on bone manifestations compared to Losartan treated mice (P<0,01), which has never been reported. Here we describe a most detailed effect of Ramipril and Losartan over the expression of genes involved with SMF manifestations, and the effect of both drugs over canonical (Smad) and non-canonical (ERK1/2 and JNK) TGF-β intracellular signaling pathways.

Curcumin facilitates a transitory cellular stress response in Trembler-J mice. *Y. Okamoto[1], K. Mehrdad[1], D. Pehlivan[1], W. Wiszniewski[1], G. Snipes[2], J. Lupski[1,3,4].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, TX; 2) Department of Pathology, Baylor College of Medicine, One Baylor Plaza, Houston, TX; 3) Department of Pediatrics, Baylor College of Medicine, One Baylor Plaza, Houston, TX; 4) Texas Children's Hospital, 6621 Fannin Street Houston, Texas 77030.

Misfolded proteins can cause neurodegenerative and genetic diseases due to molecular stress and interference with the cell function. Many myelin gene mutants (e.g. MPZ and PMP22) cause severe neuropathy evidently by protein accumulation within the endoplasmic reticulum (ER), causing Schwann cell apoptosis, and subsequently peripheral neuropathy. We previously showed that oral administration of curcumin significantly decreases the percentage of apoptotic Schwann cells and partially mitigates the severe neuropathy phenotype of the Trembler-J (Tr-J) mouse model in a dose-dependent manner [Khajazvi, et al (2007) Am J Hum Genet 81:438–453]. To identify specific molecular and cellular pathways through which curcumin functions in Tr-J mice, we performed comparative expression profiling in sciatic nerves of curcumin treated and untreated Tr-J mice. Our results showed that UPR gene markers such as Bip, Ddit3 (chop), and other ER-stress sensors are up-regulated in Tr-J sciatic nerves suggesting a persistent ER stress in Tr-J mice.. We also found that administering curcumin induces the expression of multiple heat shock proteins including Hsp70 while reducing ER stress sensors in sciatic nerves. We further tested if Hsp70 levels could influence the severity of the Tr-J neuropathy. Notably, reduced dosage of the Hsp70, strongly potentiates the severity of the Tr-J neuropathy, though the absence of Hsp70 had little effect in wild type mice. Our findings provide corroborative evidence for the importance of ER associated degradation (ERAD) pathways in the pathogenesis of peripheral neuropathy disorders. In aggregate, these data provide further insights into the pathological disease mechanisms caused by myelin gene mutations and open new avenues for the induction of heat shock protein chaperones as a therapeutic approach for ER-retained mutants.

Novel therapeutic assays for Epidermolysis Bullosa Simplex. *J. Lacroix[1], T. Farez[1], G. Leclerc[2], A. Dupérée[2], J. Powell[3], C. McCuaig[3], C. Morin[2], V. Legendre-Guillemin[1], M. Bchetnia[1], C. Laprise[1].* 1) Université du Québec à Chicoutimi, Chicoutimi, Québec, Canada; 2) Centre de santé et de services sociaux de Chicoutimi, Chicoutimi, Québec, Canada; 3) Hôpital Sainte-Justine, Montréal, Québec, Canada.

Background: Epidermolysis bullosa simplex (EBS) is a genodermatosis with a prevalence of 1/50,000 to 1/30,000 throughout the world. EBS is caused by mutations in the keratin (*KRT*) *5* and *KRT14*, leading to aggregations of keratin filaments, and is characterized by blistering of the skin. There is still no therapy available to cure this disorder but some molecules are known to reduce keratin aggregates by, among other ways, increasing the expression of other keratins. **Objective**: To assay the therapeutic potential of three molecules: trimethylamine N-oxide (TMAO), sodium 4-phenylbutyrate (4-PBA) and sulforaphane (SF). **Methods**: Two immortalized keratinocyte cell lines (1 control and 1 patient with 373C>A mutation on *KRT14*) were first pre-treated with the molecules and then subjected to heat shock. Afterwards, immunofluorescence for keratin staining and cells count were performed to determine the percentage of reduction of cells with aggregates. **Results**: The number of cells with aggregates is not significantly different after 4-PBA (p=0,13) pre-treatment. The number of cells with aggregates was significantly reduced after TMAO pre-treatment (p=0,03) but this molecule was found to be toxic for the cells. There were significantly less cells with aggregates after the SF and heat shock treatment (p=0,01). **Perspective**: We were able to establish *in vitro* the protection of SF against thermal damage in keratinocytes, which could translate *in vivo* to potential therapy in EBS with *KTR14* mutations.

Sodium Butyrate and Valproic acid as a splicing restoring agents in erythroid cells of β-thalassaemic patients. *M. Taghizadeh[1], S. Mansoori Derakhsham[2], M. Shekari Khaniani[2], A. Hoseinpour Pheysi[3].* 1) Tarbiat Modares University, Tehran, Iran; 2) Tabriz University of Medical Sciences, Tabriz, Iran; 3) Hematology Oncology Research Center, Tabriz University of Medical Sciences, Tabriz, Iran.

Beta (β) Thallassemia is a common genetic disease which affects thousands of hundreds of people around the world. More than 400 mutations play role in Beta Thallassemia and the most common mutation in Thallassemia is RNA splicing mutation. The findings suggest that the butyrate and Valproic acid are good drug candidate for Thallassemia, but no research has been carried out on its effect on splicing mutations. In 2001 Chang et al reported the first compound butyrate drug which could considerably restore splicing defect in spinal mascular atrophy. In Cystic Fibrosis, Na-Butyrate (NaBu) increase expression of SR and SR-like proteins, which are splicing factors that increase exon splicing and restores aberrantly spliced mRNA. The purpose of this study is using pharmacologic elements to study the amount of β-globin transcript in Thallassemia patients with IVSI-110 mutation. Bone Marrow aspiration was carried out from two Thallasemic patients with homozygous form of IVSI-110 Mutation and Some 3X106 Erytroid progenitor cell of Bone marrow cultures derived from Thallassemic patients were transferred into dishes using medium composed of Dulbecco's modified Eagle's medium (DMEM), FBS, BSA, β -mercaptoethanol, glutamine, penicillin-streptomycin, EPO, SCF and dexamethosone. After tree Days NaBu, V.A and IsoBu was added dropwise for a final concentration of 0.5, 100, o.5 mM, respectively. Semi-quantitative RT-PCR analysis of β-Globin mRNA from human Erytroid progenitor cell of Bone marrow cultures treated with SBu, V.A and IsoBu was carried and PCR products were visualized on a 1% Agarose gel by ethidium bromide staining. Each experiment was repeated at least tree times with different passages of the respective cell line.The amount of Wild-type of β-Globin mRNAs in Erytroid progenitor cells cultured with NaBu, V.A and IsoBu was increased 1.7, 1.5, 1.4 fold respectively relative to normal β-Globin mRNAs in untreated Erytroid progenitor cells. This study suggests that restoring transcript in IVSI110 patients by increase of SR proteins and also the role of NaBu and V.A in increase of β-globin transcript by histone deacetylase inhibitors and increase of H3 and H4 histone acetylation which make histone proteins release from DNA, can be effective. Increase in β-globin transcript in patients of IVSI110, achieved in cells treated by NaBu and V.A can cause decrease in transforming of blood and advancement of the disease in the patients.

780W

Bisphosphonate therapy in Hajdu-Cheney syndrome: response, suggested protocol and future directions in treatment. *M.D. Irving[1,3], W.M. Drake[2], J. Pittaway[2], D. Dafou[3], M.A. Simpson[3], R.T. Trembath[3].* 1) Department of Clinical Genetics, Guy's and St Thomas' NHS Foundation Trust, London, London, United Kingdom; 2) Department of Endocrinology, Barts Health, London, United Kingdom; 3) Division of Genetics and Molecular Medicine, King's College London School of Medicine, London, United Kingdom.

Hajdu-Cheney syndrome (HCS) (OMIM 102500) comprises short stature, distinctive craniofacial abnormalities, childhood-onset of progressive bone loss, both generalised (osteoporosis) and focal (acro-osteolysis), irregular dentition, congenital anomalies, neurological complications and characteristic radiographic findings. Management is mainly conservative and focussed upon preserving bone mineralisation. Surgical intervention is employed to correct the secondary mechanical effects of reduced bone density, such as bathrocephaly with basilar invagination. The mainstay of managing clinically significant reduction in bone mineral density is through the use of bisphosphonates, a group of pharmacological agents with structural similarity to pyrophosphate and that preferentially binds to calcium, inhibiting activation of osteoclast enzymes and decreasing bone resorption. There is scant documentation of the use of bisphosphonate therapy, but it seems to have a useful clinical effect in improving bone mineral density to reduce fracture risk, either as monotherapy or in combination with other therapeutic and supplementary compounds, though acro-osteolysis appears unresponsive to therapy and continues to progress. We report a case series of 10 HCS patients and their response to bisphosphonate therapy, determined by markers of bone turnover and bone mineral density, suggest a standardised protocol of administration and discuss potential new therapeutic strategies for treating HCS using knowledge of the underlying molecular mechanism.

A small chemical, TG003, enhances skipping of mutated dystrophin exons: the third example revealing a decrease of exonic splicing enhancer density in common. *A. Nishida[1,2], Y. Takeshima[2], N. Kataoka[3], M. Yagi[2], H. Awano[2], T. Lee[2], K. Iijima[2], M. Hagiwara[4], M. Matsuo[1,2].* 1) Medical Rehabilitation, Kobegakuin University, Kobe, Japan; 2) Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan; 3) Medical Innovation Center, Laboratory for Malignancy Control Research, Kyoto University Graduate School of Medicine, Kyoto, Japan; 4) Department of Anatomy and Developmental Biology, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Duchenne muscular dystrophy (DMD) is a progressive and fatal muscle-wasting disease. DMD is characterized by a deficiency of dystrophin protein in the muscles, which is caused mostly by out-of-frame deletion or nonsense mutations in the dystrophin gene. Antisense oligonucleotide-mediated exon skipping, which produces in-frame dystrophin mRNA, is recognized as the most plausible way to express semi-functional dystrophin in DMD. In our previous report, we showed that TG003, a small chemical kinase inhibitor, enhanced the skipping of two mutated dystrophin exons and produced in-frame dystrophin mRNA (Nishida et al., Nature Commun 2011). Here, we examined TG003-mediated skipping of six different exons encoding a nonsense mutation and identified the third mutated exon that showed TG003-mediated enhancement of exon skipping. Twelve hybrid minigenes containing wild-type or mutated exons were subjected to in vitro splicing in HeLa cells. Although splicing of five mutated exons was not affected by the treatment with TG003, splicing of mutated exon 39 was modulated to produce exon 39 skipping. The ratio of exon 39-skipped product to the total spliced product increased depending on the dose of TG003. Furthermore, TG003 promoted the exon39 skipping in the endogenous dystrophin gene in a dose-dependent manner and increased production of dystrophin protein in the patient's cultured muscle cells. This is the third identified mutated exon that is sensitive to TG003-mediated enhancement of exon skipping. We analyzed characteristics of splicing regulatory mechanisms of three TG003 sensitive exons. RNA-binding protein motifs, as analyzed by SpliceAid, failed to reveal common protein motif changes among the three skipped exons. Decrease in exonic splicing enhancer density by acquisition of the mutation was the sole common change. In particular, a decrease in exonic splicing enhancer density obtained by the program PESX was unique to the three exons, and could discriminate these from the five TG003-insensitive exons.

Bezafibrate as treatment option in patients with mitochondrial complex I deficiency. *B.M. Haberberger[1,2], P. Freisinger[3], V. Strecker[4], M. Steger[4], H. Heide[4], B.F. Müller[5], T. Beckhaus[5], K. Heim[2], U. Ahting[6], B. Rolinski[6], J. Mayr[7], A. Rötig[8], W. Sperl[7], M. Zeviani[9], I. Wittig[4], T. Meitinger[1,2], H. Prokisch[1,2].* 1) Institute of Human Genetics, Technical University Munich, Germany; 2) Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, Germany; 3) Department of Paediatrics, Klinikum Reutlingen, Germany; 4) Molekulare Bioenergetik, Zentrum der Biologischen Chemie, Goethe-University Frankfurt, Germany; 5) Institute for Pharmaceutical Chemistry, Cluster of Excellence "Macromolecular Complexes", Goethe-University Frankfurt, Germany; 6) Department of Clinical Chemistry, Städtisches Klinikum München GmbH, Munich, Germany; 7) Department of Pediatrics, Paracelsus Medical University Salzburg, Salzburg, Austria; 8) Institut National de la Santé et de la Recherche Médicale (INSERM), Paris, France; 9) Unit of Child Neurology, Neurological Institute `Carlo Besta'-IRCCS Foundation, Milan, Italy.

Faulty energy supply due to defective oxidative phosphorylation is the biochemical signature of the genetically heterogeneous group of mitochondrial disorders. A majority of them affect the respiratory chain complexes and the cellular ATP production. In spite of rapid progress in finding the molecular cause, in most instances no curative therapeutic options are available. Bastin et al. (2008) and Wenz at al. (2011) provided evidence from in vitro studies and mouse models that activation of the PPAR/PGC-1-alpha pathway with bezafibrate could be a new therapeutic approach. Djouadi et al. (2010) showed in a clinical study, that bezafibrate increased the resting activity of β-oxidation enzymes in patients with inherited β-oxidation disorders leading to a significant improvement in the condition of the patients. In order to verify this effect, we collected 32 fibroblast cell lines from patients with isolated complex I (CI) deficiency and a defined molecular diagnosis. The CI activity in fibroblasts ranged from 10% to 80% in comparison to control cell lines. After bezafibrate treatment we found no improvement in cell lines with mtDNA mutation (n=4); but in all cell lines with nuclear mutations an increase (15–140%) of CI activity was found. The largest effect was observed in a homogeneous group of missense mutations in the same gene, ACAD9. Analysis of genome-wide expression levels, confirmed increased expression of genes involved in lipid and fatty acid metabolism as well as transport, but provided no evidence of upregulation of genes coding for respiratory chain complex subunits (n=10). Raised CI activity was combined by a larger amount of CI assembled in supercomplexes visualized by 2D-BN/SDS-PAGE experiments (n=8). We further examined the consequences of bezafibrate treatment on protein level to get a clearer picture of the involved mechanisms. Enriched mitochondrial fractions from untreated and bezafibrate treated controls and patients with mutations in ACAD9 gene were analyzed by 2D-DIGE (n=5) and significant changes ($p<0.05$) were identified by MALDI-MS and ESI-MS. We detected reduced levels of proteins involved in metabolic pathways and stability of complexes compared to healthy controls. Proteomics data confirmed increased expression of proteins involved in lipid and fatty acid metabolism upon bezafibrate treatments. These results support bezafibrate as a promising treatment option for specific subgroups of patients with CI deficiency.

FMF patients homozygous for M694V have incomplete response to colchicine. *H. Yonath[1, 2, 6], M. Lidar[3,4,6], N. Shechter[6], F. Sikron[5], S. Sadetzki[5,6], P. Langevitz[3,4,6], A. Livneh[3,4,6], E. Pras[1,6]*. 1) Inst Human Gen, Sheba Med Ctr, Ramat Gan, Israel; 2) Department of Medicine A, Sheba Med Ctr; 3) Department of Medicine F, Sheba Med Ctr; 4) The Heller Institute of Medical Sciences, Sheba Med Ctr; 5) 5Cancer and Radiation Epidemiology Unit, Sheba Med Ctr and Gertner Institute for Epidemiology and Health Policy Research, Tel Hashomer; 6) Sackler Faculty of Medicine, Tel Aviv University, Israel.

Background: Prophylactic colchicine treatment is used in patients suffering from Familial Mediterranean fever (FMF). It is known, from previous studies, that 65% of the patients show a complete response, 30% a partial response and about 5% show minimal or no response, the cause of the difference was not known. We have observed many patients that are homozygotes for M694V in *MEFV* who do not respond well to colchicine despite being treated with maximal sustained doses. Genotyping enables us to study the response rates in different patients according to specific mutations. **Aim**: To assess the response rates to colchicine in M694V homozygous FMF patients in comparison to other prevalent genotypes. **Methods**: A telephonic survey was done, in 112 FMF patients with known gentotypes: 40 M694V homozygotes, and 2 comparison groups of 41 M694V/V726A compound heterozygotes and 31 V726A homozygotes. The questionnaire included demographic, social and clinical features, colchicine dose, response rates and reported side effects. **Results**: M694 homozygous patients had a more severe disease, and were treated with higher doses of colchicine (average dose 1.98±0.56 compared to 1.47±0.58, p=0.0001 and 1.13±0.41, p<0.001 in the M694V/V726A compound heterozygotes and the V726A homozygotes, respectively); Colchicine related side effects were noted in 40% of the M694V homozygotes. The average rate of attacks in treated M694V homozygotes (0.70±1.06) was higher compared to the two other groups (0.14±0.26, p=0.002 and 0.08±0.20, p=0.0009, respectively) and only 25% of them reported no attacks in the last year. None of the patients who took part in this study had amyloidosis. Side effects limiting the dose of colchicine were noted in 40% of the M694V homozygotes. **Conclusions**: Patients that are homozygous for M694Vhave only partial response to colchicine, even in higher doses than other genotypes. The results highlight the need for additional treatment modalities for these patients.

CNS administration of recombinant human tripeptidyl peptidase-1 attenuates neurodegeneration, improves function, and increases lifespan in a canine model of classical late infantile neuronal ceroid lipofuscinosis. *B. Vuillemenot[1], M. Katz[2], D. Kennedy[1], J. Coates[2], C. Sibigtroth[2], R. Whiting[2], F. Wininger[2], R. Reed[3], E. Adams[3], M. Butt[4], R. Cahayag[1], S. Keve[1], L. Tsuruda[1], D. Musson[1], C. O'Neill[1]*. 1) BioMarin Pharmaceutical Inc., Novato, CA; 2) University of Missouri, Columbia, MO; 3) Northern Biomedical Research, Muskegon, MI; 4) Tox Path Specialists, Frederick, MD.

cLINCL is a lysosomal storage disorder caused by deficiency of the enzyme TPP1. Patients exhibit progressive neurodegeneration and loss of motor, cognitive, and visual function, leading to death during mid-childhood. TPP1-null dachshunds recapitulate the progression of the human disease. This study was conducted to characterize the pharmacologic effects of rhTPP1 administration to the CNS of TPP1-null Dachshunds. An additional objective was to determine the pharmacokinetic (PK) profile and CNS distribution. TPP1-null dogs and wild-type controls received 4 or 16 mg rhTPP1 or artificial cerebrospinal fluid (aCSF) vehicle (N=3/group). rh-TPP1 or vehicle was administered via an intracerebroventricular catheter, or if that catheter lost patency, via an intrathecal lumbar catheter every 2 weeks from 9 weeks of age to euthanasia. In some dogs both catheters lost patency during the course of treatment, in which cases enzyme replacement was continued via intrathecal injections into the cisterna magnum. Elevated CSF TPP1 concentrations were observed for 48 hours after administration and were approximately 1000-fold higher than plasma levels. Appearance of neurodegenerative clinical signs was delayed by 3.5 to 11 weeks in the 4 mg treated animals and 10 to 28 weeks in those treated with 16 mg rhTPP1. Pupillary light reflexes were restored to near wild-type levels in animals that received rhTPP1. Cognitive function, as assessed by reversal learning, was also normalized after rhTPP1 treatment. Quantitative magnetic resonance imaging demonstrated a decrease in ventricular enlargement, indicating preservation of brain morphology after rhTPP1 treatment. Mean survival was increased from 43 weeks in the vehicle treated controls to 54 and 62 weeks in animals administered 4 or 16 mg rhTPP1, respectively. Two of the three animals treated at the 16 mg level were euthanized prior to reaching end-stage disease due to complications unrelated to disease progression. This study justifies the administration of rhTPP1 enzyme replacement therapy directly to the CNS for cLINCL patients. Analyses of CNS tissues for rhTPP1 concentration, lysosomal storage material, and neuronal injury are ongoing.

Intrathecal enzyme replacement therapy improves diffusion tensor imaging abnormalities and volume loss in the corpus callosum in canine mucopolysaccharidosis I. *P. Dickson[1], S. Chen[2], I. Nestrasil[3], V. Kovac[3], J. Jens[4], S.Q. Le[1], S.-h. Kan[1], M.A. Guzman[5], J. Provenzale[2,6], E.G. Shapiro[3], C.H. Vite[7], A. Mlikotic[1], N.M. Ellinwood[4]*. 1) LA BioMed Harbor-UCLA Med Ctr, Torrance, CA; 2) Duke University Department of Radiology, Durham, NC, USA; 3) University of Minnesota Department of Pediatrics, Minneapolis, MN, USA; 4) Iowa State University Department of Animal Science, Ames, IA, USA; 5) St. Louis University Department of Pathology, St. Louis, MO, USA; 6) Emory University Department of Radiology, Oncology and Biomedical Engineering, Atlanta, GA, USA; 7) University of Pennsylvania, School of Veterinary Medicine, Philadelphia, PA, USA.

{U}Introduction:{/U} Intrathecal enzyme replacement therapy (IT ERT) was previously shown to improve lysosomal storage in the brain in canine mucopolysaccharidosis I (MPS I). However, translation to the bedside will require clinically-relevant outcome measures. We performed diffusion tensor imaging (DTI) on 9 MPS I dogs, 4 unaffected heterozygous dogs, and 4 dogs treated with IT ERT from 4–21 months of age. Our goals were to determine 1) whether DTI studies in the brain are abnormal in the canine model, 2) whether these respond to IT ERT, and 3) what their underlying basis might be. {U}Methods:{/U} IT ERT-treated dogs received 0.058 mg/kg body weight recombinant human iduronidase diluted in artificial cerebrospinal fluid (total injection volume 2–5 ml). Enzyme was administered every 3 months into the cisterna magna. Diffusion-weighted images were acquired in the axial plane on a 3T GE Discovery MR750 using an 8-channel high-definition transmit/receive knee coil in 25 directions, number of excitations=4, b-value= 1000, matrix=128x128, thickness=1.5 mm. Eigenvalues were measured by tractography following b0 correction. Dogs were imaged twice and the results averaged. Volume was measured on T1-weighted images by manual tracing using BRAINS2. Brains were collected 48h after the final IT ERT dose and within 2 weeks of imaging. {U}Results:{/U} MPS I-affected dogs showed abnormal DTI in the corpus callosum. Fractional anisotropy was reduced by 20% in the genu (p=0.004) and 30% in the splenium (p=0.008) of affected dogs. Radial diffusivity was increased 29% in genu and 62% in splenium of MPS I dogs, suggesting abnormal myelin. Apparent diffusion coefficients and axial diffusivity were also increased. IT ERT-treated MPS I dogs showed improvements in all DTI parameters vs. untreated MPS I dogs, though these did not reach statistical significance in this small sample. Volume of the corpus callosum were diminished in MPS I dogs (0.182±0.0299 cm3, p= 0.02 vs. carriers 0.248±0.0331) and preserved with IT ERT (0.263±0.0493, p=0.006 vs. untreated MPS I). Myelin thickness appeared to be reduced in MPS I dogs and qualitatively improved with early IT ERT. Studies still underway include characterization of myelin lipid composition and levels of myelin-related transcripts and proteins. {U}Conclusion:{/U} MPS I dogs show abnormal DTI, reduced volume and abnormal myelin in the corpus callosum. IT ERT fully or partially prevented these abnormalities.

Enzyme replacement therapy using chemically modified enzyme markedly enhances therapeutic efficacies for bone lesions in mucopolysaccharidosis VII murine model. *S. Tomatsu[1], D. Rowan[2], J. Grubb[3], B. Haupt[4], A. Montaño[5]*. 1) Biomedical Research, Alfred I. duPont Hospital for Children, Wilmington, DE; 2) School of Medicine, Saint Louis University, St. Louis, Missouri, USA; 3) 3Edward A. Doisy Department of Biochemistry and Molecular Biology, Saint Louis University, St. Louis, Missouri, USA; 4) Department of Pathology, Saint Louis University, St. Louis, Missouri, USA; 5) Department of Pediatrics, Saint Louis University, St. Louis, Missouri, USA.

Mucopolysaccharidosis (MPS) type VII is a lysosomal storage disease caused by deficiency of the lysosomal enzyme β-glucuronidase (GUS), which is involved in degradation of glycosaminoglycans (GAGs). Glycosaminoglycan storage in the tissue of patients with MPS VII causes a wide spectrum of clinical manifestations that affect the central nervous system (CNS), bone, and viscera. Enzyme replacement therapy (ERT) effectively clears GAG storage in the viscera. However, clearance of storage material in CNS has been limited by the blood brain barrier. Nonetheless, recent studies showed that a chemically modified form of GUS (PerT-GUS), which escaped clearance by mannose 6-phosphate and mannose receptors, and showed markedly prolonged circulation, reduced CNS storage more effectively than native GUS. Although clearance of storage in bone is limited by the avascularity of the growth plate, prior work showed clinical improvement of skeletal disease in MPS VII mice treated from birth with weekly intravenous injections of native GUS [Sands et al., 1994]. To evaluate the effectiveness of long-circulating PerT-GUS in reducing the skeletal pathology, we treated MPS VII mice for 12 weeks beginning at 5 weeks of age with PerT-GUS or native GUS and used micro-CT, radiographs, and quantitative histopathological analysis for assessment of bones. Micro-CT findings showed PerT-GUS treated mice had a significantly lower BMD. Histopathological analysis also showed reduced storage material and a more organized growth plate in PerT-GUS treated mice compared with GUS treated mice. Long term treatment with PerT-GUS was also assessed by treating MPS VII mice for up to 57 weeks from birth. Micro-CT and radiographs demonstrated improvements in bone lesions of legs, ribs, and spine of mice treated with long-term PerT-GUS ERT. Quantitative histopathological assay also showed improvements in GAG storage and morphology of articular and epiphyseal chondrocytes.

A phase 2 multicenter, open label, switch over trial to evaluate the safety and efficacy of Abcertin®(imiglucerase) in patients with type 1 Gaucher disease previously treated with imiglucerase. *H. W. Yoo[1], B. H. Lee[1], J. S. Lee[2], J. M. Ko[3], Y. B. Sohn[4]*. 1) Medical Genetics Center, Department of Pediatrics, Asan Medical Center Children's Hospital, Seoul, Korea; 2) Department of Clinical Genetics, Severance Children's Hospital, Seoul, Korea; 3) Department of Pediatrics, Seoul National University Children's Hospital, Seoul, Korea; 4) Genetics Clinic, Department of Medical Genetics, Ajou University Hospital, Suwon, Korea.

Introduction: The Gaucher disease type is the prototype of LSD where enzyme replacement therapy proved to be effective. This switch over clinical trial was undertaken to evaluate the safety of Abcertin® for patients receiving Imiglucerase therapy for type 1 Gaucher disease. Aim: The primary objective of this study aimed at evaluating the safety. The analyses of efficacy on changes in hemoglobin, platelet, liver, spleen, biomarkers, skeletal status and BMD were the secondary endpoints. Methods: Five Korean type I Gaucher patients previously treated with Imiglucerase have been enrolled. The previous Imiglucerase dose ranged from 15 to 60 U/kg with an every other week dosing regimen. Each patient was required to be on the same Imiglucerase dose for at least six months prior to enrollment. A patient's Abcertin® dose should be the same dose as the previous Imiglucerase dose administered for immediate past six months. Results: No clinically significant adverse event was observed. In addition, no changes in the hemoglobin concentration and platelet counts, liver and spleen volumes, and skeletal status and bone mineral density were found. No patient required a dose adjustment. All the patients did not generate antibodies to Abcertin®. As the efficacy and safety of Abcertin® were demonstrated as similar to those of Imiglucerase, study drug Abcertin® could be used as an alternative therapeutic agent in patients who are treated with Imiglucerase. Discussion: Even though small numbers of patients were recruited, this was the first trial to investigate the safety and efficacy of Abcertin®. Another clinical trial is under way to verify the efficacy and safety in naïve type I Gaucher patients and the data will be available soon.

Results of 12 months use of taliglucerase alfa for Gaucher disease in an unselected cohort of adult patients on an Israeli compassionate use program. *A. Zimran, H. Maayan, G. Altaescu, M. Tiomkin, M. Phillips, D. Elstein.* Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel.

Due to the world-wide reduced availability of imiglucerase (Cerezyme™, Genzyme Corporation, Cambridge, MA USA) since June 2009, the standard enzyme replacement therapy (ERT) for Gaucher disease at the time, regulatory authorities approved early access programs (EAP) for treatment-naïve patients with taliglucerase alfa (Protalix Biotherapeutics, Carmiel Israel), which was then undergoing Phase III clinical trials..Taliglucerase alfa is an ERT produced in a high-yield plant cell system that is readily up-scalable. The cells are grown in disposable bioreactors and are free from exposure to mammalian components. This report describes results in key Gaucher disease parameters of treatment-naïve patients receiving EAP taliglucerase alfa for 12 months. EAP was approved by institutional authorities. IRB approval was not needed for this retrospective review of de-identified material. All adult patients receiving at least one dose of taliglucerase alfa were included in the safety set; the efficacy set included only patients on 30units/kg/infusion with 12 months' data. Descriptive statistics and the Student's t-test were employed. Twenty-three treatment-naïve patients were dosed (one patient at 60units/kg/infusion was only included in the safety set). Two patients (8.7%) discontinued because of hypersensitivity reactions and no results were reported. Two female patients became pregnant during the study, continuously receiving taliglucerase alfa; both gave birth to healthy, full-term babies with no maternal or neonatal complications. Results: At 12 months, mean change from baseline values (n=19) were: increased hemoglobin level 8.9% and platelet count 38.3%; and mean changes (n=14) in organ index volumes measured by ultrasound: reduction in liver -0.3% and spleen -26% volumes. It should be noted that not all patients had anemia and/or hepatomegaly at baseline. The current cohort broadens the database of 30units/kg/every-other-week of taliglucerase alfa among unselected symptomatic adult patients. These results particularly demonstrate the robust response on the platelets counts also in the patients at the lower dose of 30units/ kg/every-other-week, Safety assessments among treatment-naïve patients are comparable to those reported in the Phase III clinical trial for treatment-naïve patients (Zimran et al, Blood 2011). In May 2012 taliglucerase alfa (Elelyso™) was approved by the FDA- for treating adults with type I Gaucher disease.

Gaucher disease type 2: outcomes of enzyme replacement therapy and impact on quality of life. *C. Prada, R. Hopkin, L. Bailey, A. Lovell, N. Leslie, G. Grabowski.* Dept Pediatrics Genetics, Cincinnati Children's Hosp Med Ctr, Cincinnati, OH.

Background: Gaucher disease (GD) type 2 typically presents between 3 and 6 months of age with retroflexion of the neck, feeding difficulties, poor weight gain, laryngeal stridor, trismus, ocular paresis, hepatomegaly and hypersplenism. Untreated, these children do not speak, sit, or stand. The clinical course is characterized by rapid progression with a mean death age of 9 months. Clinical management consists of palliative and supportive care. The objective of this study was to characterize outcomes of enzyme replacement therapy (ERT) and impact on quality of life in GD type 2 patients. Methods: A retrospective analysis of clinical information was conducted for patients with GD type 2 at Cincinnati Children's Hospital from 1990 to 2010. Results: 8 patients were identified (4 untreated, 4 treated with ERT). The median age at symptom onset was 3 months (range=0 to 7). The median age at diagnosis was 3.5 months (range 1 to 7). The most common genotype was L444P/L444P (n=4), followed by L444P/G202R (n=2), L444P/R257Q (n=1), and L444P/Q414R (n=1). Untreated patients exhibited arching, gasping, and extreme irritability. Treated patients had less irritability, better interaction with caregivers, and more comfortable respirations as well as slower disease progression. No differences in brain imaging were noted between the two groups. Patients on ERT had minimal visceral disease. Untreated infants had poor weight gain and rapidly became cachectic. Patients on ERT had better growth parameters with weights between 3rd and 50thcentiles. All the treated patients survived beyond their first birthday; 3 lived longer than 20 months. Parents perceived an improvement of quality of life in the ERT group; patients appeared more comfortable and reached more milestones; one patient was able to walk. The mean ages at death were 8 months (range 5 to 10 months) and 23 months (range 15 to 35 months) for untreated and ERT groups (p=0.022), respectively. Conclusion: Motor and intellectual development was better in GD type 2 patients treated with ERT suggesting a temporizing effect on the central nervous system. The improvement in visceral disease burden and better growth parameters appear to improve cognitive development. Despite aggressive ERT GD type 2 was lethal. However, improvement in quality of life for the treated patients suggests that benefit of ERT outweighs burden of treatment and should be considered for these children.

Efficiency of various antisense oligonucleotides for correcting ATM pre-mRNA in a patient with ataxia-telangiectasia with a deep intronic splicing mutation. *S. Cavalieri[1], E. Pozzi[1], R. Cavalli[3], R.A. Gatti[2], A. Brusco[1].* 1) SCDU Medical Genetics, S.Giovanni Battista Hospital, Turin, Italy and Departrment of Genetics, Biology and Biochemistry, University of Torino, Italy; 2) Departments of Human Genetics and Pathology and Laboratory Medicine, UCLA School of Medicine, Los Angeles, CA, USA,; 3) Departments of Pharmaceutical Science and Thecnology, University of Torino, Italy.

Antisense oligonucleotides (AONs) correct the aberrant splicing of a defective ATM mutation by masking the aberrant splice site and restoring normal pre-mRNA splicing, without disturbing the surrounding splicing mechanisms. We found a deep intronic splicing (DIS) mutation (c.1236-405C>T) in an Italian AT patient. The mutation creates a novel donor (3'ss) splice site (Splice Site Predictor, score 0.22 wt > 1.00 mutated) at position -405 of intron 11 and hence activates an alternative acceptor (5'ss) splice site at position -619 of intron 11 (score 0.71). As a consequence, a 212 bp non-coding pseudoexon is inserted in the cDNA between exons 11 and 12, containing a premature stop codon that blocks protein translation. In both a lymphoblastoid cell line and primary fibroblasts from the patient we tested different AON chemistries to evaluate their potential for reversing the mutation. Using antisense morpholino oligonucleotides (AMO), designed to mask the donor splice-site created by the c.1236-405C>T mutation, we partially reverted the aberrant splicing product to a wild-type ATM transcript (26%). To improve the delivery and efficiency of the AON, we designed a structurally modified Vivo-AMO that almost completely abrogated the mutant mRNA and significantly enhanced ATM protein at nearly 50% of wild type levels. We also showed that treated cells had a restored ATM kinase activity, testing SMC1 phosphorylation after gamma-ray exposure. To circumvent the possible toxicity of Vivo-AMO, we tested a 2'-O-Methyl-phosphorotioate modification (2'-OMe), which is reported to be less toxic, with higher target affinity and longer half-life. Preliminary mRNA analysis showed a 50% rescue, even at a lower dose of 2'-OMe. Our data suggest that AONs may provide a promising approach to customized, mutation-based treatment for patients with DIS mutations. Experiments are in progress to test additional AON chemical modifications.

In utero brain-directed AAV gene therapy results in rapid, robust, and specific transduction of mouse choroid plexus epithelia. *M. Haddad, A. Donsante, S.G. Kaler.* NICHD, NIH, Bethesda, MD.

In utero gene transfer represents a powerful tool for investigating the feasibility of therapeutic approaches in early neonatal lethal neurometabolic diseases (Rahim et al., Gene Ther, 2011) and assessing whether a mouse mutant with absence of a gene product may be rescued. Incomplete knowledge exists on the transduction efficiency of AAV pseudotypes administered prenatally. The capacity of prenatally administered AAV to transduce the developing choroid plexuses, specialized epithelial structures that project into the brain's ventricular cavities, is entirely unknown. We recently achieved long-term rescue of a lethal mouse model of Menkes disease via rAAV5-mediated ATP7A gene addition to the choroid plexus (Donsante et al., Molec Ther, 2011). To further characterize mammalian choroid plexus-specific transduction, we performed individual 5 μl brain lateral ventricle injections of 5x109 rAAV5-GFP and rAAV9-GFP in E15 embryos of C57Bl/6J and CD-1 pregnant mice and quantitated GFP expression in choroid plexus from lateral, third and fourth ventricles on E17, P2, and P22. Overall surgical survival was 61%. Sagittal brain sections at E17, P2, and P22 were stained with an anti-GFP antibody and the percentage of cells from the choroid plexus epithelia showing expression was quantitated by densitometry (Image J). GFP expression at E17 ranged from 2 to 7%, at P2 from 11 to 19%, and at P22 from 2 to 15%. By postnatal 22, rAAV9-GFP showed higher transduction in choroid plexus compared to rAAV5-GFP ($P<0.01$, two-tailed t-test). In addition, rAAV9 showed a broader biodistribution and pattern of transduction including neurons and glia in the brain cortex and cerebellum in addition to choroid plexus. Our findings indicate that rAAV5 and rAAV9 administered to the fetal brain at E15 results in rapid (within 48 hrs), robust, and specific transduction of choroid plexus epithelia. This is the first study to show rapid and specific rAAV5 and rAAV9 transduction in the developing choroid plexus, 48 hours post-injection, and in two different mouse strains. Based on the detection of the transgene expression within 48 hrs, rAAV9 may enable rescue of certain prenatal lethal alleles in mouse models of human disease, e.g., the Mottled-dappled mouse model of Menkes disease.

792W

Gene and stem cell treatment for alpha-1 antitrypsin deficiency. *B. Feinerman.* Research, STEMCELLREGENMED, Aventura, FL.

Alpha-1 antitrypsin deficiency is a genetic disorder caused by a defective production of alpha-1 antitrypsin(A1AT) leading to decreased activity in the blood and lungs and deposition of A1AT protein in the liver cells. Severe A1AT deficiency causes COPD or emphysema in adults and in 10% of cases liver disease. Treatment of alpha-1 antitrypsin deficiency consists of extraction of autologous stem cells from the patient's own peripheral blood or bone marrow. A knockdown of the abnormal mutation is done by taking a AAV-1 viral vector that will insert a shRNA Serpina 1 into the autologous stem cells prior to intravenous administration. The next step is done 48 hours later and the normal Serpina 1(Myc-DDK tagged ORF of Homo Sapiens chromosome 2 open reading frame 15(C3orf15)as transfection ready)is inserted with the AAV-1 vector into the autologous stem cells and given intravenously. Following this treatment the alpha-1 antitrypsin blood levels are checked at 1,4, 8 and 12 weeks later. An alternate symbol for Serpina1 is AAT1ALPHA.

Identifying motor neuron transduction efficiencies that are efficacious in SMA mice and achievable by intrathecal delivery in a large animal model. *S. Cheng, M. Passini.* Rare Diseases Science, Genzyme, a Sanofi Company, Framingham, MA.

Spinal muscular atrophy (SMA) is a neuromuscular disease caused by a deficiency in SMN due to mutations in SMN1. A decrease in SMN levels results in motor neuron cell death in the spinal cord that leads to weakness and wasting of the muscles responsible for locomotion, swallowing, breathing and coughing. We previously reported that CNS-targeted AAV-hSMN therapy is highly efficacious in SMA mice. The goals of the current study are to determine the minimum percentage of spinal cord motor neurons that needs to be transduced for efficacy in SMA mice, and demonstrate if this transduction rate can be achieved by intrathecal (IT) delivery in large animal models. We hypothesize that AAV vector dose correlates with motor neuron transduction efficiencies to impact survival in SMA mice. Thus, doses of 5e10, 1e10, and 1e9 genome copies (gc) of scAAV9-hSMN were injected into the CNS of SMA mice. Treatment resulted in median lifespans of 153d (>800% increase compared to saline controls), 70d (>312%), and 18d (>6%), respectively. Grip strength and righting reflex tests in mice administered the two highest doses showed significant and sustained improvements in muscle strength and coordination at 14d and 175d. Analysis of the spinal cord at 14d in mice treated with 5e10, 1e10, or 1e9 gc resulted in motor neuron transduction efficiencies of 30–60%, 10–30%, and <5%, and SMN levels of 70–180%, 30–100%, and 10–20% of WT, respectively. Taken together, these data indicate that reconstituting at least 30% WT levels of SMN in 10–30% motor neurons is sufficient to improve function and survival in SMA mice, thus establishing a benchmark criteria for success in subsequent biodelivery experiments in large animal models. To this end, we performed an IT study in juvenile farm pigs to determine the feasibility of widespread gene delivery in a model whose spinal cord size and anatomy is similar to that of humans. Administration of 3e12 gc of scAAV9-eGFP showed robust vector expression in the ventral horn of the cervical, thoracic, and lumbar regions at 30 days post-injection. Importantly, double IHC staining for eGFP and ChAT showed a motor neuron transduction efficiency of 10–60% in the majority of spinal cord segments. This data confirms that a motor neuron transduction pattern predicted to be efficacious is achievable using a clinically viable delivery method, and justifies the continual development of gene therapy for SMA.

Differential response to exogenous MeCP2 in mouse models of Rett syndrome. *J. Young, V. Camarena, M. Saez, A. Abrams, K. Bayetti, A. Castle, K. Walz.* Hussman Inst Human Genomics, Univ Miami, Miami, FL.

Rett syndrome (RTT, MIM 312750) is a severe neurodevelopmental disorder that affects patient's ability to communicate, move and behave. It is one of the leading causes of mental retardation and autistic features in females, with a prevalence of 1:10–20,000 females. Clinical features of RTT include psychomotor regression, mental retardation, communication dysfunction, seizures, postural hypotonia, stereotypic hand movements, tremors, autonomic dysfunction and growth failure. The vast majority of RTT cases are caused by de novo mutations in the X-linked gene MECP2, encoding for methyl-CpG binding protein 2 (MeCP2), subject to X chromosome inactivation (XCI). MeCP2 is a nuclear protein that binds to methylated CpGs and regulates gene expression through a diverse set of mechanisms and interacting partners. Over 200 different pathogenic MECP2 mutations have been identified (see RettBASE: IRSF MECP2 Variation Database), with very different levels of incidence. Among the most frequently observed mutations are the missense mutations T158M, R133C, R306C and R106W, accounting for ~23% of genetically identified cases, and the nonsense mutations R255X and R294X that account for 11% of cases. Notably, it has been shown that the RTT-like phenotype exhibited by a Mecp2 null mouse model of the disease could be fully reversed by post-symptomatic activation of MeCP2. The majority of RTT cases, however, is caused by missense and nonsense mutations of MeCP2 rather than by deletions or other type of null mutations. Since only one allele of MeCP2 is expressed in a given cell (due to X chromosome inactivation or hemizygosity), these non-null mutant versions of MeCP2 cannot have autologous dominant negative activities. However, the possibility of mutant versions of MeCP2 exerting dominant negative effects upon purposefully expressed wild type MeCP2 cannot be excluded so far. We here report the use of a non-null mouse model of RTT to determine the phenotypic response of transgenic restoration of MeCP2. We compared the ability of exogenous MeCP2 to prevent the development of RTT-like phenotypes in Mecp2 null versus a MeCP2 truncated mouse models of RTT. Contrary to the transgenic prevention observed in Mecp2 null mice, mice carrying a truncated version of MeCP2 develop RTT-like phenotypic features regardless of the presence of a functional copy of MeCP2. These results suggest that the mutated MeCP2 interferes with the activities of the rescuing MeCP2 protein.

Preclinical Trial of Trauma-induced Osteoarthritis Therapy by Overexpressing Matrix Protein and Reducing Inflammation by Gene-transfer. *M.ZC. Ruan, K. Guse, A. Erez, B.C. Dawson, Y. Chen, B. Lee.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Osteoarthritis (OA) is a chronic debilitating disease characterized by degeneration of articular cartilage, subchondral bone, and intraatricular inflammation. To date, different treatment approaches have resulted in limited success due to the complex genetics and environmental interactions in the development of the disease. Here, we report novel effective gene transfer as treatment for mice with trauma-induced OA by cartilage matrix preservation and decreased inflammation. *Proteoglycan 4*, (*PRG4*), is one of the few genes known to be associated with OA and its loss of function mutation results in early onset OA in humans presented in Camptodactyly-Arthropathy-Coxa Vara-Pericarditis syndrome (CACP). PRG4 knockout mice also develop early OA. In addition, interleukin 1 receptor antagonist (*Il1ra*) has been shown in several studies to alleviate OA in different models. Hence, we hypothesized that gene transfer of *Prg4* and *Il1ra* to the intra-articular space would be beneficial in OA. To test our hypothesis, we generated a transgenic mouse over-expressing *Prg4* under the cartilage-specific promoter, *collagen 2a1* (*Col2a1*). Using a modified surgical OA model, involving cruciate ligament transection, we recapitulated the post-traumatic human OA in a mouse model. Our results show that PRG4 transgenic mice are protected against the development of OA as compared to WT mice. Moreover, to evaluate the potential synergistic therapeutic effects of PRG4 and IL1Ra, we injected helper-dependent adenoviral vectors expressing PRG4 (HDAd-PRG4) and IL1Ra (HDAd-IL1Ra) separately or in conjunction to wild type mice after induction of post-traumatic OA. Injections of either HDAd-PRG4 or HDAd-IL1Ra, resulted in a protective effect against OA while co-injection of the both had a positive synergistic protective effect. These data suggest that this combinatorial treatment may be effective in prevention and/or treatment of OA. In summary, we identified *PRG4* as a novel target for OA chondroprotection. The successful gene delivery of *PRG4* and *IL1Ra* using HDAd could potentially have therapeutic implications for OA.

Towards lentiviral gene therapy for the treatment of MNGIE. *R. De Coo[1], M. Stok[2], R. Yadak[2], H. Smeets[3], N. Van Til[2], G. Wagemaker[2].* 1) Dept Child Neurology & Neurology, Erasmus MC Rotterdam, Rotterdam, The Netherlands; 2) Dept of Hematology, Erasmus MC, Rotterdam, The Netherlands; 3) Dept of Clinical Genomics, Maastricht University Medical Center, Maastricht, The Netherlands.

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is caused by mutations in the TYMP gene, encoding the enzyme thymidine phosphorylase (TYMP) resulting in elevated levels of the substrates thymidine (Thd) and deoxyuridine (dUrd). Due to the imbalance in the nucleotide pool, the mitochondrial DNA (mtDNA) pool becomes instable and leads to mitochondrial dysfunction. The disease is characterized by progressive gastrointestinal dysmotility, cachexia, ptosis, peripheral neuropathy and leukencephalopathy and may cause death between early to mid-adulthood with an unpredictable start of initial symptoms, but it usually starts between the first and fifth decade. Several attempts have been made to reduce the circulating nucleosides, including hemodialysis, and platelet infusions. Recently, an allogeneic hematopoietic stem cell transplantation (HSCT) trial showed elevated TYMP activity with reduction or complete disappearance of the plasma substrates. The longterm clinical benefit of this treatment needs further evaluation. The risks of transplant related morbidity and mortality due to the conditioning regimen and adverse immune reactions are observed with allogeneic HSCT. The use of autologous HSC, genetically modified to produce normal TYMP, would eliminate those risks, and has, in addition, the intrinsic advantage to induce immune tolerance to the recombinant transgene product. The study entails development of ex vivo gene therapy of the patients' own HSC, transplanted following nonmyeloablative conditioning to achieve partial chimerism with the majority of the hematopoietic system untouched. This would result in perpetual production of TYMP by descendants of the transduced stem cells. Proof-of-principle has been obtained in the disease-specific mouse model by our collaborators. With the use of self-inactivating (SIN) lentiviral (LV) vectors we will deliver an human TYMP gene into HSCs. We will establish an optimized protocol to develop a safe and efficient therapy, with a minimum integrations per HSC. The method will be validated in human patient cells and in a MNGIE mouse model. First results will be demonstrated.

797W

Directing miRNA-regulatory PNAs to breast cancer cells with synthetic targeting peptides. *Y.-Y. Jin[1], C.-P. Chen[1], M.L. Thakur[2,3], E. Wickstrom[1,3].* 1) Biochemistry & Molecular Biology, Thomas Jefferson University, Philadelphia, PA; 2) Radiology, Thomas Jefferson University, Philadelphia, PA; 3) Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA.

Breast cancer, one of the leading causes of cancer death worldwide, must be treated by drugs with multiple activities due to its complex nature. microRNAs (miRNAs) are small non-coding RNAs that regulate many cellular activities. Multiple lines of evidence have suggested miRNAs being disregulated in cancer. Overexpressed oncogenic miRNAs, such as miR-21 and miR-17, are being studied intensively as targets for breast cancer therapeutics. miR-21 inhibits the translation of PDCD4, TPM1, maspin and PTEN mRNAs. miR-17 suppresses the translation of anti-proliferative p21 as well as proapoptotic BIM and PTEN mRNAs. Knockdown of elevated microRNAs such as miR-21 and miR-17 by a systemic drug that targets breast cancer cells specifically would offer a novel therapy for disseminated drug-resistant disease. Most breast cancer cells overexpress insulin-like growth factor 1 (IGF1) receptor. We have validated 95±0.79% knockdown of endogenous miR-21 in MCF7 cells and 98±0.51% knockdown of endogenous miR-17 in MDA-MB-231 cells using a complementary locked nucleic acid (LNA) inhibitor. But LNA required lipofection, contraindicated for systemic delivery. We hypothesize that reducing miR-21 or miR-17 activity by delivering a sequence-specific peptide nucleic acid (PNA) knockdown agent conjugated to a C-terminal IGF1 analog to enable receptor-mediated endocytosis into breast cancer cells will reduce cell proliferation, invasion and metastasis. Uptake and functional studies of PNA-IGF1 analog vs. PNA and peptide mismatch controls are underway. The effect of PNA-IGF1 analogs on miRNA activity following treatment will be measured by luciferase reporter vectors containing putative 3'UTR target sites of miR-21 and miR-17. The expression levels of suppressor proteins targeted by miR-21 and miR-17 in breast cancer cells following treatment will be compared to those in cells treated with control sequences. Changes in breast cancer cell proliferation, migration, microfilament organization, and survival will be analyzed in cells treated with PNA-peptides, vs. mismatch controls. Supported by NIH 1 R44 CA136306 and CA148565.

Effective inhibition of human cytomegalovirus gene expression and lytic replication by DNA-based external guide sequence. *H. Li, X. Jia, L. Sun, T. Zhou, Z. Deng.* Dept. Biotechnology, Jinan University, Guangzhou, Guangdong, China.

External guide sequences (EGSs), which are RNA molecules derived from natural tRNAs, bind to a target mRNA and render the mRNA susceptible to hydrolysis by RNase P, a tRNA processing enzyme. Unlike other strategies, such as antisense oligonucleotides, ribozymes, and RNA interference, the RNase P-based technology is unique because a custom-designed EGS molecule can bind to any complementary mRNA sequence and recruit intracellular RNase P for specific degradation of the target mRNA. In this study, we demonstrate that the DNA-based EGS is effective in blocking gene expression and lytic replication of human cytomegalovirus(HCMV), a leading cause of retinitis-associated blindness and other debilitating conditions such as pneumonia and enteritis among AIDS patients, and mental and behavioral dysfunctions in children that were infected in utero. We constructed DNA-based EGS molecules that target the mRNA encoding HCMV DNA polymerase, and we administered them directly to human foreskin fibroblast cells infected with HCMV. A reduction of 79% in DNA polymerase expression and a reduction of approximately 77% in viral replication were observed in cells treated with a functional EGS. Our study provides direct evidence that DNA-based EGSs are highly effective in inhibiting HCMV gene expression and lytic replication. Exogenous administration of chemically synthesized DNA-based EGSs in inducing RNase P-mediated cleavage represents an approach for inhibiting specific gene expression and for treating human diseases, including HCMV-associated diseases.

Oncogenic *EGFR* allele specific inhibition by RNA interference for cancer therapy lacking adverse effects. *M. Takahashi[1], T. Chiyo[2], T. Okada[2], H. Hohjoh[1].* 1) Dept of Molecular Pharmacology, Nat Inst of Neurosci, NCNP, Kodaira, Tokyo, Japan; 2) Dept of Molecular Therapy, Nat Inst of Neurosci, NCNP, Kodaira, Tokyo, Japan.

Anti-cancer medication without adverse effects is an ideal cancer therapy, and the development of inhibitors specific for oncogene products may lead to the achievement of such a treatment. In this study, we showed that oncogenic *epidermal growth factor receptor* (*EGFR*) allele specific inhibition by RNA interference (RNAi) allowed for suppression of human lung cancer cells carrying the oncogenic alleles, but did not affect normal cells, both *in vitro* and *in vivo*. We designed siRNAs against two recurrent oncogenic EGFR deletions found in non-small cell lung cancer (NSCLC), and selected competent siRNAs that conferred effective allele-specific silencing against the oncogenic alleles by using our original assay system. Oncogenic allele-specific RNAi (ASP-RNAi) using the siRNAs resulted in a significant inhibition of proliferation of cancer cells carrying the target oncogenic alleles and induction of their cell death, even though cancer cells were less sensitive to conventional anti-cancer medicines (gefitinib and erlotinib). We further proved anti-cancer activities of the siRNAs with two types of tumor models (subcutaneous and lung tumors) in mice: local and systemic administrations of the siRNAs clearly suppressed subcutaneous and lung tumors, respectively. We also checked several toxicological and immune parameters in the treated mice. In addition to the above observations, systemic administration of siRNA targeting wild-type *EGFR* to normal mice resulted in a significant elevation of plasma alkaline phosphatase (ALP) level and increase in intestinal apoptosis in the treated mice; these results indicated adverse effects caused by the suppression of wild-type (normal) alleles. Taken together, our current study indicated that ASP-RNAi treatment of mutant *EGFR* may become a promising anticancer treatment lacking adverse effects, and be also available for treatment of cancers resistant to conventional anti-cancer drugs.

Remission induction of spinocerebellar ataxia 6 by systems therapy with medicinal herbs. *T. Okabe.* Dept Integrated Trad Med, Univ Tokoy, Tokyo, Japan.

Spinocerebellar ataxia 6 (SCA6) is an autosomal dominant cerebellar ataxia associated with small polyglutamine-dependent expansions in the alpha 1A-voltage calcium channel. At present, we have no effective therapeutic tools. We report here treatments of six cases of spinocerebellar ataxia 6(SCA6)with mixtures of traditional medicinal herbs. Genetic tests revealed expanded allele of 22~25 CAG repeats at the spinocerebellar ataxia type 6 locus. Head MRI revealed a typical atrophic image in cerebellum. For the systems therapy with medicinal herbs, the differential diagnosis by traditional herbal medicine was made according to the guideline. Mixtures of 18~26 medicinal herbs were given according to the differential diagnosis in each patient. The remedies used for the cases consist of several different ingredients, which have well-established histories of use for treatment of vertigo, tremor, or ataxia and are expected to exert their specific effects. The ingredients include sedative, anticonvulsive, neuroprotective, neuroregulatory and DNA binding herbs. The 100-point semiquantitative International Cooperative Ataxia Rating Scales (ICARS) scores were evaluated before and after the herbal therapy. In 5 of 6 cases, most of the symptoms were significantly improved in 30~ 60 days of herbal treatment. 34~85% reduction were obtained on the 100-point semiquantitative International Cooperative Ataxia Rating Scales (ICARS) scores. While slight improvements in ataxia or speech disturbance were observed, marked reduction in ICARS scores was not attained in a wheelchiared-bound patient. While discontinuation of the herbal therapy caused a relapse, marked symptomatic improvements were obtained again by repeating the herbal treatment. The results imply therapeutic potentials of the medicinal herbs for spinocerebellar ataxia 6. Further extensive investigations are required to clarify the mechanisms by which the remission induction of this genetic disease of CAG repeat expansion mutation, has been attained with the medicinal herbs.

Disease Progression in MPS IIIA (Sanfilippo Syndrome Type A) is Associated with Genotype and Age at Diagnosis. *C.B. Whitley[1], I. Nestrasil[1], K. Delaney[1], R. Cooksley[1], P. Haslett[2], C. Richard[2], E. Shapiro[1].* 1) Gene Therapy Ctr, Univ Minnesota, MMC 446, Minneapolis, MN; 2) Shire Human Genetic Therapies, Lexington, MA.

Sanfilippo syndrome type A (MPS IIIA) is an autosomal recessive disorder resulting from deficiency of N-sulphoglucosamine sulphohydrolase (SGSH) which degrades heparan sulfate. SGSH is localized to 17q25.3 and more than 68 mutations have been described. We hypothesize that genotype, age at diagnosis (a proxy for severity), and age at evaluation are associated with disease progression, measured as decrement of neurocognitive function and grey matter volume over the course of one year. Methods: Longitudinal cognitive and quantitative MRI data were collected for 24 children with documented Sanfilippo A syndrome in an ongoing natural history study (NCT01047306). Volumetric analysis obtained by automated segmentation, and cognitive developmental quotient (DQ) were assessed. Phenotypic severity was categorized by age at diagnosis (before/after age six). SGSH mutations were determined in 24 affected children (including 6 sibling pairs). Results: Within the 38 alleles, 7 novel mutations were revealed for which there was no prior knowledge of the associated phenotypic severity. Patients diagnosed before age 6, with both alleles containing mutations known to be associated with severe phenotype, had larger decrements in both cognitive and grey matter measures over one year in comparison to those with either one known severe mutation and one novel mutation or two novel mutations. Those diagnosed after age six (with mutations known to be associated with attenuated disease or novel mutations) showed little decrement in cognition or grey matter. For the entire group, age at evaluation was also significantly associated with declines in cognition and grey matter volume ($p<.01$) such that younger patients showed larger decrements. Conclusions: We conclude that severe genotype, younger age at evaluation and earlier diagnosis are associated with more rapid disease progression.

Therapeutic efficacy of D-penicillamine encapsulated alginate/chitosan nanoparticles in rat model of copper toxicity with neurobehavioral impairments. *R. Prasad[1], A. Pal[1], S. Attri[2], B. Thappa[3], R. Vasishta[4].* 1) Biochemistry, PGIMER, Chandigarh, India; 2) APC, PGIMER, Chandigarh, India; 3) Gastroenterology, PGIMER, Chandigarh, India; 4) Histopathology, PGIMER, Chandigarh, India.

Animal models of Wilson's disease (WD) viz. Long evans cinnamon rats, rarely exhibit neurological symptoms impeding the development of novel therapeutic approaches to treat neurological manifestationsin WD patients. The aim of this study was to (1) especially on copper and zinc levels in liver, kidney & brain tissues; expression of hepatic metallothionein-I (MT-I) and Atp7b gene, and MT-III and acetylcholine esterase (AChE) gene in brain, biochemical parameters, and neurobehavioral functions of male Wistar rats, and(2) therapeutic evaluation of orally administered D-penicillamine encapsulated alginate/chitosan nanoparticles for 90 days on Cu intoxicated Wistar rats. Reverse transcription-PCR and Morris water maze test were used for expression and neurobehavioral studies. Copper intoxicated animals showed significantly increased ceruloplasmin, serum & urine copper levels and decreased serum acetyl choline esterase (AChE) activity, increased expression of hepatic MT-I gene with impaired neuromuscular coordination andspatial memory. However, no changes were observed on the expression levels of hepatic Atp7b gene, and MT-III and AChE gene in brain. Cu intoxicated rats revealed asignificantincrease in the liver, brain and kidney tissuescopper content (117, 3.7 and 4 times respectively) and interestingly, increased brain zinc content (4.4 times). Histopathological studies demonstrated copper deposition in the liver and brain tissues and, copper associated proteins in liver tissues of test rats by rhodanine and orcein stains respectively. Nanoparticles based therapy resulted in significant reduction of liver and brain Cu content, serum ceruloplasmin level & increase in serum AChE activity with improvement in neurological functions.In conclusion, chronic copper toxicity may lead to increased copper content in liver & brain, increased hepatic MT-I gene expression, ceruloplasmin levels and, neurobehavioral impairments may be by interfering in acetylcholine modulated neurotransmission; however, D-penicillamine encapsulatednanoparticles may reverseimpairments caused by chronic Cu intoxication to a significant extentin Wistar rats.

High-efficiency gene correction of a Parkinson's disease associated LRRK2 gene variant in patient-derived iPS cells. *B. Schuele[1], J. Laganiere[2], S.K. Mak[1], B.J. Vu[2], M. Vangipuram[1], Y.A. Huang[1], D.E. Paschon[2], O. Macaranas[1], A. Flierl[1], R. Sundararajan[1], P.D. Gregory[2], F.D. Urnov[2], J.W. Langston[1], H.S. Zhang[2].* 1) Parkinson's Institute, Sunnyvale, CA; 2) Sangamo BioSciences, Inc., Richmond, CA.

Correction of disease-causing genetic variants from patient-derived iPS cells offers the opportunity to study such variants in an isogenic setting, to model complex diseases in a cell culture dish, and may also lead to potentially curative autologous cellular transplants. Our goal was to develop a highly efficient genome editing process based on zinc finger nucleases (ZFNs) that would require no enrichment of transfected cells (i.e. no cell sorting or drug-based selection), and that could be scaled to 96-well format without a significant increase in labor. As a model locus, we focused on the most common PD mutation in the LRRK2 gene, a single-base G->A transition that results in a missense substitution of the glycine at position 2019 for a serine. We co-delivered the ZFNs targeted to this location along with a corrective donor construct (aimed at restoring the wt LRRK2 sequence) to patient-derived iPSCs, immediately performed limiting dilution in the absence of selection, and then performed target locus genotyping using nested-PCR. Remarkably, in 64 out of 81 analyzed single-cell-derived clones, an unprecedented 77% of clones carried a ZFN edited allele at the endogenous LRRK2 locus. As expected, given the prevalence of non-homologous end-joining over the homology-directed repair pathways in human cells, a majority (67%) of the clones carried a small insertion or deletion at the target locus, either in homozygous or heterozygous form. Of significant note, 14 clones (19%) carried an endogenous allele of LRRK2 that had been corrected from the mutant to the wild-type form of the gene via homologous recombination with the corrective donor DNA, again without selection for this event. Importantly, all characterized ZFN-modified iPSC clones exhibited a normal karyotype, expressed pluripotency markers (including a demethylated Oct 4 promoter), and remained multipotent as evidenced by their differentiated into all three germ layers. Taken together our data demonstrate that the method described here permits the selection-free, sorting-free isolation of iPSCs carrying novel investigator-specified alleles at an unprecedented frequency.

Inhibition of CTR1 by antisense oligonucleotides in mouse model for Wilson disease reduces copper accumulation and improves liver pathology. *T.R Grossman, P. Lincoln, M. McCaleb.* ISIS PHARMACEUTICALS, Carlsbad, CA.

Wilson disease (WD) is an autosomal recessive genetic disorder of copper accumulation in liver, brain, kidney and cornea. Wilson disease gene ATP7B encodes a transmembrane protein ATPase which functions as a copper-dependent P-type ATPase responsible for incorporation of copper to ceruloplasmin and secreting access of copper to the bile. Clinical manifestations include hepatic disease ranging from mild hepatitis to acute liver failure or cirrhosis and neurological symptoms. WD is fatal if untreated and early recognition by means of clinical, biochemical or genetic examination and initiation of therapy with copper chelators, zinc salts or even liver transplantation in cases of acute and chronic liver failure are essential for favorable outcome. The current treatments are lifelong with severe side effects such as neurological deterioration, hypersensitivity syndrome and bone marrow depression. The high affinity copper transporter CTR1 plays a critical role in copper acquisition in the liver. Our therapeutic objective is to slow the progression of liver damage in WD by reducing the level of copper in the liver by antisense oligonucleotides (ASO) to CTR1. We developed a specific and highly efficacious ASO targeting mouse CTR1 and as a proof of concept we treated toxic milk mice with CTR1 ASO for 6 weeks. The toxic milk mouse is the commonly used mouse model for WD characterized by a gradual accumulation of hepatic copper. Analysis of liver samples from toxic milk mice treated with CTR1 ASO showed 53±1.3% reduction in CTR1 mRNA level of in liver, 45.6±2.1%; in the kidney and 54.1±2.9%; in the intestine which resulted in a dramatic reduction of liver copper level determined by MS ICP (1045±50.5 ppm in untreated compared to 327±68 ppm treated with CTR1 ASO). Moreover, animals treated with CTR1 ASO showed an improved liver pathology when compared with mice treated with control ASO or vehicle only. The hepatocyte karyomegaly, glycogenated nuclei and microvesicular changes were significantly improved with treatment. Based on our results we suggest that inhibition of hepatic CTR1 by ASO could be considered as a novel therapeutic strategy for Wilson disease patients.

Genome wide identification of human cardiac developmental genes located within regions associated with congenital heart disease. *K.D. Ajbro[1], T.A. Andersen[1], M. Bak[1], J.A. Rosenfeld[2], K. Møllgård[3], S.C. Eliasson[4], R.R. Jakobsen[1], E. Bendsen[5], N. Tommerup[1], L.G. Schaffer[2], K. Lage[4,6,7,8], I.A. Larsen[1]*. 1) Wilhelm Johannsen Centre for Functional Genome Research, Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark; 2) Signature Genomic Laboratories, Spokane, WA; 3) Developmental Biology Unit, Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark; 4) Center for Protein Research, University of Copenhagen, Copenhagen, Denmark; 5) Fertility Clinic, Department of Obstetrics and Gynaecology, University Hospital of Odense, Odense, Denmark; 6) Pediatric Surgical Research Laboratory, Massachusetts General Hospital, Boston, MA; 7) Harvard Medical School, Boston, MA; 8) Broad Institute, Boston, MA.

Congenital heart defects (CHD) are the most common congenital malformations in newborns and are a major cause of infant morbidity and mortality. Despite many genetic studies, only a fraction of the genetic mechanisms behind normal and abnormal heart development has been elucidated. To identify novel candidate loci and genes in CHD, we constructed a morbid map of CHD by determination of the overlap between copy number variants (CNVs) identified in patients with CHD. This map was compiled from 896 published and unpublished CNVs. To find connections between dosage sensitive genes in CHD and transcriptional programs during normal human heart development, we generated whole genome expression profiles from a time series of human embryonic and fetal hearts from day 41 to 68 post fertilization. Differentially expressed genes were identified using student's T-test. The set of differentially expressed genes was enriched for genes encoding sarcomeric proteins and genes known to cause heart defects when deleted in mice. The two datasets were analyzed for overlap and we identified 36 candidate genes, which are differentially expressed during heart development and positioned in a candidate locus determined by three or more overlapping CNVs. We examined the spatial and temporal protein expression pattern for selected candidate genes by immunohistochemical analysis of human embryonic hearts, and identified strong and regionally distinct protein expression patterns. In summary our data show, that CHD candidate disease genes can be identified, by combining large datasets of patient CNVs with expression profiles from human developing hearts.

Voltage-gated sodium channels are required for proliferation of embryonic myocardium in zebrafish. *J. Bennett[1], D. Stroud[2], J. Becker[2], D. Roden[1,2,3]*. 1) Center for Human Genetics, Vanderbilt University School of Medicine, Nashville, TN; 2) Department of Medicine, Vanderbilt University School of Medicine, Nashville, TN; 3) Department of Pharmacology, Vanderbilt University School of Medicine, Nashville, TN.

In mice, homozygous deletion of the predominant cardiac sodium channel *Scn5a* results in embryonic lethality at day 10.5, before robust sodium current can be detected. These mice exhibit defects in cardiac morphology, including reduced ventricle size and diminished trabeculation. In zebrafish, we have previously shown that morpholino knockdown of cardiac sodium channel orthologs *scn5Laa* and *scn5Lab* perturbs specification of pre-cardiac mesoderm through reduced *nkx2.5* expression, impairs concentric thickening of the ventricular myocardium and inhibits looping and growth of the embryonic heart. However, it is not known which developmental processes are perturbed by sodium channel knockdown and whether sodium channel knockdown reduces cell number by altering migration of cardiac progenitors into the heart, myocyte proliferation, or both.

We assayed expression of cardiac-specific genes at early stages of development by in situ hybridization. To address secondary differentiation later in development, we conducted studies in Tg(*cmlc2:Kaede*) fish we generated. Primary cardiomyocytes were marked using photoconversion of Kaede protein, and late-differentiating cardiomyocyte (non-photoconverted) were counted. Embryos deficient in the ortholog *scn5Lab* showed defects in primary cardiogenesis specific to loss of *nkx2.5*. Despite this impaired early specification of pre-cardiac mesoderm, embryos treated with anti-*scn5Lab* morpholino showed normal secondary differentiation of cardiomyocytes at the venous and arterial poles between 30 and 48 hpf. However, these embryos had significantly reduced myocardial proliferation (3.6±0.7 vs 0.7±0.4 BrdU-positive cardiomyocytes, n= 6–11) at 48 hpf, resulting in reduced chamber size and thin ventricular walls. The results suggest that while voltage-gated sodium channels are required for primary cardiac specification and later cardiac growth, they are not required for differentiation of the mesenchymal field of cardiac progenitors between 24 and 48 hours post-fertilization. The channel encoded by *scn5Lab*, either through participation in a developmental pathway or as an integral component of the structure and physiology of the cardiomyocyte, is required for normal proliferation of myocardium and growth of the embryonic heart.

807F

Modeling Early Heart Development in Down Syndrome using Sibling hESC Lines. *A. Bosman[1], A. Letourneau[1], M. Zuchelli[2], V. Tohonen[2], O. Hovatta[2], S.E. Antonarakis[1], M.E. Jaconi[1]*. 1) University of Geneva, Geneva, Geneva, Switzerland; 2) Karolinska Instituet, Sweden.

Human embryonic stem cells (hESC) carrying known diseases provide excellent models for examining the cellular consequences of a disease from the earliest time in development. Due to differing genetic backgrounds, however, hESC lines are known to display intrinsic differences in their differentiation capacities and epigenetic patterns. These genetic differences result in significant differences upon differentiation, thus making it difficult to detect small variations between diseased and control lines. Using a hESC sibling model of disease provides a more sensitive approach to detecting small variations due to greater genetic similarity. In this study, we have isolated and characterized a trisomy 21 (T21) hESC model of Down syndrome (DS) using sibling hESC lines as controls. As congenital heart defects (CHD) are the leading cause of morbidity DS, we examined the genetic pathways associated with cardiogenesis to ascertain perturbations in development which may lead to CHD. Upon differentiation, T21-hESC show many significant differences in expression of genes associated with both mesodermal and cardiac development, which is particularly evident with genes associated to the secondary heart field (SHF). Additionally, genes of the T-box transcription factor family were found to be significantly over-expressed in T21-hESC. Some of these perturbations also coincide with known causative genes for CHD observed in the general population. Furthermore, we identified at least one gene located on chromosome 21 which may account for some of these perturbations. Therefore, our work shows for the first time, that T21-hESC and their sibling control lines are a useful model facilitating the identification of differentially expressed genes associated with early cardiogenesis, which may underlie the cause of CHD observed in DS.

808F

***Ofd1* controls dorso-ventral patterning and axoneme elongation during embryonic brain development.** *A. de Angelis[1], A. D'Angelo[1], B. Avallone[2], I. Piscopo[1], R. Tammaro[1], M. Studer[1], B. Franco[1,3]*. 1) Telethon Institute of Genetics and Medicine, Italy; 2) Department of Biological Science, University of Naples “Federico II”, Naples (Italy); 3) Medical Genetics, Department of Pediatrics, Federico II University, Naples, Italy.

Oral-facial-digital type I syndrome (OFDI) is a human X-linked dominant-male-lethal developmental disorder caused by mutations in the OFD1 gene. Similar to other inherited disorders associated to ciliary dysfunction OFD type I patients display neurological abnormalities. We characterized the neuronal phenotype that results from *Ofd1* inactivation in early phases of mouse embryonic development and at post-natal stages. We determined that *Ofd1* plays a crucial role in forebrain development, and, in particular in the control of dorso-ventral patterning and early corticogenesis. We observed abnormal activation of Sonic hedgehog (Shh), a major pathway modulating brain development. Ultrastructural studies demonstrated that early *Ofd1* inactivation results in the absence of ciliary axonemes despite the presence of mature basal bodies that are correctly orientated and docked. *Ofd1* inducible-mediated inactivation at birth does not affect ciliogenesis in the cortex suggesting a developmental stage-dependent role for a basal body protein in ciliogenesis. Moreover, we showed defects in cytoskeletal organization and apical-basal polarity in *Ofd1* mutant embryos, most likely due to lack of ciliary axonemes. Thus, the present study identifies Ofd1 as a developmental disease gene that is critical for forebrain development and ciliogenesis in embryonic life, and indicates that Ofd1 functions after docking and before elaboration of the axoneme *in vivo*.

Exome sequencing identifies a single mutation in the *CCDC114* gene as the cause for Primary Ciliary Dyskinesia in the Volendam population. *A. Onoufriadis[1], T. Paff[2], D. Anthony[1], A. Shoemark[3], D. Micha[2], B. Kuit[2], M. Schmidts[1], S. Petridi[1], R. Wilson[4], C. Hogg[3], R. Emes[5],. UK10K[6], EMK. Chung[7], G. Pals[2], HM. Mitchison[1].* 1) Molecular Medicine Unit and Birth Defects Research Centre, University College London (UCL) Institute of Child Health, London, United Kingdom; 2) Department of Clinical Genetics, VU University Medical Center, Amsterdam, The Netherlands; 3) Department of Paediatric Respiratory Medicine, Royal Brompton and Harefield NHS Trust, London, UK; 4) Respiratory Medicine, Royal Brompton and Harefield NHS Trust, London, UK; 5) School of Veterinary Medicine and Science, University of Nottingham, Leicestershire, UK; 6) uk10k.org.uk; 7) General and Adolescent Paediatric Unit, University College London (UCL) Institute of Child Health, London, UK.

Primary ciliary dyskinesia (PCD) is heterogeneous genetic disorder arising from ultrastructural defects that cause abnormal function of motile cilia and flagella. The disease manifests with an autosomal recessive mode of inheritance, affecting 1 in every 15,000–30,000 births. Abnormal motility leads to a number of symptoms including chronic respiratory disease, otitis media, subfertility and situs abnormalities. So far, genetic defects in 14 genes have been associated with PCD including *DNAH5*, *DNAH11*, *DNAI1*, *DNAI2*, *DNAL1* and *TXNDC3* that encode subunits of the axonemal outer dynein arm motor structures responsible for ciliary beating. To identify the genetic defect underlying PCD in the Volendam population we whole exome-sequenced two distantly related affected individuals of an extended pedigree as part of the UK10K project. Since the Volendam population is isolated and one affected case was the offspring of a consanguineous marriage, we followed a model of rare autosomal recessive inheritance. Only protein altering variants with an estimated population frequency of <0.01 were considered as candidate pathogenic mutations. This analysis revealed *CCDC114* as the only gene harbouring low-frequency variants that were compatible with recessive inheritance. *CCDC114* is the human homolog of the biflagellate *Chlamydomonas DC2* gene, which encodes an outer dynein arm docking complex subunit. Both affected individuals were homozygous for a c.742G>A substitution (p.A248fs50*), which is predicted to result in the loss of a donor splice site leading to premature termination of the CCDC114 protein product. The same variant was observed segregating in seven additional pedigrees from the Volendam population, affecting a total of 16 patients. Transmission electron microscopy and immunofluorescence of respiratory cilia cross-sections from an affected individual showed loss of outer dynein arms. In summary, our data suggest that a single mutation in the *CCDC114* gene underlies all PCD cases in the Volendam population, providing a high priority novel target for future therapeutic intervention.

ALDH1A3 loss of function causes bilateral anophthalmia and hypoplasia of the optic nerve and optic chiasm. *M. Yahyavi[1], A.S. De Preux Charles[2], T. Xiao[2], T. Bardakjian[3], A. Schneider[3], H. Baier[2], A. Slavotinek[1].* 1) Dept. of Pediatrics, UCSF, San Francisco, CA; 2) Dept. Physiology, UCSF, San Francisco, CA; 3) Division of Genetics, Albert Einstein Medical Center, Philadelphia, PA.

Cellular levels of the major active retinoid, all-trans retinoic acid (atRA), are controlled by a balance between enzymes involved in synthesis, (including the retinaldehyde dehydrogenases ALDH1A1, ALDH1A2 and ALDH1A3), and the enzymes involved in degradation. atRA has long been recognized as critical for the development of several organs, including the eye. Mutations in STRA6, the receptor for vitamin A, in patients with Matthew-Wood syndrome and anophthalmia/microphthalmia (A/M), have previously demonstrated the importance of retinoid metabolism in human eye disease. We used whole genome sequencing (Complete Genomics, Mountain View) to investigate patients with A/M. We studied a female born to first cousin parents who had bilateral anophthalmia with hypoplasia of the optic nerve and optic chiasm. A BAC array had shown no diagnostic chromosome aberrations and mutations in SOX2, OTX2, BMP4, CHX10, PITX2 and FOXE3 had been excluded. Analysis of more than 175 novel sequence variants revealed homozygosity for a nonsense mutation in ALDH1A3 (p.Lys389X) that was verified by Sanger sequencing and that was not present in public databases (Exome Variant Server) or in 120 control chromosomes of diverse ethnicity. Both parents were heterozygotes for the same stop mutation. Aldh1a3 is expressed in the surface ectoderm of murine eye field at E8.75 and is present in the ventral retina and optic nerve at E10.5. Mice that are homozygous null for Aldh1a3 show shortening of the ventral retina, lens rotation and persistence of the primary vitreous body. Inhibition of the Zebrafish orthologue of Aldh1a3 with citral resulted in fish with absence of the ventral retina that could be rescued by RA administration (Marsh-Armstrong 1994). Conversely, provision of atRA to murine embryos early in development can cause A/M (Sulik 1995). We performed antisense morpholino studies in zebrafish to characterize the developmental effects of transcription knock down of Aldh1a3. The treatment group showed a significant reduction in eye size and retinal ganglion cell population and aberrant axonal projections to the tectum were noted. We conclude that loss of function for Aldh1a3 can cause eye defects and disordered optic nerve development in humans and animal model systems.

Differential expression of lung function genes by *in utero* smoke exposure during human lung development. *S. Sharma[1,2], A. Kho[1], K. Haley[2], C. Vyhlidal[3], R. Gaedigk[3], L. Kobzik[4], J.S. Leeder[3], K.G. Tantisira[1,2], S.T. Weiss[1].* 1) Department of Medicine, Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, MA; 3) Children's Mercy Hospital and Clinics, Kansas City, MO; 4) Department of Pathology, Brigham and Women's Hospital, Boston, MA.

Introduction: Lung function is an independent predictor of population morbidity and mortality. In utero smoke exposure (IUS) is associated with reduced lung function resulting in increased susceptibility to chronic respiratory disease. Genome-wide association studies (GWAS) have identified multiple replicated SNPs in 39 genes associated with lung function. However, the effect of *in utero* smoke exposure on the expression of these genes is not yet known. We hypothesized that genes associated with lung function in published GWAS will be differentially expressed due to IUS during human lung development. **Methods**: Genes associated with lung function in previously published GWAS were identified through a literature search. Genome-wide gene expression profiles on 370 human fetal lung tissue samples (post-conceptional age:53–137 days) were generated on the Affymetrix Human Gene 1.0 ST Array. IUS exposure was detected using placental cotinine values, measured with competitive ELISA (Calbiotech) from placenta from the same 370 individuals. Cotinine levels that were undetectable or below the limit of quantitation of the assay (2 ng total cotinine/ml) were classified as unexposed. Detectable cotinine levels >30 ng/mg total protein were classified as having had IUS exposure. Differential gene expression between IUS exposed and unexposed fetal lung tissue was performed using linear regression models adjusted for age. **Results**: In total, 39 genes have been associated and replicated with at least one measure of lung function (FEV1,FVC, or FEV1/FVC) in previously published GWAS studies. Of the 39 genes, 22 (56%) were differentially expressed by IUS exposure in the human developing lung at a genome-wide level of significance (FDR=0.05), which was more than expected by chance alone (p=0.006). Genes that were differentially expressed by IUS were enriched for genes in the regulation of smoothened signaling and dorsal/ventral pattern formation pathways. **Conclusions**: Our results demonstrate that genes associated with lung function in the general population are differentially regulated within the developing lung by smoke exposure *in utero*. Our results suggest that the changes in gene expression that result from *in utero* smoke exposure during lung development may be a biologic basis for their association with abnormal lung function. Further investigation of these biologic mechanisms is being pursued.

The *C7orf58* locus is strongly associated with both bone mineral content and density at the pediatric distal radius. *B.S. Zemel[1,2], M. Li[3], S. Deliard[4], C.E. Kim[5], L. Qu[3], R.M. Chiavacci[5], J.M. Lappe[6], H.J. Kalkwarf[7], V. Gilsanz[8], H. Hakonarson[2,4,5], S.E. Oberfield[9], J.A. Shepherd[10], S.F.A. Grant[2,4,5]*. 1) Division of Gastroenterology, Hepatology and Nutrition, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Department of Biostatistics and Epidemiology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Division of Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 6) Osteoporosis Research Center, Creighton University, Omaha, NE; 7) Division of General and Community Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 8) Department of Radiology, Children's Hospital Los Angeles, Los Angeles, CA; 9) Division of Pediatric Endocrinology, Morgan Stanley Children's Hospital of New York, Columbia University Medical Center, New York, NY; 10) Department of Radiology and Bioimaging, University of California San Francisco, San Francisco, CA.

Osteoporosis has its origins in childhood, where bone mineral accretion during growth and development is a critical determinant of future bone health. Failure to achieve optimal bone mineral content and density (BMC and BMD respectively) during the critical period of growth results in suboptimal peak bone mass, contributing to low bone mass and osteoporosis later in life. A recently reported meta-analysis of genome wide association studies of adult BMD revealed 64 single nucleotide polymorphisms (SNPs) at 56 loci were significantly associated with the trait. We elected to leverage data from an ongoing genome wide association study of pediatric bone accretion (NIH R01 HD058886) to investigate the association of these previously reported adult bone density loci with pediatric BMC and BMD of the spine, hip and radius. Our cohort is derived from the multi-center National Institute of Child Health and Development (NICHD) Bone Mineral Density in Childhood (BMDC) Study, which was initiated in 2001 to establish national reference standards for BMD and bone accrual for children ages 6 years and older. The initial cohort of 1554 subjects (ages 6 to 16) was later enriched with an additional 452 subjects 5 and 19 years of age to further strengthen the reference data. To date, 604 of the 945 subjects from the Caucasian portion of the cohort have been both genotyped on the Illumina OMNI Express BeadChip platform and imputed for ~2.5 million SNPs, enabling us to query 59 of the 64 adult BMD SNPs in our pediatric cohort. Following Bonferroni correction for both the number of SNPs tested and the six traits tested (BMC and BMD at spine, hip and radius), there was strong evidence for association between allele A of rs13245690 at the *C7orf58* locus and reduced BMC and BMD of the distal 1/3 radius ($P = 6.96 \times 10^{-5}$; $\beta = -0.217$ and $P = 1.51 \times 10^{-4}$; $\beta = -0.224$). There was also multi-site evidence of nominal association for rs1053051 (*C12orf23*), rs17482952 (*WLS*), rs2062377 (*TNFRSF11B*), rs3755955 (*IDUA*), rs7851693 (*FUBP3*) and rs9533090 (*AKAP11*). In summary, as a consequence of analyzing a unique genome-wide genotyped dataset derived from an in-depth phenotyped pediatric cohort, we are well positioned to ascertain which loci contributing to adult BMD are operating in early life and at which skeletal site(s). As our dataset continues to grow, we will follow up these observations and also aim to uncover novel loci specific to bone accrual during childhood and adolescence.

A novel *GNAI3* gain-of-function mutation associated with auriculo-condylar syndrome in a Brazilian family. *V.L.R. Tavares[1], T.T. Torres[1], H. Buermans[3], C. Masotti[1], D.F. Bueno[1], J.A. Horst[4], R.M. Zechi-Ceide[2], M.L. Cunningham[5], M.L. Guion-Almeida[2], M.R. Passos-Bueno[1]*. 1) Human Genome Research Center, University of Sao Paulo, Sao Paulo, Brazil; 2) Department of Clinical Genetics, Hospital of Rehabilitation of Craniofacial Anomalies, University of São Paulo (HRCA-USP), Bauru, SP, Brazil; 3) Leiden University Medical Center, Leiden Genome Technology Center, Leiden, Holland; 4) Division of Pediatric Dentistry, Department of Orofacial Sciences, UCSF, San Francisco, CA, USA; 5) Craniofacial Center, Seattle Children's Research Institute, Seattle, WA, USA.

Purpose: Auriculo condylar syndrome (ACS), characterized by micrognathia, microstomia, microtia and agenesis/hypoplasia of the mandibular condyle, is an autosomal dominant disorder. We have mapped ACS1 to a large candidate region at 1p21.1-q23.3. Recently, mutations in two genes, *GNAI3* and *PLCB4* were found to be mutated in ACS. Therefore, the present study has been conducted in order to elucidate the mutational mechanism in the Brazilian ACS family linked to 1p21.1-q23.3 (ACS1). Methods: We performed exome sequencing (ES) in two ACS1 affected individuals using the Illumina HiSeq2000 platform. Sanger sequencing (SS) was used to validate our findings in 3 affected and 4 non-affected individuals belonging to our previously published family (Masotti *et al*., 2008). Given that expression of *DLX5* and *DLX6* was decreased in mandibular osteoblasts of ACS patients (Rieder *et al*., 2012), we tested their expression in RNA extracted from mesenchymal stem cell (MSC) cultures. As cartilage is compromised in the ACS1 patients, we also compared the in vitro MSC chondrogenic differentiation between an ACS1 patient and a control. Results: No pathogenic mutations were found in *PLCB4*, but we found 4 variants in *GNAI3*. Of these, only one missense mutation, p.Asn269Tyr, segregates with the disease in the family, which was found to be a conserved amino acid by multiple sequence alignment, using MUSCLE software. GNAI3 protein structure modeling of specific amino acid substitution suggests that this N269Y mutation increases the stability of a natural ligand in a specific pocket, decreasing the reliance on the molecule. No significant difference was observed for *DLX5* and *DLX6* in MSCs, and neither between patient and control during in vitro chondrogenesis. Conclusions: N269Y is a mutation found in *GNAI3*, different from that previously described. Our findings suggest that the mutation is the cause of ACS1 in this Brazilian family and it is a gain-of-function mutation. If taken together our results with those from the literature, it seems that the gain-of-function mutation in *GNAI3* does not primarily compromise cartilage differentiation. Financial Support: CEPID/FAPESP, CNPq, CAPES, MCT.

Non-syndromic cleft lip/palate: a disease driven by deficiency in genomic repair? *G.S. Kobayashi[1], L.A. Cruz[1], D.Y. Sunaga[1], D.F. Bueno[1], P. Francis-West[3], A. Kutta[3], B.V.P. Almada[1], S.G. Ferreira[1], M. Aguena[1], L.C. Andrade-Lima[2], C.F. Menck[2], M.R. Passos-Bueno[1]*. 1) Human Genome Research Center, University of Sao Paulo, Brazil; 2) Institute of Biomedical Sciences, University of Sao Paulo, Brazil; 3) Dept of Craniofacial Development & Orthodontics, King's College London, United Kingdom.

Purpose: Non-syndromic cleft lip/palate (NSCL/P) is a multifactorial disease that arises from errors during embryonic development. Although much effort has been put into identifying genetic and environmental factors underlying disease susceptibility, the aetiology of this complex malformation remains obscure. Since a tight regulation of ontogenetic mechanisms is required to ensure appropriate orofacial morphogenesis, our objective was to identify dysregulated pathways involved in the pathogenesis of NSCL/P. **Methods:** We performed a global transcriptome profiling of 7 dental pulp mesenchymal stem cell cultures from NSCL/P patients by comparison to 6 controls, using Affymetrix HuGene 1.0 ST chips. Differentially expressed genes were obtained using SAM and RankProd algorithms. Functional annotation and gene network analysis were performed with Ingenuity Pathways Analysis, while gene clustering, transcription factor and functional enrichment procedures were carried out using EXPANDER. Quantification of H_2O_2-induced DNA damage was assessed with flow cytometry for anti-γH2AX in 6 NSCL/P, 2 van der Woude syndrome (VWS), and 7 control stem cell cultures. Finally, RNA *in situ* hybridisation studies were carried out to CD1 mouse embryos at E10.5, E11.5, E12.5 and E13.5, using riboprobes for *Brca1*, *Rad51*, and *E2f1*. **Results/Conclusion:** We identified, in NSCL/P cells, a dysregulated transcriptional network associated with cell cycle progression and response to DNA damage, comprising abnormal expression of important molecules for these processes (e.g. *BRCA1*, *BRIP1*, *MSH2*, *RAD51* and *BLM*). These genes, also validated with qRT-PCR, exhibited a marked pattern of co-expression, and suggest that E2F1 may be a putative upstream regulator. By quantifying γ-H2AX in H_2O_2-exposed cells, we were able to confirm that NSCL/P cells exhibit abnormal response to DNA damage, which was also observed in IRF6-haploinsufficient (VWS) cells. *In situ* hybridisation studies revealed co-localised expression of *Brca1*, *Rad51* and *E2f1* in the facial primordia and developing palatal shelves of mouse embryos. Our results suggest that impairment of DNA damage response may be involved in the aetiology of NSCL/P and indicate that IRF6 may be functionally relevant in this process. Financial support: CEPID/FAPESP, CNPq, MCT.

Genetic characterization of osteopenia and bone overgrowth in Marfan syndrome mice. *S. Smaldone, J.R. Cook, M. Del Solar, F. Ramirez.* Pharmacology & Systems Therapeutics, Mount Sinai School of Medicine, New York, NY.

Mice under-expressing fibrillin-1 ($Fbn1^{mgR/mgR}$ mice) replicate early onset, progressively severe Marfan syndrome (MFS). Like MFS patients, 3 month-old $Fbn1^{mgR/mgR}$ mice display elongated tubular bones and reduced bone mass (osteopenia). The last phenotype was previously correlated with abnormally elevated TGFβ and BMP activity stimulating osteoblast differentiation and osteoblast-directed osteoclast activity. To circumvent the lethality of MFS mice from aortic aneurysm, a conditional Fbn1null allele ($Fbn1^{Lox}$) was inactivated in skeletal progenitor cells or osteoblast precursors by crossing $Fbn1^{Lox/-}$ mice with Prx1-Cre or Osx-Cre transgenic mice respectively. Microcomputer tomography (μCT) showed reduced bone mass in 3 months old $Fbn1^{Prx-/-}$ and $Fbn1^{Osx-/-}$ mice, and additional bone loss in 6 month-old animals $Fbn1^{Prx-/-}$ but not $Fbn1^{Osx-/-}$ mice. Colony forming unit-fibroblast (CFU-F) efficiency assays performed on marrow-derived mesenchyme stem cells (MSCs) yielded comparable numbers of CFU-Fs in 3 and 6 month-old WT and $Fbn1^{Osx-/-}$ preparations, more and fewer CFU-Fs than normal in MSCs isolated from 3 and 6 month-old $Fbn1^{Prx-/-}$ mice respectively. These findings therefore suggest that premature loss of osteoprogenitor cells exacerbates osteoclast-driven osteopenia in MFS. Similar ongoing analyses of crosses between $Fbn1^{Lox/-}$ mice and Prx1-Cre, Osx-Cre or Col2-Cre transgenic mice also indicate that limb overgrowth in MFS is a postnatal abnormality that is mostly accounted for by perturbed function of the perichondrial matrix.

Evaluating the genetic disruption of lung hypoplasia in a mouse model of CDH. *S.C. Schecter, J. Wu, D. Miniati.* University of California San Francisco, Division of Pediatric Surgery 513 Parnassus Avenue HSW-1601, Box 0570 San Francisco, CA 94143-0570.

Introduction: An exponential increase in lung branching occurs between gestational days (E) 11.5 and 13.5 in mice. Treatment of pregnant mice with the mutagen combination of nitrofen-bisdiamine (N/B) causes lung hypoplasia and diaphragm defects in the fetal mice similar to the human condition of congenital diaphragmatic hernia (CDH). We hypothesized that genetic evaluation of fetuses exposed to N/B would identify specific disrupted molecular pathways critical in CDH. Methods: Pregnant CD-1 mice were treated with N/B or vehicle at embryonic day 8.5 (E8.5). Lung buds were dissected at E11.5–13.5 for histological and RNA analysis (n=6/timepoint/group), and evaluated for presence of CDH. Mutagen treatment causes two phenotypes—with and without CDH—which were analyzed separately. RNA expression profiles were derived using the Agilent whole mouse genome 4x44K Ink-jet array and analyzed using iReport (Ingenuity Systems, Redwood City). Results: Lungs of E11.5 and E12.5 mutagen-treated pups hypoplastic mainstem bronchi, dysmorphic primary lung buds, and delayed secondary domain branching. At E13.5, 30% of N/B-treated fetuses demonstrated diaphragmatic hernias along with lung hypoplasia. Analysis of N/B-treated fetuses versus control showed 365 differentially expressed genes. Among these, 237 were up-regulated and 128 were down-regulated. 8 differentially expressed genes (DEG) associated with retinoic acid receptor (RAR) activation were identified—COUP-TFII, PRKAR2A, FOS, ADCY1, and EP300 were upregulated, and AKT1, CYP26A1, and IL3RA were down-regulated. 4 DEGs associated with the Wnt/B-catenin signaling—EP300, AKT1, WNT8B, and LRP5. Exploring differences between N/B-treated E13.5 fetuses with CDH versus without CDH revealed 53 DEGs. Ion transport channel component gene ABCA9 was down-regulated in CDH, while TGFB and Wnt/B-catenin signaling FOXH1 and APC2 were up-regulated. Conclusion: N/B-administration results in changes in gene expression. Genes associated with promotion of RAR/RXR heterodimerism are down-regulated, while COUP-TFII—which inhibits RAR/RXR function was up-regulated. Ion transport may be associated with lung hypoplasia.

817F

The role of FMRP during early steps of neurodevelopment. *B. Bardoni, L. Davidovic, B. Mari, O. Khalfallah.* IPMC, CNRS UMR 6097, Valbonne, France.

The Fragile X Syndrome (FXS) is the first cause of inherited intellectual disability (ID). Affected children often manifest hyperactive, autistic behaviour, epileptic seizures, attention deficit, sleep disorders. The disease is due to the inactivation of the *FMR1* gene leading to the loss of the corresponding protein FMRP, that is a selective RNA binding protein involved in translational control. Indeed, FMRP is associates with polyribosomes and is involved in synaptic plasticity and dendritic spines development, explaining abnormal dendritic spines that are observed in FXS patients and animal model. Recently, it has been shown that FMRP plays also a role during neurogenesis suggesting that it is involved in early steps of development. Indeed, additional abnormalities have been observed in the brain of FXS young children. Moreover, several studies showed that *Fmr1*-null embryonic neural progenitors generated an altered neuron/glia ratio. Thus, we analysed the function of FMRP during neurogenesis, starting from murine embryonic stem (ES) cells using an RNAi strategy. *Fmr1*-knock-down (KD) ES cells were characterized by a microarray analysis and a quantitative proteomic analysis. Our data suggest an early signature of Fmr1 repression and it is then remarkable that at this phase of development the effects of the reduction of FMRP expression already affect also some pathways that are deregulated in FXS mature neurons. Then, we analysed the consequence of the repression of FMRP during the differentiation of ES cells into neural progenitors (NP), then into cells of the central nervous system (neurons and glial cells). NP and neurons derived from *Fmr1*-KD cells show an increased level of cell death, compared to NP obtained from *Fmr1*-WT cells and we observed that the expression of nestin is strongly reduced in Fmr1-KD NP compared with *Fmr1*-WT NP suggesting a delay or a switch in the differentiation of ES Fmr1-KD cells. Thus, these results strongly support the fact that the molecular alterations observed in ES cells have an impact on their differentiation into NP and neurons. Finally, we were able to rescue the apoptotic phenotype by treating *Fmr1*-KD cells with several drugs, interestingly some of these bio-active molecules are known to be able to rescue hallmarks characterizing the phenotype of the *Fmr1*-null mouse.

818F

[cf4]rbm24a[cf1] and *rbm24b* are required for normal somitogenesis and craniofacial development and are essential for Notch signaling.[cf1] *S. Maragh[1,2], R.A. Miller[2], S.L. Bessling[2], W. Huang[2], M.J. Parsons[2], A.S. McCallion[2,3].* 1) Biochemical Science Division, National Institute of Standards and Technology, Gaithersburg, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Molecular and Comparative Pathobiology, Johns Hopkins University School of Medicine, Baltimore MD.

We recently identified the *RNA binding motif protein 24* (*Rbm24*) as a novel gene expressed during mouse cardiogenesis, and evaluated its developmental role in zebrafish cardiac development (orthologs *rbm24a* and *rbm24b*). Morpholino-based reduction of either ortholog by morpholino antisense oligonucleotides resulted in cardiogenic defects, reduced circulation, as well as defects in vasculogenesis and early angiogenesis. We have now demonstrated that both *rbm24* genes are expressed in the forming somites and are also expressed later in developing craniofacial structures. Consistent with these observations these orthologs are also required for normal somite and craniofacial development. All morpholino-induced dysmorphic phenotypes are rescued with target mRNA. We then investigated the possible function played by Rbm in Sonic hedgehog (SHH), Bone morphongenesis protein (BMP) and Notch developmental pathways. Notch-signaling initiation and maintenance is strongly reduced, but we have not observed any evidence of SHH or BMP pathway disruption. Characterization of spatial and temporal expression of components of the Notch-pathway via whole mount *in situ* hybridization on *rbm24* morpholino injected embryos indicates there is reduced expression of genes encoding Notch-ligands; namely, *deltaC*, *deltaD* and *dll4*. Subsequently, the expression of Notch-signaling target genes *her1*, *her7* and *hey2* was also suppressed. Expression of *deltaC* and d*eltaD* is required for somite patterning, while *dll4* is required for proper cardiovascular development. Consistent with these observations *hey1*, which is expressed in somites during somitogenesis and later required for craniofacial cartilage patterning, is also reduced in expression. By contrast relative expression of the Notch-receptors is not altered. Taken together these data indicate a previously unknown requirement of *rbm24a* and *rbm24b* for normal cardiovascular, somite and craniofacial development and support the hypothesis these genes play a role in proper expression of Notch pathway ligands. The *RBM24* ortholog in *C. elegans* is known to be involved in splicing. Our ongoing studies will continue to on focus the potential mechanism of action that may connect this critical pathway (Notch) with RBM24.

Kabuki Syndrome: Functional analysis of *MLL2* and *KDM6A* in Vertebrate Development. *P. Van Laarhoven[1], L. Neitzel[1], E.A. Geiger[1], E.H. Zackai[2], K.B. Artinger[3,4], J.E. Ming[2], T.H. Shaikh[1,3]*. 1) Section of Clinical Genetics and Metabolism, Department of Pediatrics, University of Colorado School of Medicine, Aurora, CO; 2) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Molecular Pharmacology and Therapeutics and Center for Biomedical Informatics, Loyola University Chicago Stritch School of Medicine, Maywood, IL; 4) University of Colorado School of Dental Medicine, Aurora, CO.

Kabuki syndrome (KS) is a rare multiple congenital anomaly syndrome characterized by distinctive facial features, skeletal and dental abnormalities and intellectual disability. Congenital heart defects, short stature and renal abnormalities are also seen in a significant number of KS patients. The application of high-throughput sequencing technologies has led to the identification of mutations in *MLL2* as the cause of the disease in 75% of KS patients. *MLL2* is a histone methyltransferase that is an important regulator of transcription. The recent discovery of deletions in *KDM6A* in three patients with KS suggested that additional genes are likely to be involved. Interestingly, the histone H3 lysine 27 demethylase *KDM6A* is a a component of a multi-protein complex that also contains MLL2. We analyzed 40 KS patients for gene mutations using a combination of Sanger sequencing, arrayCGH and whole exome sequencing (WES). We detected *MLL2* mutations in 27/40 and *KDM6A* mutations in 3/40 KS patients. The *KDM6A* mutations included two microdeletions and one point mutation. This data led us to hypothesize that KS may result from mutations in multiple genes within a complex of interacting proteins. The 10 mutation-negative KS patients are currently being analyzed by WES to detect novel gene mutations. To further demonstrate causality and roles of candidate genes in common developmental pathways for KS, we have used morpholino-based knockdowns of gene expression in zebrafish. We knocked down zebrafish *mll2* and the two paralogs *kdm6a* and *kdm6al*. Both *mll2* and *kdm6a* morphant fish exhibited abnormal craniofacial structures which included absence of the branchial arches and otoliths, as well as absence, clefting or inversion of the ceratohyal and abnormal patterning or clefting of Meckel's cartilages. In contrast, *kdm6al* morphants did not exhibit a craniofacial phenotype. Analysis of transgenic lines expressing GFP under neuronal (*isl1*) and cardiac (*cmlc2*) specific promoters revealed that *mll2* and *kdm6al*, but not *kdm6a* morphants, exhibited gross morphological defects in neuronal patterning and cardiac development. Furthermore, the two zebrafish paralogs, *kdm6a* and *kdm6al* have functionally diverged, yet together they regulate the same developmental pathways as human *KDM6A*. These observations lend further support to the hypothesis that perturbation of a shared regulatory pathway containing *MLL2* and *KDM6A* is responsible for the Kabuki syndrome phenotype.

[cf4]Fibulin-4b[cf1] is required for cardiovascular and musculoskeletal development as an antagonist of transforming growth factor-beta.[cf1] *Z. Urban[1], S.M. Khatri[1], A.B. Maxfield[2]*. 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Pediatrics, Washington University, St. Louis, MO.

Human mutations in the *fibulin-4* (*FBLN4*, *EFEMP2*) gene cause a recessive disease with arterial tortuosity, aneurysms, developmental emphysema and cutis laxa. Our goal was to elucidate the molecular mechanisms of this disease using zebrafish as a model organism. The zebrafish genome has two paralogues of human *FBLN4*, *fbln4a* and *fbln4b*, with *fbln4b* showing greater homology and conserved synteny to human *FBLN4*. To determine the role of *flbn4b* in early development, we used antisense morpholinos to knockdown gene function. *Fbln4b* knockdown showed a severe phenotype at 2 days post fertilization including cardiac edema, decreased heart rate, muscle dysfunction leading to reduced tail twitching and circulation failure with pooling of the blood in the caudal region. The observed phenotypes caused by *fbln4b* depletion were similar to phenotypes observed in embryos with hyperactivated transforming growth factor beta (tgfb) signaling. To test if tgfb signaling was altered in *fbln4b*-depleted embryos, we treated them with a small molecule tgfb receptor 1 inhibitor, which rescued the *fbln4b*-deficient phenotype. The specific tgfb isoform responsible for altered signaling was identified by silencing *tgfb1b*, *tgfb2* and *tgfb3* in *fbln4b* morphants. *Tgfb2* and *tgfb3* but not *tgfb1b* knockdown rescued all of the defects caused by *fbln4b* depletion. Our results show that the main function of *fbln4b* is to negatively regulate the activity of *tgfb2* and *tgfb3* in cardiovascular and musculoskeletal development. The molecular mechanism of this function is unclear but likely involves stabilization of latent tgfb complexes in the extracellular matrix.

821F

Three-dimensional Study Of Ror2-/- and Wnta5-/- Mice Craniofacial Phenotype Using Two Imaging Techniques. *S. Beiraghi[1], V. Leon-Salazar[1], J. Zhang[2], D. Idiyatullin[2], M. Garwood[2], A.S.L. Fok[1], M. Maga[3], Y. Yang[4]*. 1) School of Dentistry, University of Minnesota, Minneapolis, MN; 2) Center for Magnetic Resonance Research, University of Minnesota, Minneapolis, MN; 3) Division of Craniofacial Medicine, Seattle Children's Hospital, Seattle, WA; 4) Genetic Disease Research Branch National Human Genome Research Institute Bethesda, MD.

Background: Animal studies have shown that skeletal and soft tissue phenotypes of Robinow syndrome are manifested in Ror2-/- and Wnta5-/- mice. The aims of this study were: 1) To compare the craniofacial phenotype of Ror2-/- and Wnta5-/- mice, and 2) to assess the performance of a new MRI method, known as SWIFT (Sweep Imaging with Fourier Transform), for the three-dimensional analysis of the skeletal craniofacial characteristics of Ror2-/- and Wnta5-/- mice as compared to micro-computed tomography (μCT). Methods: Eight E18.5 mouse heads (two Wnt5a-/-, two Ror2-/-, and four wild-type) were used in this study. High-resolution μCT of each head was obtained using a X-Tek XTV μCT scanner (Nikon metrology NV, Leuven, Belgium) at 90 kV, 91 μA, and 2000 projections. Qualitative and quantitative comparisons included: Craniofacial bone volume, maxillary and mandibular size and shape variation, and trabecular bone pattern. Proton MRI measurements were performed on a 31 cm bore 9.4 T scanner (Oxford Magnet/Agilent DirectDrive Console) using a home-made single loop surface coil (2 cm diameter). SWIFT images were acquired with bandwidth=125 kHz, TR=3.3 ms, matrix=256^3, number of spokes=128000, and FOV=2 cm x 2cm x 2cm. The acquisition time was 6 minutes for each SWIFT image. Results: Wnt5a-/- and Ror2-/- mice presented a significant reduction in the facial and cranial vault development when compared to the wild-type mice. Midfacial development was also reduced in both mutant mice; however the Wnt5a-/- mice presented a more severe maxillary deficiency. Mandibular length was also decreased in both Wnt5a-/- and Ror2-/- mice. The trabecular bone pattern of the maxillary and mandibular alveolar bone was dysplastic and thickened in the Wnt5a-/- mice. Interestingly, the mandible, maxilla, and teeth in the wnt5a-/- mice were more severely affected than in the Ror2-/- mice. Using SWIFT MRI it was possible to delineate craniofacial skeletal structures and the three-dimensional images were similar to those obtained by μCT. Differentiation between cortical and cancellous bone was also possible using SWIFT MRI. Conclusion: Our data confirms that mutations of the Ror2/Wnt5a pathway affect skeletal and dental growth and development and cause severe malformation of the maxillary and mandibular alveolar bone. SWIFT MRI allows visualization of the morphology of the craniofacial skeleton of fetal mice and is a promising imaging technique for phenotypic studies.

822F

Retinal disease gene identification and generation of photoreceptor gene regulatory networks by ChIP-Seq analysis of multiple transcription factorsPurpose: A network of photoreceptor transcription factors, including neural retina leucine zipper (NRL) and cone-rod homeobox (CRX), dictates the develop. *H. Hao[1], M. Brooks[1], M. Seifert[2], A. Swaroop[1]*. 1) Neurobiology Neurodegeneration & Repair Laboratory, National Eye Institute, Bethesda, MD; 2) Genomatix GmbH, 80335 Munich, Germany.

Purpose: A network of photoreceptor transcription factors, including neural retina leucine zipper (NRL) and cone-rod homeobox (CRX), dictates the development and survival of photoreceptors. Mutations in human NRL, CRX and several of their target genes are associated with retinal diseases. We aim to identify the global direct target genes of NRL and CRX during distinct developmental stages to facilitate retinal disease gene discovery and construction of gene regulatory networks. Methods: Genome-wide in vivo occupancies of transcription factors were identified by ChIP-seq analysis of P2 mouse retina and compared to published data from the adult retina. Changes in transcription profiling between wild type mouse retina and Nrl-knockout retina were used as a second filter to identify direct NRL target genes. Results: We identified direct NRL targets genes at both P2 and compared these with the previously identified targets at P28. The direct NRL target genes are enriched in retinal disease loci, suggesting that these targets genes will serve as retinal candidate disease genes. Conclusions: Genome-wide occupancy analysis of photoreceptor specific TF at distinct developmental stages allowed identification of genes that are of functional importance to photoreceptor development and maintenance. Our study will facilitate the identification of retinal disease genes and therapeutic discovery.

Genome-wide ChIP-seq analysis to identify mouse Foxl2 binding sites *in vivo*. *M. Marongiu[1], A. Sbardellati[2], L. Marcia[1], A. Meloni[1], R. Cusano[2], A. Angius[1], G. Fotia[2], F. Cucca[1,3], L. Crisponi[1]*. 1) IRGB - CNR, Monserrato (CA), Cagliari, Italy; 2) CRS4, Pula, Cagliari, Italy; 3) University of Sassari, Sassari, Italy.

The transcription factor FOXL2 belongs to the evolutionarily conserved family of winged helix forkhead proteins that regulate transcription of genes involved in cell growth, proliferation and differentiation and play a central role during development. Foxl2 is involved in female sex determination, ovarian development and follicle formation. In human, FOXL2 mutations are responsible of blepharophimosis, ptosis, and epicanthus inversus syndrome (BPES) type I and II, associated with premature ovarian failure (POF) in type I. Recently, a somatic FOXL2 mutation (p.Cys134Trp) has been found in adult ovarian granulosa cell tumors (OGCT). Foxl2 expression has been found starting at 10.5 dpc in the 1st branchial arch and it is expressed in the developing ovary starting at 13.5 dpc, when sex determination from bipotential gonad occurs, until adulthood. Foxl2 is also expressed in the developing pituitary gland starting at 11.5 dpc. To better characterize its function both in ovarian tissue and pituitary gland, we performed chromatin immunoprecipitation (ChIP) on mouse P7 ovaries, and on alpha T3-1 gonadotropic cell line. We used ChIP-seq, which combines ChIP with high-throughput massively parallel sequencing, to identify the genomic locations bound by Foxl2, and we found a high relative enrichment level of these regions in the promoters of known genes (Refseq) with respect to the genome background (5% ovary; 7% alpha T3-1). Using MEME-chip (http://meme.sdsc.edu/meme/) and CisFinder (http://lgsun.grc.nia.nih.gov/CisFinder/), specifically designed for finding over-representing short DNA motifs in ChIP-seq data, we were able to clearly identify a core consensus binding sequence for Foxl2 that is over-represented in the enriched ChIP regions from both experiments. The results of this study will help in finding new targets for Foxl2 as well as in better understanding the mechanisms underlying the role of Foxl2 in ovarian and pituitary development.

Cc2d2a is required for cilia biogenesis. *S. Veleri[1], TJ. Foskett[1], SH. Manjunath[1], A. Longo[1], MA. English[1,4], P. Liu[2], J. Lei[2], C. Gao[3], RN. Fariss[3], R. Sood[4], RA. Rachel[1], P. Liu[4], L. Dong[2], A. Swaroop[1]*. 1) NNRL, NEI, NIH, Bethesda, MD; 2) Genetic Engineering Core, NEI, NIH, Bethesda, MD; 3) Biological Imaging Core, NEI, NIH, Bethesda, MD; 4) NHGRI, NIH, Bethesda, MD.

Purpose: Mutations in CC2D2A (Coiled-Coil & C2 Domain containing 2A) are associated with Meckel-Gruber syndrome (MKS) and Joubert syndrome (JS), the two ciliopathies characterized by retinal dystrophy, mental retardation, polydactyly, liver fibrosis, and polycystic kidney. CC2D2A protein is localized to basal body and transition zone of the cilia. The purpose of this study was to elucidate how CC2D2A mutations cause human disease by loss of function studies using model organisms. Methods: We used antisense splice blocking and translational blocking morpholinos (MOs) to knockdown zebrafish cc2d2a. The splice blocking MO mimicked a disease-associated splicing defect in human patients. The Cc2d2a-knockout (KO) mice were produced by targeted deletion of exons 6 to 8 using homologous recombination. Results: Knockdown of cc2d2a by both splice and translational blocking MOs in the zebrafish embryos demonstrated dose-dependent developmental defects, including brain atrophy and microphthalmia. The Cc2d2a-/- mice exhibit embryonic lethality, with extensive developmental defects that include situs inversus, heterotaxy, polydactyly, anophthalmia, hydrocephalus and liver fibrosis. Occasionally, Cc2d2a-/- animals survive for a month but display severe hydrocephalus and retinal dystrophy. The analysis of embryonic fibroblasts, embryonic node and kidney tubules showed that cilia biogenesis is disrupted by Cc2d2a-/- mutation. Conclusion: Our studies suggest that Cc2d2a function is critical for normal body plan and organ development that involves cilia-mediated signaling pathways.

***Prdm16* is required during mouse craniofacial development.** *B.C. Bjork[1], F. Schnutgen[2], L. Furlan[1], B. Nelson[1], D.R. Beier[3]*. 1) Dept Biochemistry, Midwestern Univ, Downers Grove, IL; 2) Molecular Hematology Dept, Univ of Frankfurt, Frankfurt, Germany; 3) Div Genetics, Brigham & Women's Hospital, Harvard Med School, Boston, MA.

The autosomal recessive *csp1* mutation exhibits perinatal lethality with cleft palate accompanied by mandibular hypoplasia, incisor tooth defects, choroid plexus hypoplasia, retinal folds, and lung and cardiac defects. This mutant models Pierre Robin Sequence-type CP, a form of cleft palate exhibiting mandibular hypoplasia and ankyloglossia. PRDM16 is a regulator of TGFβ superfamily signaling, and we have shown that TGFβ signaling is perturbed in *Prdm16* loss of function mutants. *Prdm16* has been shown to be critical during brown adipose versus skeletal muscle cell fate determination and in the maintenance of stem cell populations; however, its role in craniofacial patterning is relatively uncharacterized. We aim to determine the molecular consequences of altered *Prdm16* expression during embryonic palate, mandible and tooth development.

To this end, we have generated a novel conditional gene trap null allele of *Prdm16* (*Prdm16^{cGT}*) using "targeted trapping" in mouse embryonic stem cells. We previously validated the conditional capability of this combination "*cre-loxP*" and "*Flp-Frt*"-based FLEx recombination system using ubiquitous *cre*- and *Flp*-expressing mouse strains. Using whole-mount *in situ* hybridization, we are interrogating gene trap null mutant versus wild type embryos with an array of genes of known importance during early mandible development and formation and patterning of the secondary palate to identify *Prdm16*-dependent gene expression differences. To study the mechanism by which cleft secondary palate occurs in these mutants (i.e. palate-intrinsic versus palate-extrinsic), we initiated conditional *Prdm16* ablation studies using palate mesenchyme-specific (*Osr2::cre*) and mandible-specific (*dHand::cre*) strains. These studies will allow us to dissect the genetic and developmental mechanisms that involve *Prdm16* during craniofacial development.

Examination of lungs and kidneys in a mouse model of osteogenesis imperfecta. *E. Carter[1], S. Doty[2], N. Pleshko[3], C. Raggio[1]*. 1) Ctr Skeletal Dysplasias, Hosp Special Surgery, New York City, NY; 2) Tissue Microscopy, Hosp Special Surgery, New York City, NY; 3) Mechanical Engineering, Temple Univ., Philadelphia, PA.

Background: Osteogenesis Imperfecta (OI) is a genetic disorder of the connective tissues characterized by predisposition to fracture, tissue fragility, skeletal deformities, and in severe cases, death. It is primarily caused by heterogeneous dominant mutations in the genes encoding type I collagen, the major protein of bone, skin, and tendons. Treatment options include osteoclast inhibition, through bisphosphonate therapy and/or RANKL inhibitors. The *oim/oim* mouse model is a naturally-occurring mutation resulting in a deficiency of proalpha2(I) collagen (B6C3Fe*a/a*Col1a2oim/J (Jackson Laboratories)). The phenotype is similar to that of moderate to severe OI in humans, Sillence type 3. In addition to the bony phenotype, *oim/oim* mice have a type I collagen glomerulopathy, demonstrating the negative affect of alpha1(I) homotrimers in non-osseous tissues. As part of a larger ongoing study examining the effect of osteoclast inhibition in the *oim/oim*, we collected lungs and kidneys from *oim/oim* and wild type (WT) mice across various treatment groups for histopathology and fourier transform infrared imaging spectroscopy (FTIR-IS). Our hypotheses were: (1) *oim/oim* would have decreased type 1 collagen in lung tissue compared to WT; (2) osteoclast inhibitors would not affect type 1 collagen in the lung; (3) treatment would decrease deposition of type I collagen breakdown products in glomeruli of *oim/oim*. Methods: Between 3–5 animals from each of the ten treatment groups were sacrificed at 26 weeks of age. Lungs (whole lobe) were colleted in 4% paraformaldehyde for histopathological study by H&E, picosirius red (PSR), type 1 collagen immunostaining (rabbit Ab to purified fetal mouse skin). Kidneys were collected and halved into electron microscopy fixative, formalin, and 80% ethanol for histopathology (as listed above) and FTIR-IS. Results: Lungs from *oim/oim* animals were smaller than WT specimens. On light microscopy, both the *oim/oim* and WT lungs showed some tissue compression with decreased alveolar space. This was random with no trend towards genotype. There were no significant differences between H&E, type 1 collagen, or PSR in both genotypes and all treatment groups. Immunostaining, PSR, and FTIR-IS showed expected deposition of type I collagen breakdown products in the glomeruli of *oim/oim* (glomerulopathy). Treatment with osteoclast inhibitors did not improve the glomerulopathy in *oim/oim* mice.

Pathway analysis by quantitative profiling of gene expression patterns in developing mouse retina. *M.J. Brooks[1], I. Nasonkin[1], S. Perez[1], S. Veleri[1], J. Roger[1], M. Seifert[2], A. Swaroop[1]*. 1) NNRL, NEI, NIH, Bethesda, MD; 2) Genomatix GmbH, Munich, Germany.

The developing mouse retina provides a unique model for *in vivo* investigation of gene expression and regulatory pathway analysis during differentiation of a neuronal tissue. Ganglion cells, amacrine neurons, horizontal cells and cone photoreceptors are primarily generated prenatally in mouse retinal development; whereas bipolar, Muller glia and a majority of rod photoreceptors are born after birth. Some of the key transcription factors involved in retinal differentiation have been identified, yet the regulatory pathways underlying neuronal cell fate determination are poorly understood. This study employs the power of next-generation sequencing and pathway discovery tools to investigate the transcriptional regulatory networks during retinal development. RNA from invaginated neuroectoderm of the optic cup from embryonic day (E)11 and neural retina from E14 and 16 and postnatal days 0, 2, 4, 6, 9, 10 and 21 were used for the construction of RNA-seq libraries. Using a modified Illumina TruSeq protocol, we performed sequencing of directional RNA-seq libraries of 76 nucleotides on an Illumina GAIIx. We used Genomatix, JMP 10, Ingenuity Pathway Analysis and AltAnalyze for sequence alignment, pathway and alternate splicing and promoter analysis. A range of 28–36 million uniquely mapped, pass filter reads were aligned to the reference genome mm9. Of over 17,000 transcripts that show expression greater than 1.0 RPKM at any profiled time-point, approximately half show significant differential expression over the course of retinal development. As predicted, genes involved in DNA replication, cell proliferation and mitosis are among the most down-regulated genes as differentiation proceeds. Photoreceptor specific transcripts are the most up-regulated genes. Pattern recognition analysis of known key regulatory genes has revealed a more thorough assessment of genes that are likely involved in distinct developmental pathways. Alternative splice and promoter analysis has identified many genes that exhibit different isoforms during differentiation. In addition, the transcript structure of several genes was significantly different in the retina compared to the currently published annotation. Our studies provide the framework for identifying novel candidate genes for mutation screening of patients with retinal diseases and for elucidating the regulatory network that dictates differentiation of multiple cell types in the mammalian retina.

Essential Roles of FGF Ligands in Endochondral and Intramembranous Bone Development. *I.H. Hung[1,3], D.M. Ornitz[2], G.C. Schoenwolf[1], M. Lewandoski[3]*. 1) Department of Pediatrics, University of Utah, Salt Lake City, UT; 2) Department of Developmental Biology, Washington University School of Medicine, St. Louis, MO; 3) Cancer and Developmental Biology Lab, Frederick National Laboratory for Cancer Research, Frederick, MD.

Activating mutations in fibroblast growth factor (FGF) receptors result in chondrodysplasia and craniosynostosis syndromes, highlighting the critical role for FGF signaling in skeletal development. Although the roles of the FGFRs in bone development have been relatively well-characterized, only two FGF ligands, FGF9 and FGF18, have been shown to regulate embryonic skeletogenesis. To further elucidate the roles of these FGF ligands during skeletal development, we have generated mice lacking both Fgf9 and Fgf18. Analyses of Fgf9/18 double knock-out (DKO) mice demonstrate severe defects in endochondral and intramembranous ossification. We provide evidence that FGF signaling interacts with key gene regulatory networks in osteogenesis. Together these findings provide novel insights into mechanisms of skeletal biology.

829F

Taking a different pathway: Notchless plays with p53 and Wnt during embryogenesis. *A.C. Lossie[1,2], C.-L. Lo[1,3], J.B. Sherrill[1,4]*. 1) Department of Animal Science, Purdue University, West Lafayette, IN; 2) Dept of Medicine, Indiana University School of Medicine, Indianapolis, IN; 3) PULSe Interdisciplinary Graduate Program, Purdue University, West Lafayette, IN; 4) Department of Biological Sciences, Purdue University, West Lafayette, IN.

Our interests lie in determining the genes and genetic pathways that are important for establishing and maintaining maternal-fetal interactions during pregnancy. Through a positional cloning strategy, we discovered that mutations in *Notchless* (*Nle1*) lead to embryonic lethality during peri-implantation in mice. Nle1 is a member of the WD40-repeat protein family, and is thought to signal via the canonical Notch pathway. In invertebrates and lower vertebrates, the Notch pathway is critical for directing cell fate prior to gastrulation. However, the role of Notch signaling during the earliest stages of mammalian development is unclear, as gene targeting studies of Notch family members and factors that are necessary for Notch signal transduction, demonstrate that Notch signaling is dispensable for gastrulation in mice. The phenotype of *Nle1* mutant embryos is much more severe than single *Notch* receptor mutations or even in animals where Notch signaling is blocked. To test the hypothesis that *Nle1* functions in multiple signaling pathways during pre-implantation development, we examined expression of multiple *Notch* downstream target genes, as well as select members of the *Wnt* and *Trp53* pathways in wild-type and mutant embryos. Surprisingly, we saw no indication that the *Notch* pathway is disrupted in mutant embryos; *Notch* receptors, ligands and downstream targets showed normal expression levels. Instead, we found that members of the *Wnt* pathway are downregulated in *Nle1* mutants, while *Trp53* and *Cdkn1a* were upregulated in a stage-specific manner. Induction of *Cdkn1a* was highest in morulae and full blastocysts, while *Trp53* overexpression was confined to hatched blastocysts. Our results refute the possibility that Nle1 is a negative regulator of Notch signaling during mammalian pre-implantation development, as mutation of *Nle1* does not lead to increased expression of downstream target genes. Instead, our data implicate Nle1 in Wnt signaling, cell cycle arrest via Cdkn1a, and p53-mediated apoptosis. Although Notch signaling is dispensable in mice prior to gastrulation, Wnt signaling is not. Deletion of *Wnt3* leads to failure prior to primitive streak formation, and multiple ligands and receptors are detected in blastocysts and the uterus during peri-implantation. As p53 inhibits self-renewal and promotes differentiation in ES cells, Nle1 and its co-opted Wnt and p53 pathways could provide novel targets for the design of therapeutic interventions for infertility.

Developmental defects in the retina of Pias3 conditional knockout mice. *J.E. Roger[1], H. Breit[1], D. Cheng[1], L. Dong[2], A. Swaroop[1]*. 1) NNRL, National Eye Institute, Bethesda, MD; 2) Genetic Engineering Facility, National Eye Institute, Bethesda, MD.

A stringent control of gene expression is essential for development and homeostasis. Posttranslational modifications provide a critical level of control and additional complexity. Protein Inhibitor of Activated STAT3 (PIAS3) is a transcriptional modulator that directly binds to multiple factors and modulates their activity. PIAS3 can also function as a SUMO (Small Ubiquitin-like Modifier)-E3 ligase, and covalent linkage of SUMO proteins can modify the function of target proteins. Recently, Blackshaw and our laboratory demonstrated the importance of SUMOylation in modulating activity of NR2E3 and NRL, two key regulators of photoreceptor differentiation. In order to analyze the consequence of the lack of PIAS3 expression early in retinal development and identify new PIAS3 targets, we have generated and analyzed conditional Pias3 knockout mice (CKO). Pias3 floxed mice were produced by introducing LoxP sites flanking exon 2 to 5 of the Pias3 gene through homologous recombination. Pias3 was specifically deleted in the forebrain and the retina by crossing with Rx-Cre mice. Phenotype was analyzed by immunohistochemistry (IHC), qPCR and electroretinogramm (ERG). A specific deletion of Pias3 in the retina in Pias3f/f; Rx-Cre mice was confirmed by RT-PCR and PCR on retinal cDNA and genomic DNA respectively. Immunoblot analysis confirmed the complete absence of Pias3 protein in the retina of Pias3f/f; Rx-Cre mice. Immunohistochemical (IHC) analysis with anti-S-opsin antibody and peanut agglutinin on flat mount retina revealed an increased number of S-cones along the ventral-dorsal axis but with shorter outer segments. No obvious change was observed in other retinal cell types based on IHC, with the exception of Muller cells showing displaced cell bodies in the inner nuclear layer. In 6-month old Pias3 CKO, no signs of retinal degeneration were observed. Interestingly, ERG analysis showed a significant decrease of the photopic response (both S-cones and M-cones) compared to control animals, whereas scotopic ERG (rod-mediated) appeared to be normal. The sumoylation state of key factors involved in retinal diseases is being tested, and gene expression analysis will be performed in these mice. Our studies of CKO retina reveal the importance of PIAS3 in regulating cone photoreceptor differentiation and function.

Uncovering the function of TMED2 during. *T. Heba.* Human Genetics & Pediatrics, Research Inst Place Toulon, Montreal, PQ, Canada,-tAGHREED HEBA.

Uncovering the function of TMED2 during trophoblast differentiation Taghreed Heba, Abeer Zakariyah, Loydie A. Jerome-Majewska Transmembrane emp24 domain trafficking protein 2, (TMED2) is a member of the p24 family of proteins involved in vesicle transport between the ER and Golgi. During vesicular transport between the ER and Golgi p24 proteins function as receptors for both cargos and coat proteins. Our group showed that Tmed2 is required for normal embryo and placental development in mouse and that syncytiotrophoblast cells of the mouse labyrinth placenta failed to differentiate in homozygous mutant embryos. In human placenta, we showed expression of TMED2 between 5.5 and 40 weeks of gestation in all trophoblast cell types. We noted that early in gestation TMED2 was more highly expressed in cytotrophoblast cells versus syncytiotrophoblast. The choriocarcinoma cell lines BeWo and JEG-3 are widely used for the study of trophoblast differentiation. These cells share many properties with villous trophoblast in terms of their morphology, biochemical markers, and hormone secretion. We found that TMED2 was more highly expressed in a choriocarcinoma cell line, BeWo, which can be induced to differentiate and form syncytiotrophoblast when compared to the JEG-3 cell line, which does not fuse to form syncytiotrophoblast. We hypothesized that TMED2 is required for fusion of trophoblast cells during syncytiotrophoblast differentiation. To test this hypothesis we are examining the function of TMED2 during trophoblast differentiation of BeWo and Jeg-3 cell lines. We will show our plans to ectopically express TMED2 in Jeg-3 cells and to knockdown TMED2 expression in BeWo choriocarcinoma cells with shRNA. Our work suggests that TMED2 is required for trafficking cargoes that are essential for placental development.

Mouse models of neurodevelopmental disorders: Overlap between FoxG1 and MeCP2. *S.A. Adams[1,2], R. Woods[1], S. Luu[1], J.M. LaSalle[1].* 1) Medical Microbiology and Immunology, University of California, Davis, Davis, CA; 2) Department of Biochemistry, University of Cambridge, Tennis Court Road, Cambridge, UK.

Rett Syndrome is a neurodevelopmental disorder caused by mutations in the X-linked gene *MECP2*. The role of MeCP2 in early neuronal development has not been fully investigated. More recently, mutations in the autosomal gene *FOXG1* have been identified in children with a congenital variant of Rett Syndrome. Others have suggested that *FOXG1* mutations define and overlapping but distinct syndrome from classic Rett syndrome, defined by microcephaly, severe mental retardation, dyskinesia, and corpus collosum hypogenesis. *FOXG1* encodes a developmental transcription factor, and is a known regulator of embryonic cortical development. Given that mutations in *FOXG1* and *MECP2* produce a similar phenotype, we investigated whether they are involved in parallel or overlapping molecular pathways during specific developmental time frames. We show by immunofluorescence in embryonic brain sections and cultured cortical neurons that MeCP2 and FoxG1 are expressed at increasing levels in the developing mouse cortex from E13.5 to E17.5. Using chromatin immunoprecipitation (ChIP) and quantitative RT-PCR, we found that MeCP2 and FoxG1 bind to each other's promoters and regulate each other's expression. Finally, we used ELISA to identify that IGF-1 protein levels are differentially regulated in neurons isolated from Foxg1 haploinsufficient mice ($Foxg1^{+/-}$) and MeCP2 knockout mice ($Mecp2^{-/y}$). We treated $Foxg1^{+/-}$ and $Mecp2^{-/y}$ neurons with IGF-1 at different stages in early neuronal differentiation and demonstrate that aberrant IGF-1 signaling is responsible for the defects in early neurite outgrowth that may go on to impede aspects of postnatal synapse formation. Our research demonstrates that an early cortical phenotype is associated with Rett Syndrome, and may be beneficial in the future design of treatments for neurodevelopmental disorders.

Comprehensive characterization of a Zebrafish model for pseudoxanthoma elasticum. *M.J. Hosen[1,2,4], O.M. Vanakker[1,4], A. Willaert[1], A. Huysseune[3], P.J. Coucke[1], A. De Paepe[1].* 1) Centre for Medical Genetics, Ghent University Hospital, Ghent, Flanders, Belgium; 2) Dept. of Genetic Engineering and Biotechnology, Shahjalal University of Science and Technology, Sylhet, Bangladesh; 3) Dept. of Biology, Ghent University, Ghent, Belgium; 4) These authors contributed equally to the work.

Aims: Pseudoxanthoma elasticum (PXE) is a connective tissue disease characterized by elastic fiber calcification and fragmentation, resulting from mutations in the ABCC6 gene. In a zebrafish (ZF) model, which has three abcc6 isoforms, abcc6a knockdown has been associated with abnormal longitudinal growth of the tail, which is of interest as the pro-osteogenic BMP2-Runx2 pathway - which was recently found upregulated in human and murine PXE - is important in ZF tail patterning. Consequently, we aimed to study mineralization and BMP2 signaling in PXE ZF. **Methods & Results:** Abcc6a was knocked down by injecting translational blocking or splice junction morpholinos (MO) in 1–4 cell stage embryos. At 3 days post fertilization, both groups showed curving and shortening of the tail, variable in severity, pericardial edema and decreased mobility. Moreover, decreased total body length and underdevelopment of head and eyes were observed. Calcein and Alizarin staining showed advanced skeletal mineralization compared to controls. QPCR analysis on isolated tail tissue revealed significant upregulation of BMP2a, RUNX2a and MSXc. **Discussion & Conclusion:** Our study expands the knowledge on PXE ZF and illustrates a distinct phenotype, affecting longitudinal growth and eye development. Interestingly, similar to humans, variability in severity is observed. Though we could not detect soft tissue calcification - possibly because of early demise due to pericardial edema - the mutants showed advanced skeletal mineralization, suggesting that abcc6a deficiency also influences calcium precipitation. Confirmation of BMP2-Runx2 and Msx2 involvement in the PXE pathogenesis leads us to conclude that the ZF is a useful model organism for future PXE cell signalling research.

Mouse model reveals the role of SOX7 in the development of congenital diaphragmatic hernia associated with recurrent deletions of 8p23.1. *D.A. Scott[1,5], M.J. Wat[1], T.F. Beck[1], A. Hernández-García[1,2], Z. Yu[1], D. Veenma[3,4], M. Garcia[5], A.M. Holder[6], J.J. Wat[7], Y. Chen[1,8], C.A. Mohila[9], K.P. Lally[10], M. Dickinson[5], D. Tibboel[3], A. de Klein[4], B. Lee[1,8]*. 1) Deptartment of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Universidad Autónoma de Coahuila, Saltillo, Coahuila, México; 3) Department of Pediatric Surgery, Erasmus Medical Center, Rotterdam, the Netherlands; 4) Department of Clinical Genetics, Erasmus Medical Center, Rotterdam, the Netherlands; 5) Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX., USA; 6) Department of Surgical Oncology, The University of Texas MD Anderson Cancer Center, Houston, TX, USA; 7) Department of Biochemistry and Cell Biology, Rice University, Houston, TX, USA; 8) Howard Hughes Medical Institute, Houston, TX, USA; 9) Department of Pathology and Immunology, Baylor College of Medicine, Houston, TX, USA; 10) Department of Pediatric Surgery, University of Texas Medical School, Houston, TX, USA.

Recurrent microdeletions of chromosome 8p23.1 confer a high risk of both congenital diaphragmatic hernia (CDH) and cardiac defects. Haploinsufficiency of *GATA4*—a transcription factor encoding gene located on 8p23.1—is sufficient to cause cardiac defects in humans, and GATA4-deficient mice have both CDH and cardiac defects. Although this suggests that deletion of *GATA4* contributes to the development of both CDH and cardiac defects, CDH has not been reported in individuals with cardiac defects attributed to *GATA4* mutations. We were also unable to identify deleterious *GATA4* sequence changes in a cohort of CDH patients. This suggested that haploinsufficiency of another gene on chromosome 8p23.1 may contribute, along with *GATA4*, to the development of CDH. Of the 21 other genes located in the CDH critical region on 8p23.1, *SOX7*—which encodes a retinoic acid responsive transcription factor—appeared to be the most likely to play a role in diaphragm development. To determine if haploinsufficiency of *SOX7* contributes to the development of CDH, we generated mice with a deletion of the second exon of *Sox7*. A portion of these $Sox7^{\Delta Ex2/+}$ mice developed retrosternal diaphragmatic hernias located in the anterior muscular portion of the diaphragm. Anterior CDH is also seen in $Gata4^{+/-}$ mice and has been described in association with 8p23.1 deletions in humans. Immunohistochemistry revealed that SOX7 is expressed in the vascular endothelial cells of the developing diaphragm and may be weakly expressed in some diaphragmatic muscle cells. This pattern of expression is different from that seen for GATA4 making it unlikely that SOX7 directly regulates GATA4 expression during diaphragm development. Similar to our experience screening *GATA4*, no clearly deleterious *SOX7* sequence changes were identified in our CDH cohort. We conclude that haploinsufficiency of *Sox7* or *Gata4* is sufficient to produce anterior CDH in mice and that haploinsufficiency of *SOX7* and *GATA4* may each contribute to the development of CDH in individuals with 8p23.1 deletions. These results underscore the importance of considering the possibility that two or more genes may be contributing to individual phenotypes associated with a recurrent genomic disorder. This is particularly true when mutation screens fail to identify deleterious changes in individual candidate genes.

Generation and Characterization of Humanized DUF1220 Transgenic Mice. *J.G. Keeney[1], N. Anderson[1], D. Restrepo[2], J.M. Sikela[1]*. 1) Biochemistry and Molecular Genetics, University of Colorado, Denver, Aurora, CO; 2) Cell and Developmental Biology, University of Colorado, Denver, Aurora, CO.

DUF1220 protein domains have undergone a striking recent expansion in copy number that increases generally as a function of a species evolutionary proximity to human, where the highest copy number is found (~275 copies). The increase in human represents the largest human lineage-specific copy number increase of any protein coding region in the genome. DUF1220 copy number correlates strongly with brain size (R2 = 0.98; p = 1.8 x 10^-6) and cortical neuron number (R2 = 0.98; p = .0011) across primate lineages. Copy number variations in the human 1q21.1 region, where most DUF1220 domains map, have been linked to several cognitive diseases, including deletions associated with microcephaly and duplications associated with macrocephaly. For the above reasons, DUF1220 domains are plausible candidates to underlie brain size and brain structure-related pathologies. To investigate this possibility, transgenic mice have been developed in which human DUF1220 domains have been incorporated into the mouse genome. Mice lack the recently increased primate form of DUF1220 (they have only a single ancestral copy of DUF1220 in their genome), and as a result provide an ideal background upon which to study the effects of increasing DUF1220 copy number. “Humanized” DUF1220 mice were produced by pronuclear injection of a BAC clone that contained the NBPF15 gene which encodes 6 human DUF1220 domains. Resulting transgenic mice represent the first animal model for the in vivo study of DUF1220 function and are being used to investigate the effects of DUF1220 copy number on brain structure and development using neuro-anatomical investigations and behavioral testing.

Overexpression of Sox9 in keratinocytes changes hair follicle cycling in mice. *Y. Zhang[1], Z.H. Zheng[2], Y.Q. Xu[1], S.L. Zhou[2], L. Shi[1], X. Zhang[1,3]*. 1) Research Center for Medical Genomics, China Medical University, Shenyang 110001, China; 2) The Laboratory Animal Center, China Medical University, Shenyang 110001, China; 3) McKusick-Zhang Center for Genetic Medicine and State Key Laboratory of Medical Molecular Biology, Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing 100005, China.

(ABSTRACT)OBJECTIVE: Congenital generalized hypertrichosis terminalis (CGHT) is characterized by universal excessive growth of pigmented terminal hairs and often accompanied with gingival hyperplasia. It is one of the least well understood of genetic hair disorders. Through the study of three Han Chinese families and a sporadic case with CGHT and gingival hyperplasia, we inferred that enhanced expression of Sox9 might lead to hair overgrowth. We then use transgenic mice model to explore the potential pathogenesis of CGHT. METHODS: We generated transgenic mice overexpressing Sox9 under control of keratin 14 promoter (K14-Sox9 mice), which drives expression of a transgene specifically in epidermal cells and outer root sheath (ORS) of hair follicle (HF). RESULTS: Our preliminary phenotypic analysis in the K14-Sox9 mice showed early entry into the anagen stage of the first hair follicle (HF) cycle, suggesting an accelerated HF morphogenesis. Meanwhile, these alterations are accompanied with elongation of the guard and awl hair shafts in the skin of the K14-Sox9 transgenic mice. Histological analysis shows thicker hypodermis in the transgenic skin by 16 weeks compared with that of wild-type, concomitant with irregular HF diameter. In addition, K14/hSOX9 transgenic mice also showed increased level of β-catenin, while some differentiation markers expressed properly. CONCLUSION: In summary, our primary results characterize the simultaneous, stimulatory effect of Sox9 delivery to keratinocytes on two types of regeneration processes with transgenic mouse model. The continuous expression of Sox9 in differentiated basal layer cells results in abnormalities in morphology of HF and hair cycling, which resemble only some characteristics of the human hypertrichosis phenotypes. Expression profiling experiments are being performed to search for the molecular basis for the same phenotypes. Integration of BAC transgenesis, evolutionary conservation, 3C, DNaseHS, and chIP on chip data identifies a candidate osteoblast enhancer of *Bmp2*. *E.M. Broeckelmann, S. Pregizer, D.P. Mortlock*. Vanderbilt University, Nashville, TN.

Bmp2, a member of the TGF-β superfamily of secreted signaling molecules, is an indispensable factor for vertebrate embryonic development. Furthermore, it is known to play critical roles during initial bone formation and osteoblast differentiation as well as the maintenance of bone health during all stages of life. Genetic association studies have also linked *Bmp2* with such chronic conditions as osteoporosis and osteoarthritis, and rhBMP2 has long been FDA approved for use in fracture repair and spinal fusion. In order to advance strategies to effectively treat and/or prevent various skeletal pathologies, it is imperative that we try and elucidate the factors and regulatory mechanisms that control *Bmp2* expression in osteoblasts. Our previous BAC transgenic approaches in mice not only provided evidence for the great number and complexity of cis-regulatory elements harbored within the large gene desert surrounding *Bmp2* itself, but also precisely identified a 656bp evolutionarily conserved element (ECR1) 156kb downstream of the promoter, that exhibits osteoblast-specific enhancer function. A thorough analysis of transgene expression driven by ECR1, however, revealed that it in fact cannot recapitulate the whole range of endogenous *Bmp2* expression in osteoblasts, as it fails to exhibit any activity in cranial intramembranous bones. This implies the existence of (an) additional osteoblast cis-acting enhancer(s). Subsequent transient transgenic analysis of a *Bmp2*-containing BAC transgene from which ECR1 has been deleted further supports this notion. We have generated new Chromosome Conformation Capture (3C) results for the *Bmp2* 3' gene desert that actually indicate the strongest physical interaction of the promoter to be not with the ECR1 locus itself, but somewhat further downstream. We then performed bioinformatic analysis to correlate these results with other data that are frequently suggestive of regulatory elements. This highlighted an evolutionarily conserved element, located ~10kb 3' of ECR1, that coincides not only with a DNaseHS site in human osteoblasts, but also with histone modifications (meH3K4) and remodeling signatures (H2AZ) in murine osteoblasts and embryonic calvaria. In order to investigate its function in murine osteoblasts, this putative enhancer is now being tested in luciferase reporter and DNaseHS assays.

The role of Filamin b in skeletogenesis and BMP signaling in mice. *J. Zieba, A. Sarukhanov, M. Ivanova, A.S. Kim, A.E. Merrill, D. Krakow.* Orthopaedic Surgery, University of California at Los Angeles, Los Angeles, CA.

Filamins are ubiquitously expressed cytoplasmic actin-binding proteins that affect the cytoskeletal network and intracellular signaling pathways. In 2004, the Krakow lab discovered that mutations in the FLNB gene were an underlying cause of spondylocarpotarsal syndrome (SCT), a recessively-inherited disorder due to absence of FLNB. Individuals affected by these distinct FLNB mutations suffer from abnormally fused vertebral bodies and carpal bones, as well as short stature. While the phenotypic consequences of FLNB mutations have been identified, the molecular basis for this defect in skeletal morphogenesis remains unclear. Our lab generated Flnb knockout mice that mimic the human disease and we have now shown that FLNB is expressed during chondrogenesis and joint formation. The enhanced cartilage formation observed in knockout mice led to the hypothesis that the absence of FLNB leads to an increase in the activity of bone morphogenetic proteins (BMPs). In the chondrocytes of Flnb-/- mice, we have demonstrated an increase in the levels of phosphorylated Smad 1,5,8, as compared to control, 30 and 60 minutes after BMP2 stimulation. These levels persisted in mutant chondrocytes whereas activity in control chondrocytes had returned to pre-stimulus levels. Similar elevated levels were discovered when observing phosphorylated Erk1,2 levels in mutant chondrocytes. We have also demonstrated, following BMP2 stimulation, a prolonged p-Smad 1,5,8 translocation response with persistent levels of nuclear p-Smad1,5,8 in mutants as compared to control. Furthermore, mutant chondrocytes exhibited nuclear p-Smad 1,5,8 in unstimulated cells whereas control chondrocytes did not. This suggests that the absence of FLNB leads to constitutive activation of the BMP pathway. FLNB has a juxtamembrane/subcortical location without BMP2 stimulation; however, 30 minutes after stimulation, FLNB shuttles to the Golgi but not to the endoplasmic reticulum. This demonstrates that FLNB can traffic to the Golgi upon BMP stimulation, supporting its role in endosomal trafficking. These data show FLNB modulates and acts as an adaptor molecule for BMP signaling during skeletogenesis. Our studies identify a previously unappreciated but vital role for FLNB in the development of the human skeleton and enhance fundamental knowledge regarding mechanisms involved in progressive vertebral fusions, which occur in many skeletal dysplasias.

The Role of SOX7 in Cardiovascular Development. *A. Hernandez-Garcia[1,2], M. Wat[1], M. Garcia[3], T.F. Beck[1], Z. Yu[1], R. Schwartz[5], M. Dickinson[3], B. Lee[1,4], D.A. Scott[1,3].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Universidad Autónoma de Coahuila, Saltillo, Coahuila, México; 3) Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, Texas, USA; 4) Howard Hughes Medical Institute, Houston, TX, USA; 5) Departement of Biology and Biochemistry, University of Houston, TX, USA.

SOX7 is a transcription factor encoding gene located on chromosome 8p23.1. Recurrent microdeletions of chromosome 8p23.1 that include *SOX7* area are associated with a high risk of developing cardiovascular malformations. We have shown that SOX7 is highly expressed in the endocardium of the heart and in the endothelial cells of the developing vasculature but its role in these cells remains unclear. To explore SOX7's role in mammalian development, we targeted the second exon of *Sox7* to create both standard and conditional *Sox7* knockout mice. In contrast to $Sox7^{+/-}$ mice which are viable and fertile, $Sox7^{-/-}$ embryos die around E10.5 with pericardial edema and failure of yolk sac remodeling—signs indicative of cardiac failure. A similar phenotype was seen in $Sox7^{+/-}$; $Sox17^{+/-}$ double heterozygote mice. To confirm that these abnormalities were caused by a defect in endothelial derived cells, we generated endothelial-specific *Sox7* knockout mice using a Tie2 cre transgene. $Sox7^{-/flox}$;Tie2cre and $Sox7^{+/-}$;$Sox17^{flox/+}$;Tie2 cre mice were not recovered in Mendelian ratios at weaning. Further analysis revealed that the majority of these embryos died between E10.5 and E15.5. Between these time points, mutant embryos exhibited pericardial edema, abnormal yolk sac vasculature morphology, vascular hemorrhage, atypical cardiovascular development, aberrant liver histology, and developmental arrest/retardation, recapitulating the phenotype seen in *Sox7*-null and *Sox7/Sox17* double heterozygous mice. By comparing the gene expression patterns of wild-type and *Sox7*-null embryos at E9.5 we identified a number of genes with SOX7-dependent expression including genes that play a critical role in cardiovascular development and genes expressed in the developing liver. We conclude that SOX7 expression in endothelial cells is required for normal cardiovascular development and that *Sox17* interacts genetically with *Sox7* in endothelial derived cells. These studies suggest that deletion of *SOX7* may also contribute to the development of cardiovascular malformations associated with recurrent 8p23.1 microdeletions.

Novel Mouse Models Reveal the Role of RERE in the Development of Inner Ear Phenotypes Seen in 1p36 Deletions. *H. Zaveri[1], B.J. Kim[1], O.A. Shchelochkov[2], F.A. Pereira[3], A.K. Groves[1], J.S. Oghalai[4], M. Justice[1], B. Lee[1], D.A. Scott[1].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Dept of Pediatrics, University of Iowa, Iowa City, IA; 3) Cell & Molecular Biology, Baylor College Med, Houston, TX; 4) Otolaryngology, Stanford School of Medicine, Palo Alto, CA.

Terminal and interstitial deletions of 1p36 are a common cause of cognitive and developmental delay with an incidence of 1 in 5000 newborns. Although 28% of individuals with 1p36 deletions also have sensorineural hearing loss, the gene(s) responsible for this phenotype have yet to be identified. *RERE* is located in the proximal region of 1p36, encodes a highly conserved nuclear receptor coregulator that is required for normal embryogenesis. In zebrafish, reduced expression of the *RERE* homolog *Rerea* leads to inner ear anomalies—fused otoliths and abnormal semicircular canals—and diminished microphonic potentials. We hypothesized that *RERE* plays a similar role in the development of the inner ear in mammals. To test this hypothesis, we used immunohistochemistry to show that RERE is expressed in critical regions of the mouse inner ear including the inner and outer hair cells and the marginal and basal cell layers of the stria vascularis. It is also present in the saccule and the semi-circular canals of the vestibular system. However, further studies of the function of RERE in the inner ear were hampered by the early lethality seen in Rere null mice ($Rere^{-/-}$), which die in utero at E9.5 due to cardiac failure. To overcome this, we generated an allelic series of RERE-deficient mice bearing different combinations of a Rere null allele and a hypomorphic allele (*eye3*) we identified in an ENU mutagenesis screen. $Rere^{-/eye3}$ mice have diminished startle responses to a 108 dB burst at 19.9 kHz emitted from a click box—a common preliminary test for severe hearing loss. DPOAE and ABR testing at P21 revealed that $Rere^{-/eye3}$ and $Rere^{eye3/eye3}$ mice have early onset hearing loss. $Rere^{-/eye3}$ mice also fared poorly in the dowel test which requires normal balance and coordination. Histological analyses and 3D micro-CT reconstructions of the inner ear showed that $Rere^{-/eye3}$ mice have normal cochlear morphology at P21 but have increased cross-sectional diameter of their semi-circular canals when compared to their wild type littermates. In preparation for future experiments, we have recently generated RERE conditional knockout mice which can be used to control the spatiotemporal pattern of RERE-depletion within the inner ear. We conclude that RERE is required for normal hearing and vestibular function and that deletion of *RERE* may contribute to the development of hearing loss and gross motor delay in children with 1p36 deletions.

Xenopus laevis, a model for studying the involvement of HDAC6 in a novel form of chondrodysplasia. *K. Massé[1], C. Blanchard[2], D. Simon[2], M. Barillot[2], P. Helwi[2], C. Durand[2], P. Babin[2], A. Tingaud[2], P. Thiebaud[1], N. Thézé[1], D. Lacombe[2,3], B. Arveiler[2,3].* 1) CNRS-UMR 5164, Univ Bordeaux, Bordeaux, France; 2) Univ. Bordeaux Segalen, Maladies Rares : Génétique et Métabolisme (MRGM), EA 4576, Bordeaux; 3) CHU Bordeaux, Service de Génétique Médicale, Bordeaux.

HDAC6 belongs to the superfamily of histone deacetylases, which by altering chromosome structure have important effects on transcription and therefore on cell cycle, differentiation and developmental events. However, HDAC6 is mostly located in the cytoplasm. This enzyme deacetylates tubulin or cortactin, forms complexes with other partner proteins and is involved in a variety of biological processes, in a non-histone linked manner. We previously showed that a variant of the human HDAC6 gene segregates with a form of dominant X-linked chondrosplasia in one family (1), resulting in the overexpression of HDAC6 in the patients, due to abolition of the post-transcriptional regulation of the gene's expression by micro-RNA hs-mir-433 (2). However, the physiopathological mechanisms of the disease remain unknown. We used Xenopus laevis as a vertebrate model to decipher the functions of HDAC6. We report the expression pattern of HDAC6 during development and in the adult frog and compare it to HDAC6 potential partners. HDAC6 overexpression leads to eye and neural crest formation defects. These data bring insights into the physiopathology of the disease and emphasize Xenopus laevis as a model for human pathologies. (1)Chassaing et al. (2005) Am J Med Genet A 136:307–312. Genetic interaction between Sox10 and β1 integrins during enteric nervous system development. *Y. Watanabe[1, 2], F. Bondon-Broders[3], P. Paul-Gilloteaux[3], B. Prosper[1, 2], V. Baral[1, 2], S. Dufour[3], N. Bondurand[1, 2].* 1) genetics department, INSERM U955, IMRB, Creteil, France; 2) Université Paris-Est, Creteil, France; 3) Institut Curie/CNRS UMR144, Paris, France.

The involvement of SOX10 in Waardenburg-Hirschsprung disease (hypopigmentation, deafness, and intestinal aganglionosis) in human and various animal models highlighted the importance of this transcription factor during neural crest (NC) and enteric nervous system (ENS) development in particular. Its role is now well described and numerous interactions between Sox10 and other genes involved in ENS development have been described over the years. In particular, we showed that Sox10 interactions with Zeb2 and the endothelin-3/EDNRB signaling pathway are required for proper vagal and enteric neural crest cells survival and differentiation. However, a possible function of this transcription factor during migration and cell adhesion remained elusive. The importance of Itgb1, encoding β1 integrin, in enteric progenitor adhesion and migration and its co-expression with Sox10 during ENS development prompted us to test the possibility of an interaction between this major extracellular matrix adhesion receptor and SOX10. To this end, we crossed the $Sox10^{LacZ/+}$ mice with the conditional HtPA-Cre; $\beta1^{neo/+}$ and the $\beta1^{fl/fl}$ mice and compared the phenotype of embryos of different genotypes during NC development. The $Sox10^{LacZ/+}$;HtPA-Cre; $\beta1^{neo/fl}$ double-mutant embryos presented a more severe ENS phenotype compared to single mutants which is clearly visible as early as E11.5 and that is not compensated after birth. Using time lapse imaging we showed that defects observed are due to reduced speed of migration and altered directionality of double mutant cells, resulting in severe neuronal network disorganization. Experiments are ongoing to determine the molecular origin of these observations. Together with previous studies, our results strongly support the implication of Sox10 in enteric neural crest cells adhesion and migration.

843F

Mowat-Wilson syndrome associated *ZEB2* zinc-finger mutations lead to phenotype-correlated impairment of the transcription factor function. *J. Ghoumid[1, 2, 3], L. Drevillon[1, 2], SM. Alavi-Naini[4], M. Rio[5, 6], A. Briand-Suleau[1, 2], L. Goodwin[7], P. Raymond[1], N. Bondurand[2], C. Yanicostas[4], M. Goossens[1, 2, 3], S. Lyonnet[5, 6], D. Mowat[8], N. Soussi-Yanicostas[4], J. Amiel[5, 6], I. Giurgea[1, 2, 3].* 1) AP-HP, Henri Mondor Hospital, Creteil, France; 2) Inserm, U955 equipe 11, Creteil, France; 3) Paris Est University, Faculty of Medecine, Creteil, France; 4) Inserm, U676, Robert Debre Hospital, Paris, France; 5) Department of Clinical Genetics, Necker Enfants-Malades Hospital, Paris, France; 6) INSERM U-781, Paris, France; 7) Department of Clinical Genetics, Nepean Hospital, Sydney, Australia; 8) Department of Clinical Genetics, Sydney Children's Hospital, Sydney, Australia.

Mowat-Wilson syndrome (MWS, MIM#235730) is an intellectual disability-multiple congenital anomalies syndrome. Patients harbor distinctive facial features, severe intellectual disability, microcephaly, and Hirschsprung disease. The prevalence of MWS is estimated to be 1 per 50,000–70,000 live births. Patients carry *de novo* heterozygous *ZEB2* molecular abnormalities, that consist in point mutations or small indels (85%), and deletions (15%). So far, more than 180 different *ZEB2* mutations have been identified in MWS patients and no genotype-phenotype correlation was observed. The encoded protein ZEB2 (also called SIP1 or ZFHX1B) is a transcriptional factor, member of the two-handed zinc finger/homeodomain proteins. It comprises six functional domains, among which two zinc finger clusters localized at the N-terminus (N-ZF) and at the C-terminus (C-ZF) of the protein. Integrity of both ZF clusters is critical for recognition of its promoter gene targets. Here, we report the first missense mutations in zinc-finger domains of ZEB2. Patients presented with mild phenotype of MWS, with less marked facial features, moderate intellectual disability, and no or few congenital malformations. All mutations were located in the C-ZF (p.Tyr1055-Cys, p.Ser1071Pro and p.His1045Arg). Using *in vitro* experiments we showed that the underlying mechanism of these mutations is a loss of function and not a dominant negative effect. ZEB2 mutants failed to bind to its best-characterized target, the E-cadherin promoter, and impaired ZEB2 repressive function. Using zebrafish sip1b morphants, the most conserved ortholog of human ZEB2, we performed *in vivo* rescue tests with ZEB2 human mRNA carrying the mutations. Zebrafish rescue varied following the different *ZEB2* missense mutations and correlated with patients' phenotype. These data may improve our understanding of the role of ZEB2 zinc fingers, in the molecular pathology of MWS, and more broadly, in embryologic processes in which ZEB2 has a key role.

Methylation status of a vault RNA, VTRNA2-1 (MIR886), is co-segregated with neural tube defects in Chinese Han families. *W. Li[1], C. Cai[2].* 1) Tianjin Medical University, Tianjin, China; 2) Tianjin Children's Hospital, Tianjin, China.

The etiology of neural tube defects (NTDs) is complex, although the connection between folic acid related genes and NTD is well documented, however, the epigenetic regulation of NTD remains enigmatic. We detected genomewide methylation status in 3 Chinese neural tube defects (NTDs) families. We found that the abnormal methylation of a vault RNA was co-segregated with NTDs status. DNA samples of 12 subjects in 3 families were collected. Each family had multiple NTD patients, including affected NTD sib pairs or parent-offspring pairs. Methylation status of 450,000 CpG islands was scanned in all 12 subjects, and Avg-beta values indicated the intensity of methylation signal of each loci (Illumina Genomestudio, version 2011). Methylation status of a vault RNA, VTRNA2-1, was co-segregated with NTDs. In Family A, 10 of 10 VTRNA2-1 CpG islands were highly methylated in affected siblings. In Family B, all 10 VTRNA2-1 CpG islands were hypermethylated in the affected father and proband ; the methylation level of the mother was very low. In Family C, all 10 VTRNA2-1 CpG islands were hypomethylated in both affected siblings; the father and the maternal uncle were hypermethylated on VTRNA2-1, and the mother had intermediated methylation. VTRNA2-1was transcribed by RNA polymerase III. In the general population, VTRNA2-1 is either hypo- or semimethylated in an allele-specific pattern. Previous studies suggested that VTRNA2-1might NFκB or regulates CXCL12 for cell migration. Both large-sample-size screening and functional analyses are needed to examine VTRNA2-1 methylation.

Background: Congenital defects of the kidney and urinary tract are a major cause of pediatric kidney failure. The molecular diagnosis in the majority of these cases is unknown. Data from cytogenetic studies suggest that submicroscopic structural abnormalities may contribute to the disease pathogenesis. Methods: Genome-wide search for copy number variations (CNVs) was performed with high-density Illumina arrays. We examined the burden of large, rare CNVs in 192 patients with renal agenesis and hypodysplasia (RHD). We next searched for known and novel genomic disorders and replicated findings in 330 RHD cases from two independent cohorts (total of 522 RHD cases). Comparisons were made with 13,839 population controls genotyped with equal or higher resolution arrays. Results: CNV size was significantly larger in 192 RHD cases compared to 4,733 ethnicity-matched controls, based on every standard metric examined (e.g. average CNV size 366.1 kb in RHD vs. 197.1 kb in controls, P= 1.5 x 10-6). This excess of large CNVs was attributable to known and novel genomic disorders. Altogether, we detected CNVs diagnostic of 34 known genomic disorders, such as renal cyst and diabetes syndrome, in 55/522 RHD cases (10.5%); these disorders were present in 0.2% of 13,839 population controls (P=1.2 x 10-58). Another 32 RHD patients (6.1%) harbored large gene-disrupting CNVs that were absent or extremely rare in the 13,839 population controls (frequency <0.14%), identifying 38 potential novel or rare genomic disorders for this trait. The genomic imbalances were detected in RHD patients with and without extra-urinary tract defects. Conclusions: Up to 16.6% of patients with congenital kidney defects have a molecular diagnosis attributable to a genomic disorder. A search for genomic structural variants is indicated in this patient population to diagnose their specific genomic disorders, conduct adequate genetic counseling, and individualize medical care.

Genome wide screening and proteome analysis of developing mice diastema region. *J.Y. Kim, W.J. Sohn, Y.M. Chae, Y.J. Jin, B.J. Han, Y.K. Lee, J.K. Jung, S.H. Kim, M.O. Kim, J.Y. Suh, S. Lee.* Kyungpook National University, Daegu, South Korea.

Different from humans, who have a continuous dentition of teeth, mice have only three molars and one incisor separated by a toothless region called the diastema in the hemi mandibular arch. Although tooth buds form in the embryonic diastema, they regress and do not develop into teeth. In this study, we evaluated the genes and proteins that modulate the diastema formation through comparative analysis with molar-forming tissue by genome wide screening method and liquid chromatography-tandem mass spectroscopy (LC-MS/MS) proteome analysis. From comparative and semi-quantitative proteome analysis and the microarray analysis, we identified 147 up- and 173 down-regulated signaling molecules in the diastema compared to the molar forming signaling molecules. Based on these evaluations, we selected and evaluated two candidate proteins, EMERIN and RAB7A, as diastema tissue specific markers. This study provides the first list of genes and proteins that were detected in the mouse embryonic diastema region, which will be useful to understand the mechanisms of tooth development.

FOXL2 is a member of the family of forkhead domain transcription factors and if mutated, causes gonadal dysgenesis or premature ovarian failure (POF) in women, as well as eyelid/forehead dysmorphology in both sexes (blepharophimosis-ptosis-epicanthus inversus syndrome, BPES). Mice lacking *Foxl2* recapitulate relevant features of human BPES: males and females are smaller than wild type and show distinctive craniofacial morphology with upper eyelids absent. Mouse Foxl2 is required to prevent transdifferentiation of adult ovary to testis and its inducible deletion in adult ovarian follicles leads to immediate upregulation of testis-specific genes including the critical SRY target gene *Sox9*. *Foxl2* is thus responsible for female sex determination and maintenance, in contraposition with *Sox9* which leads to male determination and development. *SOX9* was first identified as a candidate gene for campomelic dysplasia (CD), a human syndrome affecting skeletal and testis development. In these patients most endochondral bones of the face fail to develop resulting in multiple defects such as micrognathia, cleft palate, and facial dysmorphia. Sox9 is also expressed in neural crest cells, and it is involved in skeletal, cartilage and bone formation. Haploinsufficiency of *Sox9* results in defective cartilage primordia and premature skeletal mineralization. Here we report the characterization of the skeletal phenotype of *Foxl2* knockout mice, hence demonstrating its role in skeletal development and strengthening its parallelism with *Sox9* function. *Foxl2* expression had been reported at 10.5 dpc in the 1st branchial arch and here we found its expression in cartilage cells involved both in endochondral and intramembranous ossification. We analyzed Foxl2 knock-out at several developmental stages: from 12.5 to 17.5 dpc, at P0, P7, 4 weeks and 6 months. By IHC we observed premature mineralization and cartilage maturation, and osteopenia. Confocal microscopy revealed a weak expression of Foxl2 in vertebrae cartilages and its co-localization with Sox9. Furthermore, down-regulation of Sox9 expression and upregulation of Col2a1 in the skull, both cartilage maturation markers, support the premature cartilage development. Overall, our results demonstrate that Foxl2, as Sox9, is thus directly involved in skeletal development and growth through its role in cartilage and bone maturation.

Expression and functional analysis of MMACHC during mammalian development. *M. Moreno-Garcia, M. Pupavac, D.S Rosenblatt, L.A Jerome-Majewska.* Human Genetics, McGill University, Montreal, Canada.

Deficiencies of vitamin B_{12} or defects in its metabolism are known as inborn errors of metabolism. A series of inborn errors of vitamin B_{12} metabolism have been identified, designated *cblA-cblG*. These inborn errors can lead to abnormal development of the neural tube and other birth defects in humans, and result in elevation of either homocysteine or methylmalonic acid, or both, in blood and urine. The *cblC* disorder (OMIM 277400), in which there is both hyperhomocysteinemia and methylmalonic acidemia, is the most frequent inborn error of vitamin B_{12} metabolism and is due to mutation in MMACHC. Patients with this disease are unable to convert cobalamin into the two active forms, methylcobalamin and adenosylcobalamin, which are cofactors required by mammalian methionine synthase and methylmalonyl-CoA mutase, respectively. Clinical features of patients can include hematological, neurological, and ophthalmological findings, along with developmental delay. To elucidate the function of MMACHC and examine the expression pattern of MMACHC during mouse embryogenesis, we studied a gene-trap mouse line with a functional disruption of the mmachc gene and we determined sites of gene expression at 11.5 and 12.5 days post conception in WT mouse strain CD1 by in situ hybridization. Our hypothesis is that mice unable to produce functional MMACHC protein will have significant defects during organogenesis due to an inability to properly metabolize vitamin B_{12}. In situ hybridization analysis showed that Mmachc gene was expressed in head mesenchyme, dorsal root ganglia, heart, trachea, lung, esophagus, gut, mesonephric mesenchyme, and notochord during organogenesis in the mouse embryo. The gene-trap mouse line showed that heterozygous mutants were fertile and viable. However, homozygous embryos were only obtained at embryonic day 3.5. At the same time, we found by western blotting, that heterozygous mutants at E11.5 had decreased levels of MMACHC proteins and decrease in proliferation compared with the wild-type mice. Our results highlight that murine MMACHC is essential for early embryonic development.

Three novel human *VANGL1* gene mutations in 144 Slovakian, Romanian and German patients with neural tube defects. *O. Bartsch[1], I. Kirmes[1], A. Thiede[1], S. Lechno[1], H. Gocan[2], I.S. Florian[3], T. Haaf[4], U. Zechner[1], L. Sabova[5], F. Horn[6]*. 1) Institute of Human Genetics, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany; 2) Department of Pediatric Surgery, University of Cluj-Napoca, Cluj-Napoca, Romania; 3) Section of Neurosurgery, University of Cluj-Napoca, Cluj-Napoca, Romania; 4) Institute of Human Genetics, Julius Maximilians University, Würzburg, Germany; 5) 2nd Department of Pediatrics, Comenius University, Bratislava, Slovakia; 6) Department of Pediatric Surgery, Comenius University, Bratislava, Slovakia.

Human neural tube defects (NTDs) are among the most common and serious birth defects with an incidence averaging 1 per 1,000 pregnancies worldwide. NTDs are multifactorial in origin and result from defective neurulation. Neurulation is conventionally divided into a primary and a secondary phase. Primary neurulation creates the brain and nearly all of the human spinal cord, down to the upper sacral level. Defective primary neurulation typically leads to open forms of NTDs (including craniorachischisis, anencephaly and meningomyelocele). Secondary neurulation is defined as the formation of the caudal portion of the neural tube, and defective secondary neurulation results in closed forms of spina bifida, where the emerging spinal cord tissue fails to be separated from the other tissues of the tail bud (including “tethered” spinal cord). Numerous genetic and environmental factors are discussed to be relevant in the etiology of NTDs. In mice, mutants in more than 200 genes including the planar cell polarity (PCP) pathway are known to cause NTDs. It is thought that human NTDs arise in a similar fashion and heterozygous mutations in the human *VANGL1* (a gene in the PCP pathway) have been described in a small subset of patients with NTDs. We performed a mutation analysis of the human *VANGL1* gene in 144 unrelated individuals with NTDs from Slovakia, Romania and Germany and identified three heterozygous missense mutations: c.613G>A (p.Gly205Arg) with an open spina bifida (lumbosacral meningomyelocele), c.557G>A (p.Arg186His) with a closed spina bifida (tethered cord and spinal lipoma) and c.518G>A (p.Arg173His) with an unknown NTD. The c.613G>A mutation was also found in a healthy sibling. None of the mutations were described previously. Findings support that heterozygous *VANGL1* mutations represent hypomorphs or conditional mutants predisposing to NTDs and occur at a frequency of approximately 2% of open and closed spinal NTDs. The mutations (p.Arg173His, p.Arg186His, p.Gly205Arg) modified conserved regions of the VANGL1 protein and shared similarities with previously described mutants, providing further evidence for the presence of mutational hot spots in these patients. Bartsch et al., in press, Mol Syndromol.

Identification of a new ENU-induced mouse model for neural tube defects. *S. Lachance[1,2], M.C. Guyot[1], M. Justice[3], Z. Kibar[1,4]*. 1) CHU Sainte-Justine Research Center, Montreal, Quebec, Canada; 2) Biomedical Science, University of Montreal, Montreal, Quebec, Canada; 3) Departement of Human and Molecular Genetics, Baylor College of Medicine, Houston, Texas, USA; 4) Departement of Obstetrics and Gynecology, University of Montreal.

Neural tube defects (NTDs) are among the most common congenital malformations in humans affecting 1–2 infants per 1000 births. NTDs are caused by a partial or complete failure of the neural tube to close during embryogenesis. The most common forms of NTDs in humans are anencephaly and spina bifida. Their etiology is a complex combination of environmental and genetic factors. In this study, we identified and characterized a novel mouse mutant, Skam26Jus that was generated by N-Ethyl-N-Nitrosuera (ENU) mutagenesis at the Mouse Mutagenesis and Phenotyping Center for Developmental Defects in Texas Medical Center in Houston. This mutant displayed a characteristic kinky or loop tail that is considered as the minimal sign if NTDs. Complementation of Skam26Jus with Looptail showed a genetic interaction between the gene mutated into Skam26Jus and the planar cell polarity gene Vangl2. This complementation led to spina bifida in 50% of embryos with a kinky or looptail appearance. Homozygosity mapping followed by targeted next generation sequencing of the candidate region will be used to identify the gene mutated in Skam26Jus. Our study describes Skam26Jus as a new mouse model for the study of human NTDs and provides an important tool for better understanding of their underlying molecular pathogenic mechanisms.

851F

Involvement of sperm microRNAs in unidentified male factor infertility. *M. G. Katz-Jaffe[1,2], B. R. McCallie[1], J. Stevens[2], W. B. Schoolcraft[2]*. 1) National Foundation for Fertility Research, Lone Tree, CO; 2) Colorado Center for Reproductive Medicine, Lone Tree, CO.

A complex population of RNA, including microRNA (miRNA), has been identified in the nucleus of mature mammalian spermatozoa which are potentially delivered to the oocyte upon fertilization. Preliminary evidence in the mouse has revealed a potential role for murine sperm miRNAs during early embryo cleavage divisions and in mediating epigenetic inheritance. However, the role of human sperm miRNAs during human embryo development remains controversial. Even if there is no functional role for human sperm miRNAs following fertilization, they may serve as a diagnostic tool for identifying male factor infertility. Current evaluation methods for male fertility use microscopic based assessments of sperm count, motility and morphology. Though informative, a normal sperm profile does not promise fertility. The aim of this study was to investigate human sperm miRNAs in relation to subsequent embryo development and potential unidentified male factor infertility. Real-time PCR was performed on sperm RNA using the TaqMan® Human MicroRNA Array (Life Technologies). Sperm samples (n=12) were collected during infertility treatment that included fertile donor oocytes to standardize for the female gamete. Profiling results indicated that 183 human miRNAs were expressed in these sperm samples, including miR-34c, which has been shown to be required for the first cleavage division in the early mouse embryo. Statistical analysis was performed comparing: A) sperm that resulted in good blastocyst development (>30%; n=6) and B) sperm that resulted in poor blastocyst development (<15%; n=6). Results revealed 18 differentially expressed sperm miRNAs. Ten showed increased expression and 8 displayed decreased expression in sperm samples that resulted in poor blastocyst development ($P<0.05$). Three differentially expressed sperm miRNAs belonged to the let-7 family (let-7b, let-7d and let-7e; $P<0.05$), a miRNA family previously identified to be associated with abnormal sperm function. Predicted target gene lists for the differentially expressed sperm miRNAs revealed principal genes involved in spermatogenesis and development. In summary, there is evidence that the expression level of miRNAs in mature human sperm could be reflecting the potential function and/or future competence of the gamete itself. Further studies to elucidate these differentially expressed sperm miRNAs and their target genes may assist in identifying unknown mechanisms associated with male factor infertility.

852F

Comparison of the osteogenic potential of adult stem cells from different sources. *R. Fanganiello[1], F.A.A. Ishiy[1], L.P. Capelo[1], M. Aguena[1], D.F. Bueno[1], B.V.P. Almada[1], M.T. Martins[2], M.R. Passos-Bueno[1]*. 1) Dept Genetics & Evolution, University of Sao Paulo, Sao Paulo, Sao Paulo, Brazil; 2) Department of Oral Pathology, School of Dentistry, University of São Paulo, São Paulo, Brazil.

Stem cells isolated from human exfoliated deciduous teeth (SHED) and from human adipose tissue (hASCs) are interesting subtypes of stem cells to be used in bone tissue engineering due to their osteoprogenitor properties and easy harvesting. In this study we aimed to compare the in vitro osteoblastogenic and the in vivo osteogenic potentials of SHED and hASCs. SHED and hASCs were each obtained from six healthy subjects. After 9 and 21 days of in vitro osteoblastogenic induction, SHED showed a 1.61-fold increase ($p<0.05$) in alkaline phosphatase activity and a 2.24-fold increase ($p<0.0001$) in matrix mineralization, respectively, when compared to hASCs. Amongst the six biomaterials screened, the best in vivo bone induction was observed with CellCeram in combination with SHED, with 8.4-fold increase in bone formation when compared to CellCeramTM free of cells. Next, we found that association of SHED to CellCeramTM induced 7.4 times ($p<0.0001$) more bone formation than hASCs under the same condition. Besides vascularization, dense and loose connective tissue were observed in all groups. Human lamin A/C immunostaining showed that SHED and hASCs induced recipient bone formation but did not differentiate directly into osteoblasts or osteocytes. These results allow us to conclude that SHED have an intrinsically higher in vitro osteoblastogenic potential and in vivo bone induction potential when compared to hASCs. This study also reinforces that the understanding and optimization of conditions to ideally match scaffolds with osteogenic stem cells will contribute to make stem cell-based strategies a better bid than the use of autologous bone substitute for rehabilitation of craniofacial bone defects.

The NINDS Repository's Publicly Accessible Collections of Highly Characterized Induced Pluripotent Stem Cells and Primary Fibroblasts. *C. Tarn[1], K. Fecenko-Tacka[2], M. O'Rourke[2], K. Panckeri[2], C. Rhoda[2], S. Heil[1], K. Hodges[3], M. Sutherland[4], R. Corriveau[4], M. Self[1].* 1) Coriell Institute for Medical Research, Camden, NJ; 2) Stem Cell Biobank, Coriell Institute for Medical Research, Camden, NJ; 3) Cell Culture Laboratory, Coriell Institute for Medical Research; 4) National Institute for Neurological Disorders and Stroke, NIH.

Human induced pluripotent stem cells (iPSCs), and fibroblasts from which iPSCs are derived, have become increasingly utilized resources for studying human disease. iPSCs may prove especially valuable in studying neurological disorders for which disease models are challenging, effective treatments are limited, and novel therapeutics are in great demand. The National Institute of Neurological Disorders and Stroke (NINDS) Repository at the Coriell Institute for Medical Research is a public resource established to provide a centralized and open collection of biological samples with associated phenotypic data to academic, non-profit, and industry investigators. Since 2011, more than 20 iPSC lines and 100 fibroblast lines from subjects harboring mutations associated with disorders such as Parkinson's disease, amyotrophic lateral sclerosis (ALS), Huntington's disease, and dementia, as well as from neurologically normal controls, have been made available via the NINDS Repository web-based catalog (ccr.coriell.org/NINDS). For a number of subjects, both the parental fibroblasts and corresponding iPSC lines are available. To ensure the quality of these valuable materials, all iPSCs and fibroblasts undergo stringent quality control testing including for viability, sterility (microbial and mycoplasma contaminations), and DNA fingerprint analyses for identity. In addition, a set of characterization criteria designed to assess and ensure pluripotency is completed for each iPSC line distributed by the NINDS Repository. These assays include embryoid body formation, cell surface antigen expression, and qRT-PCR analysis of pluripotency; G-banded karyotyping is also performed on each iPSC line to determine chromosomal integrity. The results are summarized within a document termed the Certificate of Analysis (CofA) which is displayed on the web catalog along with culturing protocols and other pertinent information. As knowledge of the applications and limitations of iPSC research emerges, it is important that relevant data and observations describing publicly available iPSCs and fibroblasts be documented and clearly presented to potential requestors. The NINDS Repository serves as an effective, centralized forum for displaying these critical data in addition to providing well characterized cell lines for both basic and applied research.

Deciphering the *Hmx1* pathway in the mouse retina. *A. Boulling, D.F. Schorderet.* Institute for Research in Ophthalmology, Sion, Switzerland.

The *Hmx1* gene is responsible for the Schorderet-Munier-Franceschetti syndrome (MIM 612109), a new oculo-auricular defect identified in 2008, leading to eye developmental abnormalities and early retinal degeneration. Few information are known about the function of this transcription factor, excepted that it is expressed in eye and ear as in some other parts of the nervous system, and that it can recognize a CAAGTG binding site. Here, we identified *Hmx1* target genes in the retina, by using a comparative transcriptomic analysis of C57/Bl6, wild-type and Dmbo mice (carrying a *Hmx1* loss-of-function mutation), supplemented with the screening of the CAAGTG recognition motif (or CACTTG on the reverse strand) in the promoter of the differentially expressed genes. Comparative transcriptomic analysis was done at P15 and microarray data were analyzed with the DAVID algorithm and the Metacore software. Modulated genes were classified into relevant groups based on the adjusted P-Value. The Galaxy platform was used to generate an irrelevant random control group and to count CAAGTG motifs in the [-250,+200] region. Candidate target genes expression was checked by qPCR in mice retina at P15. Finally, the specific retinal cell type expression of each gene was correlated using the Gene expression profile database (http://www.fmi.ch/roska.data/index.php). Microarray results showed 146 modulated genes with $P<0.1$, and 30 modulated genes with $P<0.01$. First, the $P<0.1$ genes were classified into annotation clusters by means of the DAVID algorithm, underlining the enrichment of terms related to membrane and axonal proteins. Using the same genes, the Metacore software analysis revealed 3 enriched GeneGO Process Networks (Synaptogenesis, Visual perception, Synaptic contact). Then, the CAAGTG counting in the promoters of $P<0.01$ genes show 3 genes with 2 motifs (*Sgcg*, *Tshz2* and *Slc6a9*) that represents a 20-fold significant enrichment against a random control group, supporting the idea that these 3 genes are direct *Hmx1* targets. qPCR results confirmed microarray results and showed a dramatic Sgcg over-expression (about 1000-fold). Finally, we showed an overlap between *Hmx1* and candidate target genes expression in the amacrine cells, by inspection of the Gene expression profile database. In brief, *Sgcg*, *Tshz2* and *Slc6a9* represent *Hmx1* candidate targets in the mouse retina.

Evaluation of vitamin B12 effects on DNA damage induced by Paclitaxel. *O. Khabour[1], K. Alzoubi[2], M. Khader[2]*. 1) Medical Laboratory Sciences, Jordan Univercity of Science and Technology, Irbid, Jordan; 2) Clinical Pharmacy, Jordan Univercity of Science and Technology, Irbid, Jordan.

Paclitaxel is a cytotoxic drug used in the treatment of ovarian cancer, breast cancer and non-small cell lung cancer. Various studies have shown that paclitaxel could generate free radicals leading to irreversible cell injury. Recently, new studies have shown that vitamin B12 has antioxidative properties and can protect DNA from free radicals. In this study, we investigated the effect of paclitaxel on DNA by measuring sister chromatid exchanges (SCEs), chromosomal aberrations (CAs) and 8-hydroxy-2-deoxy guanosin (8-OHdG) in cultured human blood lymphocytes. In addition, we investigated the possible protective effect of vitamin B12 on chromosomal damage induced by paclitaxel. Our results showed that PAC significantly increased the frequencies of SCEs ($P < 0.001$) and CAs ($P < 0.001$) in human blood lymphocytes as compared to controls. These DNA damages were prevented by pretreatment of cells by vitamin B12. In addition, we show that paclitaxel induces increase in 8-OHdG, a marker of DNA damage, and this increase was prevented by vitamin B12. Therefore, vitamin B12 seems to protect against paclitaxel -induced DNA damage and genotoxicity.

856T

Evaluation of Vitamin B12 Effects on DNA Damage Induced by Pioglitazone. *K. Alzoubi[1], O. Khabour[2], N. Hussain[1], S. Al-azzam[1], N. Mhaidat[1]*. 1) Department of Clinical Pharmacy, Jordan University of Science and Technology, irbid, Jordan; 2) Department of Medical Laboratory Sciences, Faculty of Applied Medical sciences, Jordan University of Science and Technology, Irbid, Jordan.

Pioglitazone is a prototype of thiazolidinediones, used for the treatment of type 2 diabetes mellitus. Previous studies suggest that Pioglitazone might cause DNA damage by generation of oxidative species. In this study, we investigated the mutagenic effects of pioglitazone using sister chromatid exchanges (SCEs), and chromosomal aberrations (CAs) assays in cultured human lymphocytes. In addition, oxidative DNA damage was evaluated in cells culture by measuring 8-hydroxy-2'-deoxyguanosine (8-OH-dG) marker. We also investigated the possible protective effects of vitamin B12, which is associated with DNA repair, on DNA damage induced by pioglitazone. Treatment of the human lymphocytes with pioglitazone (100 uM) significantly increases the frequency of SCEs and CAs ($P < 0.01$). In addition, significant elevation in 8-OH-dG release from lymphocytes was observed after treatment with pioglitazone ($P < 0.01$). On the other hand, pretreatment of cultures with vitamin B12 (13.5 ug/ml) protected lymphocytes from the genotoxic effect of pioglitazone. Therefore, we conclude that pioglitazone is genotoxic, and it induces chromosomal and oxidative DNA damage in cultured lymphocytes and this toxicity is prevented by pretreatment with vitamin B12.

Cytogenetic study of induced pluripotent stem cells (iPSCs) derived from senescent cells of elderly persons. *F. Pellestor[1], L. Lapasset[2], F. Becker[1], J. Puechberty[1], A. Schneider[1], S. Taviaux[1], P. Sarda[1], J.M. Lemaitre[2], G. Lefort[1]*. 1) Medical and Chromosomal Genetics, Hosp Arnaud de Villeneuve, CHRU Montpellier, Montpellier, France; 2) Laboratory of Plasticity of the Genome and Aging, Institute of Functional Genomics, Montpellier, France.

Reprogramming of adult somatic cells into induced pluripotent stem cells (iPSCs) provide a unique opportunity to generate patient-specific stem cells with potential application in regenerative therapies and without the ethical concerns of human embryonic stem cells (hESCs). However, important question persist about the safety of iPSCs, their chromosomal stability and their propensity to form tumor, in particular for iPSCs derived from senescent cells. In order to assess the chromosomal consequences of reprogramming process, we performed classical and molecular cytogenetic analysis on 4 iPSC lines generated from 74- and 96-years-old men's fibroblasts. Cytogenetic analysis was carried out using standard methods and R-banding. FISH assays with both centromeric and painting probes were used for chromosomal detection on interphase nuclei. A minimum of 20 metaphase spreads and 100 interphase nuclei per cell line were analyzed. The 4 cell lines exhibited normal karyotypes. In three iPSC lines, these investigations were completed by an analysis of the telomere sizes since senescence is characterized by telomere shortening. We measured in situ the length of telomere repeat domains using PNA pantelomeric probes and Metasystems image analyzer software Isis. The Isis software was used to quantify the fluorescence intensity of telomeres from at least 20 metaphases and nuclei from each cell line. In the 3 iPSC lines, we observed a significant increase in telomere length, when compared with their parental fibroblasts and control hESCs. These data were confirmed by telomere restriction fragments analysis (TRF). The perspective of using iPSCs in regenerative medicine is of particular interest in the context of age-associated disorders, but cytogenetic and genetic screening of iPSCs need to become standard practice before these cells might be used clinically.

858T

Secondary Aneuploidy in Samples of Balanced Chromosomal Rearrangements - No Increased Rate Detected. *O. Reish[1,2], R. Amiran[1], A. Kanesky[1], S. Gerafi[1], M. Mashevich[1]*. 1) Gen Inst, Assaf Harofeh Med Ctr, Zerifin, Israel; 2) Sackler School of Medicine, Tel Aviv University, Tel Aviv,.

Background: We previously have shown that the frequency of cells with aneuploidy for randomly chosen chromosomes was significantly higher in samples derived from trisomic and Turner's syndrome patients in comparison to samples derived from control subjects with normal karyotypes. **Aim:** To evaluate frequency of cells with aneuploidy among samples derived from healthy individuals who carry balanced constitutional rearrangements. **Methods:** 20 blood, 7 amniotic fluid and 3 chorionic villous samples carrying balanced translocations, were tested and compared with age and sex matched controls. FISH (fluorescent in situ hybridization) was applied at interphase, using randomly chosen chromosomes (#8, #15, #16), not related to the basic rearrangement. 200 cells per each chromosome in each sample were tested (600 cells per each sample). T test (two-tailed) at the 95% confidence level was applied. **Results:** Frequency of aneuploidy rate was not increased in test samples in comparison to control samples ($Pv = 0.95$) for all 3 evaluated chromosomes, with no significant difference between variably evaluated tissue types. Although monosomy rate was mildly increased in comparison to trisomy, it was not significant ($Pv>0.05$). **Conclusions:** Cells with balanced constitutional rearrangements are not associated with increased sporadic aneuploidy. This correlates with no increased risk for malignancies among carrier patients versus controls.

859W

Telomere “loss” in people with Down syndrome with and without mild cognitive impairment more than doubles after T-lymphocytes have been frozen in liquid nitrogen and short-term cultured with PHA. *E. Jenkins[1], L. Ye[1], S. Krinsky-McHale[1], W. Zigman[1], N. Schupf[1,2], W. Silverman[3]*. 1) Department of Human Genetics, New York State Institute for Basic Research Developmental Disabilities, Staten Island, NY; 2) Taub Institute for Alzheimer's Disease and Aging Research, Columbia University, New York, NY; 3) The Kennedy Krieger Institute and The Johns Hopkins University School of Medicine, Baltimore, MD.

We have previously shown that telomere PNA (peptide nucleic acid) probe (DAKO, Carpenteria, CA) signal number is significantly reduced in short-term whole blood cultures with phytohemagglutinin (PHA) from people with Down syndrome (DS) and dementia/mild cognitive impairment (MCI) in comparison to people with DS and no dementia/MCI (Jenkins et al., 2008, 2012). During the course of a study on telomere loss, we modified our method of culture to include freezing mononuclear whole blood cells, obtained via ficoll paque gradient centrifugation, in liquid nitrogen, until sex- and age-matched pairs of specimens could be obtained for parallel culture studies from individuals with DS with and without MCI. When we determined the amount of telomere [signal] loss in short-term T lymphocyte cultures after freezing, we observed a striking increase in the loss of telomeres in cultures from all people with DS with and without MCI, even though statistically significant differences persisted between samples from DS/MCI individuals and samples from DS individuals without MCI. The mean number of chromosome arms with no signal in two studies where the cells were not frozen was 12.0 (3.5) and 10.0 (3.7) for people with DS and MCI versus 5.9 (2.7) and 4.2 (2.8) for people with DS without MCI, respectively, while for two other studies that involved freezing the samples, the corresponding results were 26.4 (9.3) and 20.1 (6.2) for people with DS and MCI, and 18.8 (5.50) and 9.3 (4.3) for people with DS and no MCI, respectively. We hypothesize that the etiology is related to something in the freezing process. We are anxious to investigate this further to isolate the cause since there are so many critical processes that involve the freezing/thawing cycle that may be affected including embryo implantation. Supported in part by New York State Office for People with Developmental Disabilities Institute for Basic Research (IBR), Alzheimer's Association grants: IIRG-07-60558, IIRG-96-077; NIH grants: PO1-HD35897; RO1-HD37425, RO1-AG014673, and P30-HD024061.

860T

Study of aging consequences in human mesenchymal stem cells during tandem passages. *H. Pour-Jafari[1,2], B. Pourjafari[2], F. Talebzadeh[2], A.R. Zamani[3], M. Hosseinipanah[4], H. Fazli[2]*. 1) Molec Med & Gen Dept, Sch Med, Hamadan Un, Hamadan, Iran; 2) Research Center for Mol Med., Hamadan University of Medical Sciences, Hamadan, Iran; 3) Immunology Dept., School of Medicine, Hamadan University of Medical Sciences, Hamadan, Iran; 4) Anatomy Dept., School of Medicine, Hamadan University of Medical Sciences, Hamadan, Iran.

Stem Cells by their unique characteristics are determined. One of which is high proliferation ability and the other is differentiation to various tissues. Every day around the world including Iran the results of new works released that show the growing momentum of works on the topic used in stem cell therapy. Working with stem cells from different origins is in progress, including the cells originated from fetal and adult origin (such as bone marrow, dental root, cord and etc.). Umbilical cord as a rich source of stem cells originated from human, without using invasive methods, is available in a variety of research using stem cells and then used for cell differentiation and subsequent therapy. On the other hand the fact that each of the mentioned cell after a few days growth and proliferation, will increase and will fill bottom of the flasks in tandem passages. As results of successive cultures do develop stem cells are aging and this caused damage to genetic material that can be evaluated in primary (passages numbers 1–5), middle (passages numbers 8–12) and late passages (passages numbers 15–18) by the Single Cell Gel Electrophoresis assay (comet assay). Also their karyotypes were examined; Solid technique and G-Banding staining for chromosome analysis in the stem cells were employed. Several microscopic slides from each passage were prepared. Then 20 cells were selected from those slides related to each passage randomly. In all selected cells, damages were examined and their degrees of damages were scored based on the standard patterns, from 0 to 4. The averages were compared in different groups. Average scores related to three studied different cell groups, primary, middle and late passages, were 0.4, 2.8 and 3.6 respectively. Prepared karyotypes from cells belonging to passages 1–5 were normal but in aged passages they were abnormal, numerically and also structurally. Our results showed that the aging phenomenon and its consequences such as DNA damages should be considered in works with tandem passages of stem cells. We concluded that the stem cells taken from human umbilical cord blood storage and passage in our center conditions just in the early passages (below passage five) of intact DNA is entitled. Therefore, for research work such cells must be used. We recommend because of the expensive materials needed for passage and maintenance of these cells, passages more than five should be used only for educational purposes in the laboratory.

Telomere structure and function in Cornelia de Lange syndrome preserved despite evidence for premature aging. *A.D. Kline[1], H. Riethman[2], K. Ravichandran[2], M. Kaur[3], A. Kimball[1], I.D. Krantz[3]*. 1) Harvey Inst Human Gen, Greater Baltimore Med Ctr, Baltimore, MD; 2) Wistar Inst, Philadelphia, PA; 3) Div Hum Genetics and Molec Biology, The Children's Hosp of Philadelphia, Philadelphia, PA.

Premature aging has been associated with abnormalities in genome stability, telomere length, integrity and stability, DNA repair, and oxidative stress. Evaluations of multiple individuals with Cornelia de Lange syndrome (CdLS) through an aging clinic, and at regional and national meetings, have shown evidence for premature aging, including facial features older than expected for age with wrinkles and sagging of skin, development of prematurely grey hair, Barrett's esophagus and cholecystitis occurring at a younger age than expected, prostatic enlargement by the early 40's, early development of osteoporosis, decline in adaptive skills and development of impaired corneal reflex with some evidence for neuropathy and autonomic dysfunction. In order to pursue the etiology of the premature aging seen in CdLS, we have first undertaken evaluation of telomeres in individuals of different ages. Cohesin's role in maintenance of telomeres has been unknown, although cohesion at the telomeres is known to play a crucial role in chromosome structure and genomic stability. Telomere characteristics from 11 lymphoblast and fibroblast cell lines from individuals with CdLS with mutations in one of the genes associated with cohesin were compared to 6 age-matched control cell lines without CdLS. The telomere repeat lengths were found to be similar to those of controls, with those from blood slightly longer than from skin in both study and control cells. A telomere stability assay, in which the lengths of individual telomeres are compared using a PCR-based assay showed that there is no difference in the relative fraction of short telomeres in CdLS compared to the controls. Thus, there is no evidence that there are changes in the telomeres in CdLS with aging, including DNA breakage or damage in the telomeres, or shortening of the telomeres. DNA repair in fibroblast cells as compared to controls will be the next step in the evaluation of premature aging.

Identifying Genes Associated with Hearing Loss through Chromosomal Translocations. *B.B. Currall[1,3], N.G. Robertson[1], A.M. Lindgren[1], M.E. Talkowski[2,3], C.C. Morton[1,3]*. 1) Brigham and Women's Hospital, Boston, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA.

Chromosomal translocations, an abnormal exchange of genetic material between nonhomologous chromosomes, are estimated to be as frequent as 1 in 500 newborns and may result in abnormal phenotypes as a consequence of disruptions or dysregulations of genes. By examining the connection between chromosomal translocations and their associated abnormal phenotypes, the Developmental Genome Anatomy Project (DGAP, www.DGAP.harvard.edu) aims to identify genes that are necessary for normal human development. Through DGAP, we have identified several new genes that are putatively important for development of normal hearing. DGAP176 is a male with bilateral congenital sensorineural hearing loss, cognitive impairment, lax joints, coordination difficulties, plagiocephaly and several major craniofacial anomalies. Karyotyping reveals an inversion in the X chromosome inherited from the mother, 46,Y,inv(X)(q13q24)mat, which results in a loss of genetic material including one allele of the POU3F4, a gene known to be associated with hearing loss (DFNX2). DGAP056 is a male with profound bilateral congenital sensorineural hearing loss, mitral valve prolapse, hypospadias, early onset prostate cancer (age 38), and several minor craniofacial anomalies. Karyotyping reveals a translocation between chromosomes 2 and 13, 46,XY,t(2;13)(p24.1;q22.3), which disrupts an unannotated gene, C2ORF43. Analysis by qPCR shows a reduction in the amount of C2ORF43 transcripts. Both in situ hybridization and immunohistochemisty in mice show staining in the developing and adult inner ear structures. We have recently developed a knockout mouse model to explore further the correlation between C2ORF43 and hearing loss as well as other pathological findings. DGAP120 is a male with moderate mid-frequency hearing loss, mild learning disabilities, intermittent extropia, plagiocephaly, and minor craniofacial anomalies. Karyotyping reveals a translocation between chromosomes 6 and 11, 46,XY,t(6;11)(q23~q25;q21) or (q25;q25). Next generation sequencing of the breakpoints demonstrates that the unannotated gene C6ORF103 is disrupted. Further analysis is underway to determine the association between C6ORF103 and hearing loss. DGAP has provided tools and methods to identify and characterize genes involved in hearing loss. Such studies allow us to gain not only insight into the basic biology of the auditory process, but also to investigate new therapies for those who suffer from hearing loss.

An unbalanced whole-arm translocation der(1;13)(q10;q10) in Burkitt lymphoma. *Y. Seok, S.J. Park, S.J. Kim, E.Y. Lee, J.R. Choi.* Department of Laboratory Medicine, Yonsei University College of Medicine, Seoul, Korea.

Structural rearrangements involving the long arm of chromosome 1 are common secondary aberrations in Burkitt lymphoma. Among unbalanced translocations of 1q, whole-arm translocation involving breakage and reunion of nonhomologous chromosomes at their centromeres is relatively rare. We describe here a novel unbalanced whole-arm translocation der(1;13)(q10;q10) in a case of Burkitt lymphoma. A 15-year-old male sought care for epigastric pain. Computed tomography images showed hepatosplenomegaly with innumerable tiny nodules and mesenteric lymphadenopathy. Core biopsy of the nodules confirmed Burkitt lymphoma. Bone marrow aspiration and biopsy analysis from both sides revealed normocellular marrow with significant infiltration of atypical lymphocytes, the majority of which were small to medium sized, with small amount of vacuolated basophilic cytoplasm and distinct nucleoli. Immunophenotyping of the atypical lymphocytes by flow cytometry identified B-cell phenotype with expression of CD10, CD19, CD20, CD79a, and lambda-restricted surface immunoglobulin. In addition to the primary aberration t(8;14)(q24;q32), der(1;13)(q10;q10) was detected by cytogenetic study of his bone marrow sample. By acquisition of the long arm of chromosome 1, the der(1;13)(q10;q10) resulted in trisomy 1q. The patient just recently completed induction chemotherapy with cyclophosphamide, vincristine, and prednisolone (COP). Most 1q abnormalities consist of partial duplications of 1q and have usually been reported to be associated with a poor clinical outcome in Burkitt lymphoma. However, a whole-arm translocations of chromosome 1q is unusual and so far poorly understood finding. We believe that this case represents an acquired cytogenetic abnormality which has not yet been described in Burkitt lymphoma. Keywords: Whole-arm translocation, 1q, Burkitt lymphoma.

Two Sibs with Trisomy 2q 34-qter. *Y. Wang[1], X. He[2], Y. Zhou[3], C. Wang[2], X. Yang[2], L. Zhu[2], Y. Yang[2], H. Wu[2], X. Liu[2], D. Shrestha[1], C. Lee[1], E. Carter[1], J. Martinez[1]*. 1) Pathology, University of South Alabama, Mobile, AL; 2) Cent. of Clinical Genetics, Bayi Children's Hospital, Beijing, China 100700,; 3) Biology, Baylor University, Waco, TX 76706.

The phenotype of the partial duplication at the long arm of chromosome 2, known as partial trisomy 2q, has been well described in the literature. The condition for most cases comprises of facial anomalies, visceral abnormalities and mental retardation. The phenotypic variability depends upon the breakpoints, exact portion of the duplication region involved as well as loss of another chromosome segment. We report on a brother and sister with facial anomalies and mental retardation. The clinical findings in both sibs consisted of prominent forehead, hypertelorism, low-set ears, broad nasal bridge, long philtrum, and the thin upper vermillion lip. The sister also had nystagmus, bilateral single palmar creases, and short of both 5th fingers with clinodactyly. The brother had only short of both 5th fingers. Developmental milestones of both were delayed.They also had disproportionate delay of speech. Their IQ examination showed moderate mental handicap. A brain computed tomography (CT) showed normal anatomy and they have no other visceral abnormalities. The sib's maternal uncle had similar facial anomalies and mental retardation. The patients had a karyotype with duplicated material of unknown origin in the short arm of chromosome 3. A detailed analysis of the constitutional chromosomal changes in two sibs and their parents was conducted by as microarray comparative genomic hybridization (array CGH), multiplex ligation-dependent probe amplification (MLPA) and linkage analysis using 16 short tandem repeat (STR) markers on chromosome 2. The addition of the duplicated material was found originating from the long arm of chromosome 2 (q34-qter) and size was about 31.523Mb. The parental chromosome studies showed that the mother was the carrier of a balanced translocation chromosome of 2 (q34-qter) into terminal 3p. MLPA of both sibs presented deletion of 3p CHL1 gene. The phenotype of the terminal deletion of chromosome 3p including CHL1 gene has been characterized as causing growth retardation, developmental delay, mental retardation, dysmorphisms, microcephaly and ptosis. It has been suggested that variable phenotype of patients with partial trisomy 2q results from the phenotypic expression of any accompanying chromosomal loss. Therefore, in order to better understand the phenotype-genotype relationship, it is important to employ high resolution genetic techniques, such as array CGH, to better characterize chromosomal duplications.

Subtelomere sequences on human acrocentric chromosome short arms. *S. Baaj, A. Clarke, P. Thakkar, E. Chan, M. Khan, S. Chawla, J. Leya, J. Doering.* Dept. Biology, Loyola University Chicago, Chicago, IL. USA.

The 10–15% of the human genome containing heterochromatic regions has yet to be characterized. We are determining the structure of the short arm of human chromosome 21 (HC21p) as model for the organization of these regions. While the subtelomeres of most chromosomes have been extensively studied, these regions remain poorly characterized on the acrocentric p arms. Thoraval et al. (1996) identified a 580bp sequence on acrocentric p arms, as well as HC3 and HC4. Using telomere-anchored PCR, with a degenerate telomere primer and a primer specific to the 580bp sequence, they obtained a product from total genomic DNA, thus claiming that the 580 bp sequence was subtelomeric. We used the same assay with input DNAs from human chromosome-containing hybrid cell lines, and found no PCR product from distal HC21p or from any other acrocentric chromosome. PCR products were obtained from intact HC21 and total human genomic DNA. Thus the sequence organization Thoraval et al. studied is not subtelomeric on acrocentric chromosomes, but seems to occur at a number of other loci throughout the genome. Searches of several human sequence databases confirmed that the 580 bp and degenerate telomere sequences are spread throughout the genome. Regions flanked by inverted degenerate telomere sequences are also found at a number of genomic loci that are not part of subtelomeres. Using Southern blots we showed that the 580 bp sequence is part of a 6kb tandemly repetitive element that is primarily located on the acrocentric short arms. We cloned and sequenced a copy of this element from an HC21-specific phage lambda library. Two tandemly repetitive sequences exist within the 6kb repeat: an AGGA repeat and a 147bp repeat, also located at the proximal end of the rRNA gene cluster. Additionally, there are two copies of a 500 bp direct repeat in the 6 kb element that share 80% sequence identity. PCR primers for different regions in the 6kb sequence were designed to test its presence and degree of sequence conservation on HC21 and the other acrocentric chromosomes. Several clones of the PCR products were sequenced. Copies of the 6kb repeat are highly conserved (98%) on all acrocentric chromosomes and bear 96% sequence identity to repeats found in BACs from HC22, HC4 and proximal and distal HC21p. Analysis of these BACs suggests that the 6kb tandem repeats may be subtelomeric while single or partial 6kb units are present throughout the genome.

866T

Multiple chromosomal losses and gain including the deletion of 12p13 region defined by cytogenetic microarray in a case of simultaneous T-cell prolymphocytic leukemia and renal cell carcinoma. *J. Kim[1], J. Moon[1], M. Nam[1], J. Kim[2], S. Yoon[1]*. 1) Laboratory Medicine, Koure Univ. Ansan Hosp., Ansan, Gyeonggi, South Korea; 2) Laboratory Medicine, Koure Univ. Anam Hosp., Seoul, South Korea.

T-cell prolymphocytic leukemia (T-PLL) is a rare form of mature T-cell lymphoproliferative disease which occurs mainly in the elderly. T-PLL demonstrated highly recurrent submicroscopic gains and losses previously established, in regions including the *ATM* (11q22–23 region, frequency ~95%), *ETV6* (12p13, >10%), and *CDKN1B* genes (12p13, ~48%). The *CDKN1B* gene, in particular, is a tumor suppressor gene that encodes the cyclin-dependent kinase inhibitory protein $p27^{KIP1}$, which is associated with tumor size and poor prognosis in patients with renal cell carcinoma. We report a case of simultaneous development of T-cell prolymphocytic leukemia and renal cell carcinoma with multiple chromosomal losses and gain including the deletion of 12p13 region defined by cytogenetic microarray. A 55-year-old female presented with absolute lymphocytosis (66%, 15,150/μL) at a routine blood exam. On physical exam, she had neither palpable lymphadenopathy nor skin lesions. Blood biochemical analysis and serologic studies were nonspecific. A computed tomography scan showed no hepatosplenomegaly, but revealed a left kidney mass later diagnosed to be renal cell carcinoma (RCC). Examination of a bone marrow biopsy demonstrated diffuse infiltration of abnormal lymphoid cells. Flow cytometry analysis indicated that the lymphoid cells showed aberrant T cell immunophenotype with positivity for CD3, CD5, CD7, and coexpression of CD4/8. The conventional cytogenetic analysis was normal, but cytogenetic microarray showed complex chromosomal aberrancies including deletion of the 8p11.23-p23.3, 11q14.1-q25, 12p13.2, 22q11.1-q12.2, and Xp21.3-q28, and gain of the 18q21.33–22.2 and 22q12.2-q13.313. Further research needs to be done whether the chromosomal loss and gain has also contributed to malignant transformation of RCC.

867W

A Case of Therapy-related acute myeloid leukemia with t(19;21)(q13.4;q22). *M. Nam[1], J. Moon[1], J. Kim[2], J. Kim[1], S. Yoon[1]*. 1) Laboratory Medicine, Korea University Ansan Hosp., Ansan, Gyeonggi, South Korea; 2) Laboratory Medicine, Korea University Anam Hosp., Seoul, South Korea.

AML1 (= RUNX1=CBF2) is a gene essential for normal hematopoietic development. It is the most frequent target for genetic alternations in acute myeloid leukemia (AML), and *AML1* gene rearrangement is common in therapy-related myeloid neoplasm associated with topoisomerase II inhibitors. T(19;21)(q13.4;q22), a very rare cytogenetic abnormality that has only once been reported in a case of radiation-associated acute leukemia, has been previously demonstrated to act in leukemogenesis by blocking myeloid differentiation. We now present a patient in whom AML with t(19;21) developed after six years of high-level chemotherapy (R-CHOP regimen, including both alkylating agents and topoisomerase II inhibitors) for malignant lymphoma. A 64-year-old male was diagnosed with non-Hodgkin Lymphoma (diffuse large B-cell lymphoma, stage III) on 2004, when the bone marrow biopsy showed normal marrow with no involvement of lymphoma. He was treated with the R-CHOP regimen chemotherapy and autologous PBSCT at primary remission. The patient responded well to the induction chemotherapy and was asymptomatic until 4 years later, he developed pancytopenia, and the bone marrow biopsy findings done on 2009 showed normal marrow with no involvement of lymphoma (Karyotype: 46,XY). At about this time, the patient was found to have dilated cardiomyopathy. On May, 2010, the patient showed infection signs and was admitted for the treatment of pneumonia. An initial complete blood count revealed aggravation of the pancytopenia, but blasts were not seen on the PB smear. A bone marrow biopsy revealed AML, FAB type M5b. The Hemavision multiplex RT-PCR showed no fusion transcript, and no *MLL* gene rearrangement was noted on fluorescent in situ hybridization (FISH) analysis. Subsequently, conventional cytogenetic analysis showed a t(19;21)(q13.3;q22), and *AML1* gene rearrangement was confirmed by FISH analysis. Twenty-three days after the AML induction chemotherapy, the patient died from uncontrolled pneumonia and sepsis.

Detection of Donor Cells with a Clonal Abnormality 20 years after Transplantation: Is this Evidence of Donor Cell Leukemia (DCL)? *G. Velagaleti, V. Ortega, D. Means.* Dept Pathology, Univ Texas Hlth Sci Ctr, San Antonio, TX.

A vast majority of patients achieve engraftment following allogenic bone marrow transplantation (BMT) within 2 weeks. DCL is a rare complication following BMT with unknown etiology. Here, we report on a patient who showed no cytogenetic evidence of engraftment for well over 20 years following which donor cells were detected with a clonal abnormality. A 59 year old female was diagnosed with CML in 1986 and underwent an allogenic BMT from her brother in 1987. Subsequently she developed graft-versus-host disease of the eyes, mouth and skin in 1990 suggesting possible rejection of donor cells followed by relapse of CML and progression to accelerated phase in 2000. Chromosome analysis demonstrated two Ph+ chromosomes, 46,X,-X, t(1;7)(p10;p10),add(4)(p16),t(9;22)(q34;q11.2),-15,+3mar[16]/46,XX,der(9) add(9)(p24)t(9;22)(q34;q11),add(18)(p11.3),-19,der(22)t(9;22)[4]. Treatment with Gleevec was unsuccessful due to intolerance. Follow-up studies in 2006 revealed persistence of known Ph+ clones and an additional Ph+ clone. Upon treatment with dasatinib she achieved partial remission and chromosome studies in 2007 showed, for the first time, donor cells with gain of chromosome 8 (T8) along with recipient cells with the Ph+ clone. The karyotype was interpreted as, 46,XX,t(9;19)(p24;p13.1),t(9;22) (q34;q11.2),t(14;18)(q24;11.2)[2]//47,XY,+8[3]/46,XY[20]. Subsequent karyotypes demonstrated only donor cells with T8 clone in 15–35% of cells. Constitutional T8 was ruled out as the donor's blood karyotype was normal. T8 is a unique additional anomaly in 10% of CML cases frequently emerging at the time of acute transformation and may arise after imatinib treatment. Although engraftment is an immediate response, the cytogenetic evidence of donor cells did not become apparent in our case due to the proliferative dominance of Ph+ clones. Dasatinib treatment in our patient effectively removed the dominant Ph+ clones facilitating the detection of donor cells with T8. Since the etiology of DCL is unclear, we are not certain as to the significance of the T8 in donor cells in our patient and we continue to monitor the patient for high-risk secondary MDS and AML.

869W

Xp22.31 duplications: Indistinctly benign or inconspicuously pathogenic? *E.D. Esplin[1], B. Li[2], V. Cox[2], R. Clark[3], C. Curry[4], A. Slavotinek[2], L. Hudgins[1].* 1) Division of Medical Genetics, Department of Pediatrics, Stanford Univ Medical Center, Stanford, CA; 2) Division of Medical Genetics, Department of Pediatrics, University of California San Francisco, San Francisco, CA; 3) Division of Medical Genetics, Department of Pediatrics, Loma Linda University, Loma Linda, CA; 4) Division of Medical Genetics, Department of Pediatrics, UCSF Fresno, Fresno, CA.

Submicroscopic duplication of Xp22.31 has been reported as either a possible cause of development delay or a benign variant. Though multiple cases have been reported, characteristic features attributable to this duplication have yet to emerge. The pathogenicity of chromosome Xp22.31 duplications remains unclear. We report a series of 6 new cases of Xp22.31 duplication, the largest case series thus far, and offer insights as to whether this duplication is associated with a distinct phenotype. Patients were referred for genetics evaluation for developmental delay, autism, dysmorphic facies and talipes equinovarus. They include a first born female, two males with healthy siblings and a family with three siblings. The Xp22.31 duplications in these patients were defined by array CGH analysis with breakpoints at 6,461,814-8,086,161 and 6,477,036-8,057,482 approximating 1.6 Mb. One patient has two duplications (6,461,866-7,704,162 and 7,920,089-8,124,774) totaling approximately 1.2 Mb and spanning about 1.6 Mb. In all of our cases, the Xp22.31 duplication was found to be of maternal inheritance. The most consistent clinical features in our cases include: developmental delay or learning difficulties of varying severity in all 6 cases, seizures in 3, talipes equinovarus in 2 and feeding difficulties in 2. Individual patients also demonstrated autism spectrum disorder, bilateral elbow contractures, hearing loss and dysmorphic facies. One recent case report, with breakpoints similar to our series, describes a patient with an approximately 1.5 Mb duplication of Xp22.31 at 6,526,735-8,101,017, with bilateral talipes valgus, hypotonia, and developmental delay. One survey of microarray results found 23 patients with Xp22.31 duplications similar to ours. Limited clinical data were available: intellectual disability (13/23), GE reflux or feeding difficulties (6/23) and seizures (3/23). A genomic instability study reported 14 patients with Xp22.31 duplications of about 1.6 Mb, including breakpoints 6,455,604-8,109,387. Limited clinical descriptions reported developmental delay (8/14), autism spectrum (7/14), hypotonia (4/14), feeding difficulty (3/14), and seizures (2/14). The findings in our case series provide further evidence suggesting this duplication may act as a risk factor for neurocognitive disorders, seizures, equinovarus and feeding difficulties, the severity of which may be mitigated by modifiers in the genomic background.

870T

Refining the critical region associated with Jacobsen Syndrome through the identification of a small interstitial deletion at 11q23.4-q24.1 by CGH array. *S. RASKIN[1, 2], H. SALOMAO[1], F.R. FAUCZ[1], A. BONALUMI[1], J. SOUZA[1], P. GROSSFELD[3], J. ROSENFELD[4], V. SOTO-MAIOR[1].* 1) Group for Advanced Molecular Investigation (NIMA), Graduate Program in Health Sciences (PPGCS), Center for Biological and Health Sciences (CCBS), Pontifícia Universidade Católica do Paraná (PUCPR) Curitiba, PR, Brazil; 2) Genetika - Centro de Aconselhamento e Laboratório de Genética, Curitiba, PR, Brazil; 3) Division of Pediatric Cardiology, Department of Pediatrics, Rady Children's Hospital of San Diego, California, USA; 4) Signature Genomic Laboratories, PerkinElmer, Inc., Spokane, Washington, USA.

Jacobsen Syndrome (JBS) is characterized by pre- and postnatal physical growth retardation, psychomotor retardation, skull deformities, thrombocytopenia and characteristic facial dysmorphism. A subset of patients have heart, central nervous system and other malformations. It is usually caused by 11q terminal deletions, with sizes varying from 5 to 16 Mb, but more recently, interstitial deletions have been identified. We report a four-year-old Caucasian female born from healthy non-consanguineous parents, with a clinical diagnosis of JBS, based on postnatal physical growth retardation, hypotonia, psychomotor retardation, speech delay, facial asymmetry, ogival palate, thrombocytopenia and microcephaly. Oligonucleotide-based aCGH was performed using a 135K-feature whole-genome microarray (SignatureChip Oligo Solution version 2.0, Signature Genomic Laboratories, Spokane, WA, U.S.A.), and identified a “de novo” 1.4 Mb deletion at 11q23.4-q24.1 including the GRIK4, TBCEL, TECTA, SC5DL, SORL1, MIR125B1, MIR100HG and BLID genes. A second “de novo” deletion of approximately 9.3 Mb at 2q14.1q14.3 that includes the genes DDX18, CCDC93, INSIG2, EN1, MARCO, C1QL2, STEAP3, DBI, TMEM37, SCTR, TMEM177, PTPN4, EPB41L5, RALB, INHBB, GLI2, TFCP2, CLASP1, MKI67IP, TSN and CNTNAP5 was also detected, and although mutations of GLI2 have been associated with holoprosencephaly and deletions of CNTNAP5 have been implicated as a risk factor for autism and dyslexia, normal individuals with overlapping deletions have also been described in the published literature. This patient has, therefore, the smallest 11q interstitial deletion reported to date, but many features of JBS. She has no congenital heart malformation, consistent with the previously published papers implicating ETS-1 as the cardiac gene. Against previous knowledge, direct deletion of the platelet function critical genes ETS-1, FLI-1, NFRKB and JAM3 may not be crucial for thrombocytopenia, but deletion of GRIK4, TBCEL, TECTA, SC5DL, SORL1 and/or BLID and/or a positional effect may be. We are aware that careful in the interpretation of this results is needed, as we report a single case and we do not know the exact impact of the second deletion detected, so reports of further cases with similar 11q deletion size, position and gene content, but no other chromosomal abnormality are needed to confirm our findings. Our results reiterate the benefits of array-CGH to clarify genotype/phenotype associations.

871W

Triploid-diploid mixoploidy presenting with gastrointestinal complaints and growth failure. *F.I. Bhamani[1], G.L. ELsner[2], M.B. Beg[3], R.R. Lebel[4].* 1) Ziauddin University Hospital, Karachi, Sindh, Pakistan; 2) Section of Medical Genetics, SUNY Upstate Medical University, Syracuse, NY, MS2; 3) Division of Pediatric Gastroenterology, SUNY Upstate Medical University, Syracuse, NY, MD; 4) Section of Medical Genetics, SUNY Upstate Medical University, Syracuse, NY, MD.

A female infant was delivered by cesarean section at 32 weeks of gestation because of growth arrest and poor movement patterns. Her mother was a 26 year old G2P2 woman of English and Welsh ancestry who had a Wilms tumor when she was 2 years of age. The father was 41 years old with type II diabetes, hypercholesterolemia, and hypertension; his family history was notable for multiple close relatives with cancers of the breast, colon, and pancreas. The infant had feeding problems which were based on gastroesophageal reflux, laryngomalacia, and decreased gut motility. Hypotonia was notable from the outset, and she eventually displayed significant delays in both motor and cognitive milestones. Meanwhile, lymphocytes had yielded a normal karyotype (46,XX) but at two years of age she underwent a skin biopsy and mosaicism for a 68,XX cell line was discovered in fibroblasts. At five years of age, the patient is very short of stature but has a weight at the 25th percentile and head circumference at the 90th. Other phenotypic features include: low set ears, piebald irides and scalp hair, eyelid ptosis, strabismus, broad nasal bridge, anteverted nares, upswept eyebrows, hypoplastic teeth, pectus excavatum, hypoplastic labia, scoliosis, 3–4 finger syndactyly, 2–3 toe syndactyly. We present this case with a review of the literature for mixoploidy (the rare event of mosaicism for diploid and triploid cell lines). We also compare the clinical phenotype with that typical of children affected by the Russell-Silver syndrome. The complexity of the gastrointestinal problems make this case unusual.

Trisomy 14 mosaicism in a girl: Clinical cytogenetic and molecular analysis. *R. Cruz-Alcivar[1], E. Lieberman[1], C. Salas[1], P. Navarrete-Meneses[1], C. Cantú[3], K. Buiting[4], C. Durán-McKinster[2], V. Del Castillo-Ruiz[1], P. Pérez-Vera[1], Alcivar.* 1) Laboratorio de Cultivo de Tejidos, Departamento de Investigación en Genética Humana, Instituto Nacional de Pediatria, Mexico DF, México; 2) Departamento de Dermatología, Instituto Nacional de Pediatria, Mexico DF, México; 3) Genomi-k Monterrey NL, Mexico; 4) Institut für Humangenetik Universitätsklinikum Essen, Essen, Germany.

Trisomy 14 mosaicism is a rare cytogenetic abnormality, at present approximately 26 patients have been reported. These patients exhibit growth and developmental delay with variable severity, congenital anomalies, pigmentary skin lesions, and dysmorphic features. We report a 13 year old female from non-consanguineous healthy parents who had one previous miscarriage. She has one sister with hip dysplasia. At six months old she had short stature, cleft palate, face asymmetry, hyperpigmented linear streaks in arms and legs. Developmental delay, oesophagical reflux and hip dysplasia were documented. At present, she has mild facial dysmorphism, moderate mental retardation, bilateral conductive deafness and nocturnal enuresis. She has undergone palate closure, Nissen funduplication, hip myotomy, brain MRI shows arachnoid cysts. At 1 year and 2 months of age a GTG-banding chromosome analysis of peripheral blood lymphocytes was performed, revealing mos 47,XX,+mar[20]/47,XX,+14[1]/46,XX[4]. Four months later, karyotype in fibroblasts from hyper and hypogimented skin were obtained showing two cell lines, 47,XX,+mar and 46,XX. Parental karyotypes were normal. At 12 years old the patient was analyzed with a DNA array-Oligo 180k (Agilent), revealing a trisomy 14 mosaicism (arr 14q11.1q33.32(18,127,052–106,358,550)x2~3); the marker chromosome is originated from chromosome 14 and probably duplicates the proximal region between 19.5 Mb and 21.3 Mb. Metaphase FISH analysis performed with DNA BACs probes for 14q11.2 and 14q32.33 revealed the presence of three cell lines one normal (55.8%), one with +14 (9.6%) and another with +del(14q)(34.6%). Original peripheral blood slides were re-evaluated increasing the analyzed metaphases. The result obtained combining the performed analyses was: mos 47,XX,+del(14)(q11.2)[45]/47,XX,+14[10]/46,XX[45]. Patient was also analyzed for maternal uniparental disomy 14, but it was not showed evidence for abnormal methylation. In our knowledge, this is the first case of complete trisomy 14 coexisting with a cell line with partial proximal trisomy. The complete delineation of this proximal region might be useful for finding important genes associated with the phenotype of the proband.

873W

Low Klinefelter mosaicism in a male with azoospermia detected by FISH. *P. A. Delgado[1], B. Crandall[2], N. Rao[3], P. Bui[3], C. A. Tirado[3]*. 1) Department of Ecology and Evolutionary Biology, UCLA; 2) Department of Medical Genetic and Prenatal Diagnosis, UCLA; 3) Department of Pathology and Laboratory Medicine, UCLA.

Gonosomal aneuploidies such as Klinefelter syndrome (47,XXY) are the most frequent chromosomal aberrations in infertile men. Herein we present a 39 year old male with history of infertility with mild left sided gynecomastia, but without facial dysmorphic features noted. A physical exam revealed abnormally small testes, and a bilateral testicular biopsy showed absence of spermatogonia. Follicle-stimulating hormone (FSH) was 56.1 mIU/ml (very high), and his testosterone was minimally low at 247.7 (normal 249 to 836), for which he received testosterone therapy. Azoospermia, gynecomastia, very small testes and high FSH levels, low testosterone levels are all associated with Klinefelter syndrome. Cytogenetic analysis of the peripheral blood showed an apparently normal male chromosome complement in all cells examined. However, FISH studies using the XRY and the CEP X revealed a small cell population (3.6%) with two signals for the X chromosome and one signal for the SRY gene, consistent with low level mosaicism for the XXY cells. Klinefelter-like patients with a normal karyotype are usually mosaic. Our patient showed a very low level of mosaicism which may be attributed to the mosaicism in his germinal cells. The patient Klinefelter patients with low level mosaicism have been reported and may be likely to have such mosaicism in their germinal cells.

874T

A balanced translocation t(2;16)(q35;q24.1) associated with limb defects and craniofacial dysmorphism through presumptive misregulation of the *IHH* (Indian hedgehog) gene. *A.C.S. Fonseca, S. Antonini, A. Bonaldi, P.A. Otto, A.M. Vianna-Morgante.* Department of Genetics and Evolutionary Biology, University of São Paulo, São Paulo, São Paulo, Brazil.

We report an apparently balanced de novo translocation t(2;16)(q35;q24.1) in an 8-year-old girl with abnormal number and insertion of digits affecting the four extremities, club feet, and craniofacial dysmorphism. No microimbalances were detected by array CGH (180K whole-genome platform; Agilent) that could explain the phenotype. The chromosome 16 breakpoint was mapped by FISH to a 134 kb gene negative region (chr16: 86,058,168–86,192,535; hg19). The chromosome 2 breakpoint was mapped to a 40 kb "gene desert" (chr2: 220,942,287–220,983,218), ~1Mb upstream from the *IHH* (Indian hedgehog) gene (chr2:219,919,142–219,925,238), which encodes a hedgehog family signaling molecule involved in chondrocyte differentiation and cortical bone formation. Considering the phenotype of the patient and absence of direct involvement of any structural genes, we speculate that *IHH* might be involved through disruption of its regulation by the translocation. Limb and craniofacial defects have been associated with copy number variations upstream from the gene, in mouse (doublefoot mouse mutant; Babbs et al. Mech Dev 2008; 125:517) and in humans, and a putative regulator was identified ~50 kb 5' of *IHH* (Klopocki et al. Am J Hum Genet 2011; 88:70). A more distal *IHH* regulatory region might have been disturbed by the t(2;16) here described. Two enhancers, hs1507 (chr2:220,713,868-220,717,300) and hs1635 (chr2:220,771,085–220,773,279), which drive gene reporter expression in limb and/or facial mesenchyme in mouse embryos (VISTA enhancer browser), appear as potential *IHH* regulators; mapped ~200 kb proximal to the der(2) breakpoint, one or both might have become functionally altered. Alternatively, a more distally located regulatory element might have been disrupted by the breakpoint or become isolated from *IHH* through translocation to chromosome 16. Although no genes on chromosome 16 seem to have contributed directly to the phenotype, an enhancer mapping ~300 kb distal to the der(16) breakpoint (hs1;chr16:86,430,087-86,430,726), which drive gene reporter expression in the limb, cranial nerve, hindbrain and neural tube in mice embryos, was translocated to the der(2), and this might have impacted *IHH* expression. Financial support: FAPESP (CEPID 98/14254-2; 2011/ 14293-4).

Detection of parental origin and meiotic error type in abortions and born alive with aneuploidies. *S. Frias[1,4], S.P. Mendoza-Constantino[1], S. Sánchez[1], L. Torres[1], B. Molina[1], P. Grether[2], D.G. Mayén[3], R. Meléndez[3], E. Yokoyama[1], C. Villarroel[1], E. Lieberman[1], V. Del Castillo[1]*. 1) Human Genetics, Instituto Nacional de Pediatría, D.F., Mexico; 2) Instituto Nacional de Perinatología, México D.F. México; 3) Hospital Angeles Lomas, Huixquilucan, Edo. Mexico, México; 4) Instituto de Investigaciones Biomédicas UNAM, D.F. México.

Aneuploidies have been identified in at least 5 percent of clinically recognized pregnancies and are the leading genetic cause of spontaneous abortions and birth defects. To date there is no a known reason why an aneuploid fetus continues to develop or is aborted. The meiotic error type and parental origin of aneuploid chromosome could be factors of lethality or fetal survival. We detected the parental origin of aneuploidy and meiotic error in 14 abortions and 31 live born with trisomy of chromosomes 13,18,21 and monosomy X. A segregation analysis using at least five short tandem repeat (STR) markers per chromosome was made with Aneufast Kit for QF-PCR in an ABI PRISM 310 Genetic Analyzer. A comprehensive analysis of all STRs on each chromosome involved in aneuploidy was made. The allele more proximal to the centromere was considered as the main marker to determine the type of meiotic error. For monosomy X, we determined the origin of the chromosome X and therefore nondisjunction occurred in the parent that alleles absent belong to. To determine the meiotic error type, we compared all the alleles in three chromosomes involved in trisomy. In the case of monosomy X, it was not determined. (Table 1). The maternal origin and MI nondisjunction, were the most frequent in samples of live born as reported in the literature. The error in MII was more frequent in abortions than in live born, although this should be confirmed by increasing the number of cases studied. If so, one might assume that the presence of two identical chromosomes, generates more areas of homozygosis than in type MI errors and this could have deleterious consequences and lead to spontaneous abortion.Project funded by FONCICYT 95419.

TABLE 1 T13 live-born	T18 live-born	T21 live-born	45,X live-born	T13 miscarriage	T18 miscarriage	T21 miscarriage

876T

Non-mosaic trisomy 9: A new case report. *T. Greer[1], B. Powell[1], N. Hauser[1], J. Shen[1], L. Mahon[2], R. Owen[2], T. Sahoo[2], A. Anguiano[2], F. Boyar[2]*. 1) Med Gen/Metabolism, Children's Hosp Central CA, Madera, CA; 2) Quest Diagnostics, San Juan Capistrano, CA.

Background: Trisomy 9 is a chromosomal abnormality rarely seen in live-born infants. It is believed non-Mosaic Trisomy 9 is ultimately lethal, and surviving infants with Trisomy 9 represent mosaicism. Previously, conventional karyotype was used to evaluate patients to determine if genetic mosaicism was present. Microarray technology is now able to detect low levels of mosaicism, providing a better method to truly determine if mosaicism is present. Case Report: The infant was born to a 23yo G3P1 female. Pregnancy was complicated by abnormal ultrasound findings showing bilateral ventriculomegaly and premature closure of the ductus. The mother declined aneuploidy screening. Born at 39 weeks, the infant required intubation for stridor and poor respiratory effort. Physical features included: scaphocephaly, frontal atrophy with deep forehead creases, microphthalmia with small palpebral fissures, broad nasal bridge, short philtrum, small mouth, retrognathia, low-set crumpled ears, loose nuchal skin, poorly developed phallus, and undescended testicles. Lower extremities were breech with retroflexion of the knees, feet bilaterally were dorsiflexed, with excessive plantar creases, and prominent calcanei. Upper extremities revealed broad thumbs with short fourth metacarpals. Abdominal ultrasound revealed a left bladder diverticulum. Brain ultrasound revealed partial agenesis of the corpus callosum, no ventriculomegaly. Chest radiographs revealed congenital scoliosis with posterior rib fusions at T5-T6 and vertebral fusions at T11-T12, with a right sided pneumothorax. An ophthalmologic examination was performed showing right Peter's anomaly with left clinical anophthalmia/synophthalmia. Genetic Testing: Quest Diagnostics performed an oligo-SNP assay using a microarray containing over 2.67 million probes, (1.9 million copy number probes, 750 thousand SNP probes). Analysis of the child's blood revealed arr 9p24.3q31.3(353,113-113,023,818)x3, suggestive of non-Mosaic Trisomy 9. To verify, 100 interphase and 50 metaphase cells were studied by FISH using chromosome 9 centromere and 9p21 region probes (Abbott Molecular/ Vysis; CDKN2A and D9Z1). All cells showed Trisomy 9. Conclusion: In this report we describe an infant found to have non-Mosaic Trisomy 9 by microarray analysis on leukocytes with no evidence of mosaicism. This report adds to the previous reports describing characteristics of infants born with this extremely rare condition.

877W

A Unique Phenotype of 2q24.3–2q32.1 Duplication: Infantile-Onset Epilepsy without Mesomelic Dysplasia. *B. Lim[1], J. Ko[1], J. Choi[2], M. Woo[2], J. Chae[1]*. 1) Department of pediatrics, Seoul Natinoal University Hospital, Seoul, South Korea; 2) 3Institute of Reproductive Medicine and Population, Medical Research Center, Seoul, South Korea.

The voltage-gated sodium channel genes and HOXD genes are clustered on chromosome 2q, and duplication of this region is associated with 2 clinical phenotypes: early-onset epilepsy and mesomelic dysplasia Kantaputra type, respectively. We report a case involving 2q24.3–2q32.1 duplication encompassing both the voltage-gated sodium channel and HOXD gene clusters, which were detected by a comparative genomic hybridization array. The associated clinical features were early infantile-onset epilepsy, hypoplastic left heart syndrome and global developmental delay. However, no features of mesomelic dysplasia were found. A fluorescent in situ hybridization study showed that the noncontiguous insertion of the duplicated chromosome 2q segment into chromosome 6q was inherited from the father, who has a balanced insertional translocation. The unique genotype-phenotype correlation in the present case suggests that dosage-sensitive effects might apply only to the voltage-gated sodium channel genes.

Importance of chromosome breakage testing in Fanconi's anemia - involvement of specific chromosomes. *V. Mohan[1, 2], G. Archana[2], T. Preethi[2]*. 1) Genetics, Vasavi Medical Research Centre, Hyderabad, India; 2) Cytogenetic and molecular laboratory, Tapadia Diagnostic Centre, Hyderabad, India.

Chromosomal breakage syndromes are a group of genetic disorders that include Ataxia telangiectasia, Bloom's syndrome, Fanconi's anemia. Fanconi's anemia (FA) is a paradigm of aplastic anemia and has the similar features of pancytopenia but is characterized by spontaneous or induced chromosomal instability and a variety of congenital anomalies. A cytogenetic breakage study is essential for the diagnostic differentiation between FA and the idiopathic aplastic anemia. Many cases of FA are not diagnosed in a timely manner. FA should be tested in any infant born with the thumb and arm abnormalities, with signs of progressive bone marrow failure, in cases of adult-onset aplastic anemia and elevated hemoglobin F levels, solid tumors presented at an early age in the absence of other risk factors or even with unusually toxic reactions to chemotherapy or radiation. It is absolutely essential to rule out FA before contemplating bone marrow transplantation for aplastic anemia. The regimen used to prepare patients for transplant is very different for FA patients as FA patients tolerate radiation and chemotherapy very poorly. In culture, exposure to claustogenic agents such as mitomycin C (MMC) induces a higher rate of chromosomal abnormalities in patients with FA than in normal individuals. Spontaneous chromosomal breaks in these patients are also higher than normal. The adequate dose of MMC used in our tests for diagnosis of FA was 25 ng/ml. It is important to establish the adequate dosage and time of exposure to the claustogenic agent using known positive cases and normal controls. An sex/age matched normal control as well as a culture without MMC from the patient is used to determine the baseline breakage rate. Cytogenetic analysis was performed in samples from 12 FA patients in our laboratory who were tested under MMC stress. We present the results of G -banded chromosomes from these samples indicating specific chromosomes involved in damage.

Collaborative Multicenter Cytogenetic Study of Microdeletion Syndromes - Brazilian Network. *M. Riegel[1,2], N. Barcellos[3], R. Mergener[1], R. Gus[1], R. Giugliani[1,2,3], Brazilian Network members.* 1) Medical Genetics Service, Hospital de Clínicas de Porto Alegre-RS, Brazil; 2) Post-Graduation Program in Genetics and Molecular Biology, Universidade Federal do Rio Grande do Sul, Brazil; 3) Post-Graduation Program in Medical Sciences, Universidade Federal do Rio Grande do Sul, Brazil.

It has been estimated that the frequency of microdeletion syndromes (MS) is over 1:1000 liveborns. Although the clinical picture of many MS is well defined, the diagnostic facilities are available only in few centers of the public health system in Brazil; systematic studies are limited to some specific common microdeletions, and the actual overall frequency of these syndromes in Brazil has not been reported. With the main goal of joining efforts for the diagnosis and research in MS we proposed a collaborative multicenter study with the following goals: 1) To build a database for the diagnostic studies and information (abstracts, publications) performed by Brazilian research groups, 2) To support the cytogenetic diagnosis of suspected cases and; 3) to support the development of public cytogenetic laboratories. The RedeBRIM (Brazilian Network of Reference and Information in Microdeletion Syndromes) is formed by a coordinating center (SGM/HCPA) and 25 participating centers which operate in the Brazilian Public Health System (SUS). Communication with the centers is coordinated by the administrative basis of the project (Molecular Cytogenetics Lab/HCPA). We hope that this initiative will allow the development of a database for reference and information on MS; to contribute to the knowledge, assistance and research in the area of human cytogenetics and to lead to the stablishment of an organized network for research and diagnostics of microdeletion syndromes involving public health services in Brazil. Financial support : CNPq/National Council for Scientific and Technological Development - Brazil.

identification of chromosome aberration in fragile x syndrome patients in tamil nadu population south India using cytogenetic techniques. *A. Sundramoorthy.* Bharathiar University, Unit of Human Genetics, Department of Zoology, Coimbatore, Tamil Nadu, India.

identification of chromosome aberration in fragile x syndrome patients in tamil nadu population south India using cytogenetic techniques arun s1*, balachanadar v1, sasikala k1, manikantan p1, arun m1, karthick kumar a1, mustaq ahamed s1 1human genetics laboratory, department of zoology, bharathiar university, coimbatore - 641 046, tamil nadu, india objective: Fragile X syndrome is the most common inherited form of X-linked mental retardation (XLMR). The aim of this study was to screen for and identify fragile X syndrome-affected individuals using Cytogenetic approaches at a special education school for the mentally retarded in Tamil Nadu, South India. materials and methods: 3 micro litres of blood sample was collected from 45 individuals with mental retardation, including 20 males and 25 females, was analyzed using Cytogenetic techniques and Microscope coordinates of all digitized G-banded preparations were recorded so that the metaphase cells analyzed by G-banding technique. results: A total of 75 individuals with mental retardation were in the category of mild to moderate the syndrome. Sixteen males (6.25%) and two female (0.75%) were found to express fragile X site at q27.3. The frequency of fragile X-positive cells in males ranged between 7% and 57%, while in the females it was between 14% and 20%, respectively. conclusion: We established a cytogenetic report the incidence of fragile X syndrome in a mentally retarded population in Tamil Nadu south India. The frequency of fragile X positive cases found in this study is similar to other reports of fragile X syndrome in preselected patients. The Cytogenetic, molecular study and genetic counselling for other family members will continue in the future research. Keywords: Chromosome aberration test, DNA damage, Lymphocytes; Fragile x syndrome *Corresponding author: Arun S, E-mail: asmarun@gmail.com.

A Defect in the TUSC3 Gene is Associated with Syndromic Intellectual Disability. *A. Battaglia[1], L. Bernardini[2], S. Loddo[2], V. Doccini[1], V. Parisi[2], A. Novelli[2], T. Filippi[1]*. 1) Dev Neurosciences, Stella Maris nst/Univ Pisa, Calambrone, Pisa, Italy; 2) Mendel Lab. IRCCS Casa Sollievo della Sofferenza Hospital San Giovanni Rotondo (FG), Italy.

Defects in the TUSC3 gene have been identified in nonsyndromic autosomal recessive mental retardation (ARMR) individuals, due to either point mutations or intragenic deletions. We report on a boy with a homozygous microdeletion 8p22, sizing 203 Kb, encompassing the first exon of the TUSC3 gene, detected by SNP-array analysis (Human Gene Chip 6.0; Affymetrix). Both non-consanguineous parents, coming from a small Sicilian village, were heterozygous carriers of the microdeletion. The propositus had a few dysmorphic features (mid-parietal whorl; mildly prominent forehead; hypoplastic philtrum; mildly anteverted ears; hirsutism on limbs and dorsum; small hands; superficial venous reticulum; left cryptorchidism), and a moderate cognitive impairment. Verbal communication was impaired, with an inappropriate phonetic inventory, important phono-articolatory distortions, and bucco-phonatory dyspraxia. Comprehension was possible for simple sentences. Behavior was characterized by motor instability, high tendency to irritability and distraibility, anxiety traits, and an oppositional-defiant disorder. His parents were of normal intelligence. TUSC3 is thought to encode a subunit of the endoplasmic reticulum-bound oligosaccharyltranferase complex that catalyzes a pivotal step in the protein N-glycosylation process. This is the fourth case with alteration of TUSC3 causing ARMR and the third family in which a deletion has been described. Although the pathogenic mechanism has not been clarified yet, our report argues for a more prominent role of TUSC3 in the etiology of intellectual disability and for the possibility that deletions encompassing this gene could be more common than expected.

882T

An apparently balanced translocation t(5;6)(q35.2;p22.3) disrupting the *CDKAL1* gene in a girl with clinical features of Silver-Russell syndrome. *A. Bonaldi, S.A.S. Fonseca, A.C.S. Fonseca, A.M. Vianna-Morgante.* Department of Genetics and Evolutionary Biology, University of São Paulo, São Paulo, São Paulo, Brazil.

Silver-Russell syndrome (SRS) is characterized by severe intrauterine and postnatal growth retardation associated with a typical small triangular face and other variable features. Most frequently, SRS is caused by altered gene expression on chromosome 11p15 due to hypomethylation of the telomeric imprinting center that is present in about 40% of the patients. Maternal uniparental disomy of chromosome 7 (matUPD7) accounts for 5–10% of SRS cases. Thus, about half of the SRS patients remain without a causative diagnosis. We report on a girl with the clinical diagnosis of SRS carrying a de novo apparently balanced translocation t(5;6)(q35.2;p22.3). She was born at term, with 2,300 g and 42 cm (<3rd centile), her stature and weight being below the 3rd centile until her last clinical evaluation at 3 8/12 years of age. No (epi)genetic defect on 11p15 or matUPD7 were found. Array-CGH analysis (180K whole-genome platform; Agilent) did not detect any micro-imbalances that could explain her phenotype. Chromosome 5 breakpoint was mapped by FISH to a ~93 kb gene negative segment (chr5:173,684,023–173,777,440; hg19). On chromosome 6, the breakpoint was mapped to a ~152 kb segment (chr6:20,820,370-20,972,522) within the *CDKAL1* (cyclin-dependent kinase 5 regulatory subunit associated protein 1-like 1) gene (chr6:20,534,688-21,232,634). *CDKAL1* encodes a highly conserved 579-residue protein that contains the conserved domains of the MTTase family. Variants within *CDKAL1* intron 5 have been reproducibly associated with elevated risk for developing type 2 diabetes, and with decreased insulin secretion and reduced birth weight. Our finding that one of the translocation breakpoints disrupted *CDKAL1* prompted our screening for *CDKAL1* point mutations in SRS patients negative for (epi)mutations at 11p15 and matUPD7. In a small group of 30 patients no potentially pathogenic variants were detected. In addition to the possible phenotypic effect of *CDKAL1* haploinsufficiency, the translocation might have impacted the regulation of developmental genes in the vicinity of breakpoints (e.g. *SOX4* on chromosome 6; *MSX2* on chromosome 5). Interestingly, the enhancer hs1340 (VISTA Enhancer Browser) is localized in *CDKAL1* intron 9, in the breakpoint region, and might have been disrupted or isolated from its target. Financial support: FAPESP (CEPID 98/14254-2; Student fellowship 2011/12486-0).

883W

Report of the first case of robertsonian translocation in Down-Turner mosaicism (mos 45, X / 46,XX, + 21, rob (21;21)(q10;q10)) with clinical evolution. *M.F. Carvalho[1,2,3], E.F. Carvalho[4], K.M Carvalho[1].* 1) Unidade de Genética Médica, Universidade Estadual do Ceará-UECE/APAE-CE, Fortaleza, Ceará, Brazil, MD, PhD; 2) Unidade de Genética Médica, Christus, Fortaleza, Ceará, Brazil, MD, PhD; 3) Genpharma, Fortaleza, Ceará, Brazil,MD; 4) Unidade de Genética- Instituto da Criança do Hospital das Clínicas, Universidade de São Paulo,MD.

Double aneuploidy involving both autosomal and sex chromosomes is very rare. Down's/Turner's mosaic, occurs in about 1 in 2 000 000. We report the first case of Down's/Turner's mosaic with robertsonian translocation. The patient was the first child of non consanguineous parents. It was a female whom born a term, by uneventful cesarean section, weighting 2,220g and with length of 46 cm, without neonatal complications. At birth, the pediatrician made the diagnosis of Down syndrome. At 3 months, in consultation with routine pediatric a heart murmur was heard, so the patient was referred to a cardiologist. Echocardiography was performed and diagnosed congenital heart disease (patent ductus arteriosus). There were performed two surgeries to repair the heart defect, one with 6 months of life and another with 2 years. She also had mild developmental delay. At 3 years old she was examined at our outpatient Genetic unit. The patient showed more clinical findings of Down syndrome than Turner syndrome: low weight and height for age, microcephaly, flat facial profile, upslanting palpebral fissures, epicanthal folds, short nose with depressed nasal bridge, hypotonia with tendency to keep month open and protrude the tongue, short neck, single palmar creases, and prominent ears. Abdominal ultrasound and thyroid function were normal. Cytogenetic analysis of peripheral blood preparations by using G-banding revealed mosaicism with 2 cell lines (mos 45, X [21] / 46,XX, + 21, rob (21;21)(q10;q10)[9]). Additional genetic studies (karyotypes) are required to define the cause which probably originated this double aneuploidy with this translocation. So we present the first case related of Down-Turner mosaicism with robertsonian translocation and we review the previous reports of Down-Turner syndrome.

Copy number variation in imprinted regions: Narrowing critical imprinted intervals. *B.C. Ballif[1], N.J. Neill[1], J.E. Fox[2], M. Descartes[3], F. Brewer[3], T. Stroud[4], J.B. Ravnan[1], L.G. Shaffer[1], J.A. Rosenfeld[1].* 1) Signature Genomic Laboratories, PerkinElmer Inc, Spokane, WA; 2) Division of Medical Genetics, Steven and Alexandra Cohen Children's Medical Center of New York, Manhasset, NY; 3) Department of Genetics, University of Alabama at Birmingham, Birmingham, AL; 4) Division of Developmental Pediatrics, University of Missouri School of Medicine, Columbia, MO.

While it is known that uniparental disomy (UPD) of certain chromosomes with imprinted genes is a mechanism of disease, these imprinted genes can be disrupted in other ways, including variation in their copy number, which can also cause similar phenotypes. With the increasing use of single nucleotide polymorphism (SNP)-based microarrays, which have the ability to detect segments of uniparental isodisomy, a more precise understanding of the critical imprinted regions and genes is necessary for accurate diagnostic interpretations and phenotype predictions. We surveyed our database of over 53,000 probands studied by microarray-based comparative genomic hybridization (aCGH) and identified over 50 individuals with small (<1.5 Mb) copy number variations in or near imprinted genes in 10 distinct chromosomal regions. We gathered additional clinical information on three individuals with small deletions involving the imprinted region on 14q32, two of whom have the previously described, recurrent 1.1-Mb deletions of 14q32.2q32.31. Using SNP arrays, we determined the parent of origin for cases in which parental specimens were available. The parental origins correlated with the individuals' phenotypes, with a 1.1 Mb deletion on the paternal chromosome in one case being associated with a UPD(14)mat-like phenotype including precocious puberty, feeding problems, and growth and developmental delay. In a second patient, the deletion was 120 kb in size and included a portion of RTL1/RTL1as, maternally expressed MEG8, and one of the maternally expressed snoRNA clusters in the region; paternally expressed DLK1 and maternally expressed MEG3 were not deleted. The clinical features of this patient with the smallest deletion included a bell-shaped thorax, polyhydramnios, and rib abnormalities, which are consistent with a UPD(14)pat-like phenotype and over expression of RTL1. The potential influence of reduced MEG8 and snoRNA expression on this patient's phenotype is uncertain. To our knowledge, this represents the smallest maternal deletion of this region and further refines the clinical features associated with deletion of these imprinted genes.

Detection of Partial Tetrasomy 12pter-12p11.22 Region by Array CGH and FISH in a Newborn with Multiple Congenital Abnormality. *S. Ebrahim[1,2], D. Stockton[3], AM. Jay[3], M. Hankerd[2], D. Schloff[2], M. Kristofice[2], AN. Mohamed[1,2].* 1) Department of Pathology, Wayne State University School of Medicine, Detroit, MI; 2) Detroit Medical Center University Laboratories, Cytogenetics laboratory; 3) Division of Genetic & Metabolic Disorders, Children's Hospital of Michigan. USA.

We report on the molecular detection and characterization of partial tetrasomy of chromosome 12p13.33–12p11.22 region in a 4-day-old girl without an obvious clinical diagnosis of Pallister-Killian syndrome (PKS). Her prenatal course involved an abnormal ultrasound showing short femurs and flat facial features. An amniocentesis was suggested but was not done. The infant was born at 39 and 3/7 weeks of gestation to a 19-year-old gravida 2, para 2 mother via cesarean section. At birth dysmorphic features, an imperforate anus, rectovaginal fistula and tethered cord were noted. Blood chromosome analysis and oligonucleotide-based array comparative genomic hybridization (array-CGH) was performed. High resolution chromosome analysis of PHA stimulated peripheral blood culture revealed a normal 46,XX female karyotype in all cells examined. Array-CGH detected a 29.23 Mb copy number gain involving chromosome 12p11.22–12p13.33 short arm region. FISH using DNA probes specific for chromosome 12p13 region and CEP-12 alpha-satellite probe localized to chromosome 12p11.1~q11 centromere region was performed on three sample types. The hybridization demonstrated four copies for 12p13 in 6.5%, 36%, and 86% on cultured and uncultured blood samples and buccal mucosa interphase cells respectively while only two copies of CEP12 were present in 100% of cells. This demonstrates the patient to be mosaic tetrasomic for part of chromosome 12 short arm and disomic for CEP 12 chromosome/no extra CEP-12/alpha-satellite DNA, likely due to neocentromere formation (analphoid marker chromosome formation) or due to duplication within the same chromosome. A skin biopsy was requested for chromosome analysis to clarify the abnormalities. PKS is a clinically characteristic rare genetic disorder caused by tissue-limited mosaicism for tetrasomy 12p, normally as a result of the presence of a 12p isochromosome. Few patients with mosaic partial tetrasomy 12p and variable PKS phenotypes have been identified. This case demonstrates the effective use of array CGH in conjunction with FISH for the diagnosis of PKS in peripheral blood samples in a newborn without an obvious clinical diagnosis of PKS.

Duplication Xq28 and Deletion of SHOX in a family with short stature, intellectual and developmental disability. *E.F. Andersen[1,2], E.E. Baldwin[3], S. Ellingwood[4], R. Smith[4], A.N. Lamb[1,2]*. 1) Cytogenetics Laboratory, ARUP Laboratories, Salt Lake City, UT; 2) Department of Pathology, University of Utah, Salt Lake City, UT; 3) Technical Operations, ARUP Laboratories, Salt Lake City, UT; 4) Department of Pediatrics, Division of Genetics, Maine Medical Center, Portland, ME.

Copy number changes on the X chromosome may be associated with developmental delays and intellectual disability (DD/ID) in a manner specific to both sex chromosome complement and gene content. We report a familial case of a 774 kb Xq28 duplication (154,459,273–155,233,730) and a 570 kb Xp22.33 deletion (168,546–738,792) detected by CMA. The proband, a 20-month-old female, presented with failure to thrive, short stature, gross motor and speech delays, and mild dysmorphic facial features. Two brothers, ages 12 and 16 years, also with short stature, dysmorphic features and a history of developmental delays, were also noted to have intellectual disability and ADHD. The 12-year-old also exhibited aggressive behaviors and was diagnosed with a mood disorder. In addition, the 16-year-old had a 722 kb gain of 2q33.3, encompassing 9 genes, of unknown clinical significance. These findings, concomitant deletion and duplication of the terminal ends of a chromosome, are suggestive of a recombination event in a balanced pericentric inversion or inheritance of a recombinant X chromosome. Parents were not tested; however the pattern of inheritance is suggestive of maternal transmission. The Xp22.33 deletion encompasses 5 genes within the PAR1 region including *SHOX,* a gene known to cause short stature when haploinsufficient. The duplicated region includes the PAR2 region, which is not known to be dosage sensitive, and 14 proximal genes, which individually have not been associated with functional disomy. El-Hattab *et al*. (*J Med Genet*, 2011) report a recurrent interstitial Xq28 duplication that partially overlaps with the duplication detected here, associated with intellectual disability, behavioral abnormalities, and characteristic facial features in males and in females with unfavorably skewed X chromosome inactivation; many of these features were also noted in the present family. Minimally, the region of overlap of these duplications is 101 kb and includes *RAB39B*, the 3' end of *VBP1* and part of *CLIC2*. Hemizygous mutation of *RAB39B*, a neuronally enriched small GTPase involved in vesicular trafficking, is associated with ID, autism, epilepsy, and macrocephaly (Giannandrea *et al*., 2010); however, functional disomy of *RAB39B* has not been established. We suggest that duplication of *RAB39B* may be responsible for the dysmorphic features, DD/ID, and other features observed in patients with duplications of the distal region of Xq28.

887W

Deafness and Infertility Syndrome (DIS): an under-diagnosed cause of hearing loss? *U. Aypar[1], N. Hoppman-Chaney[1], D. Babovic-Vuksanovic[2]*. 1) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) Department of Medical Genetics, Mayo Clinic, Rochester, MN.

Hearing loss is the most common birth defect and the most prevalent sensorineural disorder in developed countries. More than 50% of prelingual deafness is genetic, most often autosomal recessive and nonsyndromic, of which approximately 50% is caused by mutations in GJB2 and GJB6. Sensorineural hearing loss and male infertility (Deafness-Infertility Syndrome; DIS) is a contiguous gene deletion syndrome resulting from homozygous deletion of the CATSPER2 and STRC genes on chromosome 15q15.3. Females with DIS have only hearing loss and are fertile. DIS has been recently described in three consanguineous families and only one patient from a nonconsanguineous family, implying a low carrier frequency. Recently, a patient with hearing loss presented to the medical genetics department at Mayo Clinic. Due to the presence of macrocephaly in addition to hearing loss, she was tested by array comparative genomic hybridization (array CGH) and was found to be homozygous for deletion of both CATSPER2 and STRC, consistent with a diagnosis of DIS. Her parents are not consanguineous, and FISH testing demonstrated that both were heterozygous carriers, ruling out uniparental disomy. Upon receiving this result, we retrospectively examined our internal database of patients tested by array CGH in order to determine the carrier frequency of this deletion in our patient population. We discovered that 56 of our 5151 patients (1.09%) are heterozygous for this deletion, excluding one patient who had a sibling with the same deletion. If this number is representative of the general population, this implies a 1% carrier frequency in the general population and a prevalence of DIS of 1 in 40,000 individuals. These results are consistent with the studies performed by Knijnenburg et al. in which they determined the carrier frequency of this deletion in a much smaller sampling of normal individuals to be approximately 1.6%. Therefore, we propose that DIS is a greatly underdiagnosed cause of deafness and should be considered as a differential diagnosis in all children with hearing loss. Likewise, current molecular genetic testing panels for hearing loss should be expanded to include deletion/duplication analysis for this region since chromosomal microarray is the only platform currently capable of detecting deletions that result in DIS in clinical laboratories.

Identification of 90 first-reported abnormal chromosome karyotypes in population of Eastern China with G-band and/or C-band banding techniques. *L. Li[1], S. Zheng[1], J. Zhang[1], W. Fan[2]*. 1) 1. Genetics Counselling Department, Genetics Institure of LinYi Peoples' hospital, 27# Eastern Liberation Road, LinYi, Shandong, 276003, China; 2) 2. School of Life Science, Hebei University, 180# Eastern Wusi Road, Baoding,Hebei Province 071002, China.

[Abstract] Purpose: To characterize the chromosomal structure abnormality in genetic counseling population in Shandong Province of Eastern China, and to understand their association features with the corresponding diseases. Methods: Peripheral blood lymphocytes were cultured and analyzed by the G-band and/or C-band techniques. Abnormal karyotypes were recorded according to International System for Human Cytogenetic Nomenclature. Results: A total of 1046 abnormal karyotypes were identified in the past 10 years from 7566 patients who suffered from abnormal pregnancy, infertility, primary/secondary amenorrhea, mental retardation/congenital malformation and others, and the average positive rate is 13.82% (1046/7566). Among them, 282 abnormal karyotypes were from 5178 patients with abnormal pregnancies (5.45%); 74 from 223 patients with male infertility (33.18%); 121 from 209 patients with primary/secondary amenorrhea (57.89%); 524 from 811 patients with putative mental retardation and congenital malformation (64.61%); 45 from 1145 patients with variety of other disorders (3.93%). Within the 1046 abnormal karyotypes described above, 90 are the first reported cases in the world (8.6%; 90/1046) that has been confirmed through consulting with the International Human Chromosomal Abnormalities Directory of Registration. These 90 first-reported karyotypes came from 41 males and 49 females, which include 79 balanced translocations, 5 cases of pericentric inversion, 1 case of paracentric inversion/insertion translocation, 1 case of partial trisomy of 6q, 1 case of partial trisomy of 7p, 1 case of partial haploid of 15/16, and 1 case of false dicentric chromosome of 7 respectively. Very interestingly, we have identified a familial 46, XX testicular disorder of sex development (DSD) containing 3 DSD patients in two generations from a family of three generations. Conclusions: Chromosome abnormalities show a higher incidence in Shandong province of Eastern China due to isolated living status of the residents. It is particularly indispensable to perform chromosomal karyotype analysis for any patients with putative developmental disorders in this area, and it also offers a good resource for human genetics study, especially the cytogenetic analysis and disease-gene identification.

Intellectual Disability (ID) is the most common developmental disorder, affecting cognitive and adaptive functions with a frequency of approximately 2–3% in the general population. Microarray genomic hybridization has shown that submicroscopic genomic imbalances cause ID in at least 10% of idiopathic cases. Recently, microdeletions of the 5q14.3 region including the MEF2C gene have been described in patients featuring severe ID, stereotypic movements, epilepsy and cerebral malformations. Point mutations in MEF2C have been observed in a small number of patients with ID. However, the phenotypes caused by MEF2C point mutations are not different from those caused by 5q14.3 deletions. The protein encoded by the MEF2C gene has a crucial function in the homeostatic control of activity-dependent synaptogenesis that plays a role in the establishment of functional neuronal circuits during development and memory storage. In brain, MEF2C is essential for early neurogenesis, neuronal migration and differentiation. To delineate the MEF2C syndrome phenotype and to determine genotype-phenotype correlations, we report on 4 patients presenting a 5q14.3-q15 deletion including the MEF2C gene and 6 patients presenting overlapping 5q14.3-q15 deletions that did not span MEF2C. Comparison of these new patients together with the 25 previously reported MEF2C cases revealed that MEF2C haploinsuficiency leads to severe ID, seizures and hypotonia often associated with poor visual contact, failure to thrive or to walk independantly. In constrast, when we compared the latter patients with those presenting a 5q14.3-q15 deletion that did not include MEF2C, we found a less severe phenotype, although comprising hypotonia, ID and seizures. In conclusion, our data support the role of MEF2C in brain development and motility and suggest that another gene in the 5q15 region might as well be responsible for ID and epilepsy.

Full-blown expression of paternally inherited Fabry disease in a young woman due to complete skewed X-inactivation of a der(X)t(X;Y)(p22.13;p11.2)mat.ishYp11.3(SRY+). *F. VIALARD[1], K. BENISTAN[2], C. BELDJORD[3], S. HEIDE[2], D. MOLINA-GOMES[1], F. JABBOUR[4], P. DE MAZANCOURT[5], D.P. GERMAIN[2, 5]*. 1) Division of Cell Biology, University of Versailles, CHG Poissy, France; 2) Division of Medical Genetics, University of Versailles, CHU Raymond Poincaré, Garches, France; 3) Laboratory of Biochemistry, CHU Cochin, University Paris V Descartes, Paris, France; 4) Laboratory of Biochemistry, CHU Raymond Poincaré, Garches, France; 5) UPCG, EA 2493, University of Versailles, Montigny-le-Bretonneux, France.

Background : Fabry disease (FD, OMIM 301500) is an X-linked lysosomal storage disorder caused by the deficiency of the enzyme alpha-galactosidase A (α-Gal A). Females with FD often develop clinical manifestations. However, the disease generally follows a milder course in heterozygotes. Patient and Methods : We report on a young female patient with full-blown expression of FD including angiokeratoma, kidney failure (measured glomerular filtration rate (mGFR) = 37 mL/min/1,73 m2), cardiac manifestations (hypertrophic cardiomyopathy) and CNS involvement (periventricular white matter hyperintensities) from the age of 22 years. The proband was the patient's father. Alphagalactosidase A enzymatic assay, GLA gene sequencing, standard caryotype, comparative genomic hybridization (CGH) and X-inactivation studies were performed. Results : Alpha-Gal A activity, measured in leukocytes, was totally absent (0.0 ng/mmol/h). Gb3 urinary excretion was markedly elevated (603.1 mmol/mmol creatinine). The familial mutation in the GLA gene (c.154 T>C, p.C52R) was detected. Sequencing of all exons and flanking intron/exon boundaries revealed no other mutations in the girl. Standard caryotype revealed a 46,X,der(X)t(X;Y)(p22.3?;p11) formula. Fluorescent in situ hybridization (FISH) showed a der(X)t(X;Y)(p22.3?;p11).ishYp11.3(SRY+). To characterize the derivative chromosome, a CGH was done which confirmed the t(X;Y) translocation and identified a large 16.6 Mb deletion spanning from Xp22.13 to Xp22.32. As FD was inherited from her father and feminine phenotype was present on physical examination, we hypothesized a maternal inheritance of the derivative chromosome together with skewed X-chromosome inactivation. Using polymorphic markers at the androgen receptor locus, a 100% skewed X-inactivation of the der(X)t(X;Y)(SRY+) was observed in leukocytes. Furthermore, the maternal inheritance of the derivative was confirmed through its identification in the patient's mother. Discussion : This is, to our knowledge, the first report of a 16.6 Mb deletion of a maternally inherited der(X)t(X;Y)(p22.13;p11.2).ishYp11.3(SRY+) leading to (i) its completely skewed inactivation with consequent feminine external and internal genitalia in the patient despite the presence of a SRY gene (ii) expression of the cytogenetically normal X chromosome inherited from the father with a GLA gene point mutation leading to absence of residual enzyme activity and full-blown phenotype of FD.

Whole-genome array-CGH screening in patients with autosomal dominant sensorineural hearing loss points to novel susceptibility loci. *E.L. Freitas[1], D.T. Uehara[1], V.G.L. Dantas[1], A.G. Silva[2], A.C. Krepischi[2], R.C. Mingroni-Netto[1], C. Rosenberg[1]*. 1) Department of Genetics and Evolutionary Biology, University of São Paulo, São Paulo, SP., Brazil; 2) Hospital A.C. Camargo, São Paulo, Brazil.

Hereditary hearing loss is a clinically and genetically heterogeneous sensory disorder. In 20% of the cases it is inherited in an autosomal dominant pattern with no additional clinical signs (ADNSHL). To date, 59 loci for ADNSHL have been mapped to chromosomal regions. Due to tremendous genetic heterogeneity, the identification of genes that affect the process of hearing has been challenging; in order to identify novel DFNA locus, we investigated 50 patients with ADNSHL by oligonucleotide array-CGH. Copy number alterations were detected in ten ADNSHL patients (20%) at 2p23.1, 4p13, 5q32, 6q12, 6q23.2, 7q31.1, 8q13.3, 10q21.1, 17q24.3-q25.1 and 19q13.42-q13.43 chromosome regions. Some of regions were previously described as ADNSHL locus (DFNA10, DFNA15, DFNB23 and BOR1). The chromosome regions shown to be in altered copy number encompassed some biologically plausible candidate genes, including CHRNA9, SLC39A11, EYS and DOCK4. The first one, a 261 Kb duplication at 4p13 region, encompasses part of the CHRNA9 gene. CHRNA9 is an ionotropic receptor with a probable role in the modulation of auditory stimuli. This gene also interacts with SLC26A5, GRXCR1, MYO7A and POU4F3 genes, which have been described as hearing loss locus. The second one was a 87 Kb duplication at 17q24.3-q25.1 chromosome region, affecting the SLC39A11 gene. This gene belongs to the SLC family, which includes approximately 300 genes that transport various molecules across the membranes surrounding the cell and its component parts. Two SLC genes were previously described as hearing loss locus, namely SLC17A8 gene (DFNA25) and SLC26A5 gene (DFNB61). The third alteration was a 56 Kb deletion on chromosome 6q12 region, affecting part of the EYS gene. This gene is a eyes shut homolog (Drosophila) and is required to maintain the integrity of photoreceptor cells. When mutated can lead to Retinitis Pigmentosa. Many genes related to hearing loss are also involved in the development of ocular disorders. The last alteration was a 438 Kb duplication located on 7q31.1 region affecting two genes: IMMP2L and DOCK4. In this case the DOCK4 is a strong candidate gene for causing the ADNSHL since previous studies indicate that a DOCK4 harmonin-activated signaling pathway regulates actin cytoskeleton organization in stereocilia. Our results provide support for a role for rare CNVs in ADNSHL risk and reinforce evidence for the existence of novel susceptibility genes for this condition.

Comparison of HER2/neu gene amplification assessment by Fluorescent In Situ hybridization (FISH) and Immunohistochemistry (IHC) in Iranian breast cancer patients. *M. Moradi chaleshtori[1], Z. Hojati[1], H. Teimori[2], SH. Ramazi[1]*. 1) Genetics division, Biology department,Science faculty, Esfahan university, Isfahan, Isfahan, Iran; 2) Genetics-Biochemistry division, medicine faculty, Shahrekord medicine science university, Shahrekord,Iran.

The Human Epidermal Growth Factor Receptor 2 (HER2) gene encodes a 185 kd protein that acts as a cell surface receptor with tyrosine kinase activity . About 20–30% of breast cancer tumors are positive for amplification and/or overexpression of HER2.HER2 positive tumors are more aggressive than HER2 negative tumors and are associated with poor prognosis. This study designed to evaluate HER2/neu gene status in breast cancer specimens by Fluorescent In Situ hybridization (FISH) and Immunohistochemistry (IHC). In this study formalin fixed paraffin embedded (FFPE) breast cancer tissue specimens with known IHC results were evaluated by FISH technique. The copy number of HER2 gene locus at 17q11.2-q12 and alpha satellite DNA located at band region 17p11.1-q11.1 (CEP17) was estimated by FISH in interphase cells of FFPE tissue sections(4–6 μm). HER2 gene amplification status was determined as the ratio between the total number of HER2 gene signals and the number of chromosome 17 centromere signals. HER2 gene amplification was reported in cases with HER2:chromosome 17 signal ratio≥2.2 then the results of FISH and IHC were compared. The results of this study confirm FISH provides more accurate scoring method for determining HER2 amplification status than IHC and FISH analysis should be applied in IHC equivocal (IHC 2+) cases of breast cancer.

893W

Array CGH of Normal Karyotype Plasma Cell Neoplasms Reveals Hidden Recurrent and Individual Genomic Copy Number Alternations. *G. Tang[1], H. Zhang[2], C. Shaw[2], P. Hixson[2], W. Bi[1], C. Borgan[2], M. Coyle[2], D. Freppon[2], D. Vo[2], J. O'Hare[2], J. Gonzalez Berjon[2], C. Chang[3], S. Cheung[1], A. Patel[1]*. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Methodist Hospital, Houston, TX, USA; 3) Florida Hospital, Orlando, FL, USA.

BACKGROUND: The plasma cell neoplasms (PCNs) are a heterogeneous group of diseases characterized by clonal expansion of terminally differentiated B cells that typically secrete monoclonal immunoglobulin. Genomic aberration remains one of the most important prognostic factors in PCNs. We aimed to identify genomic aberrations in karyotypically normal PCNs. METHODS: 23 patients with normal karyotype PCNs (myeloma = 13, MGUS = 7, and amyloidosis = 3) were included in the study. Plasma cells enrichment was performed in 17 cases by using CD138 antibody. The median purification of plasma cells was 60% (range: 32%-93%). Array CGH was performed on DNA amplified from the enriched plasma cells using GenomePlex single cell whole genome amplification kit (17 cases)or on genomic DNA extracted from bone marrow using the Puregene DNA extraction kit (7 cases). A custom genome-wide oligo microarray was designed using the Agilent 44K platform containing 493 genes involved in carcinogenesis. DNA digestion, labeling, and hybridization were performed as previously described [PMID: 20724749]. RESULTS: 16 out of 23 (70%) patients showed at least one genomic copy number aberration. Among them, 2 patients had 1 abnormality, 2 patients had 2 abnormalities, and 12 patients had ≥3 abnormalities. Among the 7 patients with normal array CGH results, 5 patients were diagnosed with MGUS, and 2 patients with amyloidosis. All myeloma patients showed genomic imbalance. Several recurrent abnormalities were detected, including Loss in 13q12.11-q34 (x7, involving RB gene); 14q32 (x7, involving IgH gene); 16p11.2 (x5); 9p24.1 (x4); 17p11.2-13.3 (x2, involving p53); 20p13-p11.22 (x2); and 19p13.3 (x2); Gains in 5p15.33 (x4) and 1q21.1 (x3). Loss of 20p13-p11.22 was accompanied with Loss of 17p11.2–13.3. CONCLUSIONS: This study showed that 70% of PCNS with normal karyotype harbored genomic imbalances, and majority of cases showed complex aberrations. Several recurrent abnormalities were identified, some with known prognostic significance. We conclude that array CGH provides a more accurate biological or prognostic profile for PCNs than conventional cytogenetics and FISH. Future functional studies of the genes in the recurrent aberrant regions may help uncover common genetic events leading to the development of PCNs.

We report *de novo* 20q13 duplications/triplication ranging from 1,1 to 11,5Mb in three cases with multiple congenital anomalies. Patient 1 (P1) was a fetus exhibiting severe congenital heart defect, dysmorphy and brachymesophalangia. Patient 2 (P2) was a boy with developmental delay, macrosomia, dysmorphic facies, squeletal anomalies, cerebral malformations and congenital heart disease. Patient 3 (P3) was a girl with developmental delay, dysmorphy and scoliosis. Partial trisomy 20q is rare, and most reported cases result from unbalanced segregation of a balanced reciprocal translocation. So far, only four cases of *de novo* pure partial trisomies 20q have been described, and among them two have been more precisely characterized by Agilent CGHarray and reported here (duplication for P2 and triplication detected for P3 respectively initially described in Blanc P et al, AJMG 2008 and Menten B et al, JMG 2006). The third one is defined by an overlapping *de novo* duplication of 20q13.12q13.31 and thus is included in discussion (Iglesias A et al, Clin Dysmor 2006 and personal communication). The last described case doesn't overlap and thus is not included here (Wanderley H.Y.C. et al, Gene Couns 2005). Among common clinical features, all children exhibit developmental delay and some dysmorphic features. Skeletal and cardiac malformations were present in 3\4 of the patients. Among genes included in the overlapping duplications, two were of particular interest for cardiac abnormalities. *SALL4* is shared by cases 1, 2 and Iglesias et al (2006). It is associated with Duane-radial ray/Okihiro syndrome, characterized by upper limb, ocular and renal anomalies and congenital heart defects. P1 and P2 presented ventricular septal defects. Altered *SALL4* expression in mice suggested its' role in heart patterning and morphogenesis. *NFATC2* was encompassed in all duplications. In mice model and zebrafish, Nfatc2 was involved in heart valve morphogenesis. P1 and P2 shared mitral and aortic valves atresia and Iglesias et al (2006)'s patient displayed aortic coarctation. Cardiac malformations could result from abnormal expression of *SALL4* combined with *NFATC2*, as no cardiac malformations were described in P3. Nfatc2, implicated also in skeletal and cartilage development could be related to the skeletal features observed in 3\4 patients. These cases further highlight genotype-phenotype correlation in 20q13.2 interstitial duplication/triplication.

895W

Array-Based Copy-Number Analysis in Patients Associating Obesity and Developmental Delay/Learning Disabilities and Additional Features. *C. D'Angelo[1], I. Kohl[1], C. de Castro[1], C. Kim[2], D. Bertola[2], C. Lourenço[3], A-B. Perez[4], C. Koiffmann[1].* 1) Dept Genetics, Univ Sao Paulo, Sao Paulo, Brazil; 2) Genetics Unit, Department of Pediatrics, Children Institute, School of Medicine, University of Sao Paulo, Sao Paulo, Brazil; 3) Neurogenetics Unit, Department of Medical Genetics, School of Medicine, University of Sao Paulo, Ribeirao Preto, Brazil; 4) Department of Morphology, Medical Genetics Center, Federal University of Sao Paulo, Sao Paulo, Brazil.

There are numerous reports of obesity present as part of a syndromic chromosome abnormality. Many have an overlapping phenotype that poses a diagnostic challenge. The most prevalent of these conditions is Prader-Willi syndrome (PWS), which is due to lack of paternal expression of imprinted genes within chromosome 15q11q13. Other examples include deletions of chromosomes 1p36, 2q37, 6q16, 9q34, and 17p11.2. The recent introduction of genomic arrays in clinical practice has led to the identification of new genomic regions exhibiting a dosage dependent influence on body weight regulation and also learning and development. In this study, 93 syndromic patients with obesity (defined as a BMI at or above the 95th percentile) as a shared clinical feature were investigated by single nucleotide polymorphism (SNP) array platforms (Affymetrix 100K and 500K) and/or oligonucleotide array-based comparative genomic hybridization (CGH) platforms (Agilent SurePrint G3 Human CGH 8 × 60K and CytoSure ISCA 4 × 180K produced for OGT (Oxford Gene Technology, Oxford, UK) Identified deletions/duplications of at least a 300 kb region were confirmed using fluorescence in situ hybridization (FISH) or multiplex ligation-dependent probe amplification (MLPA). Parental testing was performed when parental DNA was available. We identified 21 individuals with pathogenic and potentially pathogenic CNVs as well as four patients with CNVs that are initially of unknown significance. Of the CNVs identified in this cohort, some have been previously reported in cases with obesity (e.g. deletions of chromosomes 2q37, 6q16 and 9q34). Haploinsufficiency of HDAC4, SIM1 and EHMT1 are likely to be responsible for the obesity phenotype in these cases. In addition, obesity and intellectual disability were recently reported in patients with 2p25.3 deletions overlapping minimally within MYT1L. Interestingly, the obesity-associated TMEM18 gene is located in band 2p25.3. In a number of regions, there are quite a few genes to be examined for a possible relationship to the patient's phenotype. For instance, we found a de novo deletion of 14q12 which contained only one obesity-associated gene, PRKD1. In conclusion, microarray analysis in clinical practice has facilitated the identification of new obesity-associated syndromes, while genotype-phenotype correlations are critical to determining the effects of such novel CNVs. Complex genomic reorganization in microdeletions/microduplications syndromes and molecular mechanisms for formation. *L. Kulikowski[1,2], F. Piazzon[1], E. Zanardo[1,2], R. Dutra[1,2], A. Dias[1], M. Oliveira[3], M. Moreira[1,2], G. Novo-Filho[1,2], M. Basso[1,2], C. Negretto[2], A. Zandoná[1,2], M. Melaragno[3], C. Kim[2]*. 1) Department of Pathology, Cytogenomics Laboratory, LIM 03, Universidade de São Paulo, SP, Brazil; 2) Genetics Unit of the Children's Institute, University of São Paulo, São Paulo, Brazil; 3) Department of Morphology and Genetics, Universidade Federal de São Paulo, São Paulo, Brazil.

Different mutational mechanisms shape the dynamic architecture of human genomes and occasionally result in congenital defects and disease. Detailed delineation of genomic rearrangements requires the application of advance cytogenomic techniques, such as MLPA and array-based copy number analysis. Some mechanisms have been proposed to explain the complexity of genomic rearrangements in microdeletions/microduplications syndromes:Non-homologous end joining (NHEJ) associated to microhomology and inserted sequences; replication-based model called fork stalling and template switching (FoSTeS) and a novel model called microhomology-mediated break-induced replication (MMBIR). We report on two individuals with features suggestive of microdel/microdup syndromes but lacking associated distinctive genomic anomalies: a 2.8-year-old girl with features of monossomy 1p36 syndrome and other congenital defects and a boy with atypical deletion at Williams-Beuren syndrome region and a chromosome Y supernumerary. First patient: MLPA (MRC-Holland) assay using the P070 and P036 kits revealed the deletions of the *TNFRSF4* and *TNFRSF18* genes whereas the P064 kit showed a normal copy of the *TP73* gene. Analysis by SNP-array (Affymetrix Genome-Wide Human-6.0) showed multiple copy number changes. We observed a normal copy (nml) sequence followed by a deletion (564,620–2,456,203), followed by a normal copy (nml) sequence, followed by another deletion (2,473,257-3,446,813), followed by a normal copy (nml) sequence and then by a duplication (3,474,630-3,641,681) at 1p36 region. Second patient: MLPA with P064 revealed the deletion of *CYLN2, STX1A, ELN, LIMK1* genes and the presence of *FZD9* gene. Array showed rearrangements with complex patterns including 7p14.3, 7q11.23, 13q31.3, Xp22.33, Xq28, Yp11.2 and Yq11.23 regions. Recently, the phenomenon of chromothripsis was described in cancer cells by Stephens et al (2011). Liu at al (2011) propose that both the constitutional genomic rearrangements and the chromothripsis processes reflect basic DNA metabolism and share a cellular DNA replication/repair mechanism and Kloosterman et al (2011) provided evidence that chromothripsis may be generating structural variation in the germline that results in congenital defects. The delineation of the complex genome architecture and the definition of the mechanisms for formation of the rearrangements offer an opportunity for the discovery of novel syndromes and the development of translational research.

Gene Mapping in the Finnish National Collection of Balanced Translocations and Inversions. *T.M. Luukkonen[2,3], M. Pöyhönen[1,4], P. Ellonen[2], S. Lagström[2], J.H. Lee[5], K.O.J. Simola[6], K. Aittomäki[4], J. Ignatius[7], R. Salonen[8], A. Palotie[1,2,9], J. Terwilliger[3,10,11], T. Varilo[1,3]*. 1) Dept. of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland; 2) Institute for Molecular Medicine Finland FIMM, Helsinki, Finland; 3) National Institute for Health and Welfare, Helsinki, Finland; 4) Dept. of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 5) Sergievsky Center/Taub Institute, Columbia University, New York, NY, USA; 6) Dept. of Pediatrics, Tampere University Hospital, Tampere, Finland; 7) Dept. of Clinical Genetics, Turku University Central Hospital, Turku, Finland; 8) Dept. of Medical Genetics, Väestöliitto, Helsinki, Finland; 9) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 10) Dept. of Genetics and Development, Dept. of Psychiatry, Columbia Genome Center, Columbia University, New York, NY, USA; 11) Division of Medical Genetics, New York State Psychiatric Institute, New York, NY, USA.

We have assembled a nationwide collection of all known carriers of reciprocal balanced translocations and inversions from every Medical Genetics Department and Clinical Genetics Laboratory in Finland. Our database contains relevant medical records of all available carriers in each family to include all relatives carrying the same rearrangement identical by descent. The data facilitate diagnostic purposes, genetic counseling, and subsequent follow-up. We also use this collection as a valuable research tool, focusing on identification of the precise molecular location of the chromosomal breakpoints, and correlating these to phenotypes as a natural experiment for gene mapping. To date we have systematically examined 3016 carriers and their relatives, and are in the process of collecting biological samples from them, and linking our data to national comprehensive disease registers. As a pilot study, we have focused on families identified from this resource, which appear to have a striking correlation of a balanced translocation and some phenotype. The initial investigation includes three families with (a) intracranial and aortic aneurysm (n=5), (b) short stature (n=4), and (c) tetraphocomelia (de novo) likely caused by the translocation. In the first family, the proband has a thoracic aortic aneurysm and a translocation involving a region which was previously linked to aneurysms; the proband's brother and sister both died from cerebral hemorrhage; and the proband's father and aunt each died from aortic rupture. In the second family, a 10-year-old girl presented with a growth disturbance and a translocation involving a region previously implicated affecting the height of females; the proband's mother was 164 cm, the maternal grandmother 152 cm, and the maternal great-grandmother 147 cm. In individuals from each family, we have been performing standard cytogenetic analysis, copy number analysis (genotyping and aCGH), genome-wide paired-end sequencing, and capillary sequencing with the objective of identifying the specific breakpoints for each translocation and ruling out other potentially causative genetic factors. We are in the final stages of analyzing the data from the aortic aneurysm family, and data from the other projects are forthcoming.

Combined exon array CGH plus SNP genome analyses for optimized clinical diagnostics. *A. Patel[1], W. Bi[1], C. Shaw[1], S-H. Kang[3], A.N. Pursley[1], S. Lalani[1,2], P. Hixson[1], T. Gambin[4], A.C-H. Tsai[5], H-G. Bock[6], M. Descartes[7], F. Probst[1,2], F. Sacaglia[1,2], A.L. Beaudet[1,2], J.R. Lupski[1,2], C. Eng[1,2], SW. Cheung[1], C. Bacino[1,2], J. Wiszniewska[1]*. 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Pediatrics Baylor College of Medicine, Houston, TX; 3) Allina Cytogenetics Laboratory, Abbott Northwestern Hospital, Minneapolis, MN; 4) Institute of Computer Science, Warsaw University of Technology, Warsaw, Poland; 5) Department of Molecular and Medical Genetics, OHSU, Portland,OR; 6) Department of Pediatrics, University of Mississippi Medical Center, Jackson, MS; 7) Department of Genetics, University of Alabama, Birmingham, AL.

In clinical diagnostics, both array comparative genomic hybridization (array CGH) and single nucleotide polymorphism (SNP) genotyping have proven to be powerful technologies utilized for the evaluation of developmental delay, congenital anomalies, and neuropsychiatric disorders. Many clinical laboratories offer testing using commercially available standard designs or custom-designed arrays based on either of these technologies. Differences in these arrays may constitute a challenge for clinicians when it comes to choosing the right type of array to investigate the underlying genetic cause for the disease in their patient. While both approaches are effective in detecting copy number variants (CNVs) greater than several hundred kilobases in size, only SNP arrays show higher sensitivity for detection of low level mosaic aneuploidies and chimerism and offer the ability to detect copy number neutral regions of absence of heterozygosity (AOH) which are relevant clinically to identify uniparental disomy(UPD), consanguinity and potential recessive loci. However, SNP arrays are unable to detect single exon CNVs due to the distribution of SNPs across the genome. In an effort to provide a comprehensive clinical testing service for both CNVs and copy neutral AOH, we have enhanced our custom designed high resolution oligonucleotide array (manufactured by Agilent) with exon targeted coverage of 1714 genes and 60k SNP probes referred to as CMA Comprehensive. Of the 3240 cases evaluated by this array, CNVs were detected in 452 cases (14%) including 28 clinically significant exonic CNVs. 166 cases (5.1%) showed AOH giving a combined diagnostic yield of 19.1%. This demonstrates that even though this array has a lower density of SNP probes than other commercially available SNP arrays, it was able to reliably detect AOH events >10 Mb as well as intragenic copy number changes beyond the detection limitations of SNP genotyping. Thus, combining SNP probes and exon targeted array CGH into one platform increases diagnostic yield and provides clinically useful genetic screening for identifying small exonic copy number changes, UPD and consanguinity in a cost effective manner.

Facing current diagnostic challenges in array copy number analysis. *F.B. Piazzon[1,2], R. Dutra[1,2], E. Zanardo[1,2], A. Dias[1,2], M. Moreira[1,2], G. Novo-Filho[1,2], D. Christofolini[3], V. Meloni[3], M. Oliveira[3], A. Zandoná-Teixeira[2], M. Basso[1,2], C. Negretto[1,2], C. Moreira-Filho[2], M. Melaragno[3], C. Kim[2], L. Kulikowski[1,2]*. 1) Department of Pathology, Cytogenomics Laboratory, LIM 03, University of São Paulo, São Paulo, Brazil; 2) Unit of Genetics of Children's Institute, University of São Paulo, São Paulo, Brazil; 3) Department of Morphology and Genetics, Federal University of São Paulo, São Paulo, Brazil.

The recent technological advances in array-based genomics have established the opportunity to detect several different genomic structural rearrangements in patients with congenital malformations. However, there is still no consensus for interpretation of the results and the DNA alterations responsible for phenotypic variation. We report on five patients with atypical results after array analysis: del(7q)/del(13q31.3)/dup(Xpter) and one extra Y chromosome; complex del/dup(1p36); del(Xq22.1)/del(17q23.3); del(2q33.1/del(3q) LOH in Xq21.1; dup(17q)/del(17p); add(7) and mar(15q/16p). The definition of the results is not clear in these patients part due to little understanding about the natural history and clinical variability associated with chromosomal aberrations detected by array. The presence of a deletion or duplication alone does not necessarily mean that the copy number alteration causes the observed phenotype and we cannot assure to consider a copy number imbalance as to be pathogenic. Also after confirming the diagnosis of the patients the array was able to show even more unexpected genomic aberrations whose correct interpretation became a new challenge. Ascribing clarification of recurrence risk and prognosis for atypical rearrangements remain a challenge for diagnosis and improvements in clinical ascertainment.

900T

Genetic analyses of Korean patients with unexplained mental retardation and developmental delay using the multiple ligation-dependent probe amplification (MLPA). *S. Shim[1], S. Sung[1], S. Park[1], K. Kang[1], M. Lee[1], S. Lyu[2], D. Cha[1,2], M. Kim[3]*. 1) Genetic Lab, CHA Gangnam Medical Center, Seoul, South Korea; 2) Department of Obstetrics and Gynecology, CHA Gangnam Medical Center, CHA University, Seoul 135-081, Korea; 3) Department of Rehabilitation Medicine, Bundang CHA Medical Center, CHA University, Sungnam 463–712, Korea.

Subtelomeric regions of each chromosome contain many genes so called gene-rich region and deletions and duplications of the regions result in deleterious consequences such as multiple congenital anomalies, moderate to severe mental retardation, dysmorphism, and/or abnormal growth or behaviors. Many studies have shown that unbalanced rearrangements of these regions are a cause of unexplained mental retardation and, or developmental delay (MR/DD) and approximately 5% of patients with MR/DD had the abnormalities. MLPA can detect various chromosomal imbalances, such as a whole chromosome aneuploidies, partial deletions and duplications, depending on the probe set used. As a primary screening method, it has many benefits such as high-throughput, cheap and easy to interpret. Total 249 of Korean patients with unexplained MR/DD were examined. The samples were initially analyzed using both MLPA and routine chromosome analysis. For MLPA analyses, two probe mixes for subtelomeric regions, SALSA P070 and P036B probe mix, were used. Each MLPA mix contains probes for subtelomeric regions of all 46 human chromosomes. All procedures including multiplex PCR and capillary electrophoresis were performed by manufacturer's protocol. The data were analyzed by the GeneMarker® software. MLPA results were obtained all 249 cases. The subtelomeric aberrations were identified in 13 cases (5.2%) using both P070 and P036 probe Mix. Five patients (2.0%) had partial deletion, two (0.8%) had partial duplications and six (3.2%) were complex rearrangements. The deletions were detected five different subtelomeric regions (1p, 3p, 4p, 11q, 22q) and duplications were detected in two subtelomeric regions (11p, 15p). Seven cases with partial deletion or duplication were de novo, not identified in parents. The abnormalities found were confirmed by FISH and/or array-based CGH and parental analyses. On the other hand, 18 cases (7.2%) had a partial deletion or duplication which was inherited from one of parents. They were considered as a normal variation, so called copy number variations (CNVs). In conclusion, a combined analysis, MLPA followed by FISH and array-based CGH is very useful method for screening of submicroscopic chromosomal imbalances. Especially, the MLPA, as a primary screening method, is less labour-intensive and more cost-effective than FISH and array-based CGH, though some probes might be located in the regions of CNVs in Korean population.

901W

Complex nature of apparently balanced chromosomal rearrangements in patients with autism spectrum disorder. *A.C. Tabet[1, 2], A. Verloes[1, 3], M. Pilorge[2], B. Benzacken[1, 3, 4], C. Betancur[2]*. 1) Cytogenetics Unit, Department of Genetics, Robert Debre Hospital, AP-HP, Paris, France; 2) Inserm U952, CNRS UMR 7224, Pierre & Marie Curie University, Paris, France; 3) Inserm U676, Paris, France; 4) Cytogenetics Unit, Jean-Verdier Hospital, AP-HP, Bondy, France.

Apparently balanced chromosomal rearrangements can be associated with an abnormal phenotype, including intellectual disability and autism spectrum disorders (ASD). Recent studies using microarrays have revealed cryptic genomic imbalances related or not to the initial chromosomal rearrangement in 25%-61% of patients with an abnormal phenotype carrying an apparently balanced chromosomal rearrangement. Here, we report a SNP-array study of 18 patients with ASD carrying an apparently balanced chromosomal rearrangement. We identified clinically significant de novo copy number variations (CNV) in 4/18 patients (22%); three were related to the initial breakpoints of the rearrangement and one occurred elsewhere in the genome. These CNVs ranged from 3.5 to 4.3 Mb. In two cases, the CNV encompassed regions that have already been involved in ASD, 2q37 and 7q21q22, while in other cases, the CNVs affected novel regions, pointing to potential candidate genes and loci. Of note, we report the first patient with autism carrying a duplication of the Wolf-Hirschhorn syndrome critical region, contributing to delineate the phenotype of this rare genomic disorder. These findings underscore the utility of SNP arrays for investigating apparently balanced chromosomal abnormalities in subjects with ASD or related neurodevelopmental disorders.

902T

The identification of submicroscopic gains and losses at the breakpoints of apparently balanced rearrangements. *B. Torchia, J.A. Rosenfeld, L.G. Shaffer.* Signature Genomic Laboratories, PerkinElmer Inc, Spokane, WA.

The finding of an apparently balanced translocation or inversion in a child with developmental disabilities or in a prenatal specimen with or without abnormal ultrasound findings raises questions, including whether the rearrangement is truly balanced. During the course of routine microarray investigation, we have tested 106 postnatal cases and 174 prenatal cases with known, apparently balanced translocations referred for further molecular characterization of the rearrangements. Among these, 116 were de novo, 52 were inherited from a carrier parent, and in 112 cases, the inheritance was unknown because parents were not tested. Of the postnatal cases, 7.5% showed an imbalance at one of the translocation breakpoints. In addition, 9.4% of cases showed a clinically significant copy number alteration (CNA) at another genomic location, unrelated to the translocation. Among the prenatal cases, 6.9% showed an imbalance at one of the translocation breakpoints and 2.9% showed a clinically significant finding elsewhere in the genome. Among the 84 balanced inversion cases, 12.5% of the postnatal and 4.5% of the prenatal cases showed an imbalance at one of the inversion breakpoints while 5% of the postnatal and 2.3% of the prenatal cases showed a clinically relevant CNA elsewhere in the genome. In total, including 15 cases of complex, apparently balanced rearrangements, 8.4% showed a CNA at one of the breakpoints of the rearrangement while 5.3% showed a clinically relevant CNA elsewhere in the genome. Overall, these results on a total of 379 cases demonstrate the usefulness of genomic microarrays in uncovering genomic alterations at apparently balanced chromosomal rearrangements. Moreover, a substantial number of cases had CNA elsewhere in the genome that may explain the developmental disabilities or prenatal ultrasound findings in these cases.

Complex phenotype associated with 17q21.31 microdeletion. *A. Pic-Taylor[1], H. Dornelles-Wawruk[2], C. Rosenberg[3], A.C. Krepischi[3], H.P.N. Safatle[2], I. Ferrari[2], J.F. Mazzeu[2, 4].* 1) Department of Genetics and Morphology, Institute of Biologic Sciences, University of Brasilia (UnB), Distrito Federal, Brazil; 2) Laboratory of Clinical Genetics, Faculty of Medicine and Health (FS), University of Brasilia (UnB), Distrito Federal, Brazil; 3) Human Genome Study Center, Department of Genetics and Evolutionary Biology, Institute of Bioscience, University of São Paulo (USP), São Paulo, Brazil; 4) Post-graduation in Genomic Sciences and Biotechnology, Catholic University of Brasilia (UCB), Distrito Federal, Brazil.

The 17q21.31 microdeletion syndrome was recently described and present various known symptoms such as developmental delay, neonatal hypotonia, low birth-weight and a pear-shaped nose. Microdeletion size can vary, however, a minimal chromosomal region has been defined to a segment of 424 kb genomic DNA (crh17: 41046729–41470954, hg 17) and includes the MAPT, STH, CRHR1, KIAA1267, and IMP5 genes. Recently, this critical region was narrowed to a 160.8 kb segment (crh17: 41310123–41470954, hg 18) that comprises only the MAPT and STH genes. The STH gene is located within one of the introns of the MAPT gene and its transcription follows the same sense of the MAPT gene transcription. Here we describe a patient with 17q21.31 microdeletion detected by array-CGH, presenting a complex phenotype. The patient is an 18-year old girl with friendly behavior, nasal speech and moderate mental retardation and seizures. Clinical examination revealed abundant thick straight hair, a triangular face with a high and flat forehead, ptosis, up-slanting palpebral fissures, epicanthic folds, a bulbous nasal tip, anteverted nostrils, a long and deep nasal filter, preauricular fistula, a high palate, a discreet microretrognatia, kyphosis, an umbilical hernia and a clubfoot. Previous clinical exams revealed: early cataract, inter-atrial communication (both surgically corrected), chronic anemia, conductive hearing loss in the left ear, hydronephrosis, ureterocele and agenesis corpus callosum. Chromosome analysis of peripheral blood lymphocytes by G-banding at the 550 or higher banding level showed a normal 46,XX karyotype. However, the results of the array-CGH exam identified an interstitial deletion in the long arm of chromosome 17, affecting the band q21.31 between the chr17:41012276–41707073 (hg 18) genomic positions. This submicroscopic chromosomal aberration consists of approximately 695 kb. The deleted region contains the MAPT, STH, CRHR1, KIAA1267, IMP5 genes and a hypothetical ORF (LOC644246). This deletion is comparatively larger than the critical region suggested. Comparison of our patient with other cases reported in the literature, who had a deletion size of similar length, showed that the presence or absence of a symptom is not dependent on the size of the deletion. Our patient presented most of the symptoms previously described as well as chronic anemia,a condition not yet described in this syndrome.

904T

Association of a Deletion Downstream of *NKX2-1* With Benign Hereditary Chorea: Transfer of a Benign CNV to Likely Pathogenic Category. *U. Surti, J. Liao, K. Coffman, J. Hu, M. Sathanoori, S. Yatsenko, S. Madan-Khetarpal, M. McGuire, A. Rajkovic.* University of Pittsburgh Medical Center, Pittsburgh, PA.

First described in 1966, benign hereditary chorea (BHC, MIM 118700) is a rare autosomal dominant movement disorder with onset in infancy or childhood. It is characterized by chorea with little or no progression and normal cognitive function. The phenotype is highly variable, and sometimes includes hypothyroidism and neonatal respiratory distress which is also named as brain-lung-thyroid syndrome. Since 2002, more than 20 heterozygous mutations and deletions of *NKX2-1* (also known as *TTF1* or *TITF1*), a gene located on chromosome 14q13, have been identified in a number of BHC families. NKX2-1 is a member of the homeodomain-containing NKX2 family of transcription factors. It is expressed in the developing thyroid, respiratory epithelium, and specific areas of the forebrain in which it is involved in interneuron specification and migration. Although recent evidence suggests that haploinsufficiency of this gene is responsible for the pathogenesis of BHC, there are several clinically diagnosed BHC families that did not have detectable *NKX2-1* mutations, indicating other genes or regulatory elements on chromosome 14 or elsewhere may also play a role. Here we report three BHC families where no *NKX2-1* gene mutation was identified. By using high-density array CGH analysis, we detected a 117 kb deletion on chromosome 14q13.3 region, which is located 175 kb downstream of *NKX2-1* in all affected members but not in unaffected ones of all tested families. Interspecies genomic comparative analysis of the deleted area revealed multiple evolutionary highly conserved non-coding sequences, indicating the existence of potential cis-acting regulatory elements in the region. We hypothesize that this deletion downstream of *NKX2-1* disrupts long-range regulatory elements necessary for its expression, causing haploinsufficiency of this gene and BHC phenotype in these families. Our results provide the first evidence supporting the role of non-coding regulatory elements in the pathogenesis of BHC, and also indicate that this deletion is likely to be a clinically significant pathogenic CNV instead of a benign one.

905W

Chromosomal Microarray Analysis (CMA) in 22q11.2 deletion syndrome-New insight to LCR-mediated rearrangement. *A. Tsai[1,2], D. Klepacka[2], M. Dodge[2].* 1) Molecular and Medical Genetics, OHSU, Portland, OR; 2) Childrens Hospital Colorado, Aurora, CO 80045.

Introduction: Small, crucial/complex chromosome imbalances have been reported in increasing numbers since the implementation of array comparative genomic hybridization (aCGH). Traditionally, individuals with the 22q11.2 deletion syndrome have been diagnosed by FISH along with high resolution chromosomes. However, with this method, concurrent chromosome imbalances could go undetected which may contribute to the complexity of the 22q11.2 deletion syndrome. In order to test the hypotheses that those who are clinically more affected can have a larger deletion or comorbid with other chromosomal anomalies, we performed microarray assay in patients who did not a microarray upon diagnosis. Methods: From 09/2010-03/2012, 52 patients with 22q11.2 del were seen at CHC 22q clinic. Our cohort consists of families from CO and WY. 48 patients were diagnosed initially by FISH, and 4 were diagnosed by microarray. 30 patients had microarray assay performed after the visit. The platform of microarray was oligoarray (105K-180K) with the exception of one patient who had a BAC array upon evaluation. There are 23 males and 11 females with ages ranging from 3 months to 18 years (median age of 6). Ethnicity includes Caucasians (54%), Hispanic (32%), African America (4%), Asian (2%) and 2% other. Results: The CMA results showed a variable size of deletion: 2 patients had deletion less than 0.6 MB; 3 patients had a deletion size about 1.7 Mb; 20 patients had a deletion ranging from 2.5 to 3Mb and 3 had a greater than 3Mb deletion. Of note, 8 patients had additional findings in addition to the 22q11 deletion: Translocation t(6;21)(q24.2;q22.1), gain of 3 BACs in 2p25.3, a 187 kb loss at 15q26.3, a 509kb gain at 15q13.3, a 400 kb gain at 17p13.1, 371kb gain in 10q21.1, and an 843 kb gain at 18q23.3. More profound delay,anxiety, autism and malformations were noted in those with greater than 3.0 MB deletion and additional chromosomal anomalies. Conclusion: 25% of the patients who had CMA were found to have additional chromosomal anomalies and a few presented with more severe phenotypes. This study also revealed the size of deletion seemed to vary in size instead of the predicted fragment based on common LCR. The co-existing CNVs identified in a significant portion of patients may also suggest a predisposition for rearrangement or lack of self-correction/repair system. aCGH should be considered for first line testing for children with 22q11.2 deletion syndrome.

906T

Array CGH as a first line diagnostic test in place of karyotyping for postnatal referrals - results from four years clinical application for over 7,800 patients. *J.W. Ahn[1], S. Bint[2], A. Bergbaum[2], K. Mann[2], R.P. Hall[2], C. Mackie Ogilvie[1].* 1) Cytogenetics, Guy's Hospital, London, United Kingdom; 2) GSTS Pathology, Guy's Hospital, London, United Kingdom.

Array CGH is widely used in cytogenetics centres for postnatal constitutional genome analysis, and is now recommended as a first line test in place of G-banded chromosome analysis. At our centre, first line testing by oligonucleotide array CGH for all constitutional referrals for genome imbalance has been in place since June 2008. Since then, 7,890 patients have been tested, with referral indications ranging from neonatal congenital anomalies through to adult neurodisabilites; 25% of these patients have CNVs either in known pathogenic regions or in other regions where imbalances have not been reported in the normal population. Deletions and nullisomy account for 48% of these CNVs, duplications and triplications account for 51%, and mosaic imbalances make up the remainder. The vast majority of these CNVs, 88%, are <3Mb and would not be detected by traditional G-banding analysis. All our diagnostic findings can be viewed at http://bbgre.org. Clinical interpretation of array CGH findings is complex, and simple rules cannot be used; for instance, of our de novo findings (21% of completed inheritance studies), some are for small, gene-poor regions, and may not therefore be significant, whilst of inherited imbalances, at least 20% are likely to be clinically significant. By employing a patient vs patient (phenotype mismatched) hybridization strategy, we have been able to reduce costs to that of a traditional karyotype, and provide array CGH as a first line test within the financial constraints of a state-funded health system. First line testing by array CGH provides a higher diagnostic detection rate than traditional methodology, and adds to the sum of information and understanding of the role of genomic imbalance in disease. Experience of the challenges in interpretation and reporting of array CGH results will inform the implementation into clinical diagnostic service of higher resolution technologies such as whole exome and whole genome sequencing.

Identification of the critical region for 7q32q34 deletion syndrome in a 1.5 Mb region at 7q32.3q33. *T.-J. Chen, J. Hoffman, K. Phelan, H.C. Andersson.* Hayward Genetics Center, Tulane University School of Medicine, New Orleans, LA.

Deletion of 7q32q34 is a rare genetic condition with clinical features including developmental delay, early feeding difficulties and failure to thrive, short stature, behavior problems, language delay, and learning difficulties. However, there is variable expression among affected patients and many features resolve with age. Most of the described cases carry deletions in the range of several million bases located in the 7q32q34 region. Herein we report an affected female and describe a critical region contributing to this phenotype. The two months old patient was referred to genetics clinic due to the history of poor feeding and hypotonia. The patient was delivered full term by C-section with reported history of decreased fetal movement. Apgar scores were 8 and 9 at 1 and 5 minutes, respectively. The patient spent the first 23 days of life in the NICU due to feeding problems and hypotonia, and she underwent placement of a G-tube at one week of age. Her birth weight was 3.15 kg (11–25%), and the length was 49 cm (11–25%). At the age of two months, she was fed by mouth and G-tube and hypotonia was still obvious. Her weight was 3.7 kg (<3%) and her length was 52 cm (<3%). No dysmorphic facial features were noted. Laboratory studies included karyotype, methylation and FISH assays for PWS/AS, mutation analysis for DM and SMA, and biochemical profiles for amino acids and organic acids, which were all normal. The patient had a normal brain MRI and cardiovascular evaluation by ECG, chest x-ray, and echocardiography. Chromosomal array CGH was performed and revealed a 1.5 Mb deletion at 7q32.3q33. There are only three genes, CHCHD3, EXCO4, and LRGUK, located within this deleted region. EXCO4 was showed to be haploinsufficient in a previous report, suggesting deletions including this gene might play a pathogenic role contributing to this clinical phenotype. Considering this patient presented most of the typical clinical features of 7q32q34 deletion syndrome as well as possessed a characterized deletion at 7q32.3q33, we propose that the 1.5 Mb deleted region is the critical region for this genetic condition. Parental FISH analysis showed that the patient's father, who was reportedly phenotypically normal, carries a deletion at the same location. Thus, in addition to variable expressivity, incomplete penetrance might be a genetic feature for this deletion syndrome.

908T

Clinical implementation of whole-genome array CGH in Korean patients with pediatric neurologic diseases and multiple congenital anomalies. *E. Shin[1], K. Lee[1], B. Eun[2].* 1) Genome Res Ctr, NeoDin Med Inst, Seoul, Korea; 2) Department of Pediatrics, Korea University Guro Hospital, Seoul, Korea.

Chromosomal aberrations are a common cause of multiple anomaly syndromes that include developmental delay, mental retardation, dysmorphic features and multiple congenital anomalies. Microarray based comparative genomic hybridization (array-CGH) is considered to be superior for the investigation of chromosomal aberrations in children with multiple anomaly syndromes and has been demonstrated to improve the diagnostic detection rate of these small chromosomal abnormalities. We performed a high resolution genome-wide aCGH analysis for submicroscopic chromosomal rearrangements using the Roche NimbleGen 135K oligonucleotide array on 249 children with pediatric disease and congenital anomalies. Using array-CGH we detected chromosomal imbalances in 55 of 249 patients (22.1%) ranging in size from 0.3 to 61 Mb and 33 of 55 patients with pathogenic copy number variants (60%) had normal karyotype and the others (40%) had abnormality in conventional chromosome analysis. We found 20 known syndromes such as 1p36 deletion, Mowat-Wilson, Williams-Beuren, Kleefstra and Jacobsen syndrome and CNVs containing pathogenic genes and recurrent CNVs containing the same region among different patients were detected in 35 of 55 patients (63.6%). Two cases with low level mosaicism were detected by array CGH and one of them had mosaicism for rearranged chromosome 18 in 7.9% of cell and another case showed an isochromosome 12p (associated with Pallister-Killian syndrome) using genomic DNA extracted from peripheral blood. Recent advances in the analysis of patients with congenital abnormalities using whole-genome array CGH has uncovered large scale copy number variations were frequently observed and become an important tool for the detection of chromosome aberrations and has the potential to identify genes involved in pediatric neurologic disease and multiple congenital anomalies. The detection of genomic imbalances of clinical significance using whole-genome array CGH will increase knowledge of the human genome by performing genotype phenotype correlation.

Chromosome and segmental imbalances detected by array CGH in samples of product of conception: a pilot study. *S. Xu, X. Wang, W. Xu, F. Gong, J. Lee, X. Lu, S. Li.* Department of Pediatrics, the University of Oklahoma Health Sciences Center, Oklahoma City, OK 73104.

Approximately 15 % of pregnancy complaints are pregnancy loss, including spontaneous abortion (SB), and still birth. Routine cytogenetics studies have demonstrated that only half of SB and less than one third of still birth have been detected with chromosome abnormalities, left the remaining up to 50 to 70% of cases with unknown causes. Microarray analysis, capable of detecting cryptic chromosome changes less than 100 kb, will unravel many submicroscopic chromosome abnormalities missed by conventional karyotype. In this study, we carried out microarray analysis of 53 samples of products of conception (POC), which were cytogenetically normal or failed to grow. DNAs were extracted from POC specimens and then hybridized on oligo microarrays (NimbleGen 720K v.3.1). All data were analyzed using SignalMap software. Of 16 (30.2 %) positive POC cases, 8 showed deletions or duplications, with all sizes between 47.5 kb to 1.94 Mb except for one with 32 Mb. The remaining 8 positive cases presented a gain of chromosomes Y, 9, 15 and 21 and a loss of chromosome X. In these aneuploidy-like cases, 6 of them may cytogenetically manifest as 45,X (2 cases), 47,XYY and trisomy 21(3 cases). The majority of routine karyotype data for the 16 positive chromosomal imbalance cases were not available due to culture failure resulted from macerated tissues received. Our preliminary data in this study provides evidence that array CGH should be considered when the routine cytogenetic analysis results were normal or failed to yield the results. Accumulated study in the future may help to identify genes or chromosomal regions leading fetal death. Microarray data from our lab and combination of such data from other labs, as well as further supplementary experiments and in depth parental/family surveys (whenever possible) are underway.

Hemophilia A and trigonocephaly in a male with a complex chromosome rearrangement involving chromosomes X and 1. *J. Liu, J. Chernos, R. Lamont, R. Perrier, B. Argiropoulos.* Dept of Medical Genetics, University of Calgary, 3330 Hospital Dr. NW, Calgary, Alberta, Canada.

We report on a 2½ year old male with hemophilia A and trigonocephaly. Array CGH and FISH analyses demonstrated a complex chromosome rearrangement involving two gains on the X chromosome within band q28 and one gain on chromosome 1 within band p13.1. Interestingly, the chromosome 1 gain was inserted into the X chromosome at band q28. The proximal 53 kb X chromosome gain overlaps exons 14 to 25 of the Factor 8 (F8) gene while the distal 219 kb deletion overlaps 5 RefSeq genes. These gains are separated by a 69 kb region of normal copy number. The chromosome 1 gain is 450 kb and overlaps 5 RefSeq genes, none of which are associated with disease. In light of the patient's clinical diagnosis of hemophilia A, this complex rearrangement is most likely perturbing F8 gene structure and function. Several published reports have demonstrated a strong association with X-linked trigonocephaly to chromosome band Xq28. Therefore, it is possible that at least one of the three duplications has inserted and disrupted a trigonocephaly locus at Xq28. DNA sequencing studies are underway to elucidate the genomic architecture of this complex rearrangement with the aim of identifying the trigonocephaly locus at Xq28.

Identification of cryptic genomic imbalance in congenital and development abnormalities: An institutional experience. *F. J. Sheth[1], J. Andrieux[2], M. Desai[1], J. Sheth[1], T. Mampilly[3], G. Mampilly[3], C. Neeradha[3], J. Vijayalakshmy[3], K. Godbole[4], S. Desai[5].* 1) Biochemical and Molecular Genetics, Institute of Human Genetics, Ahmedabad, Gujarat, India; 2) Laboratory of Medical Genetics, Jeanne de Flandre Hospital CHRU de Lille, Lille Cedex, France; 3) National Institute for Empowerment of Persons with Multiple Disabilities (NIEPMD) East Coast Road, Muttukadu, Kovalam Post Chennai - 603112, India; 4) Deenanath Mangeshkar Hospital, Near Mhatre Bridge, Erandawne, Pune-411004. India; 5) Shree Krishna Hospital, Karamsad, Anand. India.

Submicroscopic genomic alterations are a major cause of congenital and developmental abnormalities including dysmorphic features, mental retardation, developmental delay, and multiple congenital anomalies. Present study was carried out in 21 cases that were initially investigated for conventional cytogenetic G-Banding analysis; amongst which 8 had congenital anomalies with/without mental retardation and 13 had with developmental delay, learning disability and seizures. No structural or numerical anomalies were detected at 450-band resolution. Hence, all 21 cases were further analyzed using 44k oligonucleotide array-CGH study using Agilent platform. Cryptic genomic alteration was detected in 11 of the 21 cases; these include 62% [5/8] amongst individuals with congenital anomalies and 46% [6/13] amongst individuals with learning disability and seizures. The chromosomes involved in submicroscopic alterations were 2q, 5q, 6q, 7q, 10q 12q, 19q, 22q and Xp. Single copy number variation [CNV] was detected in 8 cases while 3 had multiple CNVs. De novo alteration was confirmed in 3 cases, parental inheritance was established in 1 case, inheritance is under evaluation in other 5 cases while in 2 cases it could not be studied for lack of consent. Array-CGH can be significantly helpful in knowing the specific cause of abnormality and in counseling parents for future pregnancies, amongst patients with congenital anomalies or developmental delay or learning disabilities with an apparently normal karyotype.

912T

Lack of Evidence for Biparental Inheritance of Copy Number Variation Contributing to Pathogenic Features in a Series of Clinical Microarray Cases. *C.E. Cottrell[1], S. Kulkarni[1,2,3], H. Al-Kateb[1], M. Evenson[1], S. Anderson[1], D. Lamb Thrush[4,5], S. Hashimoto[4], A.K. Bailes[4], L. Erdman[4], A. McKinney[4], C. Weber[4], J. Weslow-Schmidt[4], S. Ramsey[4], C. Astbury[4,6], S. Reshmi[4,6], J.M. Gastier-Foster[4,5,6], R.E. Pyatt[4,6].* 1) Department of Pathology and Immunology, Washington University School of Medicine, St. Louis, MO; 2) Department of Pediatrics, Division of Genetics and Genomic Medicine, Washington University School of Medicine, St. Louis, MO; 3) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 4) Department of Pathology and Laboratory Medicine, Nationwide Children's Hospital, Columbus, OH; 5) Department of Pediatrics, The Ohio State University, Columbus, OH; 6) Department of Pathology, The Ohio State University, Columbus, OH.

Several models evaluating the effect of copy number variation (CNV) have been proposed to account for the clinical features in patients bearing multiple copy number alterations. For example, a two-hit model has been suggested for cases of developmental delay in probands inheriting a microdeletion at 16p12.1 along with a second large alteration (Girirajan et al., 2010). Whenever possible, studies include CNV origin; however, few data focusing on the effect of biparental inheritance exist, which may be attributed to the low frequency of such events. One recent study examining CNV in 1,227 probands with neurodevelopmental phenotypes failed to identify a single instance of biparental inheritance (Girirajan et al., 2011). Consequently, we undertook a retrospective study to examine instances of biparental inheritance of CNV interpreted as variants of unknown significance (VUS) in a series of 6,322 clinical cases referred for microarray analysis at Nationwide Children's Hospital or Washington University; 47 probands were identified with 2 or more VUS with at least 1 variant inherited from each parent. No common combinations of CNV were observed in more than 1 family. Paternally inherited duplications involving the *PARK2* gene (6q26) were observed in two unrelated probands, as were paternal duplications of the *CHRNA7* gene (15q13.3), maternal deletions involving the *CTNNA3* gene (10q21.3) and maternal alteration of the *OPCML* gene (11q25). Analysis of the second biparentally inherited CNV in each of these 8 unrelated proband pairs failed to identify genes with common pathways or expression patterns suggesting that their co-inheritance may be a chance event. Interesting combinations of VUS with biparental inheritance were observed within families when multiple members underwent array analysis. One sibling-pair shared a maternally inherited 7p22.2p22.1 duplication and a paternally inherited 6q24.3 duplication, while a third sibling inherited only the paternal 6q24.3 gain. Three unrelated probands were identified with 3 inherited VUS and a fourth with 4 variants (2 paternal and 2 maternal) which may represent large CNV burdens in these cases. While this study is hindered by the limited availability of both parental samples in additional cases, these results do not support biparental inheritance as a mechanism of pathogenesis. It is possible that total CNV burden in relation to genetic content may prove a more likely mechanism for pathogenicity.

913W

7q33 deletion in a family with intellectual disability, dysmorphic features and behavioral changes. *A. Fortuna[1], F. Lopes[2,3], S. Sousa[2,3], J. Silva[1], C. Gomes[2,3], P. Maciel[2,3].* 1) Genetics, Inst.Ricardo Jorge/Centro Geneti, Porto-Portugal, Porto, Portugal; 2) Life and Health Sciences Research Institute (ICVS), School of Health Sciences, University of Minho, Braga, Portugal; 3) ICVS/3B's - PT Government Associate Laboratory, Braga/Guimarães, Portugal.

Intellectual disability (ID) is one of the most frequent and disabling neurological impairments in school-age children. Among the genetic causes of ID, genomic imbalances are one of the most frequent. With the introduction of array comparative genomic hybridization in the routine diagnostic allows the discovery of new and previously undetermined imbalances, as well as the discovery of new ID associated genes. In this work we report a maternally inherited 7q33 deletion in a 19 year old boy with mild ID (IQ= 53), familial history of ID (mother and sister affected; a second-grade cousin with ID, dysmorphic features and epilepsy), seizures, reduced vision, hypotony, dysmorphisms, aggressiveness and hyperactivity. The same alteration is present in his sister that displays mild ID (IQ=62), short stature, facial dysmorphisms (similar to the ones present in the brother) and behavioral changes (disinhibition). The mother cannot read or write and has facial dysmorphisms similar to the ones present in the daughter. The alteration was determined by aCGH analysis using a human genome CGH Agilent 180K custom array with a mean resolution of 17 Kb (Agilent, Santa Clara, CA) and the confirmation studies and inheritance analysis were carried out by qPCR using a fragment designed inside the altered region. aCGH revealed a 2 Mb deletion at chromosome region 7q33 containing 15 genes (AGBL3, AKR1B1, AKR1B10, AKR1B15, BPGM, C7orf49, CALD1, CNOT4, EXOC4, LRGUK, NUP205, SLC35B4, STRA8, TMEM140, WDR91). One of the most interesting genes covered by the deletion is the CNOT4 (CCR4-NOT transcription factor complex, subunit 4) gene. The CNOT4 protein plays both positive and negative roles in transcriptional regulation and a positive role in transcriptional elongation. In yeast, the ortholog of CNOT4 (Not4) regulates the expression of Jhd2 (the yeast ortholog of JARID1C, for which mutations have been described in patient with X-linked ID). Comparison with similar cases, expression and functional studies should help us clarify the relevance of the deleted genes for ID.

914T

Investigation of the Parental Origin and Genomic Mechanisms Involved in *de novo* Pathogenic CNVs in Congenital Disorders. *S. Hayashi[1,2], M. Naganawa[1], D.T. Uehara[1], J. Inazawa[1,2,3].* 1) Dept Molec Cytogenetics, Med. Res. Inst, Tokyo Med & Dent Univ, Tokyo, Japan; 2) Hard Tissue Genome Research Center, Tokyo Med & Dent Univ, Tokyo, Japan; 3) Bioresource Center, Tokyo Medical and Dental University, Tokyo, Japan.

We have analyzed more than 700 patients presenting with intellectual disability and/or multiple congenital anomalies of unknown etiology and normal karyotype by using several types of microarrays, and we detected pathogenic copy number variants (pCNV) in more than 20% of the cases. In most of them the pCNVs were *de novo*. Based on these results, we attempted to clarify the mechanisms responsible for the formation of these rearrengements and their parental origin. For this purpose, we determined the precise size of each pCNV using a high resolution oligonucleotide array (Human CGH 2.1M Whole-Genome Tilling Arrays, Roche-Nimblegem) and read the sequence at the breakpoint region to classify each pCNV into the three major mechanisms underlying genomic rearrengements, namely non-allelic homologous recombination (NAHR), as cause of recurrent rearrangements, and non-homologous end joining (NHEJ) or microhomology-mediated break-induced replication (MMBIR), as causes of non-recurrent rearrengements. We analyzed the breakpoints of 16 microdeletions and found that four cases (25.0%) were produced by NAHR. On the other hand, eight cases (50.0%) were originated by MMBIR, with 1–7 bp of microhomology, and two cases (12.5%), by NHEJ. The other two cases were produced by complex rearrengements. We also analyzed parental samples of nine cases and found that in eight (88.9%) the event leading to the rearrengement occurred in the paternal allele. These results were quite contrasting to our analysis in another cohort of healthy population, in which almost half (13/28=46.4%) of *de novo* CNVs had paternal origin. Our study demonstrates that *de novo* pCNVs were frequently produced by non-recurrent mechanisms rather than by the recurrent mechanism, with most of the events occurring in the paternal allele. This also suggests that *de novo* pCNVs may be generated by problems related to spermatogenesis, which is concordant with previous reports. We are currently sequencing the breakpoint regions of benign *de novo* CNVs in healthy individuals in order to elucidate the mechanisms producing these rearrangements.

Our experience of clinical implementation of whole-genome array CGH as a first-line test in postnatal cases. *V. Malan[1,2], JM. Lapierrre[1], MC. de Blois[1,2], C. Ozilou[1], S. Nusbaum[1], O. Raoul[1,2], M. Le Merrer[1,2], A. Harroche[1,2], R. Caumes[1,2], G. Baujat[1,2], F. Cartault[3], M. Rio[1,2], J. Amiel[1,2], S. Lyonnet[1,2], V. Cormier-Daire[1,2], A. Munnich[1,2], M. Vekemans[1,2], S. Romana[1,2].* 1) Département de Génétique, Hopital Necker-Enfants Malades, Paris, France; 2) Université Paris Descartes; 3) CHU de la Réunion, France.

Today, the array CGH has supplanted the karyotype for the global study of the genome with a resolution from 10 to 500 times better and with providing access to the genes content of the chromosomal rearrangement. The study of patients with intellectual disabilities and/or congenital malformations allowed to detect thanks to this technique 10 to 15% of abnormalities not visible on the karyotype. In addition, its use extended to other indications revealed anomalies associated with neuropsychiatric diseases (such as autism, schizophrenia, bipolar disorder or isolated epilepsy) and cardiac, bone, kidney isolated defects. The array CGH freeing a morphological analysis of chromosomes of the karyotype in contrast, offers the advantage of being fully automated allowing improved reliability and reproducibility of the results and a study of more patients with a constant medical and technical effective. Since April 2011, all patients have referred to Medical Genetics Center of Necker Hospital with a syndromic or isolated intellectual disability and / or autism spectrum disorders and / or birth defects benefit from evaluation of array CGH as a first line test. To date, among the 1400 patients tested by whole genome array CGH, we detected 12% of genomic imbalances considered as pathogenic (with about 2% of abnormalities that could have been visualized on the karyotype). The limit of detection of an abnormality was set at 400 kb (international standards) to reduce the detection of benign CNVs and variants of uncertain significance. Besides the expected increase in the efficiency of cytogenetic diagnosis, this change in practice has led to a real breakthrough in the organization of our cytogenetic lab. Complementary techniques of the karyotype, molecular cytogenetic techniques for the study of chromosomal anomalies are now the main part of the cytogenetic department. The analysis of genes in the unbalanced chromosome segment to establish the causal link between the genomic imbalance identified and the pathology observed is at the core of the cytogeneticist's work. This requires to redefine the training of technicians as well as those physicians who become today “internists of genomic pathology”.

916T

Copy number variation in hereditary colorectal cancer. *A.L. Martin[1,2,4,5], B.A. Talseth-Palmer[1,2], D.M. Grice[2,5], G.N. Hannan[5], R.J. Scott[1,2,3].* 1) University of Newcastle, Newcastle, NSW, Australia; 2) Hunter Medical Research Institute, Newcastle, NSW, Australia; 3) Hunter Area Pathology Service, Newcastle, NSW, Australia; 4) Australian Rotary Health-Rotary District 9650, Parramatta, NSW, Australia; 5) Commonwealth Scientific Industrial Research Orgaization, North Ryde, NSW, Australia.

Rationale: Colorectal cancer (CRC) is one of the most common cancers in the industrialised world. Hereditary non-polyposis colorectal cancer (HNPCC) is the most common form of familial CRC which describes the clustering of epithelial malignancies. Mutations in DNA mismatch repair (MMR) genes (MLH1, MSH2, MSH6 and PMS2) are clearly associated with as subset of HNPCC, termed Lynch syndrome (LS). Despite the distinct similarities of HNPCC to LS, anywhere from 30–50% of clinically tested patients fail to show germline mutations in these genes. Likewise, familial adenomatous polyposis (FAP) is the second most common form of inherited colorectal cancer characterized by the development of 100's-1000's adenomas in the colon and rectum. In 80–90% of FAP cases, disease is attributed to mutations in the adenomatous polyposis coli (APC) gene involved in regulating the WNT signalling pathway. In 10–20% FAP cases, the genetic cause of the disease remains elusive. Copy number variation (CNV) is the most recently described form of genetic variation and is yet to be fully characterized in hereditary CRC. Objective: The aim of this study is to identify if CNVs can account for a proportion of patients without a genetic diagnosis of LS or FAP. Methods and Results: 198 HNPCC, 72 FAP and 50 healthy control samples were screened for CNVs using the Cytogenetic Whole Genome 2.7M and CytoHD arrays from Affymetrix. All CRC cases had been deemed mutation negative after routine genetic testing (MLPA and Sanger sequencing). Golden Helix SVS7 CNAM was used to analyse the results. The cases were compared to controls as a means to eliminate non-pathogenic CNVs. Genome-wide analysis has identified hundreds of CNVs, some likely to be associated with HNPCC and FAP. This includes CNVs which encompass coding, non-coding and regulatory regions of genes. Single sample analysis also identified numerous cases exhibiting unique CNV profiles. This includes a patient with multiple chromosome p-arm deletions and a patient with a large deletion in the vicinity of the MLH1 gene, which is likely to be associated with disease risk. Conclusions: This study has generated a catalogue of CNVs likely to be associated with HNPCC and FAP even though the significance of any one of these remains unclear. This study supports the need for genome-wide screening for patients as a mean of more accurately delineating the genetic diagnosis in inherited cancer predispositions.

Using macrocephaly as a quantitative endophenotype in autism patients to enhance the identification of novel candidate genes. *J. Reiner[1], D. Moreno-De-Luca[1], E.B. Kaminsky[1], D.H. Ledbetter[2], C.L. Martin[1]*. 1) Department of Human Genetics, Emory University, Decatur, GA; 2) Genomic Medicine Institute, Geisinger Health System, Danville, PA.

Autism spectrum disorders (ASD) are a heterogeneous group of neurodevelopmental disorders characterized by deficits in social reciprocity, impaired language skills, and restricted interests. Although the degree of social and cognitive impairments in autism varies widely, individuals with analogous copy number variants (CNVs) often exhibit physical similarities. As such, selective genotyping of probands with specific endophenotypes may enhance the discovery of novel autism genes. We previously reported an increased incidence of autism and macrocephaly in individuals harboring a recurrent 17q12 deletion. Other recurrent CNVs have also been shown to impact head circumference in a dosage sensitive manner. For example, the 16p11.2 deletion and reciprocal duplication have been reported to predispose individuals to macrocephaly and microcephaly, respectively. Therefore, the objective of this study is to use autism plus macrocephaly as a quantitative trait to identify causative genes associated with these phenotypes. Since head circumference can be influenced by heritable factors and pathogenic mutations, we restricted the scope of our study to macrocephalic probands whose parents have a normal head circumference. We used the Simons Simplex Collection (SSC), a cohort of 2,629 families with a single individual with autism, and identified 180 probands (6.8%) with autism plus de novo macrocephaly. The SSC was recently genotyped by SNP arrays and two probands harboring large pathogenic CNVs were excluded from our experimental group, leaving 178 probands for our study. Interestingly, one of the excluded probands carries a 16p11.2 deletion, demonstrating the validity of our approach. In accordance with reports of a higher incidence of autism in males, the ratio of males to females with de novo macrocephaly is 4.8:1. However, the proportion of males and females exhibiting de novo macrocephaly relative to the total number of probands in each group is comparable, suggesting that other factors, including de novo mutations, may play a greater role in determining thisendophenotype than gender. We are interrogating the genotype of these probands using a custom-designed, exon-focused array with coverage of 1,282 genes including neurodevelopmental candidate genes and genes within 13 recurrent autism CNV regions. In light of our enrichment strategy, our approach should facilitate the identification of exon-level CNVs in genes associated with autism and de novo macrocephaly.

Study of Genomic Changes in Children with Intellectual and Developmental Disabilities Using Chromosomal Microarray. *P. Sharma, N. Gupta, M.R. Chowdhury, R. Shukla, M. Ghosh, M. Kabra*. Genetic unit, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, India, 110029.

Intellectual disability (ID) / developmental delay (DD) is a highly diverse group of disorder with multiple etiologies. Despite extensive investigations, the cause remains unknown in approximately 50% of the patients. Cryptic chromosomal imbalances have been identified as a common cause of disabilities in these children which are too small to be detected by conventional karyotyping due to its limited resolution. Chromosomal microarray (CMA) technology has emerged as a major tool to identify genomic imbalances in children with ID/DD due to whole genome coverage at higher resolution. In this study we analyzed 78 patients (50 male and 28 female) with unexplained ID/DD aged six months to eighteen years using CMA. These children were evaluated by Clinical Geneticists and were tested using CMA after no known cause for ID/DD was established by routine work up such as syndromic database search, G-banded karyotyping, MRI (brain) and metabolic testing. We used Agilent CGH Microarray Kit 8×60K and IIlumina Cyto-SNP -12 chip for our study. Data was analysed using Agilent Genomic Workbench and Genome Studio software. Regions with abnormal genotype were cross-matched with available literature and databases such as ISCA, DECIPHER, DGV to establish the pathogenicity of the changes observed. We identified significant copy number variations (CNVs) in 12 (15.3%) patients. In seven cases CNVs were in the subtelomeric region and in five they were in the interstitial region. Eleven of these CNVs were confirmed by other methods such as Multiplex Ligation Dependent Probe Amplification (MLPA) and Fluoroscence In Situ Hybridization (FISH). We were able to provide genetic counseling to all families and prenatal diagnosis in one family. In three other cases, causal relationship of CNV with ID/DD was not clear. CMA helped in increasing the diagnostic yield for cases with unknown genetic cause which is important for patient care in several ways: i) It decreases the number of diagnostic procedures that a patient is subjected to. ii) For families a diagnosis may diminish anxiety. iii) It allows for proper risk recurrence estimate and prenatal diagnosis in future pregnancies. Online databases and studies published on children with ID/DD using CMA has helped in interpreting the data and correlating the phenotype of patient with the genotype observed. Interpreting the clinical significance of novel or extremely rare CNVs when limited clinical literature is available is still challenging.

919W

Association of rare copy number variations and risk for Alzheimer's disease. *D. Villela[1], D. Schlesinger[2], C.K. Suemoto[3], L.T. Grinberg[3], A.C. Krepischi[4], C. Rosenberg[1]*. 1) Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of Sao Paulo, São Paulo, SP, Brazil; 2) Israel Institute for Teaching and Research Albert Einstein, São Paulo, SP, Brazil; 3) Brazilian Aging Brain Study Group, Department of Pathology, University of Sao Paulo, São Paulo, SP, Brazil; 4) National Institute of Science and Technology in Oncogenomics, São Paulo, SP, Brazil.

Alzheimer's disease (AD) is the most common cause of dementia in the elderly. Neuropathologically, the disease is characterized by extracellular senile plaques containing β-amyloid (Aβ) and intracellular neurofibrillary tangles containing hyperphosphorylated tau protein. So far, four genes have been definitively implicated in the etiology of AD. Mutations of the genes encoding amyloid precursor protein (APP) and presenilin 1 and 2 (PSEN1, PSEN2) cause the rare hereditary early-onset form of the disease. However, despite several genome-wide association studies using single nucleotide polymorphism (SNP) arrays have been performed over the last years, APOE is still the only confirmed susceptibility locus for late-onset of AD, the more prevalent form of the disorder. Currently, DNA copy number variations (CNVs) are recognized to be a frequent form of common genetic variation and represent a substantial proportion of total genetic variability in human population. Moreover, since the recognition of the existence of CNVs it has increased the number of studies that demonstrate its critical role in the phenotypes of complex diseases. Recently, two independent investigations reported the association of CNVs and risk for AD, but the CNVs were not selected by relevant gene content and they are common on the population. Here we used a whole-genome array-CGH to identify rare constitutive CNVs that possibly contribute to the development of late-onset AD. The Brain Bank of the Brazilian Aging Brain Study Group provided DNA from blood samples of 110 subjects, including 55 individuals with AD and 55 normal controls, matched for age and gender. The partial analysis of array-CGH revealed 11 rare CNVs (15% less frequent or never been documented as variable on the Database of Genomic Variant) in 27 subjects with AD and none of them was recurrent. Because of its relevant gene content for the investigated phenotype, we selected 5 genes that have never been associated to the disease. In summary, our results show the existence of novel susceptibility genes for the late-onset AD and reinforce the role of rare CNVs as disease-susceptibility variants for the investigated phenotype.

920T

Coronary artery disease genomics - CNV findings in the group of patients from Lithuania. *V. Kucinskas[1], I. Pepalyte[1], A. Pranculis[1], I. Bagdonaite[2], V. Dzenkeviciute[3], Z. Kucinskiene[2]*. 1) Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania; 2) Department of Physiology, Biochemistry and Laboratory Medicine, Faculty of Medicine, Vilnius University, Vilnius, Lithuania; 3) Clinic of Cardiology and Angiology, Faculty of Medicine, Vilnius University, Vilnius, Lithuania.

We aimed to evaluate quantitative and qualitative characteristics of structural variation in the group of patients with coronary artery disease (CAD). The strategy was to gather trios to identify *de novo* variants in the probands' group (32 trios were recruited). The probands' group included individuals with angiografically determined premature CAD or myocardial infarction and evaluated biochemical markers in blood samples. Genotyping was performed using Illumina 770K HumanOmniExpress-12 v1.0 array. Data was analyzed with QuantiSNP v2.1.

We presumed that parents of the probands were healthy individuals and focused only on the probands' CNV analysis, especially the *de novo* variants. In total there were 90 autosomal CNVs identified in the probands' group. According to the origin 60 CNVs were inherited and 32 - *de novo*. Out of 60 inherited variants 33 were deletions (25 heterozygous, 8 homozygous) and 27 - duplications (25 heterozygous, 2 homozygous). Out of 32 *de novo* variants 20 were deletions (4 heterozygous, 16 homozygous) and 12 - duplications (11 heterozygous, 1 homozygous). The most intriguing characteristic is the zygosity ratio of the *de novo* deletions compared to the *de novo* duplications and all inherited variants (homozygous and heterozygous duplications and deletions). *De novo* CNVs were classified using Database of Genomic Variants: out of 32 variants, 13 were classified as polymorphisms, 19 were not in the database - classified as unknown. We have also searched databases for CNVs' gene content. More than 50% of *de novo* CNVs did not include genes. Nevertheless, there were CNVs that included genes, which may provide a potential phenotype explanation.

According to our findings the zygosity's pattern in *de novo* variation could be one of the disease characteristics. *De novo* homozygous deletions, which are the dominating type of CNVs among all *de novo* variants, did not include relevant genes. Moreover not every gene spanning CNV could provide even a hypothetical reason for the pathogenesis. Thus, the link between pathogenesis of CAD and genomic findings on structural variation still remains unsolved. All in all our results improve knowledge of structural variation and provide the basis for better understanding of CAD genomics.

An unbalanced translocation causing a 21q11.2 deletion in an infertile male. *I. Holm[1], K. Eiklid[1], C. Hauge[2], V. Rønning[2], H. Wold[2]*. 1) Medical Genetics, Oslo University Hospital, Oslo, Norway; 2) Oslo and Akershus University College, Oslo, Norway.

Infertility is thought to affect about 10–15 percent of all couples in Western countries, where male infertility is the cause in about 50 percent(1). About 15 percent of male infertility is caused by genetic abnormalities(2). Many studies have shown that chromosomal aberration causing meiotic interruption can lead to oligozoospermia or azoospermia, which again can lead to infertility(3). Reciprocal translocations carriers do often produce more sperms with unbalanced chromosomes than non carriers(4). Up to 1500 genes are thought to be involved in spermatogenesis and 300–600 genes are specifically expressed in male germline. Deletions and duplications in genes that affect spermatogenesis increase the risk of infertility (1). Here we present a case report of an infertile man with a presumed balanced reciprocal translocation of 46,XY,t(12;21)(q24.33;q10). By performing array comparative genomic hybridization (Agilent Technology, 105K) we found a deletion starting at 21q11.2 going at least 0.7 Mb up to the telomeric part of chromosome 21 (arr 21q11.2(14,795,268-15,558,340)x1). We speculate if this deletion also could include the whole telomeric region. This deletion included three OMIM genes *LIPI* (OMIM *609252), *POTED* (OMIM *607549) and possibly *TPTE* (OMIM *604336) if it includes the entire short arm. These genes are all expressed in testis and are candidate genes for infertility. *TPTE* and *POTEB*, which in addition to *POTED* is a member of the ankyrin domain family, are previously described in relation to infertility(5). The deletion found in this patient will be further characterized with quantative PCR and FISH in order to confirm it and to characterize the breakpoint and the size of it. Single cell copy number profiling in a 24-hour workflow with oligo aCGH. *P. Costa, S. Fulmer-Smentek, A. De Witte*. Agilent Technologies Genomics, Santa Clara, CA.

Since its development, array-based Comparative Genomic Hybridization (aCGH) has become a widely used tool in cytogenetic and cancer applications for researchers to study genome-wide copy number (CN) changes. However, not all cells in a tissue share the same genomic background and so the ability to characterize individual genomes is becoming an area of focus in cancer, reproductive and stem cell research. Taking advantage of the high-resolution and sensitivity of the Agilent SurePrint G3 Microarrays technology, we applied the power of the aCGH platform to CN profiling in single cells. The use of Agilent's aCGH overcomes the limitations posed by the low-resolution of traditional FISH and PCR-based research techniques and, more recently, the low-resolution and poor reproducibility associated with BAC arrays. Agilent's aCGH application relies on a two-color assay to measure CN changes in a test sample relative to a reference. To increase the amount of DNA while maintaining the genomic representation, whole genome amplification (WGA) was performed. Single cells biopsied from embryos and genomic DNA (gDNA) with a known aberration diluted to single cell levels were amplified. To minimize variation associated with the extreme dilution of gDNA and the amplification process, the reference sample, which was also diluted to single cell levels, was amplified in multiple reactions and pooled prior to labeling. Test and reference amplified DNA samples were differentially labeled, combined and hybridized for 16 hours to SurePrint G3 Human Catalog 8×60K CGH Microarrays, with uniform backbone coverage and denser coverage in genes. Following hybridization, the data were extracted and analyzed for CN alterations using algorithms implemented in Agilent CytoGenomics and Genomic Workbench. With an optimized workflow for sample and microarray processing, CN aberrations were assessed in the single cells and confirmed in the gDNA, bearing a known amplification on chromosome 9 and diluted to single cell levels. A reduction in the noise level and improvement in the data was observed for samples hybridized to a pooled reference as compared to a single reference. Using an approximately 24-hour single cell workflow from sample preparation to analysis, researchers can now obtain reliable results at a high resolution while remaining cost-effective.

Four new polymorphic CNVs in cohort of 100 Bulgarian patients with intelectual disability/congenital malformations and autisme. *S.P. Hadjidekova[1], D.M. Avdjieva-Tzavella[2], B.B. Rukova[1], D.V. Nesheva[1], R.S. Tincheva[2], D.I. Toncheva[1]*. 1) Medical Genetics, Medical University-Sofia, Sofia, Sofia, Bulgaria; 2) State University Pediatrics Hospital “Queen Evdokia”, Medical Faculty, Medical University, Sofia, Bulgaria.

The increasing resolution of DNA-microarrays and the techniques optimization allow detection of a large number of small CNVs, whose clinical significance in some cases is unknown. Oligo array-CGH was applied in 100 patients, divided in two groups - with intellectual disability/multiple congenital anomalies and autism in order to unravel the underlying genetic abnormalities. We have used BlueGnome CytoChip oligo 2×105K microarray, v1.1, with 35 kbp backbone resolution. This is the first whole genome high resolution screening in a larger group of Bulgarian patients. Except causative CNVs we found 299 benign CNVs and 219 CNVs with unknown clinical significance. The interpretation of CNVs with unknown clinical significance remains still a challenge. Due to insufficient data for the Bulgarian population we made an individual assessment of each unknown variant. In our study four types of unknown CNVs in chromosomal loci 2q37.3, 10q11.22, Xp22.33 and 8p23.1 were found in higher percentage (≥5%). This gave us a reason to suppose that they were probably not pathogenic and are specific for the Bulgarian population. There is an obvious need for large population studies and the creation of detailed maps of CNV frequencies in the Bulgarian population. This would facilitate the precise interpretation of genomic imbalances of unknown nature in clinical aspect and would allow the widespread introduction of microarray diagnosis in practice. The protocol and informed consent documents were reviewed and approved by the local ethics committee. The consent forms were prepared in conformance with the Declaration of Helsinki and local country laws. All participating volunteers were asked to provide written consent after receiving an explanation of the study.

First Detection Of Clonal Trisomy 4 Cells From 3 Cases Of Ossifying Renal Tumor Of Infancy. *J. Liu[1], M. Guzman[1], B. Pawel[2], D. Pezanowski[1], J. Roth[3], G. Halligan[4], J. de Chadarévian1[1]*. 1) Department of Pathology and Laboratory Medicine, Drexel University College of Medicine and St. Christopher's Hospital for Children, Philadelphia, PA; 2) Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine and Children's Hospital of Philadelphia, Philadelphia, PA,; 3) Department of Surgery, Section of Pediatric Urology, Temple University School of Medicine and St. Christopher's Hospital for Children, Philadelphia, PA; 4) Department of Pediatrics, Section of Oncology, Drexel University College of Medicine and St. Christopher's Hospital for Children, Philadelphia, PA.

The ossifying renal tumor of infancy is a rare neoplasm diagnosed in the first two years of life, predominantly in boys. The neoplasm is primarily characterized by the presence of a large ossifying component. Its most common mode of presentation is hematuria, and it has a uniformly benign behavior. The karyotypic make-up of the process has not been reported. Thus a study was undertaken and it allowed demonstration of clonal trisomy 4, which was confirmed by the fluorescent in-situ hybridization (FISH)-probing of two additional archival formalin-fixed, paraffin-imbedded similar tumors. Based on the findings in these 3 cases, it seems that clonal trisomy 4 may be considered as a characteristic of the tumor, which makes it distinct from any other infantile renal tumor.

17p13.3 microduplication syndrome: report of additional findings. *L. Mutesa[1], E. Chabchoub[3], JH. Caberg[2], AC. Hellin[2], M. Jamar[2], H. Peeters[3], G. van Buggenhout[3], G. Pierquin[2], J. Andrieux[4]*. 1) Medical Genetics, National University of Rwanda, Kigali, Kigali, Rwanda; 2) Center for Human Genetics, University of Liège, Liège, Belgium,; 3) Department of Human Genetics, University Hospitals of Leuven, Catholic University of Leuven, Belgium,; 4) Laboratory of Medical Genetics, Jeanne-de-Flandre Hospital CHRU de Lille, Lille cedex, France.

Chromosomal duplication including 17p13 is rare and only a few patients have been reported to date. Here, we report on six additional patients with submicroscopic duplications of 17p13.3 identified by microarray-based comparative genomic hybridization. The common clinical features of all those five patients were marked hypotonic long face, downslanting fissures, low-set ears, high stature, development delay and mental retardation. Apart from the presence of other several genes, the duplicated regions contain two putatives functional genes, the PAFAH1B1 (encoding LIS1) and YWHAE genes which are involved in directing the movement of nerve cells (neuronal migration) and normal brain development, respectively. We suggest that 17p13.3 duplication is responsible for brain development delay and distinctive craniofacial dysmorphic features. The report additional allows to definitely substantiate the significance of 17p13.3 duplication and contributes to delineation of the clinical spectrum.

Chromosome aberrations among 4617 chromosomal studies at a pediatric Mexican hospital in 19-year period of time. *J. M. Aparicio[1, 13], M. L. Hurtado[2], M. P. Barrientos[3], W. B. San Martin[4], A. F. Nuñez[5], R. G. Ruiz[6], H. T. Gomez[7], S. P. Rodriguez[8], R. M. Zamudio[9], F. L. Cuellar[10], M. A. Cubillo[11], F. P. Sierra[12], M. G. Palma[13], H. O. Chavez[13], S. M. Chatelain[14]*. 1) Dept Gen; 2) Cytogenetics; 3) Endocrinology; 4) Estomatology; 5) Neumology; 6) Internal Medicine; 7) Alergology; 8) Neurosurgery; 9) Cardiology; 10) Urology; 11) Rehabilitation terapy, Hosp para el Nino Poblano, Puebla; 12) Genetics, Hosp de la Mujer, Puebla; 13) Estomatology, Benemerita Universidad de Puebla; 14) Biotechnology, Universidad Autonoma Metropolitana, Mexico.

Mutations or chromosome aberrations are considered alterations in the chromosome number or structure. They are mainly considered due to gametogenesis inborn error (meiosis) or during the zygote first cellular divisions. All these alterations might be observed during metaphase from the cellular cycle, where DNA loses are seen (clastogenic processes) due to DNA repair processes deficiency o total absence, among others. 4617 chromosomal studies were performed at Hospital Para El Niño Poblano (Pediatric Hospital) in Mexico. During 19 years period of time (from 1992 to 2011) were 34.6% (1596 patients) showed different chromosomal alterations. Among the studies population, male and female pediatric patients with different genetic diseases were chosen. These chromosome changes are classified as numeric or structural alterations, respectively. Another group of genetic alterations are known as mutations and can be inherited among generations. A wide variety of pediatric patients with genetic diseases due to chromosome aberrations are described in this study analyzing their clinical characteristics, medical or surgical treatments and their medical evolution according to the genetic disease.

927W

Study of sodium pertechnetate on bone marrow cells of mice, in vivo: Micronucleus assay Aranha IP Dept. Genética, IBRAG, Univ. do Estado do Rio de Janeiro, Brazil. *I. Aranha*. Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil.

Technetium-99m (^{99m}Tc) has become the most widely used radioisotope in the detection of inflamatory sites as well as in the diagnosis of transplanted tissues. The goal of the present work is to study the effect of sodium pertechnetate on chromosomes of mice bone marrow in vivo, using the micronucleus assay. Animals (ICR mice) were separated into three groups. In the first group, 6 animals received sodium pertechnetate intraperitoneally in a concentration equivalent to 25% of the LD50, once. In the 2nd day, animals were sacrificed by cervical dislocation, their femurs removed, the bone marrows collected and smears were made for slides preparation. After 24h cells were stained with Giemsa Gurr (2%) and analyzed under optical microscope. As positive control, 6 animals received cyclophosphamide (50mg/mL) also once. Six animals not exposed to any drug served as negative control for the experiment. In the test group, 12130 cells were observed and 143 showed micronuclei. In the positive control group, of 12000 cells analyzed, 163 had micronuclei and in the negative control group, 12173 cells were studied and 07 had micronuclei. The chi-square test for independence showed that our results were extremely significant ($P<0.0001$). They suggest that sodium pertechnetate is responsible for the micronuclei observed.

928T

Cryptic translocactions of acrocentrics chromosomes in normal couples and couples with aneuploid miscarriages. *S. Ramos[1], O. Castro[1], B. Molina[1], M. Angeles[1], P. Grether[2], D. Mayen[3], S. Frias[1,4]*. 1) Laboratorio de Citogenetica, Instituto Nacional de Pediatria, Mexico city, DF, Mexico; 2) Departamento de Genetica, Instituto Nacional de Perinatologia, Mexico city, DF, Mexico; 3) Servicio de Genetica, Hospital Angeles -Lomas, Mexico city, DF, Mexico; 4) Instituto de Investigaciones Biomedicas, Universidad Nacional Autonoma de Mexico, Mexico city, DF, Mexico.

Aneuploidy is the principal genetic cause of spontaneous abortions, approximately 90% of cases die in utero, and congenital anomalies are produced in live births. Little is known about the etiology of aneuploidy, although the main mechanism is meiotic nondisjunction, especially in the oogenesis of older women. The structural chromosomal rearrangement called cryptic translocations of acrocentric chromosomes (TCA) could generate aneuploidies by influencing meiosis and producing non-disjunction, and aneuploid conceptions. The aim of this study was to determine the frequency of TCA in couples with abortions with aneuploidies of acrocentric chromosomes. We included 59 healthy couples with at least one normal child and no history of spontaneous abortions; 12 couples with at least one abortion or offspring with aneuploidies of acrocentric chromosomes and 58 samples of aneuploid abortions. All couples agreed and signed informed consent form. All samples were subjected to GTG banding and FISH with centromeric probes for chromosome 13/21, 14/22 and 15. For both methods, at least 15 cells were analyzed per sample. Using FISH, we found a frequency of 18.6% TCA (22/118) in the individuals from the healthy couples group; 29.1% (7/24) in individuals from couples with abortions or aneuploid offspring, and 12.06% (7/58) in the abortions. The translocation more frequently found was: dic(13;15), followed by dic(14;15). The results found in the normal couples suggest that TCA may be a chromosomal polymporhism, however the high frequency of TCA we found in the couples with miscarriages with aneuploidy of acrocentric chromosomes, suggest that this TCA may interfer with the meiotic chromosome pairing favoring aneuploid conceptions. It is necessary to increase the population of study to confirm whether TCA are related to the generation of aneuploidy.

A comparative cytogenetic resolution analysis between classic chromosome aberrations and Cytokinesis-Block Micronucleus Cytome assay. *R. Saraswathy.* VIT University, Vellore, India.

Until recently the genetic instability of the syndrome was estimated by the application of classic chromosome aberrations analysis. However at present after the discovery of Cytokinesis-Block Micronucleus Cytome assay by Fenech, the situation has changed. In this study a comparative cytogenetic resolution analysis between classic chromosome aberrations and Cytokinesis-Block Micronucleus Cytome assay was undertaken. For this study the following syndromes were utilized, such as, Dilated Cardiomyopathy (n=50), Diabetes (n=25), Head and Neck Cancer (n=15), congenital anomalies (n=15), Gonadal dysgenesis (n=15), Down syndrome (n=20), Aplastic anemia (n=15). Age and sex matched controls (n=50) from Vellore region of South India were analysed for CA and CBMN. Our results indicate that in all the syndromes a significantly higher frequencies of CA, micronuclei (MNi) and genomic damages such as nuclear buds (NBUDs) and nucleoplasmic bridges (NPBs) were observed in the patient group in comparison to the control group ($p<0.001$). Even though CBMN assay is having several advantages over the other, yet it is advisable to use both the type of assays to get a better picture of genomic instability.

In vitro assessment of genotoxicity and cytotoxicity of methyl mercury chloride. *S. Tayel[1,2], M. Naim bushra[2], A. Abd Ruboh[1], S. Hilal[2], A. El Agwany[2]*. 1) Alexandria Regional Centre for Women's Health & Development, Alexandria, Egypt; 2) Anatomy & Embryology Deptartment, Faculty of Medicine, Alexandria University, Alexandria, Egypt<.

Methyl mercury chloride (CH3HgCl) exists in soil, air, fishes, shellfish and algae, rejected water system, from mining operations and lixiviation of soils after deforestation. It has become one of the most hazardous environmental pollutants reaching levels of potential toxicity especially in our aquatic ecosystems. The objective of the present study was to assess the cytotoxicity and genotoxicity of CH3HgCl in cultured human lymphocytes. Short-term human leukocyte cultures from 30 healthy donors (15 females and 15 males) were set-up by adding drops of whole blood in a complete medium. Cultures were incubated at 37°C for 72 h and doses O, 50, 500 and 5000 μg/ L of CH3HgCl were added 24 h before harvest. One hundred metaphases were analyzed by solid stain and GTG banding for each culture with a total of 3,000 metaphases for each concentration. Genotoxicity of CH3HgCl was expressed by chromosome aberrations in the form of aneuploidy, hyperploidy, chromatid endoreduplication, breaks, satellite associations, and double minutes formation in a concentration related manner where a significant increase ($P < 0.05$) in the relative frequency of chromosome aberrations was observed for all concentrations of CH3HgCl when compared to control. Cytotoxicity as assessed by the micronucleus test showed binucleated cells with one or more micronuclei and cytoplasmic bridges in a concentration related manner. Mitotic index showed an inverse relation with increase in the concentration of CH3HgCl indicating its cytotoxicity. In conclusion, CH3HgCl is geno- and cytotoxic even in low doses. The changes it induces in lymphocyte culture may be an early marker of this toxicity in humans and should be taken into account in the preliminary evaluation of the risks to populations exposed in vivo.

931W

The deletion 5q in myelodysplasia : correlation of cytogenetic, peripheral blood and bone marrow findings. *V.M. Srivastava, S. Yuvarani, U. Sitaram, A. Nancy, R. Ahmed, A. Abraham, A. Vishwabandya, B. George, V. Mathews, A. Srivastava.* Christian Medical College, Vellore, Tamil Nadu, India.

Background: Deletion of the long (q) arm of chromosome 5 (del 5q) is seen in about 15% of myelodysplasia (MDS). MDS with a solitary del 5q have a favourable outcome. When additional chromosomal abnormalities are present, prognosis is poor with early progression to leukemia, resistance to treatment and short survival. Patients and methods:The study group consisted of patients with a morphologic diagnosis of MDS and del 5q seen in the Department of Haematology between January 2003 and December 2010. At least 15–20 G-banded metaphases were studied from each patient. Cytogenetic findings were correlated with peripheral blood and bone marrow findings. Results: The del 5q was seen in 60 (11%) of the 537 patients with MDS. The median age was 56 years (range 3–76).There were 34 males (57%). The median haemoglobin was 7.2g/dl (range 2.5–14.2 g/dl), median WBC 4.6×109/L(range 0.5–48 ×109/L), and median platelet count, 118×109/L (range 5 -794 109/L).The morphologic diagnoses were: 5q- syndrome -12 ;refractory anaemia (RA) - 3;refractory anaemia with ringed sideroblasts (RARS)-1;refractory anaemia with excess blasts(RAEB)-14; refractory cytopaenia with multilineage dysplasia (RCMD) - 9;RCMD with ringed sideroblasts (RCMD-RS) - 4;hypoplastic MDS - 4;MDS unclassified(MDS-U) -13. Hypolobate megakaryocytes were noted in 14 patients (23%),dyserythropoiesis and dysmyelopoiesis in 42 each (70%)and trilineage dysplasia in 29(48%).The del 5q was solitary in 50% of patients. A single additional abnormality was seen in 13% of patients while 37% had complex karyotypes(more than two abnormalities). Most (57%) patients with a solitary del 5q were adult females (age range:27–76) and almost half (48%) had either refractory anaemia or the 5q- syndrome. RAEB and MDS-U accounted for the majority of patients with complex karyotypes (68%) or a single additional abnormality (63%).The additional abnormalities seen were monosomies 7,17,20 and 13, trisomy 21 and deletions 7q and 20q (< 9 % each). Conclusions: The overall incidence of the del 5q in MDS and its association with additional abnormalities is similar to the literature. Our findings differ from the literature with respect to the median age of our patients (lower than in Western countries but similar to reports from other Asian countries) and the frequency of the 5q- syndrome (similar to Western countries but higher than in reports from other Asian countries).This is the first detailed analysis of the del 5q from India.

932T

The quality of the bone marrow sample for successful conventional cytogenetic analysis is important. *E. Tegg[1, 2], E. Raik[2]*. 1) Haematology, University of Tasmania, Hobart, Australia; 2) Haematology, Royal North Shore Hospital, Sydney, Australia.

The role of cytogenetics in the diagnosis and prognosis of a number of haematological malignancies is well recognised. The contribution made by the quality of the sample given to a cytogenetics laboratory to successfully provide diagnostic results is not universally recognised. This was a retrospective control study made after a change to the bone marrow aspiration technique. The test group consisted of the first 65 patients who underwent a bone marrow biopsy requiring cytogenetic analysis after this change. The control group consisted of 65 patients who had undergone a bone marrow biopsy for cytogenetic analysis prior to this change. The parameters measured were disease type, morphological cellularity of the aspirated marrow, cell count in the cytogenetic sample, cytogenetic culture failure rate, number of metaphases obtained and the banding resolution achieved. Results were analysed using Microsoft Excel student t-test. The cellularity of the cytogenetic sample was significantly increased (1.23 × 109/L compared to 0.59 × 109/L; $p<0.001$). The culture failure rate fell significantly from 15% in the control group to 2%. ($p<0.01$). The optimal number of metaphases (20 metaphases per patient) was achieved in 75% of cases compared to 50% in the control group ($p<0.04$). The banding resolution, probably reflecting the increase in the number of metaphases from which to choose, was significantly increased in the test group compared to the control group ($p<0.04$). Information in the literature is sparse when assessing the effect of BM cellularity on the ability to obtain a successful conventional cytogenetic result. This study showed the positive effect of increasing the cellularity of the bone marrow aspirate sample for the successful cytogenetic investigation of haematological malignancies.

933W

Parental interstitial translocation underlie deletion in Langer-Giedion syndrome. *B. Min[1], M. Seo[1], T. Cho[2], W. Park[1]*. 1) Biomedical Science, Seoul National University, Seoul, South Korea; 2) Orthopaedic Surgery, Seoul National University College of Medicine, Seoul, Korea.

Langer-Giedion syndrome (LGS, MIM 150230), also called trichorhinophalangeal syndrome type II (TRPS2) is a contiguous gene syndrome caused by simultaneous deletion of TRPS1 and EXT, manifesting phenotypes of both trichorhinophalangeal syndrome type I and hereditary multiple exostoses. Using array CGH, we investigated genotypes of a family consisting of two siblings affected with LGS, two unaffected siblings, and unaffected parents, in order to explain the recurrence of LGS from unaffected parents. The affected siblings were found to have the exactly same 7.3 Mb interstitial microdeletion in 8q23-q24 containing TRPS1 and EXT1 genes in two patients in an exactly same way. The mother and one of the unaffected siblings were found to have a 1.3 Mb microdeletion in 8q24.1, which shared distal breakpoint with the deleted segment of the affected. In addition, 6.0 Mb microduplication spanning from proximal breakpoint was detected in the other unaffected sibling. Karyotyping and FISH revealed an interstitial translocation t(8;13)(q23–24;q33). Flanking sequences of breakpoint and junctions for 7.3Mb interstitial deletion contained 200bp-long unique sequences in 8q and 13q. Here we reports a family in which parental silent interstitial translocation caused recurrence of LGS, and this phenomenon should be taken into consideration in genetic counseling.

Concurrent deletions and duplications at 1p36. *M. Gajecka[1,2], J. Karolak[1], J. Shen[3], C. Glotzbach[4], L.G. Shaffer[4]*. 1) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Wlkp, Poland; 2) Department of Pharmaceutical Bacteriology, Poznan University of Medical Sciences, Poland; 3) Children's Hospital Central California, Madera, CA, USA; 4) Signature Genomic Laboratories, PerkinElmer, Inc., Spokane, WA, USA.

Deletions of 1p36 occur in approximately 1 in 5,000 newborns. To date, we have ascertained more than 150 cases with monosomy 1p36, representing four possible classes of rearrangements: pure terminal deletions, interstitial deletions, unbalanced translocations, and complex rearrangements. Here we present five complex rearrangements involving duplications in monosomy 1p36. For each individual, deletion and duplication sizes, and parental origin of the rearrangements were determined using array CGH and genotyping. Deletion and duplication sizes as well the breakpoints locations were different in each patient. To further understand the mechanisms for concurrent deletions and duplications, the rearrangements breakpoints were investigated using molecular cytogenetics and molecular biology methods. Fiber FISH analysis demonstrated either tandem or direct duplications in the cases. Both duplications and deletions were interrupted with insertions of material from 1p. Although numerous experiments were performed and different methodology applied, we were not able to identify all junctions in the rearrangements. Our results show higher than accepted complexity of the studied rearrangements and indicate involvement of multiple mechanisms in the DNA breakage and repair process during rearrangement formation. Support: Polish Ministry of Science and Higher Education, Grant NN301238836.

Multiple structural abnormalities involving 4q33 in a spontaneous abortion. *M.B. Sheridan[1], C. Wigner[2], D.A.S. Batista[2,3], K. Turner[4], C. DeScipio[2,5]*. 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Pathology, Johns Hopkins Medical Institutions, Baltimore, MD; 3) Cytogenetics Laboratory, Kennedy Krieger Institute, Baltimore, MD; 4) Department of Obstetrics and Gynecology, Johns Hopkins Community Physicians, Columbia, MD; 5) Department of Gynecology and Obstetrics, Johns Hopkins University School of Medicine, Baltimore, MD.

We describe a complex karyotype observed in cultured placental villi from a first trimester (8 weeks) loss from a 24 year-old woman with no significant reported drug or environmental exposures. An abnormal male karyotype was seen with multiple cell lines, each with a structurally aberrant chromosome 4 with an apparent breakpoint in band 4q33. Abnormal cell lines, each observed in multiple cultures, include: (1) addition of material of unknown origin to 4q33 in 9 of 20 cells; (2) a derivative chromosome 4 that is the result of an apparently unbalanced translocation between the long arms of chromosomes 1 and 4 with breakpoints at bands q21 and q33, respectively, in 3 of 20 cells; (3) an apparently terminal deletion with a breakpoint at 4q33 in 2 of 20 cells. Additionally, single cell and single culture abnormalities also involving 4q were observed in three cells. Three cells, all present in the same culture, appeared to have two structurally normal chromosome 4 homologs (46,XY). Fetal tissue was not available for analysis; therefore, confined placental mosaicism cannot be ruled out. Pregnancy history includes four previous first trimester losses and a healthy 2 year old daughter. Parental karyotypes are normal. Chromosomal microarray studies to assess copy number and delineate chromosome 4q breakpoints are pending. Collectively, this analysis revealed a complex, unbalanced karyotype with apparent loss of material from 4q33 to 4qter plus gain of various other chromosomal regions. Potential mechanisms to explain these findings include a jumping translocation or the presence of a fragile site at 4q33. Jumping translocations typically involve one donor and multiple recipient chromosomes; however, in this case, the converse is seen. Breakage at 4q33, due to a fragile site, with subsequent repair with multiple chromosomal partners appears to be a possible mechanism. To our knowledge, however, this type of repair at a fragile site has not been reported. In summary, we have described a complex karyotype that includes distinct abnormalities with similar breakpoints that may be the result of a yet undescribed mechanism of chromosomal rearrangement.

936T

When transmission modifies the complexity of familial chromosome rearrangements. *V. GATINOIS[1], G. LEFORT[1], C. COUBES[2], J. PUECHBERTY[1,2], A. SCHNEIDER[1], S. TAVIAUX[1], M. TOURNAIRE[1], M. DI NICOLA[1], M. GIRARD[1], P. SARDA[2], F. PELLESTOR[1]*. 1) Department of Cytogenetics, Hospital Arnaud de Villeneuve, CHRU Montpellier, France; 2) Department of Medical Genetics, Hospital Arnaud de Villeneuve, CHRU Montpellier, France.

Complex Chromosome Rearrangements (CCR) are rare events, defined by the occurrence of at least 3 chromosome breakpoints. The degree of complexity of CCRs can be very high and the related meiotic disturbances result in important chromosomal imbalance in gametes. Only 30% of reported cases are familial and transmission is mainly through males. Conversely 70% of CCRs are de novo, caused by an error during spermatogenesis and frequently lead to male infertility. During meiosis, crossing-over between involved chromosomes can modify the complexity of the rearrangement with numerous possibilities of chromosomal imbalance in gametes. We report 2 familial cases in which meiotic events result in a new chromosome rearrangement. In our first case, karyotyping was done following the discovery of a multiple malformation syndrome on ultrasound examination. The fetal karyotype showed an unbalanced CCR with 3 breakpoints. Subsequent analysis of the mother's chromosomes revealed an apparently balanced CCR with 4 breakpoints. For the second case, a male carrier of a simple reciprocal translocation inherited through his mother fathered a girl with a more complex rearrangement involving a third chromosome. For both cases, breakpoint studies led to an understanding of the involved mechanisms underlying the simplification or complexification of the parental rearrangement.For the breakpoint studies, in addition to the technics used routinely in our lab (metaphase karyotype, chromosome painting and array-CGH) we developed 2 additional methodological approaches : “chromosome walking” and Array Painting.

937W

Evidence of a Trisomy 9 Rescue Event in Amniotic Fluid. *L.E. Northrop, M.J. Macera, V. Johbanputra, B. Levy*. Pathology, Columbia University, New York, NY.

Trisomy 9 is rarely seen in a live birth as the natural outcome is usually a spontaneous abortion within the first trimester. Those cases that do survive are primarily mosaics with a high risk for fetal abnormalities, diminished life expectancy and variable phenotype, depending on the level of mosaicism. The phenotype described in the small number of reported live-birth cases includes: facial dysmorphism, skeletal abnormalities, hypotonia, congential heart defects, skin lesions and severe pyschomotor retardation. At our clinic, a 44 year old, G4P1woman, underwent a transcervical chorionic villus sampling at 13 weeks gestational age because of advanced maternal age. Cytogenetic analysis revealed level III mosaicism for trisomy 9 with the remaining cells showing a 46,XY chromosome constitution. Amniocentesis at 16 weeks of gestation was performed to distinguish between confined placental mosaicism (CPM) and true fetal mosaicism. FISH using a centromere-specific probe for chromosome 9 (CEP 9) was performed on uncultured cells and revealed an extra centromeric signal, indicative of trisomy 9, in 88% on interphase nuclei. Routine chromosome studies (G-banding) on cultured cells revealed a minute supernumerary marker chromosome (SMC) in 85% of cells analyzed. The SMC was identified as being derived from chromosome 9 using the CEP 9 probe. The final karyotype was: 47,XY,+mar[17]/46,XY[3].ish der(9)(D9Z1+). The fetal ultrasound was normal with no indication of malformations. The finding of trisomy 9 mosaicism at the time of CVS coupled with the results from the amniotic fluid analysis indicate that a rescue event likely occurred with one of the chromosomes 9 reducing to a minute, centric fragment. Microarray analysis was recommended to determine the extent of euchromatic material present on the chromosome 9 marker; however the patient elected to terminate the pregnancy. Without analyzing additional fetal tissue, it is uncertain whether the amniocentesis results reflect fetal wide rescue.

Large-Scale Sequence Analysis of Translocation Breakpoint Junctions. *B. Weckselblatt, M.K. Rudd.* Human Genetics, Emory University, Atlanta, GA.

Translocation is one of the most common structural chromosome abnormalities observed in humans. Germline unbalanced chromosome translocations result in partial monosomy and partial trisomy of many genes, leading to intellectual disability and birth defects. We have analyzed chromosome breakpoints from 54 human subjects with unique unbalanced translocations using a combination of array comparative genome hybridization (CGH), targeted sequence capture, and next-generation sequencing. Included in this group of 54 rearrangements is a subset of translocations between three, four, or five nonhomologous chromosomes. Breakpoints with complex junctions involving multiple chromosomes may be indicative of chromosome shattering, a recently described process that plays a role in germline and somatic chromosome rearrangements. We fine-mapped breakpoint locations in 47/54 translocations with high-resolution array-CGH, and then captured breakpoint junction regions with SureSelect target enrichment and next-generation sequencing. Sequence analysis of breakpoint junctions allows inference of the type of DNA repair at translocation breakpoints and can reveal a more complex rearrangement structure than expected from array CGH alone. Consistent with recent publications that demonstrate the variability in breakpoint characteristics, we have sequenced four junctions that have either no microhomology, a few basepairs of microhomology, or insertions. Sequence analysis of the remaining translocation junctions is ongoing. Results from this large-scale study of patient breakpoint sequences will pave the way to more complete models for chromosome rearrangement by translocation.

Analysis of the nucleotide sequence diversity within the *SUZ12* gene and its pseudogene *SUZ12P* as a means to investigate the signature of nonallelic homologous gene conversion. *T. Muβotter[1], J. Vogt[1], K. Bengesser[1], J. Högel[1], D.N. Cooper[2], H. Kehrer-Sawatzki[1].* 1) Institute of Human Genetics, University of Ulm, Ulm, Germany; 2) Institute of Medical Genetics, School of Medicine, Cardiff University, Cardiff, United Kingdom.

Double Holliday junctions (dHj) formed between paralogous sequences are recombination intermediates that are either resolved by crossover in a process termed *nonallelic homologous recombination* (NAHR) or by the non-crossover pathway associated with *nonallelic homologous gene conversion* (NAHGC). These pathways of resolution constitute alternative processes. However, since NAHR gives rise to putatively deleterious deletions and duplications, the products of the non-crossover pathway are observed more frequently. The molecular signature of meiotic NAHGC detected within the recombining paralogs is an increased SNP density as compared to the genomic average. Following this line of reason, several low-copy repeats (LCRs) exhibiting meiotic NAHR activity were found to be involved in frequent NAHGC-mediated sequence exchange as reflected by an increased SNP density. In addition, the LCRs located within the *NF1* gene region (termed NF1-REPs), which mediate meiotic NAHR causing type-1 *NF1* microdeletions, manifest an increased SNP frequency suggestive of frequent NAHGC resulting from meiotic nonallelic homologous recombination. Whereas nonallelic homologous recombination with or without crossover during meiosis has been studied in greater detail, the features of these processes during mitotic cell divisions are not well delineated. In this study, we have investigated whether NAHGC might also operate during mitotic nonallelic homologous recombination. To this end, we determined the SNP density within the paralogous *SUZ12* gene and *SUZ12P* pseudogene that undergo predominantly mitotic (postzygotic) NAHR giving rise to mosaic type-2 *NF1* microdeletions. We noted an increased SNP density (4.4 SNPs/kb) within the mitotic NAHR hotspot PRS4 recently identified in patients with type-2 *NF1* microdeletions as compared with the genome average of 1 SNP/kb ($p<0.0001$). The increased SNP frequency within the mitotic NAHR hotspot PRS4 is suggestive of sequence exchange by NAHGC operating between *SUZ12* and *SUZ12P*. Since PRS4 is a hotspot of mitotic (but not of meiotic) NAHR, we surmise that the increased SNP density is indicative of enhanced NAHGC activity operating during pre-meiotic mitoses. Our analysis suggests that not only meiotic but also mitotic dHj intermediates of nonallelic homologous recombination are resolved by non-crossover pathways leading to gene conversion in regions flanking the recombination-initiating DNA double-strand breaks.

An Examination of the Origin of the Excess of Males Liveborn with Trisomy 21. *C. Walker[1], S. Gandy[1], J. Jones[1], A. Harden[1], T. Naluai-Cecchini[3], E. Cheng[3], S. Sherman[2], T. Oliver[1, 2].* 1) Department of Biology, Spelman College, Atlanta, GA; 2) Department of Human Genetics, Emory University, Atlanta, GA; 3) Department of Obstetrics and Gynecology, University of Washington, WA.

The best estimate for the sex ratio among live-born individuals with Down Syndrome is 1.15 whereas the sex ratio among normal individuals is 1.05, thus there is an excess of males with trisomy 21 that survive gestation. What could lead to an excess of males among live-born individuals with Trisomy 21 (T21)? Research shows there is an excess of live-born (LB) females with a heart defect among individuals with T21. Thus it is possible that the excess of LB males with T21 could be due to an excess of females being aborted with T21 and a heart defect. In order to explore this hypothesis, we examined the frequency of heart defects among aborted individuals with a prenatal diagnosis of T21. The presence or absence and type of heart defect were detected by prenatal ultrasound and our final population consisted of 245 cases. 122 heart defects were detected in our population. These included atrial ventricular septal defects (61/122), atrial septal defects (16/122), ventricular septal defects (44/122) and Tetralogy of Fallot (1/122). In our approach, logistic regression was used to determine if there was an excess of females with a heart defect among aborted fetuses with T21. Results from our analysis showed that among aborted individuals with T21, the odds of having a heart defect did not differ between males and females (OR: 1.50, $p = 0.14$), thus aborted females with T21 were not more likely to have a heart defect than aborted males. In addition, upon looking by type of heart defect, we did not find that the odds of having an atrial ventricular septal defect (OR: 0.16, $p=0.98$), an atrial septal defect (OR: 0.44, $p=0.36$), or a ventricular septal defect (OR: 0.18, $p=0.10$) differed between sexes. Thus, neither type of heart defect was more common in aborted females compared to aborted males. Thus our findings do not support the hypothesis that the excess of males LB with T21 could be due to an excess of females being aborted with T21 and a heart defect.

941W

Down - Turner mosaicism. *L. Martelli[1,2], C.G. Picanço[2], C.H.P. Grangeiro[2], C.S. Pereira[1], R.M. Scaparo[2], S.A. Santos[1], J. Huber[2], E.S. Ramos[1,2].* 1) University of Sao Paulo, Dept Genetics, Ribeirao Preto, SP, Brazil; 2) Medical Genetics Division HCRP, Ribeirao Preto, SP, Brazil.

The occurrence of double aneuploidy in the same patient, although rare, has been described in the literature. The most common involves trisomy 21 and monosomy X, with estimated prevalence of 1 to 2 million live births. We describe the presence of Down-Turner mosaicism, diagnosed in a patient with syndromic facies and developmental delay. The cytogenetic diagnosis by GTG banding after 100 metaphase analysis was 45, X [79] / 47, XX, + 21 [21]. The patient, 30yo, was born at 36 weeks of gestation, with 2150g and 47cm, lymphedema of hands and feet, and hypotonia with weak suckling. Hypothyroidism was diagnosed at 2yo. She presented secondary sexual characteristics and spontaneous menarche at 14 years old. Physical examination showed moderate intellectual deficit, brachycephaly, sparse hair, flat facial profile with hypoplasic midface, upward slanted palpebral fissures and ptosis, apparent macroglossia, dysplastic small ears, short neck, increased interval between 1 and 2 toes and ligamentous laxity. The double aneuploidy could be caused by non-disjunction pre-zygotic resulting in zygote 47, XX, +21, followed by delayed post-zygotic anaphase of the chromosomes X and 21, resulting in 45,X cell line. Harada et al (1998) suggested that the origin of mosaicism 45, X/47, XX, +21 could be the non-disjunction in maternal first meiotic division, followed by loss of chromosomes X and 21 derived from the mother during the first mitotic division. Supported by CNPq and FAEPA-HCRP.

Accurate, Precise, and Tunable Cytogenetics with Next-Generation Sequencing. *M.A. Eberle, T. Royce, F. Kaper, J. Cottrell, J-B. Fan.* Dept Bioinformatics, Illumina, Inc, San Diego, CA.

Technological advances in whole-genome shotgun sequencing have led to the successful diagnoses of once-enigmatic illnesses resulting from rare, de novo point mutations. Application of this same technology to the discovery of cytogenetic abnormalities holds similar promise, with the full range of capabilities yet to be completely described and quantified. To explore the effectiveness of sequencing for cytogenetics applications, we analyzed sequence data from several cytogenetically interesting samples with documented chromosomal abnormalities each paired with a cytogenetically normal cell line. Each sample was sequenced and we informatically down sampled the data to simulate various amounts of total sequencing. We used this down sampled data to simulate copy number gains and losses of varying size. To explore the limit of resolution for detecting copy number gains and losses, we informatically combined sequence data from different samples to simulate losses and gains of varying sizes. This method of creating simulated copy number events allows us to generate a large number of events of relatively small size to accurately assess the sensitivity of detecting these features with sequence data. After sampling the sequence data down to the throughput of the MiSeq personal sequencer, we find that the technique has the ability to detect 95% of copy number losses of 200 kb and 95% of copy number gains of 400 kb. Additionally, at these limits of resolution, we find virtually no false positive calls. The technique is extendable to genetically mosaic events and uniparental disomy, albeit at a higher limit of resolution. Increasing the total amount of reads improved all capabilities. With appropriate study design, the same shotgun sequencing technologies routinely used to identify simple point mutations can be employed for sensitive and precise detection of cytogenetic abnormalities. At current sequencing throughputs, measures of sensitivity and specificity are on par with array technologies. As shotgun sequencing throughputs improve, sequencing will become an increasingly compelling alternative to existing cytogenetics technologies.

Two new cases of interstitial 6q deletion, associated to microcephaly, corpus callosum hypoplasia and further brain and cerebellar malformations. *V. Parisi[1], S. Loddo[1], L. Travaglini[2], A. Ferraris[1], G. Vitiello[3], G. Zanni[2], L. Bernardini[1], M.L. Di Sabato[4], M.C. Digilio[2], A. Novelli[1], E. Del Giudice[5], A. Rossi[6], E. Bertini[2], B. Dallapiccola[2], E.M. Valente[1].* 1) Cytogenetics Lab, CSS-Mendel Inst, Rome, Italy; 2) Bambino Gesù Children Hospital Rome-Italy; 3) Department of Biopathology and Diagnostic Imaging, Tor Vergata University, Rome, Italy; 4) Sapienza University of Rome Department of Child Neurology and Psychiatry Rome-Italy; 5) Department of Paediatrics, “Federico II” University, Naples, Italy; 6) Departments of Pediatric Neuroradiology, IRCCS G. Gaslini, University of Genoa, Genoa, Italy.

Rare distal 6q deletions show a broad phenotypic spectrum depending on the size and position of deleted segments. The chromosome region 6q25.2q25.3 has been described as critical for microcephaly, growth delay, hearing loss and corpus callosum agenesis/hypoplasia (ACC). In this region, two genes (TIAM2 and SYNJ2) have been indicated as candidate for microcephaly and ACC. We report on two new distal 6q deletions, detected by microarray platforms: patient 1 showed a deletion, extended about 13 Mb, at 6q25.1q27 (4×44K; Agilent); in patients 2 a deletion was disclosed at 6q25.3q27 (~11.3 Mb) (Human GeneChip 6.0; Affymetrix). The two patients showed brain malformations, in particular ACC, and shared other clinical features, such as psychomotor delay, facial dysmorphisms, microcephaly. Haploinsufficiency of TIAM2 and SYNJ2 could be the direct cause of ACC in patient 1, as the deleted region included both genes. In patient 2 the deletion was more distal and did not encompass these genes, although preliminary analysis indicated a reduced expression of TIAM2, suggesting the presence of a regulatory element in the hemizygous distal 6q25.3q27 region. Our data confirm and expand neuroradiological phenotype associated to distal 6q deletion and suggest the hypothesis that the reduced expression of TIAM2 gene, due to deletion or other mechanism, is causative of ACC.

Ring chromosome 13: an eventual risk for intellectual disability, surdity, congenital malformations and leukemia. *I. BEN-ABDALLAH-BOUHJAR[1,2], H. HANNACHI[1,2], S. MOUGOU-ZERELLI[1,2], H. BEN-KHELIFA[1,2], A. LABALME[3], D. SANLAVILLE[3], H. ELGHEZAL[1,2], A. SAAD[1,2].* 1) Cytogenetics and Reproductive Biology Department, Farhat Hached University Teaching Hospital,, SOUSSE, sousse, Tunisia; 2) Cytogenetics and Reproductive Biology Common Service Units for Research in Genetics, Faculty of Medicine of Sousse, Avenue Mohamed Karoui, University of Sousse, Tunisia; 3) Hospices Civils de Lyon, Service de Cytogénétique Constitutionnelle, Lyon, France.

The 13q deletions syndrome are currently known to share several common semiologic features, including, in particular intellectual disability ranging from moderate to severe, marked short stature, neural tube, brain and heart defects, microcephaly, genital malformations in males including undescended testes and hypospadias and characteristic facies. However, the hearing and speech delay in our cases are uncommonly reported in either the deletions of chromosome 13, so hearing and speech impairments are suggested as another new clinical feature to 13q deletion Syndrome, in this study we report three cases of ring chromosome 13 and we compare the growth and clinical features of these patients with previously reported cases, with a similar deletion on the long arm of chromosome 13. The patient karyotypes were 46,XY,r(13)(p11;q34) dn for the patient 1, 46,XX,r(13)(p11;q34) dn for the patient 2 and 46,XY,r(13)(p11:q14) dn for the patient 3, as a result of the deletion in the telomeric regions of chromosome 13. They were, therefore, monosomic for the segment 13q34◊13qter, in addition for the patient 3 the deletion was more large encompassing the segment 13q14◊13qter. Fluorescence in situ hybridization analysis showed loss of a specific subtelomeric 13q region in r(13) in three cases and loss of a specific locus 13q14/RB1 in the patient 3, who died from Multiple Myeloma during the cytogenetic analysis, FISH on fixed Bone Marrow cells of the patient 3 diagnosed with MM, using the probe RB1gene showed deletion in 13q14.2. Array CGH exploration of DNA's of patient 2 revealed a loss of at least 2.9 Mb on the short arm of chromosome 13 and a deletion of 4.7 Mb on the long arm of the same chromosome 13. Initially FISH defined, the chromosome breakpoints and were precisely localized by array CGH on 13q11 [arr 13q11q11 (18601703- 21593561)×1 dn] instead of 13p11, and 13q34 [arr 13q34 (109599699- 113964366)×1 dn]. In our patients the deletion included the gene EFNB2, GJB6, ARHGEF and MYO16 are probably involved respectively in genital development, hearing loss, microcephaly and growth retardation. To the best of our knowledge, our patient 3 with Multiple Myeloma is the first report in which constitutional deletion of RB1 gene is also detected in Bone Marrow cells. We conclude that the Ring chromosome 13 is an eventual risk for intellectual disability, surdity, congenital malformations and leukemia.

Use of Oligo-SNP array for the detection of abnormalities in CLL. *N.C. Christacos[1], M.L. Slovak[1], M.A. Sanidad[1], Y. Hsu[1], J.C. Kelly[1], P.N. Mowrey[1], D.M. Jones[2]*. 1) Dept. Cytogenetics, Quest Diagnostics, Chantilly, VA; 2) Dept. Pathology, Quest Diagnostics, Chantilly, VA.

B-cell chronic lymphocytic leukemia (CLL) is a hematologic malignancy characterized by the clonal expansion and significant accumulation of immunophenotypically similar (usually co-expressing CD5 and CD23) mature B-lymphocytes. Conventional cytogenetics and fluorescence in situ hybridization (FISH) studies are used worldwide to subdivide CLL into different pathogenetic and prognostic subgroups. Newer molecular cytogenetic studies using microarray technology promise to expand our knowledge of the genetic aberrations in CLL. To address this supposition, we used the high resolution genome-wide Affymetrix Cytoscan HD array which combines oligonucleotides and single nucleotides polymorphisms (SNP) (OSA) as a tool to detect both copy number changes (CNAs) and acquired isodisomy (aka, uniparental disomy). We performed OSAs on samples from 21 patients with a clinical indication of CLL and compared the microarray results with either the conventional cytogenetics and/or FISH analyses. All samples had karyotypic or FISH detectable abnormalities. OSA showed a total of 127 CNAs (average CNAs per sample,6; range, 2–22 CNAs). Deletion 13q was missed in two patients with 6% and 15% mosaicism and one patient with deletion 11q in two mitotic cells after culturing in CpG-oligonucleotide DSP30 plus IL-2 for 72 hours; however, the other two clonal aberrations in that sample were detected. Trisomy 12 and TP53 deletions showed 100% OSA/FISH concordance. Overall, clonal mosaicism detected by OSA correlated well with the percentage of interphase cells showing the FISH abnormalities. Seven samples (33%) showed acquired isodisomy >5 Mb (range, 5.4–36 Mb). Two samples showed non-CLL aberrations consistent with either t-AML or hairy cell leukemia, indicating the ability to obtain valuable genetic information for those samples that would be missed using the targeted CLL FISH probe panel. Furthermore, at relapse and in secondary leukemia, the karyotype often shows a high degree of genetic complexity with multiple tumor subclones. Such clonal diversity reflects the underlying biologically selected alterations that can, if carefully mapped, highlight the locations of oncogenes and tumor suppressors underlying disease progression. Genetic aberrations including acquired isodisomy are common in CLL and are easily detected by OSA. This relatively new technology may be able to reliably support or succeed current cytogenetic methods.

Array Based Comparative Genomic Hybridization Identifies Unique Copy Number Alterations in Diffuse Large B-cell Lymphoma Subtypes: A Review of Published Microarray Data. *R. Garcia*. The UT Southwestern Medical Center at Dallas-Department of Pathology, Clinical Cytogenetics.

Diffuse large B-cell lymphoma (DLBCL) accounts for more than 30% of adult non-Hodgkin lymphoma cases and it is characterized by a heterogeneous set of lymphomas. Many conventional and molecular cytogenetic studies along with morphological, biological, clinical and microarray studies have made an effort to better classify these sets of lymphomas. However, in spite of these, many remained unclassifiable. In fact, most of these lymphomas remain undistinguishable and fall into the not otherwise specified (DLBCL-NOS) category. The goal of this current study was to review the literature for currently published microarray data; particularly array based comparative genomic hybridization (aCGH), classical CGH and gene expression profiles for DLBCL. Copy Number Alterations (CNA) with greater than 20% on any given subset were catalogued in a table form. Based on this, two separate chromosome ideograms were generated depicting similarities and differences between subsets. Consequently, this review identified unique CNA specific for DLBCL subtypes. These included: primary mediastinal large B-cell lymphoma (PMLBCL), gain at 2p15, 9p24, 9q34, Xp11.4–21, Xq24–26; LBCL of the bone, gain at 2p16, 6p21 and loss at 15q15-q26; DLBCL of the CNS, loss at 6p21–25,17p12–13; Leg type DLBCL, gain at 2p22, 2p12, 3p21–25, 3q28–29, 9p12–21,16q23,22q11and loss at 4q, 8p11,14q, Xq13–25; CD5+ DLBCL, gain at 13q21–34; Plasmablastic lymphoma, gain at 10p12, 14q32, 16q24,17p12–13 and primary effusion lymphoma with gains at 4q28–35, 8q11.2–23.1, 11p, 17q23–24, 19p13 and loss at 11q24–25. However, a number of unclassifiable DLBCL subtypes post-microarray studies remains. These include intravascular LBCL, Epstein-Barr virus DLBCL of the elderly, LBCL arising in HHV8+ multicentric Castleman disease, Lymphomatoid granulomatosis, LBCL with features intermediate between DLBCL and Hodgkin lymphoma and pyothorax associated lymphoma. In brief, although this review re-classified some of the DLBCL subsets by distinct CNA, better classification models are clearly needed for DLBCL. Keywords: DLBCL, aCGH, Copy number alterations.

947W

Subtype of ETV6/ABL1 fusion transcript is associated with different leukemia phenotype. *A. Kwon[2], J. Park[1,2], J. Lim[1,2], Y. Kim[1,2], K. Han[1,2], S. Lee[3], H. Kim[3], W. Min[3], J. Kim[2], M. Kim[1,2]*. 1) Department of Laboratory Medicine, The Catholic University of Korea, Seoul, South Korea; 2) Catholic Genetic Laboratory Center, The Catholic University of Korea, Seoul, South Korea; 3) Division of Hematology, Department of Internal Medicine, Catholic Blood and Marrow Transplantation Center, The Catholic University of Korea, Seoul, South Korea.

The ETV6/ABL1 fusion transcript is thought to be a very rare aberration in hematopoietic malignancies and only 22 cases were published; 9 atypical chronic myeloid leukemia, BCR/ABL1 negative (aCML), 3 myeloproliferative neoplasm (MPN), 4 acute myeloid leukemia (AML), and 6 acute lymphoblastic leukemia (ALL). There are two types of the fusion transcript at the mRNA level; one transcript, type A composed of the first 4 exons of ETV6 fused to the second exon of ABL1, and the other, type B where the ETV6 exon 5 fuses to the ABL1 exon 2. The biological consequences of ETV6/ABL1 show a significant similarity with BCR/ABL1. Herein, we described two new cases of acute leukemia with the ETV6/ABL1 fusion, one with AML with eosinophilia (Case 1) and the other with B cell ALL (Case 2), which was screened by multiplex RT-PCR. Cytogenetics of case 1 showed a normal karyotype, but RT-PCR revealed positive to ETV6/ABL1 type B fusion transcript. In case 2, karyotying represented 46,XX,del(9)(p22),der(10)t(9;10)(q22;p15)[12]/46,XX[8], but RT-PCR revealed both type A (595 bp) and type B (1141 bp) fusion transcripts. Fluorescence in site hybridization using mixture of BCR/ABL1 and ETV6/RUNX1 probes revealed that the ETV6/ABL1 fusion were located on 12p13 which meant the crucial event resulted by the insertion of a part of C-terminus region from ABL1 gene into the intron 1 of ETV6 gene. This fusion signals were also detected in eosinophils of case 1, so that we considered the clonal eosinophilia as the characteristics of AML with ETV6/ABL1. This eosinophilia has been known to accompany with MPN and AML but not always with ALL. A thorough review of all published cases about ETV6/ABL1, including our new cases, all ALL patient possessed type A fusion transcript. Otherwise, type B fusion transcript accompanied with MPN, aCML, and AML. These findings are very similar that BCR/ABL1 fusion transcript with minor BCR breakpoint is associated with ALL phenotype. Reported patients including present study, 6 out of 7 ALL, 4 out of 5 AML were died. Therefore, ETV6/ABL1 is probably a poor prognostic factor in acute leukemia. Transient response to inhibit ABL1 kinase in such patients suggested that those drugs maybe in ETV6/ABL1 positive acute leukemia therapeutically useful but not sufficient to induce remission. It is helpful to develop a modified treatment modality including ABL1 kinase inhibitor.

Detecting Chromosomal Inversions Using Chromatid Painting Strategies- Applications. *F.A. Ray[1,2], E. Zimmerman[2], M.N. Cornforth[2,3], E.H. Goodwin[2], J.S. Bedford[1,2], S.M. Bailey[1,2]*. 1) Env Rad Hlth Sci, Colorado State Univ, Fort Collins,CO 80523-1618; 2) Kromatid Inc., 515 East Laurel St., Fort Collins, CO 80524-3151; 3) 3Department of Radiation Oncology, University of Texas Medical Branch, Galveston, TX 77555-0884, USA.

Chromosomal inversions are symmetrical exchanges resulting from two DNA double strand breaks within a single chromosome that are incorrectly rejoined in an inverted orientation. Using banding methodologies, large inversions, (i.e. >10 Mb) are often difficult to detect and inversions smaller than a typical metaphase chromosome band are rarely detected. We developed a new methodology to detect chromosomal inversions with a 10 fold improvement in resolution over existing techniques. Chromatid painting, like chromosome painting requires chromosome-specific fluorescent probes, the difference being that all of the probes in a chromatid paint are designed to bind to only one of the two 5' to 3' DNA strands. Newly-replicated (nascent) strands are removed from metaphase chromosomes and genomics is used to develop probes directed to unique targets on one chromatid and not the other. The first chromatid paint was developed to human chromosome 3. The chromatid paint behaves as envisioned, i.e. chromosomes have one chromatid per targeted chromosome with fluorescent signal and the other without, inversions appear as a fluorescent signal switch to the corresponding position on the other chromatid Radiation of cells prior to chromatid painting resulted in a dose dependent increase in the inversion frequency. Dose responses using our chromatid 3 paint following γ-ray or HZE ion exposures were determined. Comparison of inversion vs. translocation frequencies involving chromosome 3, suggests that inversions are approximately 6 times more frequent than translocations. Intriguingly while preliminary, the slope of the dose response following HZE irradiation was much steeper than that for the γ-rays suggesting the possibility of using radiation-induced chromosome inversions to discriminate between and high and low LET radiations. We also developed an assay for for a thyroid cancer-specific, radiation-induced inversion based on chromatid painting. Using this assay, the PTC 1 inversion was detected at low frequency in human thyroid cells immediately after irradiation, and at an increased frequency after these irradiated cells were cultured for additional population doublings. Detection of the specific inversion after radiation demonstrates a new application for the assay and the increased inversion frequency after multiple cell divisions, indicates that this specific inversion was selected for in the population of cells. Other cytogenetic applications will be discussed.

949W

Efficacy and Implementation of a SNP Microarray for the Evaluation of Patients with Multiple Myeloma. *S. Schwartz, R.D. Burnside, J. McElligott, I. Gadi, J. Kesler, V. Jaswaney, K. Phillips, J. Tepperberg, B. Williford, P. Papenhausen.* Lab Corp of America, Research Triangle, NC.

The laboratory confirmation of multiple myeloma (MM) is problematic since chromosome analysis (CA) and FISH analysis are often normal due to indolent, low percentage disease. The utilization of magnetic CD138 cell sorting increases the frequency of abnormalities by FISH, but fails to detect the clone for many of these patients. Microarray analysis is common in constitutional studies, but for neoplasia in general it is still limited. In order to determine the efficacy of this technology in MM patients, a novel approach was undertaken involving 18 patients. All patient marrow aspirates were studied initially with CA and/or FISH after CD138 cell sort enrichment. This was followed by SNP microarray analysis utilizing the Cytoscan HD platform on both the CD138 positive and negative fractions. This approach revealed that 82% of patients with a normal karyotype had a detectable abnormality by the array analysis. It also showed that in CA abnormal patients, numerous additional abnormalities could be detected by the array analysis and that many of these had diagnostic implications. The results from these studies show the importance and efficacy of utilizing microarrays in the study of MM. The important findings from this work include:(1)The superior detection of abnormalities by microarray in 82% of cases that were initially diagnosed as normal by CA and in 50% of cases that were normal by FISH;(2)In cases determined to be abnormal by CA and/or FISH, additional abnormalities were detected by the microarray analysis in all of patients; (3)Prognostic/diagnostic information was obtained in over 93% of the patients studied; (4)Homozygosity associated with acquired uniparental disomy(aUPD) was detected in 36% of the patients with abnormal findings. Comparison of the positive and negative CD138 fractions provided clear resolution of constitutional homozygosity from acquired UPD; (5)Chromothripsis was identified in 21% of patients with abnormal findings. Specific allele ratios in the array permitted delineation of chromosomal structure and mechanism of formation of a number of complex abnormalities; (6)Homozygous deletions of tumor suppressor genes were identified in 22% of patients with abnormal findings; (7)Different clonal abnormalities could be found in the positive and negative CD138 fractions in two cases, indicating at least one where the patient had both MM and MDS; (8)These studies provide a new unique paradigm for the evaluation of patients with suspected MM.

950T

A de novo intragenic deletion of *AUST2* in a patient with autism spectrum disorder. *S. Kantarci[1], I.E. Amarillo[1], J. David[1], E. Vilain[2], X. Li[1]*. 1) Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Pediatrics, Medical Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Autism spectrum disorder (ASD) is a clinically heterogeneous developmental disorder with a strong genetic component. The prevalence of ASD is estimated to be 1 of 85 children and five times as many boys as girls. Although ASD is known to be highly heritable (about 90%), the genetics underlying ASD is complex and remains largely unknown. About 5–15% of ASD cases have an identifiable genetic etiology corresponding to known single-gene disorders and various chromosomal abnormalities. Microarray studies have revealed that rare de novo or transmitted copy number variations (CNVs) appear to contribute significantly to the pathogenesis of this complex disease. De novo CNV events have been observed in about 10% of ASD cases. We report a 4.5 year-old female with ASD who has been found to have a de novo copy number loss on chromosome 7q11.22. The proband was born by normal vaginal delivery at term following an uncomplicated pregnancy. She was noted to drool constantly at the age of 6 months. She was then noted to have developmental delays and started speech therapy at 18 months of age. She presented tonic-clonic movements, lasting for up to a minute and followed by a period of decreased alertness at 3 years old. She does not have dysmorphic features and her CT scan and neurological exams are normal. Chromosomal microarray analysis (CMA) using Affymetrix SNP array 6.0 revealed a potentially pathogenic de novo 62 Kb microdeletion on chromosome 7q11.22. This interval overlaps with a single exon (exon 6) of *AUTS2* (autism susceptibility 2 gene) and has a 5% overlap with benign CNVs. Affymetrix CytoScan HD array confirmed the deletion in proband. *AUTS2* consists of 19 exons and spans 1.2 Mb on the genomic DNA. Although the function of the protein encoded by *AUTS2* is still unknown in humans, it is highly expressed in the mice developing cerebral cortex and cerebellum. Disruptions of the *AUTS2* gene by de novo chromosomal rearrangements have been previously reported in seven cases with ASD and/or intellectual disability. In addition, a whole genome array comparative genomic hybridization study in a cohort of individuals with mixed types of idiopathic epilepsy identified rare overlapping deletions within *AUTS2* intronic region in two cases. To our knowledge, this study identified the first de novo intragenic deletion of *AUST2* in ASD. This study not only supports the association of *AUTS2* with autism but also highlights the significant role of CMA in genetic evaluation of ASD.

951W

22 q 11.2 syndrome in a group of patients who attended Operation Smile Foundation in Colombia, between 2005 and 2012. *I. Briceno[1,2], JC. Martinez[1], A. Venegas[2], O. Moreno[2], M. Sarmiento[2], S. Bohorquez[1], M. Montiel[1], A. patino[1]*. 1) Universidad de La Sabana, Chia, Colombia; 2) Universidad Javeriana. Bogota Colombia.

Velocardiofacial syndrome (VCFS) is a genetic condition characterized by abnormal pharyngeal arch development that results in defective development of the parathyroid glands, thymus, and conotruncal region of the heart. More than 180 different clinical features are associated with velocardiofacial syndrome, with no single anomaly present in every patient. Affected individuals may present with structural or functional palatal abnormalities, cardiac defects, unique facial characteristics, hypernasal speech, hypotonia, and defective thymic development. An estimated 75% of patients with velocardiofacial syndrome have cardiac anomalies. Palatal abnormalities predispose to speech and feeding difficulties. The defective thymic development is associated with impaired immune function. In addition, affected individuals may present with learning disabilities, overt developmental delay, psychiatric disorders, and renal and musculoskeletal defects. About 10% of patients with velocardiofacial syndrome have DiGeorge syndrome, as many as 15–20% of patients have Pierre Robin syndrome. Velocardiofacial syndrome is a specific syndrome that includes as part of its phenotypic spectrum the DiGeorge sequence, the Pierre Robin sequence, and disorders associated with CHARGE syndrome. Is considered Genetically, 90 percent of patients with the features of this syndrome are missing a small part of their chromosome 22 at the q11 region. This region encompasses about 30 individual genes and results in developmental defects in specific structures throughout the body. It is not known why this region of chromosome 22 is prone to become deleted, but this is one of the most frequent chromosome defects in newborns. Deletion 22q11.2 is estimated to occur in one in 3,000 to 4,000 live births. Most of the 22q11.2 deletion cases are new occurrences or sporadic (occurs by chance). However, in about 10 percent of families, the deletion is inherited and other family members are affected or at risk for passing this deletion to their children. En este trabajo nosotros reportamos el study among 2000 patients attending “Operation Smile” in Bogota, 2 cases of 22 q 11.2 syndrome were diagnosed, confirmed by cytogenetics, in situ fluorescence hybridization showed the 22q11 microdeletion. which corresponds to 0.1 of the population studied. This result indicates a frequency significantly higher than that reported in the literature for general population. The Clinical description is presented.

952T

Incidence of mosaicism detected by exon-targeted, high-resolution array comparative genomic hybridization (aCGH) in 10,362 consecutive cases with special emphasis on detection of complex unbalanced structural rearrangements. *W. Bi[1], J. Pham[1], C. Shaw[1], P. Hixson[1], A. Ester[1], A. Pursley[1], K. Plunkett[1], P.L. Magoulas[1], S.-H.L. Kang[1,2], S.R. Lalani[1], C. Bacino[1], P. Stankiewicz[1], A. Patel[1], S.W. Cheung[1].* 1) Medical Genetics Laboratories, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston TX, 77030; 2) Allina Medical Laboratories, Minneapolis, MN, 55440.

Chromosomal mosaicism, the presence of two or more different cell lines in an individual, is clinically important as it has been established to cause miscarriage, birth defects, developmental delay, or cancer and to contribute to phenotypic variation. However, somatic mosaicism is usually under-diagnosed due to various factors, which include subtle phenotypic abnormalities, technical limitations, and inherent tissue-specific mosaicism. Here, we studied 10,362 patients, most of whom had a clinical indication of cognitive impairment, using a custom-designed, exon-targeted, whole-genome oligonucleotide array. Somatic mosaicism ranging from 6.5% to 92% was detected in 59 cases. Mosaicism for numerical abnormalities including ring chromosomes was detected in 35 cases. In the remaining 24 cases with unbalanced structural rearrangements, the following abnormal cell lines were detected: [1] simple terminal or interstitial deletions/duplications (11 cases), [2] complex structural abnormalities, involving two or more copy-number changes (5 cases), [3] derivative chromosomes (3 cases), and [4] mosaic copy-number losses encompassing or disrupting a single gene (5 cases). For complete characterization, it was necessary to perform additional studies such as FISH analysis, chromosome analysis, and/or using other molecular methods. We present here two cases in which patients had two abnormal cell lines, one of which was beyond the resolution of chromosome analysis and thus, only detectable by array CGH. Patient 1 is a 1- year-old girl with global developmental delay, seizures, and short stature, who has mosaicism for a cell line with a der(17), resulting from an unbalanced translocation between 5p and 17p in 25% of cells whereas the remaining cells had an isolated 17p13.3 deletion. Patient 2 is an 8-year-old boy with developmental delay and seizure disorder. Array studies showed mosaicism for a copy-number loss at chromosome 17p13.3p13.1, suggesting two different-sized deletions of this region. FISH analysis confirmed a smaller terminal deletion at band 17p13.3 in 77.5% of cells whereas a larger terminal deletion spanning to band 17p13.1 was found in 22.5% of cells. In summary, increasing array resolution indicates that chromosomal mosaicism may be more frequent than previously thought and particularly that patients with mosaic chromosomal rearrangements may have an additional abnormal cell line that is only detectable by aCGH.

953W

A Cryptic Derivative Chromosome 12 Detected by Oligo-SNP Array. *Z. Dai, N.C. Christacos, S. Schonberg, J. Kelly, E. Wallenhorst, K. Sullivan, C. Adams, Y. Hsu, H. Walker, T. Simanivanh, P. Mowrey.* Cytogenetics, Quest Diagnostics, Chantilly, VA.

We report the cytogenetic and microarray results of a 1 year old male with failure to thrive. Conventional cytogenetic analysis failed to identify any apparent structural abnormality or rearrangement. Concurrent high resolution microarray analysis using an oligo-SNP array (Afffymetrix Cytoscan HD) indicated a derivative chromosome 12 resulting from an unbalanced translocation between chromosomes 8 and 12. Two variants of unknown significance were also detected. With respect to the identified imbalance, an approximately 3.2 MB terminal loss on the distal short arm of chromosome 12 at p13.32p13.33 was detected. Additionally, an approximately 7.0 Mb gain of terminal chromosome 8 long arm material at 8q24.23q24.3 was detected. Together, these findings are consistent with a derivative chromosome 12 from an unbalanced t(8;12)(q24.23;p13.32) which was confirmed by subtelomere FISH studies using probes for the subtelomeric regions of 8q and 12p. The rearrangement on the short arm of chromosome 12 (net gain of 3.8 Mb of 8q material) was “cryptic” by conventional cytogenetic G-band analysis. Multiple genes are contained in the regions partially monosomic on 12p and partially trisomic on 8q; therefore, this finding is considered to be causative in the abnormal phenotype seen in this child. Both of these rearrangements are rare and as such, a clearly recognized syndrome for either rearrangement has not emerged. Reported patients with 12 p deletion have in common a mild phenotype with moderate mental retardation and severe behavioral problems. The few reported cases with duplication of 8q had in common severe mental retardation, growth delay and epilepsy. This case illustrates how oligo-SNP array testing is crucial to identifying “cryptic” rearrangements in apparently karyotypically normal patients with multiple congenital anomalies and/or developmental delay.

GLUT1 Deficiency and Chromosome Microarray Analysis. *A.J. Dawson[1,2,3], A. Mhanni[2,3], F. Booth[4], D. Bernier[1], M. Tomiuk[1], J. Hartley[3,5], M. Strecker[6], K. Hovanes[6].* 1) Dept Cytogenetics, Diagnostic Services Manitoba/Univ Manitoba, Winnipeg, MB, Canada; 2) Section of Genetics and Metabolism, Department of Pediatrics and Child Health, Health Sciences Centre, Winnipeg, Manitoba, Canada; 3) Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, Manitoba, Canada; 4) Section of Pediatric Neurology, Department of Pediatrics and Child Health, Health Sciences Centre, Winnipeg, Manitoba, Canada; 5) Genetics and Metabolism Program, Winnipeg Regional Health Authority, Winnipeg, Manitoba, Canada; 6) Combimatrix Diagnostics, Irvine, California, USA.

The patient, an 8 month old boy, presented with recurrent seizures with his first event of tonic, clonic afebrile seizure occurring at 5 months of age. He was the first born to a non-consanguineous healthy 35 year old mother and a 41 year old father. The prenatal and perinatal histories were unremarkable. An amniocentesis had been performed because of advanced maternal age. A de novo, apparently balanced, reciprocal translocation was detected: 46,XY,t(1;20)(p34.1;q13.1)dn. The child's seizures were difficult to control despite the use of multiple anti-epileptic medications. The child's physical examination was remarkable for microcephaly with an OFC below the 5th centile, with weight and height at the 25th centile. No other abnormalities were noted. An extensive biochemical work up on plasma and urine was undertaken with no specific etiology identified. The findings on neuroimaging, including an MRS, were nonspecific. An extensive metabolic work-up revealed a ratio of CSF to blood glucose of 0.378 (normal ratio: 0.65 +/ − 0.01), suggesting a biochemical diagnosis of glucose transporter type1 (GLUT1) deficiency (De Vivo disease). The results of chromosome microarray analysis, performed at the same time, showed a single copy number decrease of 1.2 Mb of the 1p34.2-p34.1 region: arr 1p34.2p34.1(42,871,391–44,074,069)x1. The genes involved in the loss of 1p34.2-p34.1 include SLC2A1. Mutations and deletions of the SCL2A1 gene are responsible for GLUT1 deficiency, an autosomal dominant disorder. Parental chromosomal microarray analyses were performed and did not detect the deletion. This and FISH results confirmed that the deletion was due to the translocation and was de novo. This deletion is likely the result of an unbalanced translocation between chromosomes 1p and 20q. The translocation breakpoint on 20q could not be determined by this microarray since it did not involve any copy number change. The patient has been on a ketogenic diet for four months. He has generally been well and has been making considerable developmental progress, with seizures remaining under control. This case clearly demonstrates the value of genomic arrays in the investigation of children with developmental delays by increased resolution of cytogenetic rearrangements, which leads to correlation of clinical manifestations with specific changes in gene copy number. Specifically, in our patient, chromosome microarray analysis detected a condition that was treatable.

Clinically relevant mosaic findings in a total of 9,605 patients and parents by using genome wide high resolution SNP array analysis in constitutional diagnosis. *N. de Leeuw, J.Y. Hehir-Kwa, B.H.W. Faas, T.K. Rinne, M.J.E. Kempers, S.A. de Munnik, N.F.A. Leijsten, G.C. Machielsen, S.L.J. van Gessel, M. Wunderink, M.J.G. Banning, R. van Beek, M. del Rosario, B.B.A. de Vries, D.F.C.M. Smeets, R. Pfundt.* Dept Human Genetics, Radboud University Nijmegen MC, Nijmegen, Netherlands.

We routinely perform genome wide SNP array analysis as the first-line diagnostic test for patients with intellectual disability and/or congenital anomalies and in prenatal diagnosis in case of structural ultrasound anomalies.

In 28.8% of patients a potentially causative, rare copy number variant (CNV) was detected. We categorized 6.5% as de novo, 9.1% inherited, 0.8% X-linked, and in 12.4% the inheritance patterns still needs to be determined. We observed a significantly increased percentage of homozygosity in an additional 6.1% of our patients. These homozygous regions subsequently led to the identification of pathogenic mutations in recessive disease genes, uniparental disomies, or low-mosaic aneuploidies in more than 30 patients. In November 2011, we switched from the Affymetrix 250K SNP array to the CytoScan HD array platform (Affymetrix, Inc., Santa Clara, CA, USA) which further enhanced the CNV detection resolution, improved the detection of mosaic imbalances and also enabled us to detect clinically relevant, mosaic, copy neutral changes of homozygosity in three patients. A mosaic finding (CNV, aneuploidy or allelic imbalance) was detected in 24 of 7,294 patients, two of 247 unborn babies, and in eight of 2,064 parents.

Mosaic abnormalities appear to be relatively common not only in patients (1 in 304) and unborn babies with structural ultrasound anomalies (1 in 124), but in parents (1 in 258) as well. It is crucial to determine whether an apparently de novo imbalance in an affected child, is in fact due to a mosaic aberration in the (unaffected) parent, highlighting an (often dramatically) increased recurrence risk. The percentage of mosaicism often differed between tissues samples of mesodermal or ectodermal origin from each of these individuals. In two patients such tissue-dependent differences were shown to change over time, most likely due to a rescue mechanism.

Genome wide SNP array analysis is a suitable and highly effective method to apply in genome diagnostics for the detection of CNVs and homozygosity pre-screening in one single test.

Genomic differences between spontaneously aborted fetuses and live-born children with 45,X monosomy. *J. Domínguez Ortiz[1], L. Torres[1], S. Sanchez[1], V. del Castillo[1], L. Orosco[2], A. Carnevale[2], P. Grether[3], D. Mayen[4], S. Frias[1,5].* 1) Genetica Humana, Instituto Nacional de Pediatría, Ciudad de México, Mexico; 2) Instituto Nacional de Medicina Genomica, Ciudad de México, Mexico; 3) Instituto Nacional de Perinatologia, Ciudad de México, Mexico; 4) Diagen, Ciudad de México, UNAM; 5) Instituto de Investigaciones Biomedicas, Ciudad de México, UNAM.

It has been described that for all the pregnancies with monosomy 45,X only 1% survives. To find some explanation we analyzed the genomic differences between live-born and abortions. We studied 11 patients and 3 abortions with 45,X karyotype performed conventional cytogenetic. gDNA was extracted from peripheral blood or from tissues of the miscarriages. For the precise characterization of the genomic differences we performed individual arrays for 11 live born cases and 3 spontaneous abortions using Affymetrix Genome Wide Human SNP 6.0 arrays. We identified some common regions with loss or gain of genomic material; each region was analyzed using UCSC genome browser, Database of Genomic Variants, DECIPHER, NCBI, Gene Ontology, miRBASE and miRANDA. The genomic differences observed in the SNP 6.0 array were the following: in Live-Born the lost of the next regions: 1q31.2 (Promoter of RGS18), 6q23.3 (KIAA1244), 8p23.1 (XKR6), 15q24.3 (SCAPER), 21q22.13 (DYRK1A, KCNJ6, DSCR4, DSCR8). In Abortions we saw gain of 17q12.2 (CNV), and lost of 2q32.1 (CNV), 3q26.1 (CNV), 4q32.2 (FSTL5, CNV), 7q22.1 (CUX1), 13q14.13 (LRCH1, HTR, SUCLA2, MED4), 14q21.1 (CNV), 19p13.2 (INSR, TRAPPC5, CD209, CLEC4G, RETN, STXBP2, ZNF358, PNPLA6), 22q13.1 (APOBEC3A). We found one coincident region lost in miscarriages as compared with live-born genomes, 7q22.1 which includes CUX1 gene, involved in the transcriptional regulation of several genes implicated in embryonic development, the lost of this region may cause an imbalance in the fetus that could originated a transcriptional de-regulation during development triggering a development failure. The most evident difference between the groups is that abortions presents more regions deleted and in consequence this imbalance could compromise the normal development. Our study provides the first genomic evidence for possible reasons for 45,X embryo lethality. Funding FONCICyT 95419.

957W

Characterization of a rare 16.25 Mb duplication of Xp21.2p22.2. *M.J. Macera[1], E. Bornstein[2], V. Aggarwal[3], L. Northrop[3], M. Shirazi[3], A. Sorbrino[1], B. Levy[3], D. Warburton[4], V. Jobanputra[3].* 1) New York-Presbyterian Hospital, Columbia University Medical Center, New York, NY; 2) Lenox Hill Hospital North Shore-LIJ, New York, NY; 3) Departments of Pathology and; 4) Genetics and Development and Pediatrics, Cloumbia University, New York, NY.

Partial duplications associated with the short arm of the X chromosome remain rare. Found in both sexes, precise delineation of the individual breakpoints was not possible until the use of microarray analysis; to date, only five dup(X) cases have been analyzed by microarray. We report an Xp21.2-Xp22.1 duplication discovered in a 30 year old primi-gravida woman, who presented for chorionic villi sampling at 12 weeks of gestation due to an abnormal first trimester screen. Prior family history was unremarkable. Cytogenetic analysis revealed an abnormal 46,Y,dup(X)(p21.2p22.1).ish dup(X)(wcpX+) in all fetal cells examined. The father was normal 46,XY, while the mother was found to have a 46,X,dup(X)(p21.2p22.1) karyotype. SOMA Microarray analysis on fetal DNA identified a 16.25 Mb gain of chromosomal material in the p arm of the X chromosome from positions 13,458,031-29,710,794, corresponding to Xp21.2 to Xp22.2 The karyotype was revised to: 46,Y,dup(X)(p21.2p22.2).arr Xp22.2p21.2(13,458,031–29,710,794)x2. This duplicated region has 58 OMIM annotated genes; 18 of these are disease-associated genes (TRAPPC2, OFD1, FAAP95, PIGA, AP1S2, NHS, CDKL5, RS1, PHKA2, PDHA1, RPS6KA3, SMPX, MBTS2, SMS, PHEX, SAT1, ARX, and IL1RAPL1) Mental retardation and/or congenital abnormalities in males has been associated with duplication of this region. Analysis of DNA from the mother, using the HUMARA test for X-inactivation skewing, showed the same X to be active in 89% of maternal cells. It is likely that this is due to preferential inactivation of the X with the duplication, providing a normal gene dosage and explaining the mother's normal phenotype. Skewed inactivation has been shown in phenotypic normal females identified with different X chromosome duplications; although the Xp21.2-Xp22.1 duplication appears to be unique. The patient's unremarkable family history would suggest a de novo origin of the duplication in the mother. This information was provided to the parents who elected to terminate the pregnancy and pursue IVF with preimplantation diagnosis for future pregnancies. Precise delineation of genes involved in these rare Xp duplications should improve the ability to predict associated pathology.

958T

Single Nucleotide Polymorphism-Based Microarray Comparison for Detection of Constitutional Copy Number Variation and Absence of Heterozygosity. *H. Mei[1], S.A. Scott[1], H.M. Kearney[2], D. del Gaudio[3], J.D. Weisfeld-Adams[1], M.P. Wasserstein[1], S. Das[3], N. Cohen[1], L. Edelmann[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY 10029; 2) Fullerton Genetics Center, Mission Health System, Asheville, NC 28803; 3) Department of Human Genetics, University of Chicago, Chicago, IL 60637.

Although microarray-based comparative genomic hybridization is a widely accepted method for detection of copy number variants (CNVs), single nucleotide polymorphism (SNP)-based microarrays can detect genotype and absence of heterozygosity (AOH) in addition to copy number. Three major SNP-based microarray platforms are commercially available (180K ISCA CGH+SNP, Agilent Technologies; CytoScan® HD, Affymetrix; HumanCytoSNP-12, Illumina) and this study aimed to compare them using 24 DNA samples representing a range of constitutional cytogenetic abnormalities. Using platform-specific software, CNVs over 200 kb were also compared among the diploid samples, and the 180K CGH+SNP, CytoScan® HD, and HumanCytoSNP-12 arrays identified an average of seven, one, and three CNVs per sample, respectively. Among these, an average of only one CNV per sample was identified by all three platforms and one additional CNV identified by two platforms. Samples with UPD for chromosomes 2, 6, 7, 8, 14, and 15 were detected by all platforms with strong concordance between identified regions of AOH. Parental samples were available for one UPD15, which indicated a maternal origin by all three platforms. Probands from two consanguineous families were tested, which suggested second and fifth generation parental relationships based on their ~10% and 1.8% of genomic regions identical by descent, respectively. Triplicate testing of one proband sample indicated excellent CNV and AOH reproducibility for all platforms, with slightly greater concordance for the CytoScan® HD and HumanCytoSNP-12 arrays. Triploid samples (69,XXX and 69,XXY) were identified using the HumanCytoSNP-12 array by both aberrant genotype and increased genome-wide copy number, whereas the 180K CGH+SNP and CytoScan HD® arrays identified these samples as abnormal by aberrant genotype and X and Y copy number. Of relevance to prenatal SNP-based microarray testing, artificially derived 46,XX MCC specimens were detected at ≥50% contamination by mosaicism for genome-wide AOH using the CytoScan HD® and HumanCytoSNP-12 arrays. In conclusion, all three arrays reproducibly detected constitutional regions of AOH and parent of origin; however, differences in resolution resulted in differences in the number of detected CNVs. Additionally, the interpretation of genotype information by the native software of the CytoScan® HD and HumanCytoSNP-12 platforms provided an advantage when assessing triploidy and other rare mosaic abnormalities.

Atypical copy number abnormalities in patients with suggestive phenotype of 22q11.2 Deletion Syndrome. *M.C. Molck[1], T.P. Vieira[1], I.C. Sgardioli[1], M. Simioni[1], A.C. Xavier[2], J. Souza[3], V.L. Gil-da-Silva-Lopes[1].* 1) Department of Medical Genetics, University of Campinas (UNICAMP), Campinas, São Paulo, Brazil; 2) Center for Research and Rehabilitation of Lip and Palate Lesions (CRRLPL) Centrinho Prefeito Luiz Gomes, Joinville, SC, Brazil; 3) Center for Intregral Assistance of Cleft Lip and Palate (CIAC), Curitiba, PR, Brasil.

22q11.2 Deletion Syndrome (22q11.2 Del S.) is the most common microdeletion syndrome in humans, affecting 1 in 4,000 live births and with a highly variable phenotype. Chromosome 22q11.2 region contains low copy repeat (LCR) sequences that mediate non-allelic homologous recombination and predispose to copy number abnormalities (i.e. deletions and duplications) at this locus. The most common one is the proximal microdeletion of 3 Mb spanning LCRs A to D. Atypical copy number abnormalities spanning other LCRs have been described, associated or not with the phenotype of 22q11.2 Del S. Three patients with suggestive phenotype of 22q11.2 Del S. with atypical deletion or duplication in 22q11.2 region are described. The chromosomal aberrations were detected by Multiplex Ligation-dependent Probe Amplification (Kit P250, MRC-Holland MLPA®) technique. Patient one showed the ~3 Mb typical deletion and an atypical duplication at distal region (22q11.23) between LCRs F and H. Array analyses by Genome-Wide Human SNP Array 6.0 (Affymetrix) showed a 2.5 Mb deletion at 22q11.21 and a 1.3 Mb duplication at 22q11.23. Patient two demonstrated a ~1.6 Mb atypical deletion at distal 22q11.2 region located between LCRs D and E. Patient three exhibited a ~4.2 Mb atypical deletion overlapping proximal and distal 22q11.2 region and spans the genomic region between LCRs B and F. The breakpoints reported in patients one and three have not been described previously. These findings exemplify the complexity and genetic heterogeneity observed in 22q11.2 Del S. and corroborate the idea that genetic modifiers contribute to the phenotypic variability found in this syndrome. Financial support: FAPESP, CAPES and CNPQ.

Mosaicism in live born and spontaneous abortions with trisomy 13, 18, 21 and monosomy X. *S. Sánchez[1, 4], P. Grether[2], D.G. Mayén[3], B. Molina[1], M.J. Zavaleta[2], J. Domínguez[1], R. Meléndez[3], S. Frias[1,5].* 1) INSTITUTO NACIONAL DE PEDIATRIA, MEXICO CITY, Mexico; 2) INSTITUTO NACIONAL DE PERINATOLOGIA, Mexico; 3) HOSPITAL ANGELES LOMAS, Mexico; 4) POSGRADO EN CIENCIAS BIOLOGICAS, UNAM, Mexico; 5) INSTITUTO DE INVESTIGACIONES BIOMEDICAS, UNAM, Mexico.

In humans, the study of first trimester abortions by conventional and molecular cytogenetics, have shown that the frequency of chromosomal abnormalities is 60%, mainly trisomies and monosomy X. Over 90% of aneuploid pregnancies are lost as early abortions, 5.8% as still births and only 4% born alive. Aneuploidies that survive are trisomies (T) 13, 18 and 21 and monosomy X. There are several studies on aneuploidy as a cause of spontaneous abortion, but remains unknown why a fetus with trisomy or monosomy comes to birth? The evidence shows that newborns with T13, 18, 21 and 45,X are exceptions to the rule of lethality and the reason for this has remained unexplored. Mosaicism with a normal cell line in embryos 45,X has been proposed as a survival factor, however there is no information regarding the autosomal trisomies. The aim of this study is to determine if there exist differences in the presence of mosaicism and the amount of disomic cells between born alive and abortions with the same aneuploidy. We analyzed peripheral blood samples (n=35) and desquamation bladder cells (n=20) of born alive and spontaneous abortions tissues (n=33). We searched for the presence of a normal cell line, in 500 to 1000 cells by fluorescence in situ hybridization (FISH) with probes for the detection of loci: 21q22.13-q22.2 (LSI21), 13q14.13 (LSI13-RB), α-centromeric 18 (CEP 18), α-centromeric X (CEP X) and α-centromeric Y (CEP Y). Samples with more than 3% of normal cells were considered mosaics. We detected mosaicism in live born in 1/3 cases with T18, 3/15 with T21 and 3/12 with 45,X; in T21 normal cells where found only in desquamation bladder cells; T13 cases did not show mosaicism. We analyzed 33 spontaneous abortions samples, and found mosaicism in 3/6 with T13, 1/7 T18, 2/8 T21 and 3/10 45,X. In one case with T13 and other with monosomy X the mosaicism was found in chorionic villi and amniotic membrane from de same miscarriage. In conclusion, we detected mosaicism with normal cells in 20% of born alive samples and in 27% of miscarriages. Most of them were found in cases with 45,X karyotype. These results suggests that the mosaicism is a frequent finding in live birth and abortions with trisomies 13,18,21 and monosomy X and due to the similar frequency, it is possible that mosaicism does not confer a biological advantage that explain the survival of live births with aneuploidy. Array-CGH analysis in patients with Goldenhar Syndrome. *P.AC. Santos[1], E.L. Freitas[2], H.P.N. Safatle[3], C. Rosenberg[2], I. Ferrari[4], S.F. Oliveira[4], J.F. Mazzeu[1,5].* 1) Programa de Pós-graduação em Ciências da Saúde, Universidade de Brasília, Brasília, Distrito Federal, Brazil; 2) Departamento de Genética e Biologia Evolutiva, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brazil; 3) Hospital Universitário, Universidade de Brasília, Distrito Federal, Brazil; 4) Laboratório de Genética, Departamento de Genética e Morfologia, Instituto de Ciências Biológicas. Universidade de Brasília, Brasília, Distrito Federal, Brazil; 5) Programa de Pós-Graduação em Ciências Genômicas e Biotecnologia, Universidade Católica de Brasília, Brasília, Distrito Federal, Brazil.

Goldenhar syndrome (GS), also known as oculo-auriculo-vertebral syndrome, is a congenital defect from anomalous development of first and second branchial arches. GS presents a spectrum ranging from mild to severe forms and the patients may exhibit anomalies including ear malformations, facial asymmetry, cleft lip/palate, eye, vertebral and congenital heart defects. GS is heterogeneous and its etiology includes environmental factors, unknown genetic factors and different chromosome aberrations. Deletions involving 2p11, 2q11, 5p15, 12p13, 13q21, 14q32 and 22q11 as well as duplications at 4q35, 8q11, 9q34, 11q21, 13q13, 14q22, 18p11, 20p12 and a translocation at t(4;8)(p15.3;q24.1) disrupting *BAPX1* have been previously reported in GS patients . A candidate region at 14q32 was proposed as by linkage studies. We investigated eight patients with GS for chromosome rearrangements by G-banding and array-CGH (44K, Agilent technologies). G-banding did not disclose any rearrangements. In one patient, array-CGH revealed a ~2.5 Mb deletion at genomic position chr22: 17,276,772-19,770,655 (Build36/hg18) at 22q11.21. This patient presents clinical features of both Goldenhar and DiGeorge syndromes, namely: hemifacial microsomia, ptosis, dysplastic right ear, retrognathia, aphasia and hearing loss. She also presents with joint laxity and myopia. ECG showed a mitral valve prolapse. 22q11.2 microdeletions have been described in patients with GS, however they do not overlap with the deletion here reported. In another patient array-CGH revealed a ~550 Kb duplication at genomic position chr20:8,794,395-9,336,676 (Build36/hg18) at 20p12.3-p12.2. He presents macrocephaly, facial asymmetry, microtia on the left and cryptorchidism. The duplication was inherited from the phenotypically normal father and have not been reported in other GS patients or normal controls. Only one gene maps to this segment *PLCB4*, that is part of a gene family which operates in intracellular transduction of extracellular signals. Further studies are needed to infer the relation of this microduplication and the occurrence of GS clinical signs. No abnormalities were identified in the six remaining cases. This study corroborates previous reports indicating that patients with GS should be screened for chromosomal imbalances. Financial support: CAPES, FAPDF/PPSUS.

962T

Complex rearrangements involving five chromosomes and at least fourteen breaks. *J. Wang, B. Huang, R. Habibian, A. Hajianpour.* Integrated Genetics, Monrovia, CA.

Array CGH (aCGH) was performed on a 20-month old child with psychomotor delay, facial dysmorphism, cryptorchidism, and dermal sinus. Chromosome analysis performed previously in another laboratory revealed a de novo apparently balanced three-break reciprocal translocation: 46,XY,t(4;6;10)(q31.1;q25.1;q22.1). aCGH revealed interstitial deletions of chromosomes 4, 6, and 20 [arr 4q31.22(145,181,574-145,568,241)x1,6q25.3(155,961,736-156,674,789)x1, 20p12.1(13,142,859-13,806,764)x1,20p12.1(14,314,316-14,622,432)x1]. Multiple FISH analyses were performed. Combining cytogenetic, FISH, and aCGH analyses, a complex rearrangement involving five chromosomes (4, 6, 9, 10, 20) was detected. There was an unbalanced three-way translocation between chromosomes 4, 6, and 10, with deletion of DNA sequences around the breakpoints at 4q and 6q. In addition, further rearrangements involving chromosomes 9 and 20 were also observed. These included (1) a small portion of the segment deleted from 6q25.3 was inserted into the proximal short arm of chromosome 20 at p11.2; (2) two non-contiguous interstitial deletions in the short arm of chromosome 20 at 20p12.1 were detected by array. FISH analyses indicated the intervening sequence and the sequence proximal to the two non-contiguous interstitial deletions were inserted to the proximal long arm of chromosome 9 at 9q13; (3) another segment of chromosome 20, possibly also 20p12.1, was inserted to the long arm of chromosome 4 possibly at 4q31.22. There were two breaks on der(4), three on der(6), at least one on der(9), one on der(10), at least seven on der(20), with a minimum of fourteen breaks. Complex chromosome rearrangements, both familial and de novo, balanced and unbalanced, have been reported repeatedly. Massive chromosomal shattering and reorganization, a phenomenon termed chromothripsis, has recently been reported and suggested to occur in 2%-3% of all cancers. Chromothripsis has also been shown to occur in constitutional de novo structural rearrangement. The rearrangement in this child is potentially more complex than described. Further study of this and other similar cases may provide additional insight to the mechanism of genomic rearrangements.

Trisomy Xp and partial tetrasomy Xq resulted from gain of a rearranged X chromosome in a female fetus: pathogenic or not? *M. Yiu[1], Z. Qi[1], A. Ki[3], K. Hashimoto[3], M. Ernster[2], J. Yu[1]*. 1) Laboratory Medicine, UCSF, San Francisco, CA; 2) Golden Gate Pediatrics, San Francisco, CA; 3) Clinical Cytogenetics Lab, UCSF Medical Center, San Francisco, CA.

A mosaic karyotype with gain of a rearranged X: 47,XX,add(X)(q?22)[11]/46,XX[9], was detected by cytogenetic analysis of chorionic villous sampling due to advanced maternal age. Microarray and additional studies indicated that the rearranged X carried a 39.5 Mb inverted duplication between Xq11.1 and Xq22.1, a 53.8 Mb deletion distal to Xq22.1 and a satellited Xqter. Both parental karyotypes were normal. Gain of this rearranged X was confirmed in all analyzed cells from a follow-up amniocentesis and in approximately 92.5% of the cells from a postnatal cord blood sample. Nonetheless, prenatal ultrasonography imaging including fetal echocardiography appeared to be unremarkable and a full-term baby girl was born at 39 4/7 week via a spontaneous vaginal delivery. The infant appeared to have normal development at the 2-month follow-up examination. Late replication studies showed that the rearranged X was inactivated in all abnormal cells examined. This skewed X-inactivation might suppress potentially detrimental phenotypic effects of genomic imbalance. Although, the possibility of tissue-specific mosaicism that result in mild phenotypes cannot be excluded. Gain of X chromosomes, particularly rearranged X chromosomes, often presents challenges for prenatal genetic counseling. It is well-known that gain of X chromosomes is associated with abnormal phenotypes, and the increase of additional Xs is often associated with more severe phenotypes. However, the regions responsible for the abnormal phenotypes on X chromosome are poorly understood. Long-term follow-up of this case may provide better understanding of phenotypic effects of X inactivation and X chromosome abnormalities.

964T

A de novo 0.24-Mb microdeletion of 16q24.3 encompassing ANKRD11 in a patient with KBG syndrome. *HJ. Cho[1], EJ. Seo[1,2], JH. Lim[1,2], JO. Lee[4], HW. Yoo[1,3], CK. Cheon[5]*. 1) Medical Genetics Center, Asan Medical Center, Seoul, South Korea; 2) Department of Laboratory Medicine, Asan Medical Center, Seoul, Korea; 3) Asan Medical Center Children's Hospital, University of Ulsan College of Medicine, Seoul, Korea; 4) Asan Institute for Life Sciences, Asan Medical Center, Seoul; 5) Department of Pediatrics, Pusan National University, Pusan, Korea.

KBG syndrome is a rare condition characterized by macrodontia of the upper central incisors, distinctive craniofacial findings, skeletal anomalies, short stature, and neurologic involvement that includes seizure, intellectual disability, and global developmental delay. The diagnosis of KBG syndrome is mostly based on clinical features. Recently, it has been reported that the mutations in ANKRD11 cause KBG syndrome, Now we present a boy with the phenotype of KBG syndrome with the microdeletion of ANKRD11. The patient at the age of 6 years was referred to our hospital because of short stature and developmental delay. He showed short stature, macrodontia of permanent dentition, and craniofacial dysmorphism including triangular face, prominent forehead, epicanthal fold, anteverted nostrils, broad mouth, and prominent ears. He had also neurologic involvement such as delay of speech and motor function, intellectual disability (IQ 70) and partial seizure on EEG. Brain MRI showed a thickened corpus callosum. Bone X-ray showed narrowing and elongation of both iliac wing and body, small femoral heads, small distal tibial epiphyses and tibiotalar slanting, and delayed bone age. Conventional chromosome analysis was normal, but a de novo heterozygous 0.24-Mb deletion at 16q24.3 including ANKRD11 and a part of the SPG7 genes was detected by the 244k oligonucleotide based array-CGH (Agilent). Recent study reported that patients with heterozygous microdeletion of ANKRD11 showed the phenotype similar to that of KBG syndrome. ANKDR11 encoding ankyrin repeat domain 11 seems to function in transcriptional repression and promoting transcription. However, it is uncertain how the pathogenic mechanism of ANKRD11 mutations cause KBG syndrome. The phenotype shown in this patient was compatible with clinical features described in KGB syndrome with ANKRD11 mutations. We suggest that the heterozygous microdeletion of ANKRD11 could also cause the KBG syndrome.

The Evaluation of Subtelomeric Fluoresent in situ Hybridization Analysis of Idiopathic Mental Retardation / Multiple Congenital Anomaly Cases. *B. Durmaz[1], E. Karaca[1], A. Durmaz[1], T. Atik[2], H. Akin[1], O. Cogulu[1,2], F. Ozkinay[1,2]*. 1) Department of Medical Genetics, Ege University, Izmir, Turkey; 2) Department of Pediatrics, Ege University, Izmir, Turkey.

Mental retardation is a life-long disability that occurs in approximately 2–3% of the population. The etiology of intellectual and developmental anomalies remain unknown in about 50% of cases which limits the effectiveness of genetic counseling on recurrance risks, prognosis and treatment. Conventional cytogenetic analysis is the standard method for investigating chromosomal abnormalities however, small (<5 Mb) DNA changes could not be detected. Fluoresent in situ Hybridization (FISH) analysis is used to show those cryptic changes. The subtelomeric regions of chromosomes which can be visualized by FISH, are considered to be gene-rich and rearrangements involving these regions have been shown to cause mental retardation in many studies varying from 5 to 10% of the affected cases. In this study, subtelomeric FISH analysis of 161 cases with idiopathic mental retardation / multiple congenital anomalies (MR/MCA) which do not have any abnormalities in classical cytogenetic analysis were retrospectively evaluated between January 2005 - April 2012. In 9 patients (5.59%), subtelomeric deletions were detected . These were deletions of 14q in 2 cases, 18q in 2 cases, 18p in 2 cases, 15q in 1 case, 7p in 1 case and 8p in 1 case. Deletions of 18p, 18q and 8p were familial, the others were de novo. The prevalence of subtelomeric deletions in our cohort of moderate to severe mental retardation patients is consistent with the literature. In conclusion, subtelomeric FISH was shown to be feasible and cost-effective in determining the etiology of MR/MCA patients.

Mechanism-based Analysis of Human Cell Lines of Prader-Willi Syndrome. *Z. TANG, D. Berlin, M. Wineburg, A. MacMillan, D. Altamuro, L. Toji, C. Beiswanger, S. Madore, N. Gerry*. Coriell Institute for Medical Research, Camden, New Jersey 08103.

Prader-Willi Syndrome (PWS) is one of the most common conditions seen in genetics clinic, and it is the most common genetic cause of obesity seen in both sexes and all races. The National Institute of General Medical Sciences Human Genetic Cell Repository (NIGMS repository) housed at Coriell Institute has collected a group of cell lines originating from PWS patients and their family members. A total of 32 lines consisting of 24 proband and 8 family members are currently available to the research community. We have characterized each of these cell lines using conventional G-banded karyotyping and molecular cytogenetic methods such as fluorescence in situ hybridization (FISH) and chromosomal microarray analysis (CMA). Based on these findings and potential genetic mechanisms causing PWS, the cell lines can be categorized into 4 different groups. Group 1 consists of 18 cell lines (16 proband and 2 family members) containing a deletion ranging from 45 kb (partial or whole SNRPN gene) to >6 Mb (the whole region) affecting 15q11.2q13. Group 2 includes 2 cell lines that have no deletion in 15q11.2q13 but do contain a maternal uniparental disomy (matUPD) in this region. One line is homozygous, indicating two identical alleles, while the other is heterozygous. Group 3 includes 2 cell lines with a microdeletion affecting the imprinting center (IC). Group 4 contains 4 cell lines with an as yet uncharacterized PWS genotype. Two of the cell lines in Group 4 have a chromosomal translocation involving the 15q11.2q13 region as detected by G-banded karyotyping and FISH studies, but no copy number change in this region was seen by CMA. Further studies such as DNA sequencing for potential imprinting mutations are needed to clarify the underlying mechanism(s) in these 4 cell lines. These groups of cell lines comprise a useful PWS-specific reference panel for research and clinical diagnostic applications.

A child with Pitt-Hopkins syndrome and maternal somatic mosaicism at 18q21.2. *K. Doudney[1], V. Bickley[1], M. Robertson[2], J. Watt[2], J. Taylor[2], A. Kidd[3], P. George[4].* 1) Molecular Pathology, Canterbury Health Laboratories (CHL); 2) Cytogenetics, CHL; 3) Clinical Geneticist, CHL; 4) Clinical Director, CHL, Canterbury District Health Board, Christchurch, New Zealand.

Pitt-Hopkins syndrome (PTHS) is a neurodevelopmental disorder often caused by heterozygous mutations in TCF4, a transcription factor important during embryonic development. Typical PTHS characteristics are severe intellectual disability, breathing abnormalities and abnormal facial morphology including a wide mouth. Following a diagnosis of global developmental delay at 21 months of age, patient 1 was referred to our laboratory for arrayCGH. We detected an approximately 600kb heterozygous deletion at 18q12.2, encompassing the 5' half of TCF4 and 300kb of upstream genomic sequence. Analysis of the proband's mother revealed a mosaic pattern of deletion at this locus, identified by FISH in 11% of interphase nuclei and confirmed in metaphase cells. Mosaicism at 18q21.2 (TCF4) is rare, with only a few examples reported (1–3). This finding provides further evidence that TCF4 underlies Pitt-Hopkins syndrome and establishes haploinsufficiency at this locus as underlying the disorder's dominant mode of inheritance. 1 Steinbusch et al. (2012) Clin Genet doi: 10.1111/j.1399-0004.2012.01857.x. [Epub ahead of print] 2. De Pontual et al. (2009) Hum Mutat 30(4):669–676 3. Stavropoulos et al. (2010) Eur J Med Genet 2010: 53(6): 396–399.

Microarray benefits diagnostic pregnancy loss studies. *D.L. Pickering, B.J. Dave, D.M. Golden, A.A. Haggerty, D.L. Bishay, R.L. Smith, S.A. Fisher, W.G. Sanger*. Human Genetics Laboratories, Munroe Meyer Institute, University of Nebraska Medical Center, Omaha, NE.

Chromosome studies of spontaneous abortion tissue provide important diagnostic information; however, these tests are hampered by culture failure and maternal cell contamination. FISH analysis circumvents the need for cell culture yet aneuploidy screening for selected chromosomes does not provide comprehensive genomic data. Microarray studies in products of conception (POC) are useful because they eliminate the need for cell culture, interrogate the entire genome, and can distinguish maternal contamination upon comparative analysis with maternal blood specimen. From August 2011-May 2012, our laboratory performed 54 pregnancy loss microarray tests using a combination 180K array with approximately 140,000 oligonucleotide probes for copy number analysis and 40,000 SNPs for genotype assessment. DNA extraction was successful and microarray results were obtained in all 54 cases, 35 females and 19 males. Nine out of 54 (16.6%) cases were abnormal by microarray analysis. There were six cases with whole chromosome aneuploidies including trisomy 2 (one case), trisomy 21 (three cases), and monosomy X (two cases). Structural abnormalities of 22q were observed in three cases. One was a common 22q deletion observed in a male POC specimen. The other two were female POC studies that showed duplications of 22q11.2 in maternal blood and POC tissue. Microarray studies thus helped determine subtle maternal abnormalities during POC genomic investigations. Maternal contamination was determined in nine out of 35 female POCs (7/29 normal; 2/6 abnormal) which could not have been detected by FISH. Maternal contamination was also detected in a male POC specimen and confirmed by interphase FISH in 70% of cells from a tissue touch preparation, emphasizing the ability of microarray to detect mosaicism. Furthermore, the use of microarray reduced the turnaround time of pregnancy loss studies to 8.2 days. Incorporation of microarray testing for miscarriage tissues has thus improved patient care by increasing success and abnormality rates, reducing the time to report, and providing more accurate results in cases with maternal contamination. Additionally, detection of maternal abnormalities during pregnancy loss investigations underscores the need for genetic counseling and peripheral blood microarray studies among couples with recurrent miscarriage.

Method Comparison Study of the Illumina InfiniumDx CytoSNP-12 Assay for the Detection of Chromosomal Abnormalities in DNA Extracted from Peripheral Blood. *M. Porter, R. Golshani, J. Fabian, M. Harris.* Illumina Inc, San Diego, CA.

Introduction / Background: The InfiniumDx™ CytoSNP-12 Assay is intended for use as an aid in post-natal diagnosis of autism spectrum disorders, developmental delay and/or intellectual disability, congenital anomalies, and dysmorphic features in conjunction with other currently used information. To demonstrate the utility of this assay, 402 samples with reported chromosomal abnormalities were analyzed using the InfiniumDx CytoSNP-12 Assay and at least one other method, including karyotype, FISH, PCR, Multiplex Ligation-dependent Probe Amplification (MLPA), qPCR, or an in-house confirmatory method for loss of heterozygosity (LOH). Materials and Methods: The InfiniumDx CytoSNP-12 Assay, based on Illumina BeadArray™ technology and run on the iScanDx System, consists of CytoSNP-12 assay kits and KaryoStudioDx™ analysis/reporting software. The 402 samples were run in singlet. Karyotype, MLPA, FISH, and PCR were performed externally with commercially available assays. qPCR and LOH were performed using methods validated in-house. Sample success rate (percent of samples passing defined QC metrics/total samples run), positive percent agreement (percent of regions reported by a comparator method and the assay/total regions expected) and false positive rate (percent of regions detected by the assay but not by a comparator method/total regions detected by the assay) were calculated to measure the performance of the InfiniumDx assay against the comparator methods. Results: Sample success rate upon first attempt was 98% (393/402). The 95% lower bound for positive percent agreement for all chromosomal abnormality types was 93% (1034/1098). For gains, losses, and copy-neutral LOH (CNLOH), the 95% lower bound for positive percent agreement for each type was 87% (22/224), 91% (25/365), and 95%(17/445), respectively. False positive rate across all regions detected by the assay was 12% (144/1170). For gains, losses, and CNLOH, the false positive rate for each type was 10% (25/248), 9% (37/392), and 15% (82/530), respectively. Conclusions: Our study demonstrates comparable performance of the InfiniumDx™ CytoSNP-12 Assay to many of the standard clinical methods used to determine copy number variation. This assay reports all chromosomal abnormalities within the entire genome of a sample, making it more comprehensive than FISH, PCR, MLPA, and qPCR. In addition, this assay reports CNLOH regions, unlike karyotyping or FISH. This test is For Investigational Use Only.

970T

A CML case with normal karyotype and positive *BCR/ABL1* fusion. *C.A. Tirado[1], JW. Boles[2], J. Ochoa[2], R. Collins[3].* 1) Pathology & Laboratory Medicine, UCLA, Los Angeles, CA90024, CA; 2) Department of Ecology & Evolutionary Biology UCLA; 3) UT Southwestern Medical Center- Department ofHematology & Oncology.

Chronic myeloid leukemia (CML) is cytogenetically characterized by the presence of the Philadelphia chromosome (Ph) in 90–95% of cases. Ph variants are found in approximately 5% of CML patients. In these cases, FISH is always useful to determine the location of the BCR/ABL1 fusion gene. Herein, we present a 47 year old patient who presented with splenomegaly, dizziness, vertigo and high WBC (> 700×10^9). Morphologic examination of the bone marrow (BM) biopsy was consistent with CML in chronic phase with no increase in blasts. Chromosome studies revealed a 46,XY,t(9;22) in all cells examined. He started with hydroxyurea and Gleevec. After six months his WBC was $53x\ 10^9$ with mild thrombocytopenia and recurrent chronic phase with no increase of blasts but 95% cellularity. Chromosome analysis on BM at this time showed a normal chromosome complement but FISH on interphase nuclei showed only one fusion *BCR/ABL1* signal in 195/200 of the cells examined. Seventeen of those cells showed an extra *BCR* signal. FISH on previously G-banded metaphases showed a fusion signal on the Ph which confirmed the cryptic translocation. This finding was characterized as ins(22;9)(q11.2;q34q34). The patient then had increase in the dose of Gleevec (800 mg) but due to some pancytopenia this was switched to 600 mg. Pancytopenia did not improve so he was switched to sprycel 70 mg. After treatment his WBC are 4.2, Hb 9.6, platelets 67×10^9 although mild anemia and thrombocytopenia was noted. To date, the patient has remained stable in a chronic phase with partial hematological remission. Our study confirms the advantage of using FISH to determine the location of the *BCR/ABL1* fusion gene in cases where conventional cytogenetics is normal and FISH on interphase nuclei show evidence of *BCR/ABL1* fusion.

Computational methods for detecting whole-genome triploid samples with Agilent CGH+SNP arrays. *A. Vadapalli[1], B.J. Peter[2], A. Ashutosh[1], J. Ghosh[1], B. Curry[2], A. Rajkovic[3], U. Surti[3], S.A. Yatsenko[3]*. 1) Genomics R&D, Agilent Technologies, Santa Clara, CA; 2) Agilent Labs, Agilent Technologies, Santa Clara, CA; 3) Department of Obstetrics, Gynecology and Reproductive Sciences, University of Pittsburgh, PA.

Array-based comparative genomic hybridization (array CGH) is a tool to provide high-resolution copy number measurements of the genome. Array CGH has become important for research in identifying constitutional diseases, cancer biology and in conducting pre or postnatal studies. The addition of single nucleotide polymorphism (SNP) measurements to CGH microarrays enables the detection of copy-neutral loss of heterozygosity (cnLOH) events and allelic imbalances.

Fetal loss, or miscarriage, is one of the most common complications of pregnancy, occurring in 15 to 20% of clinically recognized pregnancies. Cytogenetic abnormalities are present in approximately 50% of miscarriages, and the majority of these are due to whole chromosome aneuploidy or triploidy. Karyotyping has limited resolution and depends on successful culturing of cells from the product of conception. High resolution array CGH analysis can be performed on genomic DNA, but copy number analysis alone cannot detect cases of triploidy when a whole haploid set of chromosomes is present in three copies.

A novel algorithm has been developed in Agilent Genomic Workbench 7.0 software that allows for the detection of triploidy when CGH+SNP arrays are used. In an earlier version of the algorithm, samples with whole-genome triploidy were normalized and previously assigned to be non-aberrant. For constitutional triploid samples, the algorithm identifies a pattern of SNP log ratio distribution of the majority of genome consistent with triploidy. The parameter values of the fitted peaks in the SNP log ratio distribution are used to automatically detect and adjust log ratios to represent the non-diploid state across a majority of the chromosomes in such samples. Upon determining the correct ploidy, the total copy number and the SNP genotype of the genomic regions is adjusted accordingly.

A new algorithm has been applied to study samples with 69,XXX, 69,XXY, and 70,XXY,+2 chromosome complements. We have shown that the new algorithm allows researchers to determine the genotypes, the total copy numbers and SNP allele specific copy numbers in triploid samples. Since 1–2 % of all pregnancies are triploid, this novel algorithm provides an improved research tool for the detection of chromosomal abnormalities.

Genome-wide resolution study of CNV detection by the CytoScan® HD Cytogenetics Array through a large-scale experiment. *Y.S. Wang, A.H. Roter*. Informatics, Affymetrix, Santa Clara, CA.

Accurate estimation of functional performance of genomics technologies is challenging due to limited access to clinical samples representing the wide range of aberration possibilities across the genome. The nature of their non-probability sampling and low sample availability increases the risk of bias in estimates of population parameters. We hypothesize that random sampling with available samples can overcome these drawbacks. We tested our hypothesis using this method to estimate array functional resolution for Affymetrix' CytoScan® HD Array. CytoScan HD Array is a 2.6 million marker high-density microarray designed to detect whole-genome copy number variation (CNV) for constitutional and hematological malignancy cytogenetic research applications. To assess functional performance, it is critical to determine of the number of markers required to make an accurate and reproducible CNV call across the genome. A non-existent ideal sample set is a collection of biological DNA samples with CNV regions of different sizes at all genome locations. Developers could randomly sample and run microarrays to estimate performance. Alternatively, developers could use synthetic or sub-cloned DNAs and targeted deletions spiked into normal genomic DNA. Arrays could then be run to estimate performance. Conducting such experiments is expensive and impractical. As a highly effective alternative, we designed an in silico experiment that simulates the above studies using the actual behavior of markers on real clinical samples. We obtained a set of samples from the Coriell Institute with abnormal copy number regions collectively covering a large proportion of the genome and ran these on CytoScan HD Arrays. We randomly sampled DNA pieces of different sizes from the karyotype-confirmed large CNV regions. Each sample was flanked with copy number markers from normal regions and subsequently processed for CNV detection. This experiment used real clinical samples and enabled an estimation of sensitivity. The derived statistics summarized millions of specific cases across the genome. Based on these data, we have established the relationship between number of markers to make a high-confidence CNV call and the associated sensitivity of CNV detection. In addition, we have characterized the difference in sensitivity between copy number losses and gains. This study demonstrates the feasibility of accurate estimation of population parameters using limited non-probabilistic samples.

973W

A new case of inverted duplication with terminal deletion of chromosome 12p caracterized by FISH and SNP array analysis. *E. Pipiras[1], B. Jeandidier[2], S. Chantot-Bastaraud[3], B. Benzacken[1], A. Delahaye[1]*. 1) Hopital Jean Verdier, Service de Cytogénétique, APHP, Bondy, France; 2) Hopital Jean Verdier, Service de Pédiatrie, APHP, Bondy, France; 3) Hopital Trousseau, Service de Génétique, APHP, Paris, France.

Objective: So far, the inverted duplication with concomitant terminal deletion (invdupdel) has been identified for several chromosomes but was not studied for the short arm of chromosome 12. We describe clinical features and molecular characterization of an invdupdel 12p in a child with a developmental delay. **Methods:** Clinical work up included clinical histories, physical, neurological, and ophthalmologic examinations. A standard karyotyping was performed. The structural abnormality was characterised by molecular cytogenetic methods as FISH (Fluorescence in situ Hybridisation) using whole chromosomes painting 12, 12pter subtelomeric probe, bacterial artificial chromosome (BAC) probes and chromosomal microarray analysis (CMA) using whole genome HumanCyto-12 SNP (Illumina) array. **Results:** The patient is a one year-old girl (non consanguineous parent) who was referred to clinic because of hypotonia, hyperlaxity, psychomotor retardation, developmental delay, mild dysmorphic features including upslanting palpebral fissures and a hockey-stick palmar crease. A 46,XX,add(12)(p13) was suspected in the routine karyotype analysis of the patient while both parents revealed an apparently normal karyotype. The subtelomeric probe 12p showed terminal deletion. Painting of chromosome 12 excluded translocation and confirmed the interstitial duplication. The inverted orientation of the duplication was determined by either the banding pattern and dual coloured FISH. Molecular characterization of the deleted region by SNP array confirmed 12p terminal deletion, a 0,8Mb region that comprises 9 genes. The inverted duplication region spans 27,2Mb and encompasses 272 genes (hg18-build 36.3). SNP array failed to identify single copy region, between the duplication regions. **Conclusions:** We are reporting the first case of inverted duplication of 12p13.33p11.22 with a deletion of 12p13.33-pter. Our cytogenetic molecular results and their correlation with the phenotype of the patient are discussed, mechanisms (U-type exchange or NAHR) of invdupdel also are reviewed. In this study we have described a case in which, molecular cytogenetics (FISH and CMA analysis) can determine breakpoints and the exact size of the chromosome abnormality detected by karyotype.

GISH Analysis of Genome Discrimination in Two Interspecific Hybrid of Sweet Potato. *Z. Li.* Jiangsu Normal University, Xuzhou, China.

To understand the genomic structure and chromosomal composition of two interspecific hybrids 59-1 and 67-1 from I. batatas cv. Xushu18 and I. grandifolia and I. hederacea. Jaq., comparative genomic in situ hybridization was used to study the sweet potato, wild species and interspecific hybrids. The results significantly indicated the vast majority of genome of 59-1 and 67-1 were from that of Xushu18. The chromosome number of the two hybrids was 75 and 90, respectively, different from the theoretical number. GISH detected two or more chromosomes and or some chromosomal segments from the male parent wide species. Sequences homologous with the genome of male parent wide species were more distributed in the regions of centromere, subcentromere, telomere, subtelomer. GISH signals of large size and strong intensity were distributed along entire lengths of most chromosomes. Presumably, in the process of nurturing, We speculate that in the process of hybrid cultivation, a or of the parents may have occurred in genome of the two hybrids. the parental genome in hybrids 59-1 and 67-1 occurred chromosome combination or genome reorganization, amplification, and structural rearrangement.

Latest innovations in oligo FISH enable high resolution detection of chromosomal aberrations. *M. Ruvolo[1], V. Kulkarni[1], B. Mullinax[1], A. Bergstrom Lucas[1], P. Tsang[2], N. Faravashi[1], A. De Witte[1], M. Srinivasan[1], E. LeProust[1], S. Fulmer-Smentek[1]*. 1) Agilent Technologies Genomics, Santa Clara, CA; 2) Agilent Laboratories, Santa Clara, CA.

The discovery of complex structural variations that exist within individual genomes has prompted a need to visualize chromosomes at a higher resolution than previously possible. In response to this need, we have developed a new generation of fluorescent in situ hybridization probes for the detection of chromosome aberrations, including translocations and copy number changes. These new probes, Agilent SureFISH probes, are designed using an in silico design strategy that specifically avoids placing oligonucleotides in repetitive regions of the genome, including repeat-masked regions and segmental duplications, allowing for highly specific detection of the region of interest. Each SureFISH probe is designed to a specific region of the genome with different design strategies employed for different applications. The probes are generated from complex libraries containing hundreds to thousands of unique high quality long oligonucleotides. The resulting probes provide high specificity and enable users to detect aberrations in targeted regions of the genome as well as aberrations near highly repetitive elements. These results can be obtained using a workflow compatible with existing technologies, with the improvement that suppressive hybridization agents are not required and the hybridization time can be shortened. Because of their unique design methodology, Agilent SureFISH probes provide superior resolution and specificity as compared to other available technologies.

976T

Deletion 2q24.1q24.2 in a boy with generalized hypotonia and developmental delay: further delineation. *V. del Castillo[1], E. Yokoyama[1], C. Villarroel[1], J.L. Castrillo[2], S. Avila[2], S. Sánchez[3], B. Molina[3], S. Frías[3]*. 1) Departamento de Genética Humana, Instituto Nacional de Pediatria, Mexico, DF, Mexico; 2) Laboratorio Genetadi, Bilbao, España; 3) Laboratorio de Citogenética. Departamento de Genética Humana, Instituto Nacional de Pediatria, Mexico, DF, Mexico.

BACKGROUND: Many patients with hypotonia and developmental delay/mental retardation have a chromosomal etiology, and often the submicroscopic deletion or duplication is only evidenced by molecular cytogenetic methods, as array-CGH. To date, there are only three previous cases with an interstitial deletion involving 2q24.2 so we present the first Mexican patient with this alteration. CASE REPORT: The patient is the first child of an 18-years-old mother and 20-years-old father. The parents were healthy and non-consanguineous. He was born after an uneventful pregnancy. There was no family history of children born with congenital disease, intellectual disability, autism, seizures, neurologic disorders, metabolic disorder, recurrent pregnancy loss or infertility. Birth weight was 2600 g (centile 5), height was 47 cm (centile <5). At 6 months of life the patient showed generalized hypotonia, developmental delay and cryptorchidism. Karyotype was normal. At this time he is almost 7 years-old boy who have no started to speech and has not bladder and bowel control. Facial appearance is normal. His weight is 12,5 Kg (centile <5), height is 102 cm (centile <5), and cranial circumference 48 cm (centile <5). Tubular renal acidosis and gastroesophageal reflux disease has been documented. Cerebral computed axial tomography imaging (TAC) did not reveal any alteration. RESULTS: Oligonucleotide array-CGH was performed using the Agilent Human Genome CGH microarray 44K (Agilent Technologies, Santa Clara, CA, USA) and revealed a 7.3Mb interstitial deletion of chromosome region 2q24.1q24.2 encompassing 30 genes, which was absent in parents. DISCUSSION: Only one of the three patients has almost the same interstitial deletion, and our patient share clinically with the other cases the hypotonia and the developmental delay/mental retardation. Palumbo O et al, suggested 5 candidate genes, however only 3 of them (SLC4A10, TBR1, KCNH7) were present in all patients including our case. We considered that these genes have an important role in the brain development and the haploinsufficiency of them could be related to the developmental delay in all patients. Finally, in conclusion we agree with Palumbo O et al that deletions of chromosome region 2q24.1q24.2 could be associated to a specific phenotype. REFERENCES: 1) Palumbo O, et al. SNP arrays provide incremental, clinically significant information for patients undergoing chromosome microarray testing. *V. Aggarwal[1], O. Nahum[1], B. Marmol[1], K. Anayane-Yeboa[2], B. Levy[1]*. 1) Pathology and Cell Biology, Columbia University, New York, NY; 2) Pediatrics, Columbia University, New York, NY.

Chromosome microarray analysis is currently recommended as first tier testing in evaluation of children with developmental disability, autism or multiple congenital abnormalities. Most of the literature supporting this is experience with array comparative genomic hybridization (aCGH) platforms. We describe our experience using the Affymetrix SNP arrays for 150 patients referred for the same reasons mentioned above. An abnormal result was identified in 20% of the patients. Strikingly, most of the abnormalities detected are clinically significant copy neutral changes. These changes can be identified with the help of the allele tracks plotted using the SNP probes on the array. Copy neutral changes identified include isodisomy for entire chromosome 7 in a patient with clinical history and findings suggestive of Russell- Silver Syndrome as well as mosaic segmental isodisomy for the short arm of chromosome 11 in a pediatric patient with hepatoblastoma. Another copy neutral change detected is identity by descent (IBD). Regions of long contiguous stretches of homozygosity (LCSH) identified in such patients can be used to delineate genes for identification of causative mutations. As an example, to identify causative mutations in a patient with deafness, we are currently sequencing CDH23 gene which was narrowed down by LCSH regions present as a result of consanguinity. We thus demonstrate the use of SNP arrays in providing incremental clinically significant information in our patients. Based on our results, we emphasize the importance of a SNP microarray analysis in pediatric patients and underscore its utility in the clinical setting.

978T

Non-mosaic duplication of chromosome 6p in a child, inherited from his mother with a mosaic unbalanced der(14)t(6;14)(6pter→6p22.3::14p13→14qter). *S.M. Bain[1], J.K. Nicholl[1], W. Waters[1], A.H. Attwood[1], J. Samuel[1], T.A. Hocking[1], S.G. Brown[1], E.A. Haan[2], S. Yu[1]*. 1) Cytogenetics, SA Pathology, Women's & Children's Hospital, North Adelaide, South Australia, Australia; 2) South Australian Clinical Genetics Service, SA Pathology, Women's & Children's Hospital, North Adelaide, South Australia, Australia.

A female patient was referred at 10 weeks of pregnancy. Her clinical features included mild intellectual disability, short stature, abnormalities of chest and finger shape and past history of ventricular septal defect. Chromosome analysis of venous blood showed a mosaic karyotype, 46,XX, add(14)(p12)[9]/46,XX[111]. Subtelomere MLPA and locus specific FISH failed to identify the origin of the additional euchromatin due to the low level of mosaicism. Prenatal diagnosis was recommended but was declined. The baby had normal chromosomes at birth. The mother's next child had cytogenetic testing soon after birth. He was born at 33 weeks gestation with weight and length on the 10th centile, dysmorphic facial features and minor hypospadias and had necrotising enterocolitis in the neonatal period. Both array CGH and routine cytogenetics were initiated. Cytogenetic studies showed a non-mosaic karyotype 46,XY, add(14)(p12)mat and array CGH documented a terminal 15.9 Mb gain of 6p22.3-p25.3. The add(14) could now be described as der(14)t(6;14)(6pter→6p22.3::14p13→14qter) mat. Once the origin of the additional euchromatin on 14p had been identified, two different microarray platforms were used to assess the mosaicism that had been detected in the mother by cytogenetic methods (7.5% mosaicism). A BlueGnome oligo ISCA (4080-5) 8×60K array using BlueFuse software and an Illumina HumanCytoSNP-12 BeadChip using KaryoStudio software were used to analyse the mother's original DNA sample. Both platforms failed to call the low level mosaicism identified by chromosome analysis. Array CGH has become the standard approach in our laboratory for the investigation of intellectual disability, autism, dysmorphic features and malformations and would have detected the chromosome abnormality in the affected boy. It would not have detected the mother's mosaicism and her clinical features would have gone unexplained. Only empiric risk counselling could have been offered prior to her first pregnancy and an opportunity to prevent the birth of her more severely affected son would have been missed. Nonetheless, array CGH will remain the first line investigation in spite of its well known limits for detection of mosaicism. As in other situations, the clinician needs to consider other lines of investigation when faced with a patient with clinical features suggestive of a chromosome abnormality.

Diagnostic array analysis and the necessity of high quality SNP information. *R. Pfundt, J. Hehir-Kwa, N. Leijsten, S. van Gessel, M. Wunderink, T. Machielsen, R. van Beek, M. Banning, M. Rosario, N. de Leeuw.* Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

Genetic centres worldwide, have adopted the microarray technology as the replacement of routine chromosome analysis by karyotyping, for the detection of genomic copy number variation (CNV). In our genome diagnostics laboratory, array analysis was implemented in 2003, initially using "homemade" BAC arrays, that were replaced by commercially available SNP arrays in 2007 (Affymetrix 250K NspI SNP arrays). To date over 9000 samples have been analysed in our diagnostic array facility. SNP based microarrays not only provide reliable data for CNV analysis, but also generate a genotyping profile for every individual that is hybridized. Here we present our diagnostic workflow in which we have optimized the use of this genotype information to both enhance the quality assurance of this diagnostic test and to increase the diagnostic yield of the array analysis. For the quality assurance of the array test, genotyping data of patient and parental samples is used to check sample consistency in patient-parent duo and/or trio combinations. By doing so, we can check for sample mix-ups, potential non-paternity and determine the parental origin of de novo CNVs. In addition to this we have increased our diagnostic yield with >1 % by analysing the genotyping data for homozygous stretches that has led to the identification of >25 cases of uniparental disomy (UPD), and has pinpointed the location of pathogenic mutations in disease genes that were located in stretches of homozygosity identified in the array test. In 2011 we switched to the CytoscanHD array of Affymetrix that harbours over 2.6 million array probes of which ~750,000 generate high quality SNP calls that can be used to calculate allele ratios. This high quality SNP data has led to a further increase in diagnostic yield by revealing not only stretches of homozygosity but also more subtle allelic imbalances caused by e.g. mitotic recombination leading to stretches of mosaic UPD and (low level) mosaic CNVs. We conclude that high quality and high resolution genotyping information from SNP based array platforms is essential for a practical diagnostic array workflow that maximises the diagnostic yield of a single array test.

Copy-number variation and UPD(16) mosaicism in a patient with apple peel intestinal atresia, ocular anomalies, microcephaly and bone-marrow failure. *F.A.T. de Vries[1], Y. van Bever[1], I.M. Appel[2], H. Kart[1], L.J.C.M. van Zutven[1], H.B. Beverloo[1].* 1) Clinical Genetics, Erasmus Medical Centre, Rotterdam, Netherlands; 2) Pediatrics Div. Oncology/Hematology, Erasmus Medical Centre- Sophia Children's Hospital, Rotterdam, Netherlands.

We report a 6-year-old female patient born from healthy, non-consanguineous parents. Amniocentesis and cytogenetic studies following ultrasound detection of a double bubble showed a 46,XX karyotype. The proband was born at 34+3 weeks of gestation. Postpartum she had a large hematoma at the left occipito-temporal region, probably due to forceps assisted extraction. The double bubble was caused by apple peel jejunal atresia, for which she had surgery. There was a slight neonatal thrombopenia explained by the hematoma and surgery. The patient has mild facial dysmorphisms, microcephaly, brittle hair, microphthalmia and major visual impairment due to corneal clouding. These ocular anomalies are associated with Axenfeld-Rieger malformation/Peters anomaly. Motor and mental development at 2 years were estimated to be within normal limits. Analysis of *PITX2, FOXC1, PAX6* and *MYCN* genes, implicated in Axenfeld-Rieger/Peters anomaly showed no mutations. Additional MLPA (MRC-Holland) analysis of these genes and all subtelomeric regions showed no deletion/duplication. (van Bever et al., 2008) At the age of ~6 years, the child developed pancytopenia and mild aplastic anemia. Hemato-cytologic or immunophenotypic bone-marrow examinations exposed no signs of hematologic malignancies or a myelodysplastic syndrome. Cytogenetic analysis of the bone-marrow showed a normal female karyotype. Fanconi anemia was excluded in a chromosome breakage test on both blood and fibroblasts. Because of the presence of congenital abnormalities, SNP-array analysis (Illumina HumanCytoSNP-12) was performed and identified 3 maternally inherited copy-number variations: a 2,5 Mb loss in chromosome 2q13 (published as a risk factor for developmental delay and dysmorphism), an 0.2 Mb loss in 5q21.1 (unknown clinical significance) and a 1.6 Mb gain in Xp22.31 (published as causative of intellectual disability or a benign variant). Moreover an aberrant B-allele frequency (BAF) pattern was observed for chromosome 16q. LogR results of this region were normal and a (mosaic) deletion/duplication was excluded by FISH. The aberrant BAF suggested mosaic uniparental disomy for 16q. Further investigations showed that this partial upd(16) resulted from mosaic loss of the maternal allele. Since the upd(16q)pat was not observed in DNA sampled in the first year of life, this acquired upd may be linked to the bone-marrow failure. This is currently under investigation.

Tumor suppression in *Apc*$^{Min/+}$ mice by the prostaglandin D_2 receptor PTGDR. *H. Lin[1], A. Kwong[1], O. Lee[1], V. Buslon[2], S. French[2], E. Salido[3].* 1) Division of Medical Genetics, Harbor-UCLA Medical Center, Torrance, CA; 2) Department of Pathology, Harbor-UCLA Medical Center, Torrance, CA; 3) CIBERER, Hospital Universitario Canarias, La Laguna, Tenerife, Spain.

Prostaglandin D_2 may prevent intestinal tumors, as shown by more adenomas in *Apc*$^{Min/+}$ mice that lack hematopoietic prostaglandin D synthase (HPGDS) and fewer tumors in *Apc*$^{Min/+}$ mice that over-express this enzyme (Park et al. Cancer Res 2007; 67: 881-9). Knockout of PGD_2 receptor PTGDR also led to more tumors, in our earlier work. Here, we expand data on *Ptgdr*, with *Apc*$^{Min/+}$ mice examined at 6 weeks (50 mice, including 13 controls) and 14 weeks (64 mice, including 22 controls). Intestines were removed, opened, fixed, coiled into Swiss rolls, embedded, sectioned, and mounted on slides. To score adenomas, we used 10 Swiss roll sections spaced 250 Δm apart. Small tumors were those seen on only 1 section, whereas large tumors were those seen on multiple sections. Heterozygous *Ptgdr* knockouts did not increase the median number of total tumors in *Apc*$^{Min/+}$ mice at 14 weeks (84 tumors versus 71; P = 0.16). However, the median number of large tumors was higher with heterozygous *Ptgdr* knockouts (33 versus 24; P = 0.023). Homozygous *Ptgdr* knockouts raised median numbers of total tumors (100 versus 71; P = 0.0060) and large tumors (38 versus 24; P = 0.0040) at 14 weeks. At 6 weeks, median numbers of total and small tumors were higher for both heterozygous and homozygous *Ptgdr* knockout mice (e.g., for homozygous knockouts versus controls — 65 versus 43 for total tumors, P = 0.0031; 58 versus 37 for small tumors, P = 0.0025). Numbers of colon tumors also increased (0–6 for homozygous knockouts versus 0–1 for controls; P = 0.015). We examined younger *Apc*$^{Min/+}$ mice (one mouse at 1 week; 6 mice at 3 weeks), for data on when tumors appear. We saw tumors by 3 weeks. Roughly 60% of tumors that will occur over 14 weeks arise during the first 6 weeks — when tumors form 1.5-fold faster in *Ptgdr* knockout mice, compared to controls. After 6 weeks, tumors occur at similar rates in knockout and control mice, perhaps allowing controls to "catch up."

Mice are born without intestinal crypts, which form by rapid expansion of the crypt stem cell pool, followed by a switch to production of non-stem cells (Itzkovitz et al. Cell 2012; 148: 608-19). More tumors in *Ptgdr* knockout mice in the first 6 weeks of life support an interpretation that PTGDR slows proliferation of crypt stem cells. PTGDR agonists may be an approach for preventing tumors in familial adenomatous polyposis.

982T

Effects of Western-style diet and genetic predisposition on the protein expression and cancer susceptibility in normal colonic mucosa. *S. Lowndes[1], D. Dermadi Bebek[1], M. Pussila[1], N. Reyhani[2], L. Sarantaus[1], M. Nyström[1].* 1) Department of Biosciences, University of Helsinki, Finland; 2) Aalto University, School of Science, Helsinki, Finland.

Lifestyle and diet have a major effect on the development of colorectal cancer (CRC). Dietary habits of Western populations in particular are recognized as a risk factor for CRC. Most probably unhealthy features in Western diet (WD) induce expression changes in key regulatory pathways that affect normal metabolic processes in colonic mucosa. Since cancer development needs accumulation of several genomic changes, the individuals, who already have the inherited susceptibility, may be extremely sensitive for diet effects. Indeed, disease phenotypes such as age of onset and tumor spectrum vary considerably between mutation carriers even in a same CRC family suggesting implication of lifestyle factors on risk accumulation. Here, by using a mouse model for intestinal cancer we studied whether and how WD and a genetic predisposition may separately and in interaction change the protein expression and thus increase a cancer risk in normal colonic mucosa.

Mlh1$^{+/-}$ mice were used as a model for Lynch syndrome (LS), the most common CRC syndrome, and *Mlh1*$^{+/+}$ wild type littermates were used as healthy controls. After a 12 months feeding experiment the effects of WD compared to effects of a control diet (AIN-93G) in different mouse genotypes were studied using 2D-DIGE proteomics and differently expressed proteins were identified by using mass spectrometry. Our results suggest that individuals with genetic predisposition are more susceptible to diet effects and that together they may increase the risk for CRC. Altogether 394 significant protein expression changes were detected in *Mlh1*$^{+/-}$ WD group when compared to control diet group. In *Mlh1*$^{+/-}$ mice 19 out of the 394 changes were related to the effect of diet or combination of diet and genotype. Identification of these proteins revealed substantial changes in energy metabolism linked to fatty acid catabolism, glycolysis, pentose phosphate pathway, TCA cycle and oxidative phosphorylation. Furthermore, an increased number of neoplasia/hyperplasia together with signs of inflammation, deregulation of apoptosis and higher rate of proliferation were detected in the normal colonic mucosa of *Mlh1*$^{+/-}$ mice fed with WD. Moreover, the results indicate that colonic mucosa cells exposed to WD are under higher proliferative state than cells exposed to healthy control diet, suggesting the diet itself to be a considerable risk factor.

983F

The Jackson Laboratory Rare and Orphan Disease Center. *S. Rockwood, C. Lutz, K. Fancher, A. Picard, M. Sasner, L. Reinholdt, S. Murray, D. Bergstrom, J. Morgan, L. Donahue, The GRS Team.* Genetic Resource Science, The Jackson Laboratory, Bar Harbor, ME.

In the United States, diseases are categorized as rare or orphan if the number of afflicted patients numbers 200,000 or less.About 7000 such diseases have been described, with another ~250 described each year.Historically, this subset of diseases has been associated with significant unmet medical need.Government incentives (direct grants, tax credits, market exclusivity) put in place over the last several decades have contributed to a growing interest in the orphan disease drug market. Importantly, there is growing recognition by pharmaceutical and biotech companies that orphan drug development is an economically viable activity.To further facilitate these positive developments, The Jackson Laboratory Rare and Orphan Disease Center was recently launched.The Center focuses on partnering with scientists, foundations, and other experts around the world to enable the development, standardization, optimization, and rapid distribution of preclinical mouse models for drug discovery. Being able to offer the resources and expertise to enable the design, construction and management of preclinical mouse models of disease, in combination with a global delivery system, expertise in technical transfer issues and genetic quality control, uniquely positions the Center to put new tools into the hands of scientists and thereby accelerate drug discovery.Complementing the Center's model development pipeline is one of the most comprehensive mouse repositories available, consisting of a growing collection of over 6000 distinct mouse lines.The wide array of easily accessible, well-characterized tool and mutant allele strains serves as an unmatched companion resource for the building of novel disease models with applications in translational research. Contributing your disease model enables researchers across the globe to have greater access to tools for drug efficacy testing and discovery.If you would like to donate your mouse strain to the Jackson Laboratory Mouse Repository, please see: **www.jax.org/donate-a-mouse**. Ongoing rare disease research projects involve partnerships with foundations, companies and principle investigators.Our emphasis is on the development, standardization and distribution of validated preclinical mouse models for drug discovery.We are interested in partnering with additional groups across all therapeutic areas of research. To learn more about The Jackson Laboratory Rare and Orphan Disease Center, please visit our website at **www.jax.org/rare.**.

984W

Genetic differences in transcript responses to low-dose ionizing radiation identify tissue functions associated with breast cancer susceptibility. *A.J. Wyrobek, F. Marchetti, S. Bhatnagar, N. Duru, J. Han, Z. Hu, J-H. Mao, J.W. Gray, A.M. Snijders.* Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA.

High dose ionizing radiation (IR) is a well-known risk factor for breast cancer but the health effects after low-dose (LD, <10cGy) exposures remain highly uncertain. We explored a systems approach that compared LD-induced chromosome damage and transcriptional responses in strains of mice with genetic differences in their sensitivity to radiation-induced mammary cancer (BALB/c and C57BL/6) for the purpose of identifying mechanisms of mammary cancer susceptibility. Unirradiated mammary and blood tissues of these strains differed significantly in baseline expressions of DNA repair, tumor suppressor, and stress response genes. LD exposures of 7.5cGy (weekly for 4 weeks) did not induce detectable genomic instability in either strain. However, the mammary glands of the sensitive strain showed early transcriptional responses involving: (a) diminished immune response, (b) increased cellular stress, (c) altered TGFβ-signaling, and (d) inappropriate expression of developmental genes. One month after LD exposure, the two strains showed opposing responses in transcriptional signatures linked to proliferation, senescence, and microenvironment functions. We also discovered a pre-exposure expression signature that is predictive for poor survival among human cancer patients (p=0.0001), and a post-LD-exposure signature that is predictive for patient survival (p<0.0001) with concordant expression in the LD-exposed sensitive strain, in human DCIS and in human breast tumors. Our findings support the hypothesis that mechanisms that control susceptibility to low-dose radiation induced mammary cancer in mice are similar to those that determine poor survival in breast cancer patients. We observed non-linearity of the LD responses providing molecular evidence against the LNT risk model and obtained new evidence that LD responses are strongly influenced by genotype. Our findings suggest that the biological assumptions concerning the mechanisms by which LD radiation is translated into breast cancer risk should be reexamined and suggest a new strategy to identify genetic features that predispose or protect individuals from LD-induced breast cancer.[Supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02–05CH11231 and by LBNL-LDRD].

Association of the *HLA-G* gene polymorphisms with cervical cancer risk. *T. Chang[1], Y. Yang[2,4], Y. Lee[1,3,5], T. Chen[2], S. Chang[1], W. Lin[1].* 1) Med Res Dept, Mackay Memorial Hosp, New Taipei, Taiwan; 2) Gynecology and Obstetrics, Mackay Memorial Hosp, Taipei, Taiwan; 3) Pediatrics, Mackay Memorial Hosp, Taipei, Taiwan; 4) Gynecology and Obstetrics, Taipei Medical University, Taipei, Taiwan; 5) Pediatrics, Taipei Medical University, Taipei, Taiwan.

Cervical cancer is a major cause of cancer-related death in women worldwide, in spite of extensive efforts dedicated to its preventive or treatment managements. While cervical infection with high-risk types of human papillomaviruses (HPVs) is critical to cervical carcinogenesis, infection alone is not sufficient to cause cervical cancer. It is now recognized that host immunogenetic background plays an important role in the control of HPV infection and the development of cervical cancer. HLA-G is a nonclassical HLA class I molecule with multiple immunoregulatory properties. It has been shown to inhibit the cytotoxic activity of both natural killer and cytotoxic T cells. The aim of this study is to investigate the association between *HLA-G* gene single nucleotide polymorphisms (SNPs) and the risk of cervical cancer in the Taiwanese women. We genotyped 2 putatively functional SNPs, an insertion/deletion polymorphism of 14bp (rs1704) and a missense polymorphism (rs12722477 *C/A*), in 342 cervical squamous cell carcinoma (CSCC) patients and 344 age/sex matched healthy controls by using PCR and the Pre-Developed TaqMan Allelic Discrimination Assay. The presence and genotypes of HPV in CSCC patients were determined by PCR. Our findings show significant increases of rs12722477 *C/C* genotype and *C* allele frequencies among patients with CSCC as compared with controls (OR = 1.65, 95% CI 1.13–2.41, $P = 0.02$, $P_c = 0.04$; OR = 1.54, 95% CI 1.14–2.06, $P = 0.004$, $P_c = 0.008$, respectively). In addition, significant associations of *C/C* genotype and *C* allele frequencies were observed between HPV-16 positive CSCC patients and controls (OR = 2.29, 95% CI 1.14–3.66, $P = 4.0 \times 10^{-4}$, $P_c = 8.0 \times 10^{-4}$; OR = 2.18, 95% CI 1.48–3.22, $P = 6.62 \times 10^{-5}$, $P_c = 1.32 \times 10^{-4}$, respectively). Haplotype analysis revealed the distribution of haplotype Del-C was significantly increased in women with CSCC and HPV-16 positive CSCC (OR = 1.51, 95% CI 1.15–1.98, $P = 0.003$, $P_c = 0.012$; OR = 1.60, 95% CI 1.16–2.21, $P = 0.004$, $P_c = 0.016$, respectively). In conclusion, our results suggest that rs12722477 *C/A* polymorphism of the *HLA-G* gene conferred susceptibility to CSCC in the Taiwanese population.

986F

Association of the HOXB13 G84E Variant with Familial, Sporadic, and Aggressive Prostate Cancer: the Mayo Clinic Experience. *M.S. DeRycke[1], L.S. Tillmans[2], S.K. McDonnell[3], S.M. Riska[3], J. Xu[4], Y.W. Asmann[3], D.J. Schaid[3], S.N. Thibodeau[2], International Consortium for Prostate Cancer Genetics.* 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Department of Laboratory Medicine & Pathology, Mayo Clinic, Rochester, MN; 3) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN, USA; 4) Center for Cancer Genomics, Wake Forest School of Medicine, Winston-Salem, NC.

Recently a rare, germline mutation in HOXB13 (G84E) was reported to be associated with increased risk of familial prostate cancer (PC). Increased risk was highest among men diagnosed at a young age and with a strong family history of disease. In this study, we genotyped men with familial (n=467), sporadic (n=439) and aggressive (n=196) PC, and in population controls (n=494) for the G84E variant to determine if this variant is also associated with increased risk of PC in sporadic and aggressive PC, as well as familial PC. Genotyping was performed using the MassARRAY iPLEX and genotype frequencies were compared between sporadic or aggressive PC cases versus controls using the Armitage test for trend in proportions. Familial cases were compared to a combined set of 63 unaffected relatives and the population controls (n=557), adjusting for the correlation among related subjects. The Odds Ratio (OR) for all analyses ranges from 2.27–5.17, consistent with the original report for the G84E/HOXB13 association. Although the MAF is small, the G84E variant was present statistically significantly more often in individuals with aggressive disease compared to controls, resulting in an OR of 5.17 (95% CI, 1.28–20.88). A similar magnitude of risk was found for familial PC cases versus control (OR=4.04; 95% CI, 1.39–11.72), yet not as large a risk for sporadic cases versus controls (OR=2.27; 95% CI, 0.56–9.12). These results suggest that the G84E/HOXB13 does have implication for the general population; additional, larger studies will be required to confirm this finding.

The miR-29 family of microRNA genes and let-7i associate with gastric cancer in European populations: Results from the EPIC-EURGAST study. *Y. Espinosa-Parrilla[1], X. Muñoz[2], C. Bonet[2], N. García[2], A. Venceslá[2], E. Riboli[3], C.A. González[2], N. Sala[2] on behalf of the EPIC gastric cancer working group.* 1) Ciencies Experimentals i de la Salut (CEXS-UPF), Institut de Biologia Evolutiva (UPF-CSIC), Barcelona. Spain; 2) Unit of Nutrition, Environment and Cancer, Catalan Institute of Oncology-IDIBELL, Hospitalet de LLobregat, Barcelona. Spain; 3) Department of Epidemiology and Public Health, Imperial College London, London. United Kingdom.

MicroRNAs (miRNAs) are recognized post-transcriptional gene repressors involved in the control of almost every biological process including tumorigenesis. Even though deregulation of miRNA expression has been associated with various human cancers, the contribution of these regulators to the genetic susceptibility to cancer is still unclear. We performed association studies of miRNA genes with gastric cancer (GC) risk in samples from the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort. From 719 human miRNAs (release 13.0, miRBase) we selected 90 miRNAs located in 39 miRNA regions (25 miRNA clusters and 14 isolated miRNAs) that were either involved in various types of cancer or predicted to regulate candidate genes for GC (TargeScan and miRanda predictions). A panel of 156 tagSNPs was designed and genotyped in 365 incident gastric adenocarcinoma cases and 1284 matched controls from a nested case-control study in the EPIC cohort. Regarding the histological type of tumours, 35% were intestinal and 35% diffuse. After quality control analysis and data filtering, association was analyzed by unconditional logistic regression, adjusting for age, sex and country. Six SNPs in a miR-29 cluster region were associated with the risk of diffuse gastric cancer (Best hit: OR=1.72, 95%CI: 1.30–2.28; pvalue= 0.0002) and three SNPs tagging let-7i were associated with increase risk of general gastric cancer (Best hit: OR=1.69, 95%CI: 1.25–2.29; pvalue= 0.0008). Evaluation of target genes for let-7i and miR-29 using the miRanda and TargetScan algorithms revealed that at least 17 and 13 target genes for miR-29 and let-7i, respectively, are involved in cancer: Among these there are *VEGFA* and the DNA methyltransferases *DNMT3A* and *DNMT3B* target genes for miR-29 and *TP53* for let-7i. Interestingly, SNPs in *VEGFA* and in *DNMT3B* showed a significant interaction with miR-29 SNPs. Furthermore, miR-29 has been shown to up-regulate p53 and induce apoptosis in a p53-dependent manner. Sequencing of miR-29 and of let-7i genes did not reveal any causal variant for the association. These results indicate that miR-29 and let-7i are associated with the genetic susceptibility to GC and that this association could be at least partially related to the regulation of p53 and its function as tumour suppressor. Supported by “LaCaixa” (BM06-130-0); Spanish Ministry of Health (PI070130 and PI081420) and Science (BFU2010-18477); European Commission FP7 (PIOF-GA-2009-236836).

3' UTR Variation in *PTEN* and *PTENP1*: implications for microRNA binding. *B.G. Hernandez, C. LaViolette, T. Begay, J.A. Wilder.* Biological Sciences, Northern Arizona University, Flagstaff, AZ.

PTEN is a tumor suppressor gene that is associated with prostate cancer when downregulated. Dysregulation of the gene can be caused by several mechanisms, including microRNA interactions with the mature transcript. *PTENP1* is a processed pseudogene of *PTEN* that shares a similar 3' untranslated region (UTR). Due to this similarity *PTENP1* acts as a sink for microRNAS that may otherwise bind to and downregulate *PTEN*. In this project, we aim to characterize single nucleotide polymorphisms (SNPs) in the 3' UTRs of both *PTEN* and *PTENP1* and to assess *in silico* the effect of these SNPs on microRNA binding. We surveyed the 3' UTRs of *PTEN* and *PTENP1* in 41 Native American genomic DNA samples and publicly available polymorphism data. Several SNP loci are predicted to affect microRNA binding at both *PTEN* and *PTENP1*. Variability at these sites has the potential to affect *PTEN* expression, both directly and indirectly, and therefore may affect cancer progression.

Replacement therapy for lung adenocarcinoma risk in never-smoking women. *C. Hsiao[1], K. Chen[2], G. Chang[3], Y. Tsai[4], W. Su[5], Y. Chen[6], M. Huang[7], C. Hsiung[1], C. Chen[8], P. Yang[2], GELAC Study Group.* 1) Biostatistics & Bioinformatics, Natl Health Research Inst, Miaoli County, Taiwan; 2) Division of Pulmonary Medicine, Department of Internal Medicine, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan; 3) Division of Chest Medicine, Department of Internal Medicine, Taichung Veterans General Hospital, Taichung; Department of Medicine, School of Medicine, National Yang-Ming University, Taipei, Taiwan; 4) Division of Pulmonary and Critical Care Medicine, Department of Internal Medicine, Chang Gung Memorial Hospital, Taipei, Taiwan; 5) Division of Hematology/Oncology, Department of Internal Medicine, National Cheng Kung University, Tainan, Taiwan; 6) Chest Department, Taipei Veterans General Hospital; School of Medicine, National Yang-Ming University, Taipei, Taiwan; 7) Department of Internal Medicine, Kaohsiung Medical University Hospital; School of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 8) Genomics Research Center, Academia Sinica; and Graduate Institute of Epidemiology, College of Public Health, National Taiwan University, Taipei, Taiwan.

EGFR single nucleotide polymorphisms(SNPs) and hormone replacement therapy (HRT) have been demonstrated to be risk factors for lung carcinogenesis. This study is to investigate the interactive effect of EGFR SNPs and HRT on the lung adenocarcinoma risk in never-smoking women. This case-control study included 532 never-smoking female lung adenocarcinoma patients and 532 controls. All the subjects are Taiwanese. The EGFR SNPs were retrieved from a genome-wide association study. The associations of EGFR SNPs with the lung adenocarcinoma risk were estimated by multivariate-adjusted logistic regression. The Haploview program was used to select tagged EGFR SNPs interacted with HRT and to construct haplotype blocks. The Benjamini and Hochberg method was used to reduce the multiple testing effect. Among 84 EGFR SNPs retrieved, 11 tagging SNPs showed a potentially interaction with HRT use and lung adenocarcinoma risk. Most SNPs were located near the EGFR tyrosine kinase domain. Eight of the tagged SNPs were in two haplotype blocks, block 1 and 2. The interactions for HRT use and numbers of high-risk EGFR SNPs on lung adenocarcinoma risk in block 1 and 2 are significant (p for interaction =0.0002, and 0.0032 respectively). A trend of increased lung adenocarcinoma risk was found in subjects with HRT harboring an increasing number of at-risk EGFR SNP genotypes in block 1 and 2 (p=0.0008 and 0.0023 respectively). HRT use may modify the association of EGFR SNPs with lung adenocarcinoma risk. The EGFR SNPs have a cumulative effect on increasing the lung adenocarcinoma risk in never-smoking women with HRT use.

Application of molecular diagnostic techniques on the study done on phosphatase and tensin homologue deleted on chromosome 10 (PTEN). *R. Issa.* imolecular diagnostics, institute of genetic engineering, cairo, Egypt.

Background:PTEN is one of the tumor suppressor genes involved in secondary cancer progression prevention.In egypt,prostate adenocarcinoma,recorded the highest incidence and mortality among cancers of the genito-urinary system. Aim:The aim of this stuyis to detect the presence of mutations in the tumor suppressor PTEN gene in begnin prostate hyperplasia patients,and prostate cancer patients,and corrolate between PTEN and the pathogenesis of both patient groups. Patients and methods:Twenty begnin and malignant patients were recruited,as well as seven apparently normal subjects taken as control.Whole blood samples were collected from diagnosed patients using TRUS-biopsies.Control subjects were free of chronic disorders and tumors,yet some had family history of begin and malignant tumors,yet some had family history of begnin and malignant tumors.Studied group had age range between 54 and 77 years,and average PSA level of 2,3,19.9 and 35 ng/ml for control,BPH and PCa groups respectively.PCR were performed using intronic primers,specific for exons 5 and 7,to map possible mutations(for positive PCR reactions sequensing done using forward and reverse primers) Results:Analyzing mutations mapped for the selected studied groups proved the likeliness of correlating between both BPH and PCa patients.PTEN association in PCa patients was corrolated with their pathology finfings and clinical picture.One patient out of ten showed complete deletion and the highest Gleason score(9)and worst clinical picture,two out of ten showed partial deletion, (one losing the phosphatase function and the other losing the C2 domain of the direct protein binding).The remaining results showed the high occuring genotypes.All 5 potentially significant mutations (g.74482dupA,g,74818dupG,g.74845dupC and g.99506C G,g.99582dupA) shared the presence of the highly occurring genotypes except g.99506cG of exon 7 begnin patient(7b6) Conclusion:Mutations mapped have revealed some potentially significant mutant variants of PTEN pointing towards its role in both BPH and PCa pathology and the possibility of a bridging correlation between both begnin and malignant proatate tumors,.

Adami[1,11], T.B. Haugen[2], T. Grotmol[3], F. Wiklund[1].* 1) Department of Medical Epidemiology and Biostatistics, Karolinska institutet, Stockholm, Sweden; 2) Faculty of Health Sciences, Oslo and Akershus University College of Applied Sciences, Oslo, Norway; 3) Department of Etiologic Research, Cancer Registry of Norway, Oslo, Norway; 4) Translational Cancer Research Group, Institute of Clinical Medicine, University of Tromsø and Department of Oncology, University Hospital North Norway, Tromsø, Norway; 5) Section of Oncology, Institute of Medicine, University of Bergen and Department of Oncology, Haukeland University Hospital, Bergen, Norway; 6) Department of Clinical Cancer Research, The Norwegian Radium Hospital, Oslo University Hospital, Oslo, Norway; 7) Faculty of Medicine, The Norwegian Radium Hospital, University of Oslo, Oslo, Norway; 8) Department of Oncology, Ålesund Hospital, Helse Sunnmøre HF, Ålesund, Norway; 9) Cancer Centre, Ullevål University Hospital, Oslo, Norway; 10) Department of Oncology, St Olavs University Hospital, Trondheim, Norway; 11) Department of Epidemiology, Harvard School of Public Health, Boston, MA, USA.

Purpose: Testicular germ cell tumors (TGCT) are rare, but the most common malignancy in young men. Genome-wide association studies (GWAS) have identified single nucleotide polymorphisms (SNPs) associated with TGCT risk in the genes *ATF7IP*, *BAK1*, *DMRT1*, *KITLG*, *SPRY4*, and *TERT*. The present study aimed to validate and characterize these associations, and to assess effect modification by parental sex and histological subtype.

Methods: We invited TGCT cases and parents identified from Swedish and Norwegian national registries to the study. 2162 cases consented, distributed as 1004 case-parent triads, 440 dyads, and 718 singletons. 1135 TGCTs were seminomas, and 935 non-seminomas or mixed tumors. 118 SNPs tagging common variation in the genes were genotyped in saliva-derived DNA on Sequenom MassARRAY iPLEX Gold chemistry. 3922 unrelated controls were included from TWINGENE, a population-based sample of Swedish twins. TWINGENE DNA was blood-derived, and genotyped on the Illumina OmniExpress platform. Additional SNPs were imputed using BEAGLE software and reference haplotypes from the 1000 genomes project. SNP-TGCT association was tested in the combined sample using UNPHASED software. Forward stepwise regression within each gene was applied to find independent association signals. Effect modification was tested for the strongest associations in each gene.

Results: 831 triads, 474 dyads, 712 singletons, 3922 controls, and 98 SNPs passed sample and genotyping quality control. After imputation 852 SNPs were analyzed. All genes had significant associations with TGCT (lowest unadjusted P: *ATF7IP* 6.2e-06; *BAK1* 2.1e-10; *DMRT1* 6.7e-25; *KITLG* 2.1e-48; *SPRY4* 1.4e-29; *TERT* 1.8e-18). Most genes had more than one independent association, and one signal in *TERT* has not been reported previously to our knowledge. A significant parent-of-origin effect was observed for rs10463352 in *SPRY4* (interaction P=0.0008, OR_{mat}=1.56, OR_{pat}=1.03). No significant effect modification by histological subtype was found.

Conclusions: We validated previous associations, and may have found a new, independent association in *TERT*. Assessment of parent-of-origin effects indicated a *SPRY4* SNP as only associated with TGCT when inherited maternally.

Genome-wide germline DNA autosomal copy number variation analysis in Finnish *BRCA1/2*-founder mutation-negative hereditary breast and/or ovarian cancer individuals. *KM. Kuusisto[1], O. Akinrinade[1], M. Vihinen[1,2], S-L. Sallinen[3], J. Schleutker[1,4]*. 1) Institute of Biomedical Technology / BioMediTech, University of Tampere and Fimlab Laboratories, Tampere, Finland; 2) Department of Experimental Medical Science, University of Lund, Lund, Sweden; 3) Department of Pediatrics, Genetic Outpatient Clinic, Tampere University Hospital, Tampere, Finland; 4) Department of Medical Biochemistry and Genetics, University of Turku, Turku, Finland.

Introduction: Genetic factors account for 5–10% of all breast cancer (BrCa) cases. Several BrCa susceptibility genes have been identified and the two most important ones are *BRCA1* and *BRCA2* being responsible for approximately 20% of hereditary breast and/or ovarian cancer (HBOC) cases in Finland. However, genetic factors underlying majority of the HBOC cases remain unexplained and this makes genetic counseling challenging. Recently, copy number variations (CNVs) have been discovered to play an important role in diseases. Germline CNVs have been implicated to predispose many types of cancers including neuroblastoma, colorectal, and prostate. We aimed to investigate germline DNA autosomal CNVs in HBOC individuals in the Finnish population and to get new clues to genetic counceling. **Methods:** Whole genome SNP genotyping analysis by Illumina HumanCytoSNP-12 BeadChip was performed for 81 well-characterized, hereditary breast and/or ovarian cancer *BRCA1/2*-founder mutation-negative individuals and 35 healthy controls in a Finnish population to identify breast/ovarian cancer-associated CNV regions. Four algorithms, PennCNV, cnvPartition, QuantiSNP, and CNstream, were applied for the analysis. CNV carrier frequencies between 81 HBOC individuals and 35 controls were compared by using the Fisher's exact/chi-square test. Gene Ontology (GO) analysis, the Database of Genetic Variants search and the Online Mendelian Inheritance in Man Database search were performed to analyze the importance of the identified CNV affected genes. Four CNV regions were further validated by quantitative RT-PCR. **Results:** A total number of identified CNV regions in HBOC individuals and controls (n=116) ranged from 211 to 404 by different algorithms and the majority of the CNV regions sized from 10 to 50 kb. The most frequent CNV identified by four algorithms was a 14.6 kb loss at 3p11.1 observed in 9.9% (8/81) of the HBOC individuals but not in controls. Other frequent CNVs observed in HBOC individual included losses at 1q21.1, 2q35, and 5q15, and gain at 19q13.41. Several CNV affected genes have been previously associated with human disorders. **Conclusions:** This is the first study to analyze germline DNA autosomal CNVs in HBOC individuals in Finland. Our study provides new information of potential CNV regions that could be associated with the increased risk of HBOC susceptibility in Finland but the current results warrant validation in larger study group.

993W

***Mediator complex subunit 12* (*MED12*) mutations in uterine leiomyosarcomas.** *M.M. McGuire[1], M. Jones[2], G. Trucco[2], U. Surti[1], R.P. Edwards[1], A. Rajkovic[1]*. 1) Department of Obstetrics, Gynecology and Reproductive Sciences, Magee-Womens Research Institute, Pittsburgh, PA; 2) Department of Pathology, Magee-Womens Hospital of UPMC, Pittsburgh, PA.

Uterine leiomyosarcomas (ULMS) arise from the smooth muscle cells of the uterine wall, the myometrium. These rare malignant tumors are often solitary and large (>10cm, diameter), and their behavior is highly variable. The annual incidence rate of ULMS is less than 1% worldwide, and they primarily occur in women 40 to 60 years of age around the time of menopause. The etiology of ULMS is largely unclear, and their rare nature has limited research on identifying possible risk factors. It is common for benign uterine leiomyomas (fibroids), which also arise from uterine smooth muscle tissue, and ULMS to be present in the same uterus, though it is debated whether uterine leiomyomas can transition into ULMS. Recent histopathologic data suggests that a subset of ULMS may derive from uterine leiomyomas. *Mediator complex subunit 12* (*MED12*), an X-linked gene which encodes a protein involved in transcriptional regulation of RNA polymerase II-dependent genes, was identified as being strongly associated with uterine leiomyoma development. Exon 2 of *MED12* harbors damaging somatic variants in 60–70% of uterine leiomyomas. Therefore, we examined exon 2 of *MED12* in genomic DNAs from 60 FFPE ULMS samples. A gynecologic pathologist confirmed the absence of contamination of ULMS samples with benign leiomyoma tissue. In this sample set, 6.7% (4/60) of ULMS samples harbored variants in exon 2 of *MED12*, and all variants were single heterozygous missense mutations confined to codon 44. These data support that a subset of ULMS harbor *MED12* mutations which are also found in uterine leiomyomas. Our results therefore support the hypothesis that a subset of ULMS may arise from uterine leiomyomas.

994T

Association of breast cancer risk factors and HLA-G gene InDel 14bp polimorphyms in a Brazilian population. *Y.CN. Muniz[1], M. Damiani[1], L.D. Hausmann[1], B.S. Almeida[1], B. Fernandes[2], R.T. Simões[3], A.R. Marrero[1], I.R. Souza[1]*. 1) LAPOGE, Federal University of Santa Catarina, Florianopolis, Santa Catarina, Brazil; 2) HU, Federal University of Santa Catarina, Florianopolis, Santa Catarina, Brazil; 3) Instituto de Ensino e Pesquisa da Santa Casa de Belo Horizonte - IEP/SCBH. Laboratório de Biologia Molecular e Biomarcadores.

Breast cancer is the second most common type of cancer in the world. The HLA-G protein is related to the escape of immuno response and was found at high levels in tumor cells of breast cancer patients. The insertion of the 3'UTR 14bp of HLA-G is related to an increased expression by promoting the development of tumor cells. The aim was to investigate the influence of polymorphism in the manifestation of breast cancer related to risk factors. The DNA was extracted from whole blood, genotyping by PCR carried out, viewed PAGE and stained with silver nitrate. We genotyped 198 patients and 200 controls (matched for age). In the comparison of risk factors were more patients with familial history of disease (22%) and smokers (16%) and lower proportion of patients who became pregnant (8%) when compared with control (13%, 7%, 15%, respectively). The presence of precoce menarche, late menopause and hormonal contraceptive use were similar between the two groups. The insertion frequency was 0.492 and 0.453 in the patient group in the control group, respectively. There was no statistical difference in the comparisons between the polymorphism and disease, as well as considering the risk factors. To clarify the relationship of the 3'UTR of the HLA-G with breast cancer and its risk factors, other markers related to mRNA stability will be further analyzed by the group (Financial support: PNPD CAPES, FAPESC, CNPq).

995F

Fine-mapping of prostate cancer susceptibility locus 11q13.5. *R. Nurminen[1], R. Lehtonen[2], T.L. Tammela[3], T. Wahlfors[1], J. Schleutker[1,4]*. 1) Institute of Biomedical Technology/BioMediTech, University of Tampere and Fimlab Laboratories, Tampere, Finland; 2) Department of Biosciences, University of Helsinki, Helsinki, Finland; 3) Department of Urology, University of Tampere and Tampere University Hospital, Tampere, Finland; 4) Department of Medical Biochemistry and Genetics, University of Turku, Turku, Finland.

Prostate cancer is a complex disease with estimated heritability of 19–40% but so far only few susceptibility genes have been identified. It would be especially important to identify genetic variants that predispose to aggressive disease in order to recognize those men at risk early enough and to develop treatment methods for life-threatening disease outcome. Finnish population is well suited for finding disease associated genetic variants because it is genetically homogeneous.

Chromosomal region 11q13 has been connected with prostate cancer in linkage and genome-wide association studies. Previously we screened *EMSY* at 11q13.5 in a Finnish case-control study in over 3000 samples. A rare, intronic variant IVS6–43A>G was observed to associate with familial disease and aggressive disease outcome in unselected prostate cancer patients. The functionality of the variant is unclear.

The aim of this study was to determine if IVS6–43A>G is in linkage disequilibrium (LD) with another variant(s) at 11q13.5 and to characterize the region further in relation with prostate cancer predisposition. The fine-mapping study included 2128 unselected Finnish prostate cancer patients and 906 controls. A total of 31 tagging single nucleotide polymorphisms (tagSNPs) covering 0.4 Mb at 11q13.5 were genotyped using TaqMan assay, KASPar assay, High Resolution Melt analysis and sequencing. Imputation was conducted with 1000 Genomes and HapMap3 reference panels using IMPUTE v2.2. The association of the imputed SNPs with prostate cancer was tested using SNPTEST v.2 and the association of the tagSNPs using PLINK v1.07. TagSNPs that deviated from Hardy-Weinberg equilibrium in controls were excluded from the analysis prior imputation. Haplotype blocks and LD structure were visualized and the haplotype association was calculated using Haploview v4.2.

The previously identified variant IVS6–43A>G was not observed to be in high LD with any of the tagSNPs or the imputed variants. However, the strongest association with prostate cancer was observed for a tagSNP in close approximation to IVS6–43A>G ($p = 0.0008$). In addition, a haplotype including the tagSNP allele was associated with prostate cancer ($p = 0.005$). The results further support the importance of 11q13.5 in prostate cancer predisposition.

Role of Copy Number Variants in the Nucleotide Excision Repair Pathway Genes and Breast Cancer Risk in Puerto Rican Women. *A. Pacheco Torres[1], J. Matta[2], J. Dutil[1]*. 1) Biochemistry, Ponce School of Medicine and Health Sciences, Ponce, PR; 2) Toxicology and Pharmacology, Ponce School of Medicine and Health Sciences, Ponce, PR.

Common polymorphisms in DNA repair genes can alter an individuals' DNA repair capacity and modify the effect of environmental exposures on cancer risk. Previous studies suggest that genetic variations in nucleotide excision repair (NER) genes may increase the risk to develop certain types of cancer, including breast cancer. However, most of these studies have been limited to single nucleotide polymorphisms (SNPs). Copy number variations (CNVs) are segments of DNA that are present at a variable number of copies in comparison to a reference genome. Together with SNPs, CNVs and may underlie heritability of complex diseases. Our objective is to determine whether CNVs in the genomic regions of the NER genes are involved in modulating DNA repair capacity (DRC) and breast cancer risk in Puerto Rican women. TaqMan CNV assays for the genes XPD/ERCC2, XPC, XPE/DDB1, LIG1, RAD23A and CHEK2 were used to genotype breast cancer cases and controls. DRC levels were measured using a modified host-cell reactivation assay. For XPD/ERCC2, CHEK2, LIG1, XPC and RAD23A genes there was no significant difference for the distribution of the CNV genotypes in cases versus controls (p=0.091, p=0.067, p=0.478, p=0.103, p=0.835 respectively). For DDB1/XPE, cases (n=49) were more likely to have more than two copies while controls (n=60) showed to be more likely to have less than two copies at this locus (p<0.001). We next compared the DRC values in study participants grouped by CNV genotype. Controls carrying more than two copies of the XPE/DDB1 genotype had a significant increase in DRC (p=0.003). This association was not observed in breast cancer cases (p=0.532). The Database of Genomic Variants (DGV) reports a total of five other genes in the CNV encompassing XPE/DDB1, including VWCE/URG11. This gene has been associated with gastric cancer and epithelial to mesenchymal transition. Therefore, the association of the CNV in the DDB1/XPE region with breast cancer risk may be due to the VWCE rather than DDB1/XPE. Our results show that CNV genotypes in NER gene regions may be associated with the modulation of DRC and breast cancer risk. To our knowledge, this is the first study assessing the role of CNV using a comprehensive pathway-oriented approach. It provides evidence supporting a role for CNVs in breast cancer susceptibility.

997T

Screening of Finnish RAD51C founder mutations in prostate and colorectal cancer patients. *L.M. Pelttari[1], R. Nurminen[2], A. Gylfe[3], L. Aaltonen[3], J. Schleutker[2,4], H. Nevanlinna[1]*. 1) Department of Obstetrics and Gynecology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 2) Institute of Biomedical Technology/BioMediTech, University of Tampere and Fimlab Laboratories, Tampere, Finland; 3) Department of Medical Genetics, Genome-Scale Biology Research Program, University of Helsinki, Helsinki, Finland; 4) Department of Medical Biochemistry and Genetics, University of Turku, Turku, Finland.

RAD51C is involved in DNA damage repair by homologous recombination. Rare, heterozygous germline mutations in the *RAD51C* gene have been identified in breast and ovarian cancer families and a homozygous missense mutation was found in Fanconi anemia like disorder. We have previously identified two founder mutations c.837+1G>A and c.93delG in *RAD51C* in the Finnish population increasing the risk of ovarian cancer. The mutations were not associated with an increased risk of breast cancer in the absence of ovarian cancer. Many of the mutation carriers had family history of diverse cancer types, for instance colon and prostate cancer. Although several studies have identified moderate penetrance mutations in the *RAD51C* gene in breast and/or ovarian cancer families they seem to be very rare with unique mutations in outbred populations. This poses considerable challenges for investigating these in large series of patients with different cancer types.
To assess the role of *RAD51C* mutations in other common cancers we took advantage of the founder mutations in Finland and genotyped the c.837+1G>A and c.93delG mutations in genomic DNA samples from 1083 prostate and 802 colorectal cancer patients using TaqMan real-time PCR.None of the prostate or colorectal cancer patients harboured the *RAD51C* founder mutations c.837+1G>A or c.93delG. The absence of the mutations among the patients suggests that *RAD51C* does not play a significant role in the development of prostate or colorectal cancer but primarily is a susceptibility gene for ovarian cancer. These results have clinical value in assessing the cancer risks associated with *RAD51C* mutations. However, to fully assess the role of *RAD51C* in susceptibility to other cancer types, screening of the whole coding region of the gene in large sample sets would be needed.

998F

Exome Sequencing in a Familial Testicular Germ Cell Tumor Kindred. *K.A. Schrader*[1], S. Shah*[1], V. Joseph[1], R. Murali[2], R. Rau-Murthy[1], K. Sarrel[1], I. Dolgalev[2], S. Cheguri[1], C. Manschreck[1], N. Socci[3], A. Viale[4], A. Heguy[2], G. Bosl[5], D. Feldman[5], M. Robson[1], Z. Stadler[1], K. Offit[1], * equal contributions.* 1) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Department of Pathology, and Human Oncology and Pathogenesis Program, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Computational Biology Program, Memorial Sloan-Kettering Cancer Center, New York, NY; 4) Genomics Core Laboratory, Memorial Sloan-Kettering Cancer Center, New York, NY; 5) Genitourinary Oncology Service, Division of Solid Tumor Oncology, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY.

Introduction: Genome-wide association studies of susceptibility to testicular germ cell tumors (TGCT) have demonstrated moderately increased risks conferred by variants in or near *BAK1*, *DMRT1*, *TERT-CLPTM1L* and *KITLG*. To date, no high-penetrance susceptibility genes have been identified. To identify candidate high-penetrant TGCT susceptibility genes, we undertook whole exome sequencing in a family with three first cousins who developed TGCT at ages 26, 40 and 19 years, respectively, to identify shared rare variants seen at a very low or zero frequency in public databases. All affected individuals were related through their mothers. The family provided informed consent and the research was IRB-approved.

Methods: DNA was extracted from saliva and subjected to exome capture using the Agilent SureSelect Human All Exon 50Mb kit followed by 75bp paired-end sequencing on an Illumina HiSeq-2000 system. Alignment and variant calling was performed by the MSKCC Bioinformatics core using BWA and Best Practice Variant Detection with the GATK v2. Downstream analysis consisted of filtering out low quality variant calls and those already reported in public databases. Under the assumption of autosomal dominant or X-linked inheritance, we identified, novel, functional (truncating, indel, splice site, nonsynonymous) variants shared by all three of the affected individuals in keeping with the patterns of inheritance. To filter out rare familial variants less likely to be associated with the TGCT phenotype, we also performed exome sequencing on an unaffected 68 year-old uncle who has two unaffected sons in their 40's, based on the assumption that he does not carry the highly penetrant TCGT susceptibility allele.

Results: The three affected first cousins each carried, respectively, 370, 395 and 436 functional single nucleotide variants (SNV) and 75, 83 and 84 indels absent in dbSNP132. Forty-eight SNVs and 38 indels were shared. After filtering out the variants seen in the uncle, 26 SNVs and 18 indels remained. Following further subtraction of reported variants and orthogonal Sanger sequence validation, the number of candidates was reduced to 9, restricted to chromosomes 1 and X.

Interpretation: The candidate variants of greatest interest occur in a Rho GTPase, a chromatin modifier gene and a gene related to the spindle assembly checkpoint. Tumor analysis and replication in other families for mutations in the candidate genes and pathways is underway.

SLX4 mutation in hereditary breast cancer. *S. Shah[1], Y. Kim[2], I. Ostrovnaya[1], F. Lach[2], R. Murali[1], K. Schrader[1], V. Joseph[1], K. Sarrel[1], R. Rau-Murthy[1], N. Hansen[1], S. Cheguri[1], J. Littman[1], L. Zhang[1], K. Offit[1], A. Smogorzewska[2]*. 1) Memorial Sloan Kettering Cancer Center, New York, NY; 2) The Rockefeller University, New York, NY.

SLX4 is a DNA repair protein that serves as a docking platform for three structure-specific endonucleases. Recent studies have reported mutations in SLX4 in a new subtype of Fanconi Anemia (FA-P). Monoallelic defects in several Fanconi Anemia (FA) genes are known to confer susceptibility to breast and ovarian cancer. Therefore, we resequenced the entire SLX4 coding region in 739 (288 Ashkenazi Jewish and 480 Non-Ashkenazi Jewish) breast cancer patients with 3 or more family members affected by breast cancer and no known BRCA1/BRCA2 mutations, to determine if SLX4 is involved in breast cancer susceptibility. We found a novel nonsense (p.W823*) mutation in one patient. In addition we also found 13 novel, 23 rare (MAF<0.1%), and 15 common (MAF1%) missense variants, of which 22 (5 novel and 17 rare) are predicted as damaging by Polyphen2 (score= 0.65–1). We performed functional complementation using p.W823* and 4 others (3 novel and 1 rare) mutant SLX4 cDNA in a SLX4 null cell line. While, wildtype SLX4 and all the other variants fully rescued the sensitivity to Mitomycin C (MMC), campthothecin(CMT), and PARP inhibitor, p.W823* SLX4 mutant failed to do so.

Contribution of ARLTS1 to prostate cancer susceptibility. *S. Siltanen[1], H. Rauhala[1], TLJ. Tammela[2], P. Kujala[3], T. Visakorpi[1], T. Wahlfors[1], J. Schleutker[1,4]*. 1) Institute of Biomedical Technology/BioMediTech, University of Tampere and Fimlab Laboratories, Tampere, Finland; 2) Department of Urology, University of Tampere and Tampere University Hospital, Tampere, Finland; 3) Department of Pathology, Tampere University Hospital, Tampere, Finland; 4) Department of Medical Biochemistry and Genetics, University of Turku, Turku, Finland.

ARLTS1 (ADP-ribosylation factor-like tumor suppressor gene 1, also known as ARL11) is a tumor suppressor gene located at 13q14.3, a region frequently deleted in both sporadic and familial prostate cancer (PCa). Previously, we have shown that ARLTS1 variants, especially Cys148Arg (T442C), revealed a statistically significant association with an increased risk for homozygous CC carriers both in unselected and familial PCa cases. Cys148Arg (T442C) was also the only variant observed with a greater frequency among malignant tissue samples, PCa cell lines and xenografts, supporting its role in prostate carcinogenesis. Further, down regulation of ARLTS1 in clinical samples and its co-expression signature showed that ARLTS1 expression was strongly associated with immune processes. In this study, we investigated the mechanisms behind the observed associations. Quantitative-RT-PCR was used to examine the ARLTS1 expression status in eight previously 5-aza/TSA treated and demethylated PCa cell lines. Bisulphite sequencing was used to examine whether promoter methylation is behind the downregulation of ARLTS1 also in PCa. By staining prostatectomy FFPE block tissue slides with an antibody we examined the differences in lymphocyte infiltration, between cancers with CC genotype and TT genotype. We studied also the ARLTS1 tumor suppressor properties, apoptosis, cell growth and migration in PCa cell lines 22Rv1 and LAPC4, by blocking ARLTS1 expression with ARL11 siRNA. TSA alone was able to restore the ARLTS1 expression in PCa cell line LnCaP and in normal prostate epithelial cell line PrEC. Both TSA and 5-aza were needed to restore the expression in PC3 and LAPC4 PCa cell lines revealing that both DNA hypermethylation and histone modifications may regulate the expression. However, bisulphite sequencing did not work as expected on the CpG islands of promoter region. Lack of official CpG islands in the CpG databases supported this result which is contrary to previous reports on ARLTS1 structure in lung and ovarian cancers. Studies on gene silencing and immunostaining are still on-going.

Previous GWAS studies have reported associations between various SNPs and prostate cancer using cases unselected for family history. We report the results of a validation study of 25 SNPs reported to be associated with prostate cancer using a novel analysis of related familial prostate cancer cases. Fourteen study sites contributed a total of 11,783 genotyped samples, including 3,786 unaffected controls, 5,628 cases with non- or undetermined-aggressive disease, and 2,368 cases with aggressive disease. The majority of genotyped samples (n = 8,573) originated from 2,276 pedigrees, the remainder were individually sampled cases. Each site contributed its own controls. We used PedGenie software to account for known relationships. We conducted separate analyses for all prostate cancer and for aggressive prostate cancer only. For the non-specific prostate cancer phenotype, our analysis showed that 16 of the 25 SNPs were statistically significant ($p < 2E\text{-}3$ (= 0.05/25)), including SNPs on chromosomal bands 6q25, 7p15, 8q24, 10q11, 11q13, 17q12, 17q24, and Xp11. For the aggressive prostate cancer phenotype, our analysis showed that 8 of the 25 SNPs, were statistically significant ($p < 2E\text{-}3$), including most of the same chromosomal bands except 6q25 and 10q11 but also included a SNP at 2p15. The results of this analysis validate strong association to familial prostate cancer for the majority of SNPs considered and demonstrate the power of a GWAS approach that integrates data for related cases.

CDH1 mutations in patients with lobular carcinoma of the breast. *A.L. Valente[1], S. Rummel[1], C.D. Shriver[2], R.E. Ellsworth[3].* 1) Clinical Breast Care Project, Windber Research Institute, Windber, PA; 2) Clinical Breast Care Project, Walter Reed National Military Medical Center, Bethesda, MD, USA; 3) Clinical Breast Care Project, Henry M. Jackson Foundation, Windber, PA, USA.

Background: E-cadherin (CDH1) is involved in cell adhesion and maintenance of tissue architecture. Loss of CDH1 has been detected in a number of cancers characterized by loose cell-cell adhesion such as hereditary diffuse gastric, endometrial, ovarian and invasive lobular carcinoma (ILCA) of the breast, and germline mutations in CDH1 have been associated with increased risk of developing ILCA but not other breast tumor types. To improve understanding of the role of CDH1 mutations in breast cancer, mutation status was determined in a breast cancer cohort of patients with ILCA with and without family history of other tumor types. Methods: The Clinical Breast Care Project database was queried to identify all patients with ILCA with or without a family history of gastric/stomach, endometrial or ovarian cancer. Genomic DNA was isolated from peripheral blood samples. DNA variants were detected for each exon of CDH1 using high-resolution melting technology and the underlying change identified by direct sequencing. Variant A617T was assayed using TaqMan SNP assay rs33935154. Results: Of the 72 patients with ILCA, five had a family history of stomach cancer. Two private mutations were detected: P825Q in a patient with a family history of stomach cancer, and G879S in a patient with no family history of cancer. In addition, the A592T variant, which has been reported as non-pathogenic, was detected in a Hispanic woman while the causative mutations 1137G-A, identified in a Caucasian woman, and A617T identified in two African American women were detected. The A617T mutation was then evaluated in an additional 166 African American patients: 12 patients carried the mutation, nine of which had IDCA, two with microinvasive disease and one with mixed ductal and lobular features. Conclusions: The frequency of CDH1 mutations in this patient population was low (<10%), with only two mutations with known clinical consequences identified. In addition, the detection of the A617T mutation previously associated with endometrial cancer in African American women, in patients with predominantly ductal carcinomas questions whether this mutation is associated with increased risk of ILCA. The low frequency of germline mutations in CDH1 suggests that inherited mutations are not the predominant mechanism but rather alternate methods, such as epigenetic modification or miRNA silencing, may be driving the suppression of E-cadherin expression and the development of ILCA.

Globally, breast cancer affects more than 1.1 million women each year and is the most common cancer diagnosis among women in the United States. Breast cancer is a genetically heterogeneous disease characterized by different penetrance, complex phenotypes, and a polygenic pattern of inheritance. Dozens of novel single nucleotide polymorphisms (SNPs) for breast cancer susceptibility have been identified by genome-wide association studies (GWAS). However, those susceptibility loci were primarily discovered and validated in women of European ancestry and Asians. Given that linkage disequilibrium (LD) is quite different among ethnic populations, we sought to evaluate common genetic variants at 23 breast cancer GWAS susceptibility regions using 1,509 breast cancer cases and 1,383 controls of African ancestry. The average age (mean ± standard deviation) was 48.0 ± 12.0 years in cases and 47.2 ± 17.2 years in controls. Ascertainment of cases and controls occurred in Ibadan, Nigeria (681 cases and 282 controls), Barbados (93 cases and 244 controls), and multiple sites in the US (735 cases and 857 controls). A total of 965 tagging SNPs (selected to capture either the targeted LD blocks or the GWAS index SNPs) and 30 ancestry informative markers were genotyped using the Illumina GoldenGate Genotyping platform. Imputation for non-genotyped SNPs across the regions was conducted using MACH with phased YRI and CEU data from HapMap Phased II (release 22) and 1000 Genome Project Nov 2010 release as the reference panels. Unconditional logistic regression models adjusting for study site and estimated African ancestry proportion were then fit by SAS and PLINK. Both allele dosage effects and genotypic effects were examined. Our fine-mapping analysis found several novel breast cancer susceptibility markers in loci such as 5p12 (P = 0.0040), 5q11 (P = 0.00053), and 10p15 (P = 0.0015), which are unique for women of African ancestry. Our study underscores the importance of fine mapping of reported breast cancer GWAS loci in diverse and understudied populations. Future studies and new GWAS in women of African ancestry hold promise to uncover additional variants for breast cancer susceptibility with implications throughout the Diaspora.

L1 encoded ORF1p facilitates tumorigenesis and suppresses nucleus accumulation of Smad-4 in HepG2 Cells. *Y. Zhu[1,2], F. Feng[3], X. Gao[4], J. Yu[5], M. Hu[6], F. Zhang[1], Y. Wang[5], Q. Zhang[7], Y. Guo[1].* 1) Tumor Center in Beijing 301 Hospital, Beijing 100853, China; 2) The institute of life sciences and bio-engineering in Beijing Jiaotong University, Beijing 100044,China; 3) 3 Beijing Institute of Pharmacology and Toxicology, Beijing 100850, China; 4) The center for liver treatment in Beijing 302 Hospital, Beijing 100039, China; 5) Beijing Institute of Basic Medicine Science, Beijing 100850, China; 6) Department of tumor molecular in Beijing 307 Hospital, Beijing 100071, China; 7) Institute of Liver Transplantation, General Hospital of Chinese People's Armed Police Force, Beijing, 100039.

L1 encoded ORF1p facilitates tumorigenesis and suppresses nucleus accumulation of Smad-4 in HepG2 Cells L1 (LINE-1, Long interspersed nucleotide element-1), an autonomous retrotransposon, comprises about 17% of the human genome, most of which appear as 5' truncated forms. The full-length sequence contains 5' untranslated region (UTR), which encompass an internal promoter for RNA polymerase II, two open reading frames (ORF1 and ORF2), and a 3' terminal polyadenylation site [2]. There are thousands of full-length L1 in human genome and many of which encode ORF1p without making ORF2p. The competent L1 is considered to have 80–100 copies. L1 is activated in early stage of germ cell and embryo development and, however, unscheduled activation in various cancer tissues. Suppressing endogenous L1 by L1-ORF2 targeted RNAi and RT inhibitors in vitro and in vivo promotes the cell transition from highly proliferating, transformed phenotypes to low proliferating, differentiated phenotypes. But however, ORF1p remains to be elucidated, even that it has an excessive expression comparing to ORF2p. L1-encoded ORF1p (L1-ORF1p), a RNA binding protein, facilitating the RNA: DNA duplex in target site suggests that ORF1p encompasses some important functions beyond retrotransposition. To elucidate the function of L1-ORF1p, the transfected HepG2 cells with over-expression and down-regulation of ORF1p were analyzed and the proteins associated with L1-ORF1p were identified by co-immunoprecipitation. As the results, ORF1p over expression facilitates cells proliferation significantly in vitro and in vivo and its down-regulation results in opposed phenomenon. By co-immunoprecipitation analysis, ORF1p is demonstrated to form a complex with Smad4 and, in turn, suppress the nucleus accumulation of Smad4 elicited by TGF-β. MH2 domain in Smad4 was identified to be responsible for its interaction with L1-ORF1p. So it suggests that (1) upon the scenario of cell regulation L1-ORF1p beyond the function of retrotransposition might involve in some important regulation in tumorigenesis or at least acts as a key molecule in this process and alteration of its expression can switch cell statues; (2) ORF1p plays some important role for tumor growth and Smad4 may act as a mediator involved in this process. Key words: LINE-1; retrotransposon; ORF1p; Smad4; interaction.

Copy number variation analysis in 222 mutation negative polyposis patients reveals potential new candidate genes. *S. Aretz[1], S. Horpaopan[1], S. Vogt[1], I. Spier[1], A.M. Zink[1], S. Herms[1,2], A. Laner[3,4], K. Wöllner[1], S. Pasternack[1], M. Draaken[1,2], D. Stienen[1], S. Uhlhaas[1], E. Holinski-Feder[3,4], M.M. Nöthen[1,2], P. Hoffmann[1,2].* 1) Institute of Human Genetics, University Hospital Bonn, Germany; 2) Deptartment of Genomics, Life & Brain Center, University of Bonn, Germany; 3) University Hospital of the Ludwig-Maximilians-University, Campus Innenstadt, Munich, Germany; 4) MGZ - Center of Medical Genetics, Munich, Germany.

Background: Adenomatous polyposis syndromes are characterized by multiple colorectal adenomas and a high lifetime risk of colorectal cancer. Germline mutations of the APC and MUTYH genes cause the autosomal dominant Familial Adenomatous Polyposis (FAP) and autosomal recessive MUTYH-associated Polyposis (MAP), respectively. However, in up to 50% of families no germline mutation could be identified. Copy number variants (CNVs), in particular heterozygous microdeletions, contribute significantly to the mutation spectrum of hereditary tumor syndromes and thus it can be hypothesized that those heterozygous deletion CNVs might also be the underlying cause in yet unidentified genes responsible for adenomatous polyposis syndromes. Methods: Genomic DNA from 222 unrelated mutation negative polyposis patients was used for genome-wide SNP genotyping with the HumanOmni1-Quad BeadArray (Illumina). Putative CNVs were identified by the QuantiSNP v2.2 algorithm, filtered according to various criteria by use of the Cartagenia Bench™software, by in-silico-analysis, and by comparison with 531 healthy controls, and validated by qPCR. The gastrointestinal expression of genes covered by the identified CNVs was examined by cDNA analysis of normal mucosa. Results: 69 unique heterozygous deletion CNVs (size 10–664 kb) containing 88 protein coding genes could be identified in 60 patients (27%) but not in controls. Of them, 62 genes are partly or completely deleted, in 26 more the deletion affects intronic regions only. All but ten patients harbor just one CNV. Almost all CNVs are present only once in the whole cohort. After further prioritisation and expression analysis, 55 deleted genes remain. These candidate adenoma genes include protein kinases, transcription factors, and potential tumor suppressors. A few of them have been reported to be associated with CRC phenotypes. Conclusions: By applying stringent filter criteria, we identified a group of rare deletion CNVs which might contain predisposing genes for adenoma formation. After prioritization of the included genes according to function, pathway, and literature, present work includes sequencing the coding regions of the most interesting candidates in all patients to look for pathogenic point mutations. Additional steps are loss-of-heterozygosity analyses in tumor DNA. The study was supported by the German Cancer Aid.

1006T

Evaluation of the RHINO gene for breast cancer predisposition in Finnish breast cancer families. *T. Heikkinen[1], E. Huovari[1], S. Vilske[1], C. Blomqvist[2], J. Schleutker[3,4], A. Kallioniemi[4], K. Aittomäki[5], H. Nevanlinna[1].* 1) Department of obstetrics and gynecology, Helsinki university central hospital, Helsinki, Finland; 2) Department of Oncology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Medical Biochemistry and Genetics, University of Turku, FI-20014 Turku, Finland; 4) Institute of Biomedical Technology/BioMediTech, University of Tampere and Fimlab Laboratories, FI-33520 Tampere, Finland; 5) Department of Clinical Genetics, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland.

Genetic predisposition to breast cancer is caused by mutations in multiple loci. Among the high and moderate penetrance risk genes are many genes involved in DNA damage response, including BRCA1, BRCA2, and PALB2. A recently identified gene RHINO (C12orf32), interacting with Rad9-Rad1-Hus1 complex and with ATR activator TopBP1, is a novel candidate for DNA damage response and thus to breast cancer susceptibility. We sequenced the coding regions of the RHINO gene in blood DNA samples of 466 index patients of breast cancer families and in 507 population controls. We identified nine variants including four missense changes and one single nucleotide substitution creating a premature stop codon c.250C>T, R84X (rs140887418). The R84X nonsense variant truncates 65% of the 238 amino acid RHINO protein and therefore seems the most likely functional variant among the RHINO changes. There was no significant difference between the frequencies of any of the missense variants in the sequenced cases and controls. To investigate the role of the R84X nonsense variant in breast cancer predisposition we determined the genotype of the R84X variant in altogether 2214 cases and 1169 controls from the Helsinki region and in 730 cases and 521 controls from the Tampere region. The variant was present in cases and controls in similar frequencies of 0.4% and 0.8% respectively (P=0.106). Involvement of RHINO in breast cancer predisposition is unlikely.

A gene-based association approach prioritizes candidate susceptible genes for chronic myeloid leukemia. *J.-H. Park[1], H.-H. Won[2], J.-W. Kim[3], D.H. Kim[4], S.-T. Lee[3], S. Kim[2], S.-H. Kim[3], C.W. Jung[5].* 1) Dept. of Health Sciences and Technology, Graduate School, Samsung Advanced Institute for Health Science and Technology, Sungkyunkwan University, Korea; 2) Samsung Biomedical Research Institute, Samsung Medical Center, Korea; 3) Dept. of Laboratory Medicine and Genetics, Sungkyunkwan University School of Medicine, Samsung Medical Center, Korea; 4) Chronic Myelogenous Leukemia Group, Department of Hematology/Medical Oncology, Princess Margaret Hospital, University Health Network, University of Toronto, Toronto, Canada; 5) Department of Hematology/Oncology, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea.

Gene-based genome-wide association methods have been developed to overcome the limited power of a single SNP-based approach especially for variants with mild effects and to investigate relationships between genes and variants. It is also important to prioritize many candidate genes from the associated loci because functional studies for all located genes are not feasible. Therefore, the gene-based approach holds promise for selecting the most plausible candidate variants that are functionally relevant to genes and etiology of diseases. In this study, we further investigated candidate genes using the gene-based genome-wide association approach for the previously identified novel locus 6q25.1 associated with susceptibility to chronic myeloid leukemia (CML) (Kim *et al*., Blood, 2011, 117(25):6906-11). We utilized the versatile gene-based association study (VEGAS) method (Liu *et al*., AJHG, 2010, 87(1):139-45) that is an association test at gene level by considering the association results from the single SNP-based approach and linkage disequilibrium between SNPs in each gene. We carried out imputation and used approximately 1.6 million autosomal SNPs after quality control. We tested the assigned 17,542 genes with genotyped and imputed SNPs using the VEGAS and CML association analysis results. We also used other gene-based methods that combine P values of assigned and correlated SNPs for a corresponding gene. As a result of the gene-based approach, we confirmed three genes (*RMND1*, P=0.000011; *C6orf211*, P= 0.000016; and *ZBTB2*, P=0.00029) in the candidate locus (6q25.1) of our previous study. The results of other gene-based methods (ProxyGeneLD (Hum Genet, 2009, 126(2):289–301) and GSA-SNP (Nucleic Acids Research, 2010, 38(2):749-54)) also strongly supported our outcomes including *RMND1*. We also examined whether the identified variants could affect gene expression functionally using accessible expression quantitative trait loci (eQTL) databases. The most significant gene,*RMND1* included several SNPs (rs963193,rs13201167,rs6931104 and *et al*.) with eQTL information (http://eqtl.uchicago.edu/), which might affect regulation or expression of the corresponding gene. *RMND1* was also shown to be expressed in whole blood in public databases. Taken together with the result that the SNPs were replicated in independent Korean and European populations in our previous study, these results suggest that *RMND1* is a highly potential, susceptible gene for the development of CML.

Proteomic analysis of gastric cancer from individuals of Northern Brazil. *M.F. Leal[1], J. Chung[2], D.Q. Calcagno[1], P.P. Assumpçao[3], S. Demachki[4], I.D.C.G Silva[5], R. Chammas[6], R.R. Burbano[7], M.A.C. Smith[1].* 1) Department of Morphology and Genetics, Federal University of Sao Paulo, Sao Paulo, SP, Brazil; 2) Department of Microbiology, Immunology and Parasitology, Federal University of Sao Paulo, Sao Paulo, SP, Brazil; 3) Surgery Service, João de Barros Barreto University Hospital, Federal University of Para;, Belem, PA, Brazil; 4) Pathology Service, Joao de Barros Barreto University Hospital, Federal University of Para, Belem, PA, Brazil; 5) Department of Gynecology, Federal University of Sao Paulo, Sao Paulo, SP, Brazil; 6) School of Medicine, University of Sao Paulo, Sao Paulo, SP, Brazil; 7) Institute of Biological Sciences, Federal University of Para, Belem, PA, Brazil.

Gastric cancer is the second leading cause of cancer-related death worldwide. The identification of new cancer biomarkers is necessary to reduce the mortality rates through the development of new screening assays and early diagnosis, as well as new target therapies. In this study, we performed a differential proteomic analysis of noncardia gastric neoplasias of individuals from Northern Brazil. All samples presented H. pylori infection. The proteins were analyzed by two-dimensional electrophoresis and mass spectrometry. For the identification of differentially expressed proteins, we used statistical tests with bootstrapping resampling to control the type I error in the multiple comparison analyses. We identified 111 proteins involved in gastric carcinogenesis. The computational analysis revealed several proteins involved in the energy production processes and reinforced the Warburg effect in gastric cancer. ENO1, HSPB1 and ANXA2 expression were further evaluated. ENO1 was selected due to its role in aerobic glycolysis that may contribute to the Warburg effect. Although we observed two up-regulated spots of ENO1 in the proteomic analysis, the mean expression of ENO1 was reduced in gastric tumors by western blot. However, mean ENO1 expression seems to increase in more invasive tumors. This lack of correlation between proteomic and western blot analyses may be due to the presence of other ENO1 spots that present a slightly reduced expression, but with a high impact in the mean protein expression. In neoplasias, HSPB1 is induced by cellular stress to protect cells against apoptosis. In the present study, HSPB1 presented an elevated protein and mRNA expression in a subset of gastric cancer samples. However, no association was observed between HSPB1 expression and clinicopathological characteristics. ANXA2 was selected due to its suggested role in cellular transformation. *ANXA2* mRNA expression was up-regulated in more than half of gastric tumors compared to control tissues and it was associated with the presence of lymph node metastasis. However, we did not observe a correlation between gene and protein expression, underling the complex control of mRNA and protein expression. The present study enhances efforts to expand knowledge about gastric carcinogenesis, especially for neoplasms of patients from Northern Brazil. These biomarkers may be also useful for the assessment of prognosis and stratification for therapy if validated in larger clinical study sets.

Fine-mapping of IL-16 gene and prostate cancer risk in African Americans. *K. Batai[1], E. Shah[1], M. Ruden[1], J. Newsome[1], A.B. Murphy[2], C. Ahaghotu[3], R.A. Kittles[1,4,5]*. 1) Institute of Human Genetics, University of Illinois at Chicago, Chicago, IL; 2) Department of Urology, Feinberg School of Medicine, Northwestern University, Chicago, IL; 3) Division of Urology, Department of Surgery, Howard University Hospital, Washington, D.C; 4) Section of Hematology/Oncology, Department of Medicine, University of Illinois at Chicago, Chicago, IL; 5) Division of Epidemiology and Biostatistics, School of Public Health, University of Illinois at Chicago, Chicago, IL.

Background: Prostate cancer (Pca) is the most common type of cancer among men in the United States, and its incidence and mortality rates are disproportionate among ethnic groups. While genome-wide association studies (GWAS) of European descents have identified candidate loci associated with Pca risk, including a variant in the IL-16 gene, replication studies in African Americans (AAs) have been inconsistent. Here we explore SNP variation in IL-16 in AAs and test for association with Pca.

Methods: We tested association of 2,257 genotyped and imputed SNPs spanning IL-16 in 605 AAs from Washington, DC. Washington, D. C. samples were genotyped as a part of a large GWAS consortium for Pca in AAs using the Illumina Infinium 1M-Duo bead array. Imputation was performed using IMUTE2 and 1000 Genomes Project data as a reference panel. Eleven of the SNPs were also genotyped in a replication population of AAs from Chicago (n=506). Allelic associations were tested adjusting for age, Global and Local west African ancestry.

Results: Analyses of genotyped and imputed SNPs revealed that a cluster of IL-16 SNPs were significantly associated with Pca risk. The strongest association was found for rs7175701 (P=9.78 × 10^{-8}). In the replication population, another SNP (rs11556218), which was not associated with Pca in the Washington, D.C. AAs, was associated with Pca risk (P=0.01). In the pooled analysis, we identified three independent loci within IL-16 that were associated with Pca risk. SNP eQTL analyses revealed that rs7175701 is predicted to influence the expression of IL-16 and other cancer related genes.

Conclusion: We were successful in the `local' replication revealing that IL-16 variants associated with Pca risk in two independent samples of AAs. Our study provides evidence that IL-16 polymorphisms likely play a role in Pca susceptibility among AAs. The significantly associated SNPs are likely to affect gene expression. Our findings are significant given that there has been limited focus on the role of IL-16 genetic polymorphisms on Pca risk in AAs.

Fas signaling pathway-based analysis of genome-wide data and risk of gastric cancer. *P.L. Hyland[1,2], S-W. Lin[1,2], N. Hu[1], Z-Z. Tang[3], L. Wang[1], C. Wang[1], H. Su[1], T. Ding[3], J-H. Fan[4], Y-L. Qiao[4], X. Xiong[5], W. Wheeler[5], C. Griffen[5], K. Yu[1], Z. Wang[6], L. Burdett[6], S.J. Chanock[6], S.M. Dawsey[1], M.A. Tucker[7], N.D. Freedman[1], A.M. Goldstein[1], C.C. Abnet[1], P.R. Taylor[1].* 1) DCEG, National Cancer Institute (NCI), NIH, Bethesda, MD; 2) CPFP, Division of Cancer Prevention, NCI, NIH, Bethesda, MD; 3) Shanxi Cancer Hospital, Taiyuan, People's Republic (PR) China; 4) Dept of Epidemiology, Cancer Institute (Hospital), Chinese Academy of Medical Sciences, Beijing, People's Republic (PR) China; 5) IMS, Inc, Silver Spring, MD; 6) Core Genotyping Facility, NCI-Frederick, SAIC-Frederick Inc, and DCEG, Bethesda, MD; 7) Human Genetics Program, DCEG, NCI, NIH, Bethesda, MD.

The populations of the Shanxi and Linxian regions in north central China are at high risk for gastric cancer (GC) and altered FAS-mediated cell signaling and/or apoptosis may contribute to this risk. In this study, we used a pathway-based approach to incorporate a priori knowledge into the analysis of existing genome wide association study (GWAS) data. We examined the association of 554 single nucleotide polymorphisms (SNPs) in 53 genes related to FAS signaling using a pathway-based (gene-set) approach in 1758 GC cases (including 1126 gastric cardia adenocarcinomas [GCA], and 632 gastric noncardia adenocarcinomas [GNCA]) and 2111 controls from the GWAS of gastric cancer in ethnic Chinese. SNP-, gene- and pathway-based associations with risk of GC overall as well as GCA and GNCA were evaluated using the adaptive rank-truncated product (ARTP) method and the additive model within unconditional logistic regressions adjusted for age and sex. Statistical significance was evaluated empirically by permutation. Significant associations were observed for genes involved in the Fas signaling pathway with risk of overall GC (P = 5.5E-04) and GCA (P = 6.3E-03), but not GNCA (P = 8.1E-02). Ten genes including *MAP2K4, FAF1, MAPK8, CASP10, CASP8, CFLAR, MAP2K1, CAP8AP2, PAK2* and *IKBKB* were significantly associated with risk of GC (nominal P < 0.05). *FAF1* and *MAPK8* were significantly associated with risk of both GCA and GNCA (nominal P < 0.05) in our high risk population. In contrast, *MAP2K4* and *IKBKB* were significantly associated with GNCA risk, but not GCA; and *CASP8, CASP10, CFLAR* and *MAP2K1* were significantly associated with risk of GCA, but not GNCA. Our examination of genetic variation in the FAS signaling pathway is consistent with an association of altered FAS signaling and/or apoptosis with risk of GC. Results suggest that this association may be driven by genetic variation in specific genes with important roles in FAS-signaling in cells. As one of the first attempts to investigate a pathway-level association, our results suggest that these genes and the FAS signaling pathway warrant further evaluation in relation to GC risk in other populations.

1011W

Fine-mapping identifies multiple prostate cancer risk loci at 5p15, one of which associates with TERT expression. *Z. Kote-Jarai[1], E. Saunders[1], D. Leongamornlert[1], M. Tymrakiewicz[1], T. Dadaev[1], S. Jugurnauth-Little[1], H. Ross-Adams[2], A. Al-Olama[3], S. Bennloch[3], S. Halim[2], R. Russel[2], A. Dunning[3], D. Neal[4], F. Hamdy[5], J. Donovan[6], D. Easton[3], R. Eeles[1], The UK Genetics Prostate Cancer Study Collaborators, The PRACTICAL Consortium.* 1) Oncogenetics, The Institute of Cancer Research, 15 Cotswold Rd, Sutton, Surrey, United Kingdom; 2) Cancer Research UK Cambridge Research Institute, Li Ka Shing Centre, Robinson Way, Cambridge, UK; 3) Centre for Cancer Epidemiology, Strangeways Laboratory, Worts Causeway,CAmbridge, UK; 4) Surgical Oncology, University of Cambridge, Hills Rd, CAmbridge, UK; 5) Nuffield Department of Surgical Sciences, Univeristy of Oxford, Oxford, UK; 6) School of Social and Communiy Medicine, University of Bristol, Whatley Rd, Bristol, UK.

We have previously reported an association between prostate cancer (PrCa) risk and rs2242652 on 5p15. rs2242652 lies in intron 4 of TERT, which encodes telomerase reverse transcriptase, the catalytic subunit of the telomerase ribonucleoprotein complex. Telomerase catalyzes the de novo addition of telomere repeat sequences on to chromosome ends and thereby counterbalances telomere-dependent replicative senescence. Associations between SNPs in the TERT region and multiple cancer types have been reported; however no correlation has been observed thus far between the cancer-associated SNPs in TERT and gene expression or telomere length. To comprehensively evaluate the association between genetic variation across this region and PrCa we performed a fine-mapping analysis by direct genotyping using either a custom Illumina iSelect array (114 SNPs on iCOGS) or Sequenom MassArray iPlex (25 SNPs) followed by imputation of 1,094 SNPs in 22,301 PrCa cases and 22,320 controls in the PRACTICAL consortium. To determine independently associated variants in this region, we performed forward and backward stepwise logistic regression; SNPs were included in the model if they were significant at $P<10-4$ after adjustment for other SNPs. Both regression models identified multiple independent associations, reflecting the complexity of this region. These SNPs fall into four regions consisting of clusters of highly or moderately correlated variants, and there is only weak LD between SNPs in different regions. To investigate whether SNPs in any of these regions were associated with TERT gene expression, we performed qPCR assays on RNA from benign prostate tissue samples using the Fluidigm Biomark™ HD system. We found evidence that the risk reducing alleles of several variants in region one associated with elevated TERT expression, providing a plausible mechanism for the differential effect of SNPs on PrCa risk. Deep re-sequencing of these loci may help to further refine this region and facilitate selection of prospective causal variants for functional validation studies.

1012T

Fine mapping of 12q24 shows a promising association locus for renal cell carcinoma. *J.R. Toro[1], S. Han[1], M. Yeager[1], L. Moore[1], M. Purdue[1], M. Johansson[2], G. Scelo[2], V. Gaborieau[2], C. Berg[3], R. Grubb[4], V. Stevens[5], M. Thun[5], W. Diver[5], D. Albanes[1], S. Weinstein[1], J. Virtamo[6], L. Burdett[1], A. Brisuda[7], J. McKay[2], J. Fraumeni[1], N. Chartterjee[1], P. Rosenberg[1], N. Rothman[1], P. Brennan[2], W.H. Chow[1], M. Tucker[1], S. Chanock[1].* 1) Division of Cancer Epidemiology and Genetics, National Institutes of Health, Bethesda, MD, USA; 2) International Agency for Research on Cancer (IARC), Lyon, France; 3) Division of Cancer Prevention, Department of Health and Human Services, National Cancer Institute, Bethesda, MD, USA; 4) Division of Urologic Surgery, Washington University School of Medicine, St. Louis, MO, USA; 5) Epidemiology Research Program, American Cancer Society, Atlanta, GA, USA; 6) Department of Chronic Disease Prevention, National Institute for Health and Welfare, Helsinki, Finland; 7) Department of Urology, University Hospital Motol, Prague, Czech Republic.

A recent genome-wide association study (GWAS) of renal cell carcinoma (RCC) observed a promising association locus on 12q24, which maps to SCARB1, scavenger receptor class B member 1 gene. SCARB1 codes for a cell surface receptor that binds to high-density lipoprotein cholesterol (HDL-C) and mediates HDL-C uptake. In follow-up, we performed fine mapping of the 12q24 locus, by genotyping 53 single nucleotide polymorphisms (SNPs) in 2,278 cases and 3,719 controls from four independent studies in United States, Finland, and Central and Eastern Europe. We used reference panels from 1000 Genomes Project and Phase III HapMap to impute genotypes of common SNPs across the region. Genome-wide level of significance was found with two SNPs that were in high linkage disequilibrium (LD). These variants could either tag or potentially cause the principal risk of the locus, but the high LD makes it difficult to assign specific causality. While this SNPs marks a promising association, further confirmatory work is required to establish its association with RCC risk. SCARB1 is a novel gene associated with RCC risk that may lead to new etiological insights.

1013F

Array CGH Analyses in a Patient with Multifocal Recurrent Meningioma. *Z. Yilmaz Celik[1], Y.K. Terzi[1], N. Altinors[2], F.I. Sahin[1].* 1) Department of Medical Genetics, Baskent University Faculty of Medicine, Ankara, Turkey; 2) Department of Neurosurgery, Baskent University Faculty of Medicine, Ankara, Turkey.

Multiple meningiomas occur in 1–9% of all meningiomas and refer to a condition in which at least two tumors are present at different sites in one patient without neurofibromatosis. Although meningioma is mostly a benign tumor, it is a very unusual tumor because of its many cytogenetic, biological, and clinical aspects. Several studies have described genetic alterations associated with meningioma initiation. Here we report a case of a sporadic recurrent multiple meningioma. A 39 year old male has been operated three times for multiple intracranial meningiomas at a different center during a time frame of nearly 20 years. He was brought to our attention by his relatives due to inability to walk for the last two weeks and inability to speak for the last six months. The attending hospital notified the family as no further treatment is indicated for this patient. The cranial MR showed multiple intracranial meningiomas including four different localizations. The patient was operated upon with the total removal of the two biggest tumors causing edema and shift of the midline structures. The histoptahologic evaluation showed atypical meningioma with extensive brain invasion of the tumor in the left frontoparietal lobe. Cytogenetic study revealed a complex karyotype from solid tumor tissue cultures taken at the time of surgery, and was reported as; 38~39,XY,-1,der(1),der(4),-5,-6,-7,der(7),-8,-9,der(9),del(11q),-12,der(12),-14,-17,del(18q),-21,der(21),-22,inc[cp8]/46,XY[1]. Roche NimbleGen Human CGH 3x720K Whole-Genome Tiling v3.0 Array was used for aCGH analysis on genomic DNA isolated from the sample. The data were analyzed by using web based Genoglyphix program (Signature Genomics). A large number of chromosome copy gains and losses were observed. Copy gains were identified on chromosomes 6, 9, 10, 15 and 22. Copy losses were identified on chromosomes 1, 6, 7, 9, 10, 14, 17, 18 and 22. According to our results, 30 chromosome regions were identified as clinically significant. 12 were of unclear clinical significance and 6 were regarded as benign. Our aCGH results mostly confirmed our conventional cytogenetic results. A conventional karyotype needs live cells and is a laborious process during both cultures and analyses, aCGH promises a more definitive and explanatory result in similar patients.

1014W

Haplotype-resolved sequencing and structural analysis of the HeLa cancer genome. *A.C. Adey, J.O. Kitzman, J. Burton, J. Shendure.* Genome Sciences Dept, University of Washington, Seattle, WA.

We present the first haplotype-resolved sequence of a cancer genome. A PubMed search of “HeLa” returns over 68,000 hits. However, a comprehensive genomic analysis of the oldest and arguably most prevalent human cancer cell line has yet to be performed. We sequenced the HeLa genome to ~88X shotgun coverage in order to accurately identify variants in the context of extreme aneuploidy. Next, we constructed and sequenced nearly 300 fosmid clone pools, each containing ~2 percent representation of the genome, thereby providing islands of haplotype-specific coverage. In addition, we performed single chromosome flow-sorting and pooled sequencing in order to boost our ability to determine haplotype relationships amongst germline variants and somatic mutations across entire chromosomes, as well as to accurately catalog chromosomal rearrangements. Shotgun, fosmid clone pool, chromosome sorting, and 4–40 Kb mate-pair data were integrated to generate the first haplotype-resolved sequence of a cancer genome. The genome of HeLa may yield insights into the biological basis for its persistence and robust growth properties. Furthermore, we are using the haplotype information to estimate the timing and order of somatic events over the 60 year history of HeLa. Finally, it has been previously shown that a number of chromosomal fragments are present in populations of HeLa cells at varying frequencies. To further investigate this, we performed flow sorting and shotgun sequencing of single nuclei to characterize the content and frequencies of these abnormal chromosomes. The methods presented here may prove broadly useful for improving the comprehensiveness and resolution at which we characterize cancer genomes.

Role of somatic mutations in the etiopathogenesis of Maffucci Syndrome. *M. Amyere[1], M. Limaye[1], N. Mulliken[2], J.B. Dompmartin[3], A. Enjorlas[4], O. Kaitila[5], I. Docquier[6], P-L. Godfraind[7], L-M. Boon[1,8], M. Vikkula[1,9].* 1) Human Molecular Genetics, de Duve Institute, Brussels, Belgium; 2) Department of Plastic Surgery, Children's Hospital and Harvard Medical School, Boston, MA, USA; 3) Department of Dermatology, Université de Caen Basse Normandie, CHU Caen; 4) Consultation des Angiomes, Hôpital Lariboisière, Paris, France; 5) Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 6) Division of Orthopedic Surgery, Cliniques Universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 7) Division of Pathology, Cliniques Universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 8) Center for Vascular Anomalies, Division of Plastic Surgery, Cliniques Universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 9) Walloon Excellence in Lifesciences and Biotechnology (WELBIO), Université catholique de Louvain, Brussels, B-1200, Belgium.

Maffucci Syndrome is a non-hereditary enchondromatosis syndrome, characterized by multiple benign central cartilaginous tumors, accompanied by vascular tumors in the form of spindle cell hemangiomas. Enchondromas can undergo malignant transformation, and patients show an increased incidence of cancers, such as glioma. The etiology of the Maffucci syndrome is unknown, and differs from the Ollier disease. Mutations in isocitrate dehydrogenases IDH1 and IDH2 have been described in gliomas, as well as solitary enchondromas, making them attractive candidates to play a role in the pathogenesis of the Maffucci syndrome. Targeted sequencing of the IDH1 and IDH2 genes identified mutations in 3\4 of tissues resected from our series of patients with the Maffucci syndrome. The mutations were somatic and mosaic, affecting particular protein residues: R132 (C) in IDH1, and R172 (G) in IDH2. Yet, patients with inherited D-2-hydroxyglutaric aciduria, which is caused by germline IDH2 mutations, do not show an increased incidence of tumors, suggesting that IDH mutations are not necessary and/or sufficient to cause tumors. Therefore, to identify the origin of Maffucci syndrome, we have performed Affymetrix SNP-array analyses to look for chromosomal alterations in a series of tissues vs. blood, from 10 Maffucci patients and two patients with Ollier disease. While chromosomal anomalies were absent in constitutional DNA, several CNVs were identified in tissues, including losses and gains. These identified chromosomal regions are shared in subsets of Maffucci patients, and are thus candidates to harbor causative mutations. Exome sequencing of these samples will allow us to further analyze these loci. (miikka.vikkula@uclouvain.be).

1016F

Association of polymorphisms in NNK metabolizing genes and lung cancer risk. *J.L. Engle[1], A.K. Hull[2], G. Liu[1], A.S. Berg[1], C.J. Gallagher[1,3], P. Lazarus[1,3], J.E. Muscat[1].* 1) Department of Public Health Sciences, Penn State College of Medicine, Hershey, PA, United States; 2) Biology Department, Lincoln University, PA, United States; 3) Department of Pharmacology, Penn State College of Medicine, Hershey, PA, United States.

Lung cancer is the leading cause of cancer related deaths among both men and women in the US. While smoking is estimated to account for over 80% of all lung cancer cases, only about 15% of lifetime smokers develop this malignancy. This discrepancy among smokers suggests that individual susceptibility to tobacco carcinogens may be modulated by genetic factors. One of the major carcinogens in tobacco smoke is the nicotine derived nitrosamine 4- methylnitrosamino-1-(3-pyridyl)-1-butanone (NNK). In order to be detoxified, NNK must first be reduced to another potent lung carcinogen 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL), which can be glucuronidated by the uridine glucuronosyltransferase (UGT) enzyme family and excreted. Metabolism of NNK to NNAL is catalyzed by four enzymes, aldo-keto reductase 1C1 and 1C2 (AKR1C1 and AKR1C2), carbonyl reductase 1 (CBR1), and hydroxysteroid dehydrogenase 11β1 (HSD11β1). The current study focuses on polymorphisms that provide high coverage in the NNK reduction pathway; *AKR1C1*, *AKR1C2*, *CBR1*, and *HSD11β1* genes. We hypothesized that the polymorphisms in the genes that metabolize NNK to NNAL may be associated with lung cancer risk in individuals exposed to tobacco smoke. We genotyped 448 whites with histologically-confirmed lung cancer (no past history of other tobacco-related cancers) and 786 white controls using a custom 48-SNP Illumina GoldenGate genotyping panel and Taqman real-time PCR. Tag SNPs were chosen in the four NNK metabolizing genes using HapMap genotypes in haploview software (tagger option) with r^2>0.8. SNP association analysis was performed adjusting for known lung cancer confounders (age, sex, and pack-years of smoking) and Hardy-Weinberg Equilibrium analysis was conducted for each SNP. Overall significant associations were observed for three SNPs from the *AKR1C1*, *HSD11β1*, and *CBR1* genes and risk for lung cancer. Smoking and sex stratification and histological subgroup analysis also showed significant findings associated with selected SNPs from all four NNK metabolizing genes. Comprehensive haplotype analysis on all NNK metabolizing genes is ongoing. The identification of genetic variants that regulate the activation and detoxification of tobacco smoke carcinogens is necessary to identify high-risk smokers and develop targeted interventions.

1017W

Myeloproliferative neoplasms and somatic mosaicism in the 23andMe participant community. *D.A. Hinds[1], K.E. Barnholt[1], J.L. Zehnder[2], A.K. Kiefer[1], C.B. Do[1], N. Eriksson[1], J.L. Mountain[1], U. Francke[1], J.Y. Tung[1], R.L. Levine[3], R.A. Mesa[4], J.R. Gotlib[5].* 1) 23andMe, Inc., Mountain View, CA; 2) Department of Pathology and Department of Medicine/Hematology, Stanford University School of Medicine, Stanford, CA; 3) Human Oncology and Pathogenesis Program, Memorial Sloan Kettering Cancer Center, New York, NY; 4) Division of Hematology & Medical Oncology, Mayo Clinic, Scottsdale, AZ; 5) Department of Medicine/Hematology, Stanford University School of Medicine, Stanford, CA.

Background: Myeloproliferative neoplasms (MPNs) are disorders that result in unregulated overproduction of one or more myeloid blood cell types by the bone marrow. Polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF) comprise the three classic MPNs. A somatic *JAK2* mutation, V617F, is present in 95% of PV and 50–60% of ET and PMF patients. Past work has identified germline variation in *JAK2* associated with risk of developing a V617F-positive MPN. **Methods:** We have recruited a web-based participatory cohort of patients with MPNs to better understand the genetic basis of these conditions. We have enrolled and collected saliva samples from more than 600 participants, including the following self-reported diagnoses: systemic mastocytosis (n=130), ET (n= 115), PV (n=107), PMF (n=50), chronic myeloid leukemia (n=70), and 79 with overlapping diagnoses. Participants have been genotyped using a derivative of the Illumina OmniExpress with additional custom content, including probes for V617F. **Results:** We can detect V617F with high specificity and sensitivity, indicating that a portion of the DNA we extract is of myeloid origin. We also observe large-scale chromosomal alterations previously seen in MPNs, including uniparental disomy of chromosome 9p. We detect V617F and larger chromosomal alterations at low frequency in the broader 23andMe community. These variants have been associated with increased cancer risk and we are developing strategies for communicating this information and conducting follow-up studies with our participants. In genome-wide association analyses, we replicate the known association between V617F and germline variation in *JAK2* (rs12340895: odds ratio=3.2, P=3.2e-41). We also detect a novel association between MPNs—ET, PV, and PMF—and rs2853677 (odds ratio=1.5, P=8.7e-08) in telomerase reverse transcriptase (*TERT*). Variation in *TERT* has previously been associated with multiple non-hematological cancers, and our lead SNP is in linkage disequilibrium with the previously associated *TERT* variants. The high-risk allele of rs2853677 is also predictive of V617F status among 23andMe participants who were not recruited into the MPN community (odds ratio=1.6, P=0.0014). **Conclusion:** We have identified a germline variant in *TERT* which is a novel predisposition allele for MPNs. These results demonstrate the potential for web-based recruitment methods to contribute to genetic research for uncommon diseases.

1018T

Acute myeloid leukemia associated with chromosome 6: Clinical and phenotypical implications in two pediatric patients with chromosome trisomy and translocation. *L. Hurtado-Hernandez[1], J. M. Aparicio[2,6], F. L. Cuellar[3], M. A. L. Cubillo[4], M. A. H. Garrido[5], S. M. Chatelain[7].* 1) Cytogenetics; 2) Genetics; 3) Urology; 4) Physical therapy; 5) Oncohematology, Hospital para el Nino Poblano, Pue, puebla; 6) Estomatology, Benemerita Universidad Autonoma de Puebla; 7) Biotechnology, Universidad Autónoma Metropolitana, Mexico.

Chromosome aberrations are considered alterations in the chromosome number or structure. They are mainly considered due to gametogenesis inborn error or during the zygote first cellular divisions. Among 4617 chromosomal studies performed during 19 years (from 1992 to 2011), at Hospital Para El Niño Poblano in México, 34.6% (1596 patients) had chromosomal alterations. Among these studies population, a male and female pediatric patients are described, with 6;9 translocation and trisomy of chromosome 6, were chromosome changes are classified as structural or numeric alterations respectively, where a number of leukemias has been associated with specific chromosomal translocations. Both cases were described in this study analyzing their hematological, clinical features, medical treatments and prognosis.

1019F

Correlating Genetic Alterations From Array Comparative Genome Hybridization And Next-Generation Sequencing With Histology And Clinical Outcome In Melanocytic Neoplasms. *Y. Liu, Y. Zhou, E. George.* Dept Pathology, Univ Washington, Seattle, WA.

The incidence of melanoma in the United States is increasing and is about one in seventy currently. Due to limited systemic therapies for treating advanced stages of melanoma, early detection is the key to improve survival. Although particular melanoma subtypes are clinically and histopathologically distinct, they do not provide independent prognostic value. Molecular studies revealed some genetic defects of several genes and pathways in melanoma, however, the etiology of melanoma development is still largely unknown. The goal of this study is to use of high-resolution, genome-wide approaches to identify genomic aberrations that contribute to melanoma transformation, development and progression and correlate these genetic findings with the histology and clinical outcome in hope of generating a molecular classification scheme for melanocytic neoplasms. The FFPE melanoma samples used in this study include malignant melanoma, metastasized melanoma, atypical nevi and benign nevi. We employed both whole genome scan using CCMC 180K CGH+SNP array and panel of actionable gene sequencing using Next-Generation Sequencing in this study. The analyses and results of these samples will be presented and its clinical utility will be discussed.

1020W

Molecular profiling of the therapy-resistant clones in the recurrent Embryonal Carcinomas of the testes based upon FISH and NGS of the isolated chromosomes. *R. Malecki[1,2], M. Malecki[1,3,4].* 1) PBMEF, San Francisco, CA; 2) SFSU, San Francisco, CA; 3) WUHS, Pomona, CA; 4) UW, Madison, WI.

Molecular profiling of the therapy-resistant clones in the recurrent Embryonal Carcinomas of the testes based upon FISH and NGS of the isolated chromosomes **Introduction.** Orchidectomy - the radical surgery of the therapy-resistant, clinically advanced cancer of the testes, leads unequivocally to infertility. Fertility sparing surgery, followed by systemic radiation or chemotherapy, may lead to genetic mutations manifested in the off-spring. Therefore, identification of the unique biomarkers is essential for specific diagnosis [1], including distinguishing between different types of testicular cancers, as the first step towards forging targeted therapy, capable of overcoming the resistance to therapeutics [2]. The specific aim of this project was to seek clones with the unique biomarkers of the cancer initiating stem cells in the recurrent, therapy-resistant embryonal carcinoma of the testes. **Methods.** Based upon the CDS library, we genetically engineered fluorescent and superparamagnetic scFvs targeting cancer stem cells: SSEA-3, SSEA-4, TRA-1-60, TRA- 1-81. Using these scFvs, we isolated single, living cancer stem cells for clonal expansion. We also designed the chromosome-specific probes and used them to isolate single chromosomes from the selected cells clones. We collected the cells from the patients suffering advanced stages of the therapy-resistant, recurrent embryonal carcinomas of the testes. **Results.** The cells were isolated using FACS and MACS as they expressed biomarkers of the embryonic stem cells SSEA-4 and TRA-1-60, confirmed with the flow cytometry, confocal microscopy, and nuclear magnetic resonance. The isolated cells retained high viability and were suitable for clonal expansion. From those clones, the isolated chromosomes helped to identify genetic mutations with FISH and NGS. The clonally expanded cells and amplified transcriptomes facilitated revealing expression of the genes specific for pluripotency Oct3/4, Sox2, Nanog. **Conclusion.** The novel biotechnology facilitated identifying, within the therapy resistant embryonal carcinomas, the clones of cancer stem cells carrying sets of very specific biomarkers. They may serve not only for the fine diagnosis, but also for designing targeted therapy. **Bibliography.** [1] Malecki M, Szybalski W. Gene. 2012 Feb 1;493(1):132-9. Epub 2011 Dec 1. 1021T

Detection of Large Rearrangements in *BRCA1* and *BRCA2* by Microarray-CGH. *D. Mancini-DiNardo, T. Judkins, N. Woolstenhulme, C. Burton, S. Chen, J. Schoenberger, M. Ryder, A. Murray, M. Balzotti, N. Gutin, J. Holladay, J. Craft, C. Colvin, J. Trost, L.A. Burbidge, C. Arnell, E. Rosenthal, B. Roa.* Myriad Genetic Laboratories, Inc. Salt Lake City, UT.

Conventional Sanger sequencing technology is capable of detecting the vast majority of mutation types in *BRCA1* and *BRCA2*, but it cannot detect large rearrangements (e.g. deletions and duplications). The proportion of clinically significant defects in *BRCA1/2* attributable to genomic rearrangements is estimated to be 6–10%. The Microarray BRAC*Analysis* Rearrangement Test (microarray BART) is a newly validated testing platform based on oligonucleotide array Comparative Genomic Hybridization (oligo aCGH) technology, which is able to detect large rearrangement (LR) mutations. We validated microarray BART by blinded analysis of 313 blood and buccal DNA samples that were previously examined for LR mutations in *BRCA1/2* using our clinically validated quantitative multiplex PCR assay. Results of our method comparison showed that microarray-CGH was 100% concordant with the original quantitative multiplex PCR results, including the precise identification of 37 mutation positive samples. Furthermore, these validation studies correctly identified two instances of an Alu insertion in *BRCA2* specific to the Portuguese population (156_157insAlu), among the 313 under investigation. Microarray-CGH offers better resolution of LR mutations due to the greater probe number and more comprehensive gene coverage. This methodology is not as sensitive to technical artifacts caused by single nucleotide polymorphisms at probe binding sites. Furthermore, this platform is amenable to high throughput processing, which can enhance testing capacity for *BRCA1/2* LR mutations. This feature is particularly significant given the recently published National Comprehensive Cancer Network (NCCN) guidelines that recommend comprehensive testing, which encompasses full *BRCA1/2* sequencing and detection of large gene rearrangements in patients who meet HBOC testing criteria. In all, microarray-CGH is a clinically validated test that can reliably detect the presence of deletions and duplications in *BRCA1/2*. Since clinical microarray BART testing was offered in May 2012, limited data have been generated mostly on high-risk patients for whom sequencing and LR testing were run concurrently. Our collective experience has shown that 6–10% of mutation positive samples had a LR, with ~88.4% in *BRCA1* and ~11.6% in *BRCA2*. We also detected two Portuguese insertions. Results will be updated as additional patients undergo clnical microarray-CGH testing for *BRCA1/2* large rearrangements in the coming months.

Effect of insecticide exposure in the generation of alterations in MLL, a gene associated with acute lymphoblastic leukemia. *M.P. Navarrete Meneses[1,2], M. Betancourt[3], E. Bonilla[3], M. Altamirano[4], A. Reyes[1], P. Pérez-Vera[1].* 1) Laboratorio de Cultivo de Tejidos, Instituto Nacional de Pediatría, Mexico City, Mexico; 2) Posgrado en Ciencias Biológicas, UNAM, Mexico City, Mexico; 3) Departamento de Ciencias de la Salud, Universidad Autónoma Metropolitana-Iztapalapa, Mexico City, Mexico; 4) FES-Zaragoza, UNAM. México, D.F, Mexico City, Mexico.

Acute lymphoblastic leukemia (ALL) is the most common childhood cancer. It is characterized by the presence of numerical and structural chromosomal abnormalities. Translocations involving MLL gene are detected in 80% of patients under 1 year old; it is proposed they arise in utero. Development of ALL and the uterine exposure to pesticides have been reported in numerous epidemiological studies; however, there is limited biological evidence supporting this association. The aim of this study was to detect alterations in MLL gene induced by two extensively used insecticides, permethrin and malathion, in human lymphocytes in vitro. Method: Lymphocytes from a healthy volunteer were cultured for 72h. Chemical grade permethrin/malathion were added (100–300μM) for the last 24h. Etoposide and insecticides solvents were used as positive and negative controls, respectively. Alterations in MLL gene were analyzed by FISH. Results: Both pesticides showed increased percentage of cells with numerical and structural alterations, compared to negative controls; the highest percentage of damage was detected with permethrin treatment. Even though damage was found in all samples, more complex abnormalities were observed in the cells treated with pesticides. Discussion: Numerical alterations, not previously reported, were detected using these insecticides. Some of the structural alterations found in this study have been observed in cells exposed to etoposide. Direct damage found in MLL gene using permethrin/malathion, resembles the effect described for etoposide, a well-known leukemogenic agent. Acknowledgement to CONACyt MPNM-385279.

1023W

Genomic analyses of paired diagnostic/relapse childhood acute lymphoblastic leukemias identify relapse-associated genetic features of pathogenetic and clinical importance. *L. Olsson[1], A. Castor[2], M. Behrendtz[3], A. Biloglav[1], E. Forestier[4], K. Paulsson[1], B. Johansson[1].* 1) Clinical genetics, University and Regional Laboratories, Skåne University Hospital, Lund University, Lund, Sweden; 2) Department of Pediatrics, Skåne University Hospital, Lund, Sweden; 3) Department of Pediatrics, Linköping University Hospital, Linköping, Sweden; 4) Department of Clinical Sciences, Pediatrics, University of Umeå, Umeå, Sweden.

Despite high cure rates of childhood acute lymphoblastic leukemia (ALL), a subset of the patients relapse and treatment failure remains a significant problem. The mechanisms underlying such unfavorable events are unclear. The fact that relapses occur not only in high risk groups but also in the standard risk group indicates that the present prognostic factors are insufficient. Therefore, it is important to identify specific relapse-associated genetic features already at the time of diagnosis in order to ensure proper risk stratification. We performed single nucleotide polymorphism (SNP) genomic array analysis, using Illumina 1M SNP arrays, on 77 ALL cases with events (60 cases with relapse, 9 with resistant disease, and 8 with induction failure) to ascertain molecular lesions associated with relapsed and resistant disease. The patients are part of a large series of patients (n = 307) diagnosed and treated according to the Nordic Society of Pediatric Hematology and Oncology ALL protocols between 1992 and 2011 at the Departments of Pediatric Oncology and Hematology, Lund and Linköping University Hospitals, Sweden. Among the 77 cases, 17 paired diagnostic/relapse samples, 41 diagnostic samples from patients that subsequently relapsed, and 4 relapse samples (without corresponding diagnostic samples) were informative. Fifteen cases were excluded due to either too low DNA concentration or because of too many normal cells in these samples. The paired samples were genetically related, identical, or harbored additional alterations in the relapse sample. However, 29% lacked some of the copy number aberrations present at diagnosis, suggesting the presence of a preleukemic clone from which the relapse clone evolved. No single aberration was linked to only relapse, but deletions involving IKZF1 (24.2% vs. 8.2%; P = 0.003) and NR3C1 (6.5% vs. 0.5%; P = 0.019) were more common compared with patients remaining in complete remission. SNP array analysis is not only an excellent tool for genome-wide profiling of cryptic structural alterations in cancer cells but also provides insights into the origin of relapse clones. Many of the changes identified at relapse are probably present in minor clones already at the time of diagnosis, and detection of these clones at diagnosis should result in improved risk stratification and hopefully in better outcome.

1024T

Loss of chromosomes is the primary event in near-haploid and low hypodiploid acute lymphoblastic leukemia. *S. Safavi[1], E. Forestier[2], I. Golovleva[2], G. Barbany[3], K. H.Nord[1], A. V. Moorman[4], C. J. Harrison[4], B. Johansson[1], K. Paulsson[1].* 1) Clinical Genetics, Laboratory medicine, Lund, Sweden; 2) Department of Medical Biosciences, Medical and Clinical Genetics,University of Umeå,Sweden; 3) 3Department of Molecular Medicine and Surgery and Center for Molecular Medicine, Karolinska Institutet, Stockholm, Sweden; 4) Leukaemia Research Cytogenetics Group, Northern Institute for Cancer Research, University of Newcastle, Newcastle Upon Tyne, UK.

Near-haploid (23–29 chromosomes) and low hypodiploid (HoL; 33–39 chromosomes) acute lymphoblastic leukemia (ALL) is associated with a poor prognosis. Both subtypes are characterized by chromosomal loss and duplicated stemlines, the latter which may lead to misclassification as high hyperdiploid ALL. Nothing is known about the pathogenetic consequences and mechanisms underlying near-haploidy and HoL. In the present study, we used SNP array analysis to investigate 12 cases of near-haploid (n=8) and HoL (n=4) ALL. A characteristic pattern of monosomies/uniparental isodisomies and retained heterodisomies/tetrasomies was identified, with the latter involving chromosomes X/Y, 14, 18, and 21 in near-haploid cases and chromosomes 1, 5, 6, 8, 10, 11, 14, 18, 19, 21, and 22 in HoL. All cases displayed widespread loss of heterozygosity (LOH). Two cases were initially diagnosed as high hyperdiploid childhood ALL and both relapsed; notably, these were unambiguously identifiable as near-haploid with the SNP array analysis, showing the potential of this technique for correct risk stratification. Cryptic genetic events were found in five cases, including four CDKN2A deletions. The pattern of deletions and LOH indicated that microdeletions occurred in a subsequent step in one case, strongly suggesting that the chromosome loss is the primary event in near-haploid and HoL ALL.

Detection of the t(8;14) chromosomal rearrangements in paraffin embedded tissue sections of Burkitt Lymphoma patients with quantitative polymerase chain reaction (PCR) and fluorescence in situ hybridization (FISH) methods. *N. Selvi[1], M. Hekimgil[2], B. Tezcanli Kaymaz[1], S. Aktas[2], N. Ozhan[2], C. Gunduz[1], B. Kosova[1], Y. Dodurga[3], N. Topcuoglu[1].* 1) Ege University, Medical Biology Department, Medicine school, izmir Turkey; 2) Ege Univiersity, Medical school, Department of pathology, izmir, Turkey; 3) Pamukkale University, Medical Biology and genetics Department, Medicine school, Denizli, Turkey.

Burkitt lymphoma (BL) is an aggressive B-cell lymphoma, with a characteristic clinical presentation, morphology, and immunophenotype. In hemato-oncologic malignancies, determination of the specific tumor chromosomal translocations and the gene amplifications has an ascending importance in view of diagnosis and prognosis of these lesions. In the current study, 17 paraffin-embedded tissue samples, which indicate the lymphoid hyperplasia feature, comprised control group. Total 26 samples were evaluated, the study group of which were composed of 18 paraffin sections, four fresh tissue, two peripheral bloods and two imprint samples diagnosed with Burkitt' lymphoma. The t(8;14) chromosomal rearrangement in the samples was investigated in terms of retrospectives using “expand long template” PCR (LD-PCR) and fluorescent in situ hybridization (FISH) molecular techniques and the results obtained using the two methods were compared with each other. t(8;14) translocation was investigated by expand long PCR and FISH methods in cases diagnosed as Burkitt lymphoma. Fresh tissue samples of three cases, imprint samples of two cases, and peripheral blood samples of two cases were determined positive for MYC/lgH rearrangement. MYC/lgH rearrangement was determined positive in paraffin sections of two samples. The paraffin tissue samples of 16 patients could not be evaluated due to DNA degradation. MYC/lgH rearrangement was determined as positive by FISH analysis in three fresh tissue samples, two imprint and two peripheral blood samples of our cases. In paraffin tissue samples, 9 cases were found positive for t(8;14) translocation and partial trisomy of 8th and 14th chromosomes was determined in one case. As a result, we think that using both different PCR methods and FISH method will facilitate the identification of tumor's genetic characterization. In conclusion, we think that basic molecular methods will bring new dimensions to current therapeutic approaches, also developments in molecular diagnosis will accelerate the step of individual specific treatment methods.

1026W

Molecular changes in Lynch syndrome associated and sporadic ovarian carcinomas. *A. Tieva[1], S. Kaur[1], L. Renkonen-Sinisalo[2], H.J. Järvinen[2], J-P. Mecklin[3], R. Bützow[4], P. Peltomäki[1].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Second Department of Surgery, Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Surgery, Jyväskylä Central Hospital, Jyväskylä, Finland; 4) Departments of Obstetrics, Gynecology & Pathology, Helsinki University Central Hospital, Helsinki, Finland.

STATEMENT OF PURPOSE Epithelial ovarian cancer has the highest fatality rate of all gynecological malignancies among women worldwide. Increased understanding of the pathogenesis is required for improvement of the diagnosis, prognosis and treatment of ovarian carcinoma. Ovarian carcinoma is overrepresented in Lynch syndrome (LS). Our aim was to classify LS associated and sporadic ovarian carcinomas by studying epigenetic, genetic and protein expression alterations. METHODS USED Normal and tumor samples of all available LS associated ovarian carcinomas were collected (21 paired samples) through a nation-wide registry. Sporadic ovarian tumors (95 cases) were chosen to match with tumors from LS families relative to histological type (serous, endometrioid and clear cell) and mismatch repair (MMR) status of the tumor. We used microsatellite instability (MSI) and MMR protein expression to study MMR defects. Epigenetic changes were studied by the methylation-specific multiplex ligation-dependent probe amplification test (MS-MLPA, ME001-C1 tumor suppressor-1 test) which detects methylation of 24 tumor suppressor gene (TSG) promoters. In addition, the samples will be examined for global hypomethylation, p53 expression, and K-RAS mutations. SUMMARY OF RESULTS Among LS associated ovarian carcinomas, 89% (16/18) showed loss of MMR protein expression corresponding to the germline mutation, and high-degree MSI was present in all the cases. In sporadic cases all four MMR proteins were expressed in the majority of cases (87%), and MSI was detected only in 5% of the cases. Ovarian carcinomas showed inactivation of certain TSGs by promoter methylation. The most frequently methylated TSGs in the entire set of ovarian tumors were RASSF1 (62%), CDH13 (60%), CDKN2B (23%), APC (22%), TP73 (16%) and GSTP1 (14%). Methylation frequencies of these six genes differed remarkably between LS associated and sporadic ovarian carcinomas as well as between different histological subtypes of ovarian cancer. Methylation of CDKN2B was specific to LS associated ovarian carcinoma (81%) in contrast to sporadic cases (10%). The methylation frequency was very low (4 to 12% depending on the TSG) in serous ovarian carcinomas compared to clear cell and endometrioid types (sporadic and LS combined). CONCLUSION MMR defects are significantly more common in LS vs sporadic ovarian carcinoma. TSG promoter methylation is frequent with patterns specific to LS vs sporadic and histological type.

A Comprehensive Genetic and Epigenetic Study of Hepatocellular Carcinoma with Microarrays. *G. Zhang[1,7], C. Wu[2,7], D. Yu[2], J. Chang[2], W. Sun[3,1], M. Li[4], L. Liang[5], Y. Li[1,3,6], D. Lin[2].* 1) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) State Key Laboratory of Molecular Oncology and Department of Etiology and Carcinogenesis, Cancer Institute and Hospital, Chinese Academy of Medical Science and Peking Union Medical College, Beijing, China; 3) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 4) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 5) Department of Epidemiology and Department of Biostatistics, Harvard School of Public Health, Boston, MA; 6) Department of Computer Science, University of North Carolina at Chapel Hill, Chapel Hill, NC; 7) These authors contributed equally to this work.

Hepatocellular carcinoma (HCC) caused by viral hepatitis is one of the most common cancers in countries where hepatitis is endemic, such as China. Recently, the emergence of various high-throughput technologies have enabled integrated genetic and epigenetic analysis of multiple omics datasets, which holds the promise to identify genetic factors of complex diseases such as HCC. Here we used multiple types of microarrays to obtain SNPs and copy number variations/aberrations (CNV/CNAs) genotypes, DNA methylation, and expressions of protein coding genes and miRNAs from 30 paired primary tumor and normal liver tissues from patients with HCC in China. Our comprehensive genetic and epigenetic analysis has revealed a remarkable number of alterations in HCC samples. In total, we identified 2528 ($p<1.8\times10^{-6}$) differentially expressed transcripts out of 28536 examined and 440 ($p<7.1\times10^{-8}$) differentially methylated probes out of 707812 in tumor versus normal liver tissue using conservative Bonferroni correction. Pathway enrichment analysis detected several significant pathways enriched of genes highly expressed/methylated in tumor tissues including cell cycle, DNA repair, inflammatory and several signaling pathways. SNP array data also identified frequent CNAs, such as gains at 1q, 5, 7, 17p, and losses at 1p, 4q, 6q, 16, 17q, 21 in tumors. Combining the expression, methylation and genetic data, we were able to illustrate the genetic and epigenetic effects on gene expression patterns that are specific in tumor or normal tissues. Our integrated analysis lays the ground for further molecular studies of HCC by identifying novel genetically and epigenetically regulated genes potentially involved in HCC development or progression.

Congenital Leukemia with Insertion of MLL into 19p13.3 and a Deletion of Half a Megabase of 19p13.3: Case Report. *H. Al-Kateb, M. Evenson, S. Kulkarni.* Pathology and Immunology, Washington University School of Medicine, St. Louis, MO.

Congenital and neonatal leukemia represent less than 1% of all childhood leukemia. The incidence of leukemia in infants under 1 month of age is 4.7 per million live births per year. The vast majority of cases of congenital and neonatal leukemia are acute myeloid leukemia (AML). Mixed-lineage leukemia gene (MLL) rearrangements occur in approximately 14.4% of cases of which t(11;19) translocation was found in half of the cases. Two translocations were described that fuse MLL to different genes on 19p, the first one is t(11;19)(q23.3;p13.3) and fuses 5' MLL to 3' of mixed-lineage leukemia translocated to 1(MLLT1); and the second one is t(11;19)(q23.3;p13.1) and fuses 5'MLL to 3' elongation factor RNA polymerase II (ELL) gene. We report about a 36-week gestation female infant who was born with blueberry muffin rash, hepatosplenomegaly and coagulopathy. Pathology examination revealed AML with monoctyic differentiation. Initial cytogenetic analysis revealed a t(11;19)(q23.3;p13.1) translocation in all cells examined. However, fluorescence in situ analysis (FISH) using MLL probe revealed that the 3' part of MLL went to chromosome 19. However, FISH studies with E2A at 19p13.3 and subtelomeric probes showed that those loci were intact on the derivative chromosome 19 indicating that 3'MLL was inserted into 19p13.3 and not translocated. Subsequent microarray analysis revealed a half megabase deletion on chromosome 19 within 19p13.1 band and no loss or gain on chromosome 11. The proximal deletion breakpoints were within ELL gene where the first 6 exons were deleted. This corresponds to deleting 289 amino acids of ELL N-terminal. Accordingly the karyotype was modified to 46,XX,ins(19;11)(p13.1;q23). arr 19p13.1(18428039–18961490)x1. In all the previously reported MLL-ELL transcripts, which have been associated with AML, MLL has been fused to ELL exon 2 or exon 3 in one case. Although the deletion of ELL in the present case affected exons 1–6, it preserved the minimal ELL region required for immortalization. This makes ELL a strong candidate for being the partner gene of MLL in this case. However, the possibility that MLL was fused to a different “cancer gene” cannot be ruled out. Work is in progress to map the breakpoints at the base pair level and to precisely determine the partner gene of MLL in this case.

CYTOGENETIC PROFILES OF 370 CASES WITH RENAL CELL CARCINOMA-UCLA EXPERIENCE. *P.H. BUI, P.N. RAO.* Pathology and Laboratory Medicine, David Geffen School of Medicine, UCLA, Los Angeles, CA.

Renal cell carcinoma (RCC) accounts for approximately 3% of adult malignancies with 90–95% of these arising from the kidney. Cytogenetic analyses have emerged as a powerful tool for diagnosis and classification of RCCs. From 2005 to 2012, tumors from 370 patients (124 females, 246 males), who underwent nephrectomy for RCCs, were cytogenetically analyzed from primary cultures following standard laboratory protocols. Various RCC subtypes were examined which included 247 clear cell (ccRCC- most common), 107 papillary (pRCC), and 16 chromophobe (cRCC) subtypes. From these analyses, we have identified recurrent and specific chromosomal aberrations associated with particular subtypes. 229 of the 247 ccRCCs showed abnormalities involving chromosome 3 (93%). These were deletions of the 3p region, monosomy 3, and unbalanced translocations resulting in deletions of 3p. These aberrations were not seen in other subtypes. In addition, monosomy 8/del 8p (24%), -6/del 6q (19%), -4/del 4q (13%), -10/del 10q (13%), -21 (9.3%), -17/del 17p (8.9%), -5/del 5q (6.9%), -12/del 12q (6.9%), -20 (3.2%), or gains of chromosomes 9 (4.9%), or 18 (4.5%), were more commonly observed in ccRCCs. Recurrent unbalanced translocations t(3;5)(p13;q15) (19%) were also specific to ccRCCs. Among the pRCCs, gains of chromosomes 12 (69%), 16 (65%), 7 (62%), 3 (42%), or 17 (41%), and translocations such as t(16;17)(q24;q11.2), t(1;14)(q32;q32), and t(3;21)(q12;p12) were more common. 10 of the 16 (62.5%) cRCCs exhibited concurrent monosomies of chromosomes 1, 2, 6, 10, 13 and 17. Besides these subtype-specific aberrations, we have also identified several other recurrent anomalies that were common to all RCCs. For instance, loss of Y was the most common aberration in males (55.7%), while loss of the X was observed in 26.6% females. Among autosomes, gains of 5, 8, 19, 20, or 22, or losses of 9, 11, 13, 14, 18, or 22 were found in all RCCs. Our results show that not only are specific cytogenetic abnormalities associated with the various subtypes but also can play an important role in the classification. In addition, such studies aid in providing valuable information of prognostic significance. Our studies, when correlated with the clinically available data, have shown that deletions of 3p and trisomy 5q are generally associated with good prognosis, whereas deletion of 4q/monosomy 4 and loss of chromosome 14 have been associated with a poorer outcome.

Acute lymphoblastic leukemia (ALL) is a malignant disorder that originates in progenitors of T or B lymphocytes. Virtually all patients with ALL acquire genetic changes, which somehow contribute to the formation and expansion of leukemic clones. The T (T-ALL) and (ALL-B) B lineage progenitors are characterized by recurrent numeric and structural alterations affecting cellular pathways in lymphoid differentiation, tumor suppression, apoptosis and lymphoid signaling through alteration of genes such as MLL, MYC, HOX11, HOX11L2, LYL1, TAL1, among others. However, experimental models have suggested that additional changes that include deletions in the genes CDKN2A/CDKN2B and NOTCH1 are required to generate leukemia (T-ALL). In this study, we performed a genetic screening by high-resolution microarrays (Affymetrix 500k platform) to identify frequent changes and characterize new copy number alterations in a group of Mexican patients with acute lymphoblastic leukemia of both subtypes. Interestingly, we observed that the CDKN2A/B deletion was present in 60% of our patients but from both ALL subtypes, suggesting a pathogenic role shared. In addition, we observed a PTPRU (Receptor-type tyrosine-protein phosphatase U) gene deletion in 60% of patients (which 83% were B-ALL). We also highlight interesting changes as cryptic microdeletions of the BCR (22q11.23), TCTA (at 3p21.31) and MLLT3 (in 9p21.3) genes not associated with translocation, whereas amplified regions involved some oncogenes such as NRAS (1p13.2), MYB (6q23.3), MYCl1 (1p34.2). Moreover, very recently some of these changes have been associated to other malignancies. Summarizing, this work is consistent with the hypothesis that implies alternative genomic changes for generating ALL including deletions of CDKN2A/B, TAL1/STIL, NOTCH1 genes or the deletion of 6q16.1 locus, and presents evidence to propose the PTPRU microdeletion as candidate for participate in B-ALL pathogenesis. This project was supported by CONACyT (convocatorias SALUD-2005-01-14125 and SALUD-2004-C02-026).

An unusual case of APL in a 14 year old girl with t(15;17)(q22;q21) and t(9;22)(q34;q11.2). *V. Jobanputra[1], C. Freeman[1], S. Hussein[1], M.J. Macera[2], B. Levy[1], V.V. Murty[1], M.L. Sulis[3], G. Bhagat[1].* 1) Department of Pathology, Columbia University Medical Center, New York, NY; 2) New York Presbyterian Hospital, New York, NY; 3) Department of Pediatrics, Columbia University Medical Center, New York, NY.

Acute promyelocytic leukemia (APL) represents approximately 1% of all childhood leukemias and 10% of all childhood AML. Children presenting with APL have a greater degree of leukocytosis than adults and often present with severe bleeding diathesis. We report a case of APL in a 14 year old girl of Mexican descent who presented with new onset headaches and easy bruising, as well as leukocytosis and thrombocytopenia. Her smear showed 44% promyelocytes. Flow cytometry was consistent with a diagnosis of APL. Of interest, G-band karyotype analysis of her bone marrow revealed 46,XX,t(15;17)(q22;q21)[1]/46,idem,t(9;22)(q34;q11.2)[19]. FISH analysis with the PML/RARA probe was positive for the t(15;17)(q22;q21) in 96% of her cells and FISH with the BCR/ABL1 probe also confirmed rearrangement in 95% of her cells. The patient was started on Idarubicin and ATRA and is currently in remission post induction chemotherapy. The hallmark of APL is the presence of the t(15;17)(q22;q21) translocation. Generally, the t(15;17)(q22;q21) is the only abnormality present, however, additional abnormalities and variants involving the 17q21 breakpoint have been reported. These additional abnormalities usually appear to be secondary events. The presence of the t(9;22)(q34;q11.2) with the t(15;17)(q22;q21) is extremely rare. Rare cases with such double translocations have been reported in patients presenting with promyelocytic blast crisis of CML. However, only one previous case of primary APL has been reported in a 38 year old woman who received ATRA and arsenic trioxide, but died of intracranial hemorrhage the following day. We report the second case of primary APL with both a t(9;22)(q34;q11.2) and t(15;17)(q22;q21). Our patient has shown typical symptoms of childhood APL without any unusual clinical presentation and responded well to chemotherapy. Six weeks after her initial cytogenetic analysis only 2/1200 cells positive for PML/RARA were noted and all 2000 cells analyzed were BCR/ABL negative. The presence of a metaphase with the t(15;17)(q22;q21) as the sole abnormality, suggests that a cell line acquired the t(9;22)(q34;q11.2) representing clonal evolution of disease. It does not appear that the presence of the t(9;22) has affected the clinical course of this patient thus far as she responded to ATRA. Analysis of this case should provide valuable insight into this leukemia.

1032W

Integration of cytogenetics and FISH studies for accurate evaluation of chromosome abnormalities. *N. Qin, M. Hibbard.* Cytogenetics, Clarient, Alisoviejo, CA.

Fluorescence in situ hybridization (FISH) provides an important adjunct to conventional cytogenetics in the evaluation of chromosome abnormalities associated with hematologic malignancies, and vice versa. We present two interesting cases to show how the chromosome rearrangements were precisely defined by employing both cytogenetic and FISH tools. In one case, the initial FISH interphase study using the probe D20S108 showed no deletion detected in the long arm of chromosome 20. However, subsequent cytogenetic analysis revealed an obvious deletion of the long arm of chromosome 20. Only the combination of FISH analysis on metaphase cells using the same probe uncovered the discrepancy. In another case, cytogenetic analysis of a bone marrow specimen revealed what appeared to be a deletion of the long arm of chromosome 11 at q23 and additional material of unknown origin attached to the long arm of chromosome 2. Concurrent chromosome analysis on peripheral blood revealed a recognizable translocation between the long arms of chromosomes 2 and 11 at bands of 2q37 and 11q23 [t(2;11)(q37;q23)] due to improved morphology. Only five cases with such a translocation have been reported in the literature; we assumed that our case could be the sixth. To confirm the cytogenetic finding, FISH analysis using an MLL break-apart probe was performed. The FISH signal pattern did confirm the translocation of chromosome of 11 material to chromosome 2; however, the MLL gene was not split apart. The entire MLL gene had moved to chromosome 2, unlike the five reported cases in which an MLL rearrangement was confirmed by FISH. Chromosome karyotypes and FISH images in both cases will be presented. In the second case, comparison of the same abnormalities in different specimen types reveals the difference in morphology, which may be beneficial in the determination of chromosome 11 abnormalities differentiating between deletion and translocation since chromosome 11 has a multitude of translocation partners. In our cases, both chromosome and FISH studies were integral to defining the acquired chromosome abnormalities; neither methodology could be dispensed with.

1033T

Evaluation of FGFR1 gene amplification status and its association with clinicopathological features in breast cancer. *R.M. Rodrigues-Peres[1], J.K. Heinrich[1], L.O.Z. Sarian[2].* 1) CAISM - Women's Hospital, University of Campinas - UNICAMP, Campinas, SP, Brazil; 2) Department of Obstetrics and Gynecology, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, SP, Brazil.

Introduction: The FGFR1 gene, located on chromosome 8p12, is a member of the Fibroblast Growth Factor Receptor Family. It regulates cell proliferation, differentiation, apoptosis and is also known to be involved in angiogenesis and wound repair, which are in turn associated with tumor development. FGFR1 was shown to be amplified in approximately 7–17% of breast tumors. Furthermore, association between FGFR1 amplification and pathological features, as ERBB2 status, estrogen and progesterone receptors, lymph node metastasis, tumor size, grade and decreased survival, was described. However, the differences between the techniques used to assess these associations, which might exhibit disputant results and the lack of studies to entirely support these evidences are critical. Objectives: 1) To evaluate the amplification and aneuploidy status of FGFR1 in breast cancer samples; 2) To correlate the FGFR1 status to ERBB2, C-MYC and CCND1 status in order to access genomic instability of the samples; 3) To verify the association between FGFR1 status and tumor clinicopathological features. Materials and Methods: For this study, 52 cases were obtained from mastectomies. A TMA slide containing these samples was set and used in FISH assays. Homebrew probes were specifically designed for FGFR1 and applied onto samples concomitantly with a commercial probe for chromosome 8 centromere (CEP8, Kreatech). Clinicopathological data were obtained from patients' records. Results: We found 19% FGFR1 amplified cases, of which 7% presented high amplification. We detected a positive correlation between the FGFR1 status and C-MYC and CCND1 status (p = 0.006 and 0.04, respectively). A gradual increase in age was found to FGFR1 amplification when comparing to normal gene status (mean = 86 y.o. X 57.42 y.o.), as well as to lymph node metastasis (mean = 3 affected lymph nodes X 2.5 affected lymph nodes). The % ER status is higher in cases where FGFR1 is amplified, reversely to the PR status, which is higher in normal FGFR1 (ER mean = 83.75% and PR mean = 53.47%). The tumor size was higher in the FGFR1 amplified cases (mean = 4.9cm). Discussion: Our results corroborate previous findings of FGFR1 amplification in breast cancer samples and on the association to the clinicopathological features, also demonstrating its involvement in genomic instability. These results suggest that FGFR1 is an important gene involved in development of breast tumors and might also be a target to new therapies.

Large scale identification of chromosomal abnormalities in familial breast and ovarian cancer. *H.WH. Yin[1], L.L. Wang[3], E. Tsui[1], Y. Elshimali[2], D.C. Chen[4].* 1) La Sierra University, Riverside, CA; 2) UCLA/Charles Drew University, Los Angeles, CA; 3) Rite Aid Pharmacy, Fontana, CA; 4) Pathology Dept, UCIMC, Orange, CA.

The examination of biochemical pathways of hereditary breast and ovarian cancer has greatly increased our understanding of the pathogenesis of breast cancer. Currently, 22 breast cancer susceptible genes have been identified and can be found in the OMIM database. This list of genes provide candidates for a technology utilizing massive and parallel DNA sequencing in what may potentially be a more comprehensive genetic testing panel for both the familial and somatic forms of breast and ovarian cancers. One challenge for current technology in genetic testing is the relative inefficiency in identifying chromosomal structure abnormalities such as deletion, inversion and/or translocations. Non-allelic homologous recombination (NAHR) and Non-homologous end joining (NHEJ) are major mechanisms responsible for such chromosomal change events. Since the locations for potential chromosomal changes are non-random and limited by the respective location and presence of homologous sequence pairs, a targeted DNA sequencing approach for chromosomal abnormalities in these candidate genes may be feasible. To test our hypothesis, we conducted a bioinformatic analysis of the genomic sequences around all 22 potential breast cancer susceptible genes and globally identified the potential target pairs for NAHR and NHEJ events; we also employed a cross-species sequence comparison to reduce potential false positive results. Overall, 356 potential genomic sequence pairs have been identified and we have designed a solution phase genomic DNA capture system targeting these 356 sites. Specifically, hybridization probes conjugated to magnetic beads have been constructed. The system has been optimized for capturing genomic DNA of tumor specimens with the potential to participate in NAHR and NHEJ mediated events. Lastly, we have conducted parallel pair-ending sequencing of genomic DNA of tumor specimens in order to determine the feasibility of this strategy in identifying chromosomal rearrangement in tumor specimen.

1035W

Homozygous deletions of *CDKN2A* are present in all dic(9;20)(p13.2;q11.2)-positive BCP ALLs and may be important for leukemic transformation. *V. Zachariadis[1], J. Schoumans[2], G. Barbany[1], M. Heyman[3], E. Forestier[4], B. Johansson[5], M. Nordenskjöld[1], A. Nordgren[1].* 1) Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden; 2) Service de Génétique Médicale, Centre Hospitalier Universitaire Vaudois, CH-1011 Lausanne, Switzerland; 3) Department of Women's and Children's Health Karolinska Institutet, Stockholm, Sweden; 4) Department of Clinical Sciences, Pediatrics, University of Umeå, Umeå, Sweden; 5) Department of Clinical Genetics, University and Regional Laboratories, Skåne University Hospital, Lund University, Lund, Sweden.

In B-cell precursor acute lymphoblastic leukemia (BCP ALL) recurrent chromosomal aberrations define unique subtypes of the disease, each with its own prognostic and therapeutic implications. The chromosomal translocation dic(9;20)(p13.2;q11.2) is reported to be present in up to 5 percent of childhood BCP ALL and is associated with a worse survival compared with the most common standard risk aberrations. Previous molecular studies of dic(9;20) have revealed heterogeneous breakpoints on chromosomes 9 and 20, failing to produce a consistent gene fusion as a result. The genetic lesions underlying leukemic transformation and propagation in dic(9;20)-positive BCP ALL thus remains largely unknown. We present a detailed genomic characterization of six childhood BCP ALL harboring dic(9;20)(p13.2;q11.2). Six diagnostic and one “pre-leukemic” sample were investigated, using high resolution single nucleotide polymorphism array, and evaluated for the presence of additional genomic imbalances that may play a role in leukemogenesis. The breakpoints on chromosomes 9 and 20 were clustered, albeit non-identical; three cases had breakpoints within the *PAX5* gene on 9p13.2 and within *C20orf112* on 20q11.2. Importantly, all six cases harbored homozygous deletions of the *CDKN2A gene*, transcribing the two tumor suppressors *P16INK4* and *P14ARF* from alternative reading frames. The *CDKN2A* deletions on the non-rearranged chromosome 9 homologue ranged from 23 to 201 kilobases, thus escaping detection by fluorescence in situ hybridization. A shared proximal breakpoint (chr9: 21998026) of the *CDKN2A* deletions strongly indicates a common underlying mechanism. In addition, one case revealed an apparent progression from a hemizygous to a homozygous deletion of *CDKN2A* during leukemic transformation, indicating that homozygous *CDKN2A* deletions are important for the pathogenesis of dic(9;20)-positive ALL.

1036T

C-MYC and IGH amplification in patients with intermediate high grade B-cell lymphomas. *A. Zaslav[1], M. Bellone[2], F. Lan[3], T. Mercado[1], H. Lee[1], Y. Hu[2].* 1) Dept Pathology, Stony Brook Univ Hosp, Stony Brook, NY; 2) Department of Pathology, Stony Brook University Medical Center, Stony Brook, N.Y; 3) Blood and Bone Marrow Stem Cell Transplantation Program, Stony Brook University Medical Center, Stony Brook, N.Y.

High grade B-Cell lymphomas (BL) with histological and clinical features intermediate between Burkitt lymphoma and diffuse large B-cell lymphoma have recently been classified by the World Health Organization (WHO) (Jaffe, E.S. et.al. (eds.) IARC Press; Lyon, France, 2008. These tumors have large and medium size cells with greater irregulatory of nuclei and more prominent nucleoli than BL. Approximately 35% to 50% have C-MYC rearrangements with non-Ig variants. We present six patients with stage IV Intermediate high grade B-Cell lymphomas demonstrating C-MYC and/or IGH low-level amplification. Standard chromosome analysis, FISH, and/or paraffin-embedded FISH on archived tissue were performed on bone marrow, and/or tumor tissue. The following probes were used: LSI IGH(14q32)/ BCL2(18q21) Dual Color, and the LSI IGH(14q32/ MYC(8q24)/CEP 8 Tri-Color Dual Fusion probes. All cases demonstrated low-level amplification with three to four copies of either C-MYC, IGH or both C-MYC and IGH. Three of six cases also had a t(14;18)(q32;q21). Two of six patients expired shortly after diagnosis. One patient continued to demonstrate progressively worsening refractory disease. Two patients achieved remission after an expanded course of treatment. Gene amplification and the subsequent over expression of the amplified oncogene play an important role in tumor pathogenesis. Few cases of Intermediate tumor patients with C-MYC amplification and a t(14;18)(q32;q21) have been reported. All were associated with a poor prognosis. Our patients demonstrated low level C-MYC and/or IGH amplification. To our knowledge, IGH amplification has not been previously reported in patients of with Intermediate high grade lymphoma. Low-level IGH and C-MYC amplification maybe predictive of a poor outcome in these patients. FISH analysis of C-MYC, IGH and IGH/BCL2 appears to be significant and is advised when Intermediate tumors are detected. Clinical data on these aggressive Intermediate lymphomas has been sparse and therapeutic regimes are controversial. Our findings, as well as further studies may be useful in the assistance of determining the best clinical course for this patient population.

1037F

Two deletions in the APC gene (an inherited deletion in exon 1 and a de novo deletion in exon 12) and a de novo MUTYH deletion causing familial adenomatous polyposis. *G. A. Molfetta[1,2], O. C. Vincenzi[2], J. Huber[3], A. A. Marques[1], W. A. Silva, Jr.[1,2].* 1) Departament of Genetics, Medical School of Ribeirao Preto, University of Sao Paulo; 2) National Institute of Science and Technology in Stem Cell and Cell Therapy, Regional Blood Center of Ribeirao Preto; 3) Medical Genetics Unit, University Hospital of the Medical School of Ribeirao Preto, University of Sao Paulo.

Familial adenomatous polyposis (FAP) is a syndrome of colon cancer predisposition characterized by the development of hundreds to thousands adenomatous colonic polyps. It presents a wide spectrum of clinical manifestations, including the following phenotypes: classical FAP, attenuated FAP, Gardner's and Turcot's syndromes. The clinical diagnosis of classic FAP includes the presence of more than one hundred colorectal polyps or a reduced number of polyps together with affected close relatives. Molecular diagnosis relies on detecting mutations in the APC gene, a tumor suppressor gene with autosomal dominant inheritance, complete penetrance, and variable expression. Molecular genetic testing of APC detects disease-causing mutations in up to 90% of individuals with typical FAP and is most used in the early diagnosis of at-risk family members, as well as in confirming the diagnosis of classical or attenuated FAP in individuals with equivocal findings. We describe here a family presenting classical FAP and DNA sequencing of the entire coding region of the APC gene that showed no mutations. Multiplex Ligation-dependent Probe Amplification (MLPA®) was also employed to detect deletions in MUTYH and APC genes and revealed that the patient inherited from her mother a deletion of the entire exon 1 in the APC gene. In addition, the same patient also showed two *de novo* deletions: exon 1 in the MUTYH gene and another deletion encompassing exon 12 in the APC gene. RFLP analysis helped to characterize the deletion extension on approximately 150 bp. Microsatellite analysis confirmed paternity as patient's father has no clinical diagnosis of FAP as well as neither mutations nor deletions within the APC gene. Regarding clinical aspects of this family, the patient showed less polyps than her mother and other relatives affected by FAP but showed more compromised organs such as intestine and stomach as she reported gastric polyps. We raise the hypothesis that the inherited deletion was the first event and caused the appearance of the other deletion due to recombination and unequal crossing over. We also speculated whether the two deletions within the APC gene are cis deletions located at the same chromosome as this gene is an important tumor suppressor and the total absence of its protein in case of trans deletions would be incompatible to the embryo life. Mutation screening in adenomatous polyposis coli gene in patients clinically diagnosed as familial adenomatous polyposis. *O. C. Vincenzi[1], G. A. Molfetta[1,2], J. Huber[3], C. Ayres[1], W. A. Silva, Jr.[1,2]*. 1) National Institute of Science and Technology in Stem Cell and Cell Therapy, Regional Blood Center of Ribeirao Preto; 2) Department of Genetics, Medical School of Ribeirao Preto - University of Sao Paulo, Ribeirao Preto, Sao Paulo, Brazil; 3) Medical Genetics Unit, University Hospital of the Medical School of Ribeirao Preto, University of Sao Paulo.

Colorectal cancer is among the most important malignant neoplasms, being the third cause of death by cancer in Brazil. Its development involves storage of mutations in oncogenes and in tumoral suppressor genes, as well as epigenetic changes. One of these abnormal genes is the Adenomatous Polyposis Coli (APC), a tumor suppressor that presents mutations in its codifying sequence and these mutations may be associated to colorectal adenomas that develop into adenocarcinomas. Defects in this gene cause Familial Adenomatous Polyposis (FAP), an autosomal dominant pre-malignant disease that usually progress to malignancy. FAP usually begins by the age of 16 years old and its main characteristic is the large development of pre-cancerous colonic polyps in the intestines, which invariably evolve for the installment of cancer. Among the goals of this project are the screening for mutations in the APC gene (GenBank M74088), using High Resolution Melting (HRM)technique and the sequencing of DNA in patients who present variations in this gene together with the search for deletions in gene APC in patients who do not show mutations. In this research are included patients with clinical suspicion of FAP which were attended in the Medical Genetics Unit and have signed for the consented blood taken in the University Hospital. After the extraction of genomic DNA, we proceeded with HRM and DNA sequencing in patients who presented variations. We also performed the technique of Multiplex Ligation-dependent Probe Amplification (MLPA) to detect deletions in patients which do not presented mutations in the APC gene. Among the 17 patients in study, we described a new mutation c.del2157T, which creates a premature stop codon at position 726 of the protein. We also found out two pathogenic mutations: a *nonsense* one, creating a premature stop codon site in position 302 (Arg302Stop), and a *missense* one in position 1822 (Asp1822Val) together with a deletion, detected by MLPA, of the complementary allele characterizing this patient as a compound heterozygous. In addition, MLPA was also employed to detect deletions in MUTYH and APC genes and revealed a family sharing a deletion of the entire exon 1 in the APC gene. Furthermore, the proband also showed two *de novo* deletions, one in exon 1 in the MUTYH gene and another deletion in exon 12 in the APC gene. Genetic counseling was offered to other members of the affected families who agreed to be tested. Financial Support: FAPESP(2011/11456-0).

High-Precision CNV Analysis of FFPE Samples with the nCounter Analysis System. G. *Geiss.* Res, NanoString Technologies, Seattle, WA.

Background The nCounter Analysis System from NanoString Technologies is a digital technology capable of precisely quantifying up 800 nucleic acid targets in a single reaction. The nCounter System has gained a strong reputation for delivering high-quality data for gene expression and miRNA analysis of FFPE samples. Here, we describe the development and optimization of a protocol for analysis of Copy Number Variation in FFPE samples and present high quality data generated using the protocol. Method A variety of fresh frozen and FFPE samples were tested against an nCounter CodeSet designed to quantify 85 CNVs known to be associated with cancer. Multiple parameters were evaluated to optimize performance of the assay. Results Four experimental parameters were found to influence the accuracy of the assay: sample quality, number of probes per region, method of fragmentation, and reference sample selection. Greater than 90% accuracy can be expected when appropriate experimental design considerations are accounted for and in many cases 95% accuracy was observed in our experiments. As expected, the quality of DNA extracted from FFPE samples quality is critical for data quality, but even poor quality samples are expected to generate reliable data with the right experimental considerations. Conclusion The nCounter Analysis System is a reliable tool for analysis of CNVs in FFPE samples. It generates unbiased, highly reproducible results from FFPE samples and the workflow advantages enable studies of hundreds of specimens to be completed quickly and efficiently.

Germline copy number variation in high-risk African American families with prostate cancer. *E. Ledet[1], X. Hu[2], O. Sartor[3], W. Rayford[4], M. Li[5], D. Mandal[1]*. 1) Dept Genetics, Louisiana State Univ HSC, New Orleans, LA; 2) Cytogenetics, Sonora Quest Laboratories, Tempe, AZ; 3) Departments of Medicine and Urology, Tulane University School of Medicine, New Orleans, LA; 4) 4Department of Preventive Medicine, University of Tennessee Health Science Center, Memphis, TN; 5) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, LA.

Prostate cancer is a complex multi-allelic disease and the most common malignancy in men. The incidence of prostate cancer in African American men is more than twice as high as that of any other race. Despite the high prevalence of prostate cancer amongst African American men, this population has been under represented in genetic studies of prostate cancer. Although genomic copy number variations (CNVs) have been detected in prostate tumors, this is the first study describing germline CNVs in African American hereditary prostate cancer families. Ten high-risk African American families with 3 or more affected individuals and with an early age of onset were recruited. From these families, 37 individuals, including 23 affected males and 14 unaffected males, were selected for CNV analysis. Array comparative genomic hybridization (aCGH) was used to characterize germline CNVs unique to African-American men with hereditary prostate cancer. Through common aberration analysis in affected family members, novel CNVs were identified at chromosomes 1 and 16. Differential analysis comparing affected and unaffected family members identified a 9.4 kb duplication on chromosome 14q which segregate with prostate cancer patients in these high risk families. Importantly, this region encompasses IGHG3 gene which has been shown to have both significant gains in copy number as well as overexpression in prostate tumors in African Americans. These CNVs may represent a component of genetic predisposition which contributes to the high prevalence and mortality of prostate cancer in African American men.

***hapLOH*: Powerful haplotype-based profiling of allelic imbalance in impure tumor samples.** *P. Scheet[1,2], R. Xia[3,1], S. Vattathil[2,1]*. 1) Dept. of Epidemiology, Univ. of Texas MD Anderson Cancer Center, Houston, TX; 2) Human & Molecular Genetics Program, Graduate School of Biomedical Sciences, Univ. of Texas at Houston, Houston, TX; 3) Div. of Biostatistics, Univ. of Texas School of Public Health, Houston, TX.

Tumor samples often contain both cancer cells and normal cells due to difficulties in tumor excision. In these cases, cancer-associated allelic imbalance events such as copy-neutral loss of heterozygosity (LOH), deletions and other aneuploidies will exist in a fraction of the sampled cells only. Multiple SNP-array based methods have been developed specifically for detecting allelic imbalance in impure tumor samples, but they lose sensitivity when the tumor proportion is below 10%, as the signal from allelic imbalance resembles noise when analyzed at the single-marker level. However, for many cancer types (e.g. breast, leukemias, myelomas) and due to incomplete dissection, analysis of cancer genomes at low levels of tumor purity is a reality.

To address these problems, we have created *hapLOH*, a hidden Markov model-based computational tool that applies to observed B allele frequencies and total intensity data from SNP microarrays. The key to our approach is that we address directly the dependence among frequencies within a region of allelic imbalance that results from loss or gain of a contiguous set of alleles on an individual's germline chromosome. To do so, we infer germline haplotypes to inform expected patterns in the B allele frequencies at heterozygous markers in regions of imbalance. We offer both parametric and nonparametric strategies to accommodate haplotype uncertainty and magnitude of signals.

Our methods are sufficiently powerful to allow inference of LOH as short as 10 Mb in tumor purities of 3–4% using a 317K SNP chip applied to serial dilutions of breast cancer cell line CRL-2324. With a hypothetical 5M SNP array, we estimate we can detect aberrant cells at purities of less than 1%, depending on the level of genomic aberration. Finally, our method substantially improves the estimation of the lost or gained haplotype within the tumor genome; at 5% purity, we observe an absolute 16% gain in accuracy over methods that fail to account for germline information. Our method can be used to profile allelic imbalance in samples for which efficient methods have not previously existed.

1042T

Protein Tyrosine Phosphatase Receptor Type J (PTPRJ) is implicated in lymphomagenesis of Follicular (FL) and Diffuse Large B-cell (DLBCL) lymphomas. *C.A. Aya-Bonilla[1], M.R. Green[1, 2], E. Camilleri[1], M. Benton[1], C. Keane[3, 4], P. Marlton[4], R. Lea[1], M.K Gandhi[3, 4], L.R. Griffiths[1].* 1) Genomics Research Centre, Griffith University, Gold Coast, QLD, Australia; 2) Department of Oncology, School of Medicine, Stanford University, Stanford, CA, USA; 3) Clinical Immunohaematology Laboratory, Queensland Institute of Medical Research, Brisbane, Australia; 4) Department of Haematology, Princess Alexandra Hospital, Ipswich Road, Woollongabba, Australia.

Diffuse Large B-Cell Lymphoma (DLBCL) and Follicular Lymphoma (FL) account for around 50% of all Non-Hodgkin lymphoma (NHL) cases. However, despite their high variability in morphology, tumour biology and clinical outcome, common genetic alterations across DLBCLs and FLs have suggested the existence of shared molecular mechanisms in the lymphomagenesis of these diseases, which could have biological/clinical relevance. The use of the Hidden Markov model (HMM) approach in the analysis of SNP array data from unpaired tumour DNA samples has allowed the detection of loss of heterozygosity (LOH) regions and possible tumour suppressor genes (TSGs) that might play a role in oncogenesis. A HMM algorithm was used for the analysis of loss of heterozygosity (LOH) on SNP array data from FLs (n=21) and DLBCLs (n=21). This revealed a high frequency of LOH over the chromosomal region 11p11.2, containing the gene encoding the protein tyrosine phosphatase receptor type J (PTPRJ), which was validated by significantly increased rates of homozygosity of PTPRJ-targeting microsatellites in NHL cases. Although, PTPRJ regulates components of key survival pathways in B-cells (BCR, MAPK and PI3K signaling), its role in B-cell development is poorly understood. LOH of PTPRJ has been described in several types of cancer but not in any hematological malignancy. Interestingly, FL cases with LOH exhibited down-regulation of PTPRJ, in contrast non significant variation of expression in DLBCL cases. Moreover, we undertook a sequence screening in exons 5 and 13 of PTPRJ to identify the G973A (rs2270993), T1054C (rs2270992), A1182C (rs1566734) and G2971C (rs4752904) coding SNPs (cSNPs) and showed that the A1182 allele was significantly more frequent in FLs and in NHL cases with LOH. Significant over-representation of the C1054 allele (rs2270992) and the C2971 allele (rs4752904) were also observed in LOH cases. A haplotype analysis, performed on the cSNPs, found a significant lower frequency of the GTCG haplotype in NHL cases, but it was only detected in cases without LOH. Conversely, the GCAC haplotype was over-represented in cases with LOH. Altogether, these results implicate inactivation of PTPRJ as a common lymphomagenic mechanism in DLBCL and FL. In addition, it also suggests that the detection of polymorphisms in the PTPRJ ectodomain, together with LOH events, could affect the ligand-mediated activation of this receptor-like protein tyrosine phosphatase in these B-cell lymphomas.

1043F

Computational Techniques to Detect BFB in Tumor Genomes. *S. Zakov, M. Kinsella, V. Bafna.* Computer Science and Engineering, University of California, San Diego.

Breakage-Fusion-Bridge (BFB) is a mechanism of genome instability characterized by increased copy numbers of chromosomal segments. BFB begins with the loss of a telomere followed by the fusion of telomere-lacking sister chromatids. During anaphase, as centromeres migrate to opposite ends of the cell, the fused chromatids are torn apart, resulting in one chromosome with a terminal inverted duplication and another with a terminal deletion. After several such BFB cycles, repeated inverted duplications can yield dramatic amplifications of chromosome segments.

Observing an ongoing BFB process directly is rare, so evidence for BFB is generally only available from the modified genome after BFB has ceased. But, the proper interpretation of such evidence is not obvious. Clearly, much information can be inferred from the modified genomic sequence itself. Unfortunately, the expected genomic amplifications create significant difficulties when applying current sequencing methods, due to high ambiguity during read reassembly. Additional BFB evidence can be inferred from inversions detected by paired-end sequencing, identification of chromosomal segment locations by FISH analysis, and examination of copy number variations of enhanced chromosomal segments.

In this work, we present computational techniques to aid the interpretation of the types of BFB evidence mentioned above. We first pose the *BFB Count Vector* problem: given a genome segmentation and corresponding segment copy numbers, decide whether BFB can yield a genome with the given segment counts. We present the first polynomial time algorithm for the problem, improving a previous exponential time algorithm. We also show, that for certain alternative rearrangement models, count vectors, inversion patterns, and FISH analyses are sufficient for detecting BFB, while for other models such analyses are not enough for distinguishing BFB from non-BFB modifications. We apply the presented techniques to SNP array data from cancer cell lines and osteosarcoma biopsies and paired-end sequencing data from pancreatic tumors, and demonstrate their practicality for BFB identification and rejection.

1044W

Evaluation of cytogenetic and gene polymorphic variants in workers occupationally exposed to Silica-stone quarry industry. *R. Chandirasekar[1], K. Sasikala[1], B. Lakshman kumar[2], R. Raichel Jacob[1], H. Kavitha[2].* 1) Unit of Human Genetics, Department of Zoology, Bharathiar University, Coimbatore, Tamil Nadu, India. 641 04; 2) Department of Biotechnology KonguNadu arts and science college, Coimbatore, India 641 046.

Abstract Stone workers are exposed primarily to silica, there is strong epidemiological evidence to support an association between occupational crystalline silica exposure and several diseases such as silicosis, lung cancer, pulmonary tuberculosis, and chronic obstructive pulmonary disease, autoimmune diseases (systemic sclerosis, systemic lupus erythematosus, and rheumatoid arthritis), and renal diseases. Aim of the present study was, to evaluate the chromosome aberrations of workers exposure to silica dust in stone quarry industry. The cases for this study include workers exposed to silica for a long term. They were divided into two groups in accordance with duration of exposure and tobacco smoking habits. We observed changes in the frequency of chromosomal aberrations and micronuclei among the exposed subjects when compare to age matched controls. In this context, the results were observed in significantly ($P < 0.05$) high. Occupational exposure to crystalline silica was associated with an increased risk of lung cancer. a higher number of micronuclei and chromosomal aberrations were recorded in the workers exposed to silica-stone quarry industry (group I non-smokers and group II smokers). When XRCC1 and Tp53 gene polymorphic variants were carried out, based on that homozygous polymorphic variants were found have increased level of chromosome and micronuclei frequency. From this study we conclude that homozygous polymorphic variants has an increased association with cytogenetic parameters among the long term exposed workers of stone quarry industry.

1045T

Differential expression of AURKA and AURKB genes in bone marrow stromal mesenchymal cells of myelodisplastic syndrome: Correlation with G-banding analysis and FISH. *F.M. Oliveira[1,2], A.R. Lucena-Araujo[1,2], M.C. Favarin[1], E.M. Rego[1,2], R.P. Falcão[1,2], B.P. Simões[1,2], D.T. Covas[1,2], A.M. Fontes[2].* 1) Internal Medicine - Hematology, Faculty of Medicine of Ribeirão Preto, Riberão Preto, São Paulo`,Brazil; 2) National Institute of Science and Technology in Stem Cell and Cell Therapy, Ribeirão Preto, Brazil.

It has been demonstrated that genomic alterations of cells in the hematopoietic microen-vironment could induce myelodysplastic syndromes (MDS) with ineffective hematopoi-esis and dysmorphic hematopoietic cells, and subsequent transformation to acute mye-loid leukemia. This investigation is the first attempt to correlate the gene expression profile of AURKA and AURKB in a cytogenetically stratified population of mesenchymal stem cells (MSCs) from MDS patients. We found that AURKA mRNA was expressed at significantly higher levels in MSCs even with normal/altered karyotype when compared with hematopoietic cells and healthy donors. Additionally, we found that the presence of chromosomal abnormalities (mainly aneuploidies) in hematopoietic cells/ MSCs was also associated with higher levels of AURKA. Different form previous investigations, our findings, regarding AURKA expression support the hypothesis that the presence of chromosomal abnormalities in MSCs from MDS is not a consequence of the method used for chromosome preparation. They may reflect the genomic instability present in the bone marrow microenvironment of MDS patients. This information is also supported by differences observed in the growth kinetics between MSCs from healthy donors (normal karyotype) and from MDS patients with abnormal karyotype. In summary, our results may not be considered evidence that MDS and MSCs are originated from a single neoplastic clone. In fact, both cells (hematopoietic and MSCs) may probably be altered in response to damage-inducing factors and the presence of genomic abnormalities in MSCs suggests that an unstable bone marrow microenvironment may facilitate the expansion of MDS/leukemic cells.

1046F

A new function for the VHL tumour suppressor protein: Prevention of genome instability through promotion of homologous recombinational DNA repair. *M.S. Meyn[1,2,3], J.L. Metcalf[4], P.S. Bradshaw[1], M. Komosa[1], S.N. Greer[4], W.Y. Kim[5], M. Ohh[4].* 1) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 3) Department of Paediatrics, University of Toronto, Toronto, ON, Canada; 4) Department of Laboratory Medicine and Pathology, University of Toronto, Toronto, ON, Canada; 5) Department of Haematology Oncology, The Lineberger Comprehensive Cancer Centre, University of North Carolina, Chapel Hill, NC.

Germ line mutations in the *VHL* tumour suppressor gene cause Von Hippel Lindau syndrome, a condition associated with a high risk of renal carcinoma. Loss of VHL function also occurs in the vast majority of sporadic clear-cell renal carcinomas. One characteristic of these tumours is a high degree of genome instability. The molecular mechanism underlying the link between genome instability and loss of VHL is not easily explained by VHL's known function: targeting the transcription factor HIFα for ubiquitylation-mediated destruction. We now report that VHL is a member of the DNA Damage Response (DDR) network that coordinates DNA repair and other cellular functions following induction of DNA Double Strand Breaks (DSBs).

We find that SOCS1 (suppressor of cytokine signalling 1) promotes K63-ubiquitylation of VHL in response to DSBs. Loss of VHL results in impaired phosphorylation of H2AX, a key component of the platform of modified chromatin that develops around DSBs. VHL loss also causes attenuation of DSB-induced foci of the DDR sensor protein MRE11, decreased homologous recombination (HR) repair of DSBs and persistence of unrepaired DSBs. These effects on the DDR network are VHL K63 ubiquitylation-dependent but HIFα-independent, as a *VHL* mutant that cannot undergo K-63 ubiquitylation but retains its ability to target HIFα is deficient in these DDR responses.

Our results identify VHL as a novel component of the DDR network, a major defense against genome instability. Like the Fanconi anemia proteins FancD2 and FANCI, VHL must be ubiquitylated in order to facilitate HR repair of DSBs. Our observations support the idea that loss of VHL impairs both the cell's DDR network and HIFα-dependent apoptosis, defects that act synergistically to promote the survival of cells with increased DNA damage and genome instability, cells that likely contribute to the development of cancer.

A new role for the ATM protein: Homologous recombination repair of DNA damage. *P. Bradshaw[1, 2], M. Komosa[1], M.S. Meyn[1, 2].* 1) Program in Genetics & Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Dept of Molecular Genetics, University of Toronto, Toronto, ON, Canada.

Ataxia-Telangiectasia (A-T), an autosomal recessive disorder caused by ATM mutations, is characterized by progressive cerebellar ataxia, immunological defects, radiation sensitivity, cancer predisposition and genomic instability. Following induction of DNA Double Strand Breaks (DSBs), the ATM protein kinase plays a critical early role in triggering the cellular DNA Damage Response (DDR), which leads to local establishment of a megabase region of modified chromatin surrounding the DSB, as well as activation of cell cycle checkpoints and stress responses, DDR functions that together determine cell fate (survival, senescence or death) following DNA damage. We now report a new role for the ATM protein: facilitating Homologous Recombination (HR) repair of DSBs. We find that ATM recruitment to DNA damage sites differs from those of other DDR proteins: ATM forms small discrete foci that do not diffuse with time but remain tightly confined to regions proximal to the DSB. Interestingly, ATM foci do not directly co-localize with foci of RPA, FANCD2 and Rad51, proteins implicated in HR repair. Rather, the kinetics and spatial dynamics of ATM and HR protein foci suggest that ATM may mark a subset of DSBs for subsequent HR-mediated repair. Consistent with these findings, ATM promotes HR repair by facilitating CtIP-mediated resection of DSBs, thereby allowing RPA access to DSBs, a key initial step in HR repair. Further, while MDC1 is required for the association of most DDR proteins with the megabase region of modified chromatin that surrounds a DSB, it is dispensable for ATM accumulation at DSBs and for ATM activation of the DDR, supporting the notion that ATM action occurs in small localized regions immediately proximal to DSBs. Our results demonstrate a direct role played by ATM in the repair of DSBs and suggest that ATM-mediated processing of DNA damage is restricted to those DSBs that are destined to undergo HR repair. Further, ATM-mediated signaling does not extend along megabase chromatic regions but is restricted to localized regions proximal to the DSB. The data represents a paradigm shift in our understanding of the role played by ATM in the repair of DSBs and activation of the DDR network.

1048T

A crosstalk between ATM and FA/BRCA proteins is necessary to preserve DNA integrity during G2/M phase. *L.C. Torres Maldonado[1], D. Sosa[1,2], M. Castañon[2], A. Rodriguez[1], B. Molina[1], C. Lopez Camarillo[2], S. Frias[1,3].* 1) Genetica Humana, Instituto Nacional de Pediatria, Mexico DF, Mexico DF, Mexico; 2) Posgrado en Ciencias Genomicas. Universidad Autonoma de la Ciudad de México. Mexico D.F. Mexico; 3) 3Departamento de Medicina Genomica y Toxicología Ambiental, Instituto de Investigaciones Biomedicas, Universidad Nacional Autonoma de México. Unidad INP. Mexico D.F. Mexico.

Fanconi Anemia (FA) is a recessive disease, characterized by chromosomal instability, pancytopenia, congenital abnormalities, predisposition to malignancy and hypersensitivity to DNA interstrand crosslinking agents. FA is caused by mutations in one of 15 genes involved in the FA/BRCA pathway of DNA repair. Recent evidence suggests that in order to preserve their genome integrity FA cells are dependent on alternative DNA monitoring and repair proteins, such as ATM. We have observed that hydroxyurea (HU), applied during G2, is able to enhance the DNA damage produced by MMC in FA-A cells. Therefore, we hypothesized that HU interferes with a DNA integrity checkpoint orchestrated by ATM and the FA/BRCA pathway that operates during G2. In order to corroborate this hypothesis we analyzed the chromosomal aberrations (CA), ATM mRNA levels by real time RT-PCR and ATM phosphorylation status by flow cytometry during G2 in FA-A and normal cell lines, cultured and treated with 1) MMC, 2) HU, and 3) MMC+HU, and 4) an untreated control. FA-A cells displayed a larger number of CA compared with normal cells in all treatments; but the highest frequency of CA was observed with the MMC+HU treatment. ATM mRNA levels were significantly elevated in FA-A cells treated with MMC or HU, being five times higher with the MMC+HU treatment in comparison to the FA-A control; in contrast normal cell lines showed no differences in any treatment. Finally, the phosphorylation of ATM was increased in FA-A cells even without treatment, predominantly during G2 regardless of the experimental condition, in comparison with normal cells, Our data suggest that normal cells with a proficient connection between ATM and the FA/BRCA proteins transit from G2 to M with low chromosome damage despite the presence of MMC or HU. Moreover the elevated levels of ATM mRNA in FA-A cells suggests that effectively these cells are over activating the ATM pathway to compensate their DNA repair deficiencies. However, the increased number of CA in FA-A cells induced by HU during G2, suggest that FANCA and ATM belong to a DNA damage checkpoint pathway that operates before the progression to M phase, and that the connection among these proteins is lost in the presence of FANCA mutations, rendering FA cells with an excess of chromosomal aberrations that otherwise should be eliminated. HU could interfere with this alternative pathway inhibiting downstream effectors of ATM. CONACYT 84259.

1049F

A dynamic model of the FA/BRCA DNA repair pathway. *A. RODRIGUEZ[1], L. TORRES[1], D. SOSA[1], E. CORTES[2], A.M. SALAZAR[3], R. ORTIZ[2], P. OSTROSKY[3], L. MENDOZA[3], S. FRIAS[1, 3].* 1) Laboratorio de Citogenética, Departamento de Investigación en Genética Humana, Instituto Nacional de Pediatría, Mexico; 2) Departamento de Ciencias de la Salud, Universidad Autónoma Metropolitana-Iztapalapa; 3) Instituto de Investigaciones Biomédicas, Universidad Nacional Autónoma de México.

The FA/BRCA pathway repairs DNA interstrand-crosslinks (ICLs). Mutations in the genes coding for this pathway cause Fanconi anemia (FA), a chromosome instability syndrome with increased spontaneous chromosomal aberrations and high sensitivity to ICL inducing agents. Despite the presence of DNA damage, FA cells are able to progress throughout the cell cycle, suggesting that the FA/BRCA pathway deficiency affects the function of the DNA integrity checkpoints and that FA cells could process the damage by using alternative error-prone DNA repair pathways. Given the complexity of the ICL repair process, in this work we have developed a Boolean network model of the FA/BRCA pathway to generate some predictions about the functioning of the pathway and its mutants. To obtain the model we have thoroughly analyzed the FA literature, reconstructed the simplest network that contains all the relevant information and generated a Boolean network model using the logic operators AND, OR and NOT. The program BoolNet has been used to perform computational simulations of the model. The in silico simulations suggest that FA cells: 1) Activate primarily the non-homologous end-joining pathway as an alternative DNA repair process, followed by the homologous recombination repair to deal with the double strand breaks generated during ICL processing. 2) Continue throughout the cell cycle, even with unrepaired DNA double strand breaks, activating the mechanism known as Checkpoint Recovery. These proposals were partially addressed in the lymphoblastoid cell lines FA- A VU817 and NL-49, exposed to mitomycin C. To validate proposal no. 1, the presence of the phosphorylated DNA-PKcs protein was evaluated by flow cytometry, a critical protein in the non-homologous end-joining pathway. Experimental results and simulations concur that the non-homologous end-joining pathway is the main alternative DNA repair pathway in FA-A cells. To validate proposal no. 2, the presence of the phosphorylated CHK1 protein was evaluated, this protein is involved in the cell cycle arrest when the DNA has been damaged. Moreover, the entrance and exit from mitosis has been evaluated by using the MPM2 antibody and a cytokinesis block essay. Both, the model and our experimental approach concur that despite FA-A cells efficiently activate the CHK1 protein and accumulate on the G2 phase of the cell cycle due to the large amount of DNA damage, they are still able to divide and proceed throughout the cell cycle.

1050W

Fanconi anemia pathway proteins act together and independently to regulate homologous recombination and synthesis of telomeric DNA in ALT-immortalized human cells. *H. Root[1,2], M. Komosa[1], A. Larsen[1,3], D. Bazett-Jones[1,3], M.S. Meyn[1,2,4].* 1) Program in Genetics & Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Dept Molecular Genetics, University of Toronto, Toronto, ON, Canada; 3) Dept of Biochemistry, University of Toronto, Toronto, ON, Canada; 4) Dept of Paediatrics, University of Toronto, Toronto, ON, Canada.

Fanconi anemia (FA) is an inherited disorder characterized by bone marrow failure, congenital malformations and cancer. To understand how FA proteins function in replication and genetic recombination, we are studying their role in ALT, the recombination-dependent telomere maintenance pathway used by the 10–15% of human cancers which are telomerase negative.

We find that FANCD2, FANCJ, FAN1 and FANCP/SLX4 form nuclear foci that colocalize with telomeric foci in cells that utilize ALT telomere maintenance. This colocalization typically occurs during S/G2 within ALT associated PML bodies (APBs). Our electron spectroscopic and immuno-FISH imaging demonstrates that APBs primarily contain extrachromosomal telomeric repeat (ECTR) DNA that is partially single stranded in nature. SiRNA depletion of FANCD2, FAN1 or FANCP in ALT cells leads to a rapid and dramatic increase in ECTR DNA synthesis, while depletion of the DNA helicases FANCJ or BLM leads to a decrease in ECTR DNA synthesis. Using siRNA co-depletion we find that ECTR DNA synthesis in FANCD2-depleted cells requires BLM, FANCJ, and ATR expression, but is independent of RAD51 and POLH. To characterize the ECTR DNA within individual cells, we have developed a novel diffusion based FISH approach and find that the ABPs in FANCD2, FAN1 or FANCP depleted-ALT cells contain tangled complexes of hundreds to thousands of individual G and C strand ECTR DNA ranging from <1 to >50 kb in length. Production of excess ECTR DNA occurs within the first few doublings post protein depletion, consistent with a mechanism involving rolling circle replication. This ECTR DNA is not the result of rapid telomere deletion events, as there is no increase in telomere free ends in FANCD2-depleted ALT cells. Instead, interactions between telomeric DNAs increase upon FANCD2 depletion, with cells showing an increase in telomere sister chromatid exchanges and more frequent or stable interactions between telomeres and APBs.

Although siRNA depletion of FANCD2, FAN1 or FANCP all results in the common phenotype of ECTR DNA amplification, siRNA depletion of any one of these three proteins does not reduce the localization of the other proteins to APBs. This, taken together with our FANCJ results, suggests that FA proteins do not function in a single linear pathway, but rather, work both together and independently to regulate genetic recombination.

Transcriptome sequencing of tumor subpopulations reveals a spectrum of therapeutic options in squamous cell lung cancer. *C.L. Barrett[1,2], R.B. Schwab[1,4], H. Jung[1], B. Crain[1], D.J. Goff[5], C.H.M. Jamieson[5], P.A. Thistlethwaite[4], O. Harismendy[1,2,3], D.A. Carson[6], K.A. Frazer[1,2,3,7].* 1) Moores Cancer Center, UCSD, La Jolla, CA; 2) Department of Pediatrics and Rady Children's Hospital, UCSD, La Jolla, CA; 3) Clinical and Translational Research Institute, UCSD, La Jolla, CA; 4) Division of Cardiothoracic Surgery, UCSD, La Jolla, CA; 5) Department of Medicine, Stem Cell and Moores Cancer Center, UCSD, La Jolla, CA; 6) Sanford Consortium for Regenerative Medicine, La Jolla, CA; 7) Institute for Genomic Medicine, UCSD, La Jolla, CA.

The cancer stem cell (CSC) hypothesis predicts that the tumor subpopulation responsible for chemotherapy resistance is comprised of CSCs, making CSC-targeted therapies a priority. Here, we sorted a squamous cell non-small cell lung carcinoma into CSC and non-CSC subpopulations based on the CD133 marker and performed whole-genome analysis and transcriptome sequencing (RNA-seq) to gain insights into the molecular mechanisms underlying their phenotypic differences and to identify new potential therapeutic targets. We determined that approximately half of the genome in both the CD133+ and CD133- subpopulations was highly deranged by copy number alterations in a largely indistinguishable manner. Transcriptome analysis identified highly expressed cell surface (CD molecule, GPCR, and ion channel) mRNA isoforms in the tumor cells whose protein products are actively being pursued as drug targets for other cancers. Interestingly, many of these gene isoforms are differentially expressed between the CD133+ and CD133- subpopulations and potentially contribute to their phenotypic differences. Expression analysis suggests that both subpopulations proliferate due to very high levels of c-Myc and the TRAIL long isoform (TRAILL) and that the normal apoptotic response to this was likely blocked by very high levels of Mcl-1L, Bcl-xL and c-FlipL —isoforms for which targeted therapies are now in clinical development. We also detected expression of two oncofetal isoforms in the tumor subpopulations. Transcriptome sequencing data for 221 squamous cell lung cancers confirmed the generality of our findings for this disease. Our study demonstrates that transcriptome sequencing can provide deep insights into the phenotypic differences and similarities of CSCs and non-CSCs and, importantly, can be leveraged to identify new potential therapeutic options for cancers beyond what is possible with DNA sequencing.

1052F

A novel bi-allelic MSH2 mutation associated with constitutional mismatch repair deficiency syndrome, and review of the clinical phenotype. *P-Y.B. Au[1], R. Perrier[1], E.G. Puffenberger[3], S. Hume[4], R. Anderson[5], L. Lafay-Cousin[5], D. Strother[5], B. McInnes[1], J. Parboosingh[1,2], F. Bernier[1,2].* 1) Medical Genetics, Alberta Children's Hospital, Calgary, Alberta, Canada; 2) Alberta Children's Hospital Research Institute for Child and Maternal Health; 3) The Clinic for Special Children, Strasburg, Pennsylvania; 4) Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 5) Department of Hematology and Oncology, Alberta Children's Hospital, Calgary, Alberta, Canada.

DNA mismatch repair (MMR) is important for genomic stability and DNA replication fidelity. Lynch syndrome is due to mono-allelic mutations of MMR genes. However, bi-allelic mutations that affect MMR genes result in constitutional mismatch repair deficiency syndrome (CMMR-D). Patients with CMMR-D frequently develop malignancy in childhood, often within the first decade. Malignancies include childhood leukemia, lymphoma, and brain tumours. Lynch related tumours such as colorectal cancer are also possible, and can present in adolescence. Interestingly, these patients have skin findings similar to neurofibromatosis type 1 (NF1). We report a novel mutation in MSH2 causing CMMR-D in several children in a large extended consanguineous Southeast Asian family. The index patient presented at 4 years with T cell lymphoblastic lymphoma, and then developed gliobastoma multiforme at age 10. His sister and his first cousin once removed also developed glioblastoma at ages 7 and 6 respectively. Another cousin developed a primitive neuroectodermal tumour at 7 years. All 4 children had multiple café au lait macules and axillary freckling. However, unlike NF-1, many of their café au lait macules were atypical. SNP array homozygosity mapping identified a region identical by descent on chromosome 2, corresponding to both MSH2 and MSH6 loci. MSH2 and MSH6 were absent on immunohistochemical staining of tumour tissue. Sequencing of MSH6 revealed no mutation. MSH2 was sequenced, and the mutation hMSH2 c.[1276+3A>C] was identified on both alleles in the index patient. The other affected children of this extended family were also homozygous for this mutation. This mutation affects the MSH2 intron donor sequence and is predicted to be pathogenic. Mutations affecting the +1 and +2 donor positions of this donor site have been described for Lynch syndrome and are known to affect splicing, but this mutation at +3 is novel, particularly in the context of bi-allelic mismatch repair deficiency. PMS2 is the most common MMR gene associated with CMMR-D. However, MLH1, MSH6 and MSH2 related CMMR-D have also been described, with MSH2 being more rare. There are now at least 10 cases of MSH2 related CMMR-D in the literature, involving 5 families. We will review the literature around CMMR-D and MSH2 mutations, and describe the skin pigmentary abnormalities seen in these children. The skin phenotype has not been well characterized for CMMR-D and exhibits some differences from NF-1.

Clinical and histopathologic characteristics between familial and sporadic melanoma in Barcelona, Spain. *C. Badenas[1], P. Aguilera[2], C. Carrera[2], J. Malvehy[2], JA. Puig-Butille[1], E. Martinez-Barrios[1], J. Palou[2], S. Puig[2].* 1) Biochemistry and Molecular Genetics Unit, Hospital Clinic-IDIBAPS. CIBERER, Barcelona, Spain; 2) Dermatology Department. Melanoma Unit. Hospital Clínic. IDIBAPS. CIBERER. Barcelona. Spain.

Background: About 6 to 14% of melanoma cases occur in a familial setting. In 20 to 40% of melanoma families germline mutations in *CDKN2A* are detected. **Objective**: to further characterize the clinical and histopathologic characteristics of familial melanoma to provide more information to clinicians and also contribute to understand the complex interplay of genetic and environmental factors in the pathogenesis of melanoma. **Methods**: Clinical, histopathologic and immunohistochemical characteristics of 62 familial melanomas were compared with 127 sporadic melanomas from our melanoma unit. **Results**: The most representative variables associated to familial melanoma were earlier age at diagnosis (OR 1.036; 95% CI 1.017–1.055), lower Breslow thickness (OR 1.288; 95% CI 1.013–1.683) and *in situ* melanomas (OR 2.645; 95% CI 1.211–5.778). And the most representative variables associated to *CDKN2A* mutation carriers were earlier age at diagnosis (OR 1.060; 95% CI 1.016–1.105), in situ melanomas (OR 6.961; 95% CI 1.895–25.567), the presence of multiple melanomas (OR 8.920; 95% CI 2.399–33.166) and the immunopositivity of the tumors for cytoplasmic survivin (OR 9.072; 95% CI 1.025–85.010). **Limitations**: the study is limited to patients from the Mediterranean area. **Conclusions**: familial occurrence of cutaneous melanoma was significantly associated with the earlier age of onset, lower Breslow thickness and a higher proportion of in situ melanomas; and also with the higher risk of multiple melanomas and the cytoplasmic survivin immunostainig in the case of carriers of *CDKN2A* mutations.

1054T

A survey of stromal responses and their clinical associations defined by the fibromatosis signature in different types of carcinomas. *JL. Chen[1], I. Espinosa[1,2], AY. Lin[3,4], OY. Liao[5], M. van de Rijn[1], RB. West[1].* 1) Department of Pathology, Stanford University Medical Center, Stanford, California, United States of America; 2) Department of Pathology, Hospital de la Santa Creu i Sant Pau, Institute of Biomedical Research (IIB Sant Pau), Autonomous University of Barcelona, Barcelona, Spain; 3) Department of Medicine, Santa Clara Valley Medical Center, San Jose, California, United States of America; 4) Department of Medicine, Stanford University Medical Center, Stanford, California, United States of America; 5) Department of Statistics, Stanford University, Stanford, California, United States of America.

Purpose: The fibromatosis signature developed from desmoids-type fibromatosis (DTF) was able to define a robust stromal response in breast carcinoma and identify a subset of breast tumors with better clinical outcome. The purpose of this study is to examine (1) this DTF fibromatosis signature in determining stromal responses and (2) its prognostic value in different types of malignant carcinomas. Experimental Designs: Gene expression profiles were collected from five ovarian, five lung, two colon and three prostate cancer datasets constituted by the total of 1127 ovarian, 519 lung, 493 colon and 279 prostate tumors. DTF fibromatosis signature was applied to each dataset to identify the subset of tumors with strong DTF stromal responses. Additionally, two different tissue microarrays of 204 ovarian tumors and 140 colon tumors were constructed for immunohistochemistry studies to examine the expression of protein markers of DTF fibromatosis signature, SPARC and CSPG2, in these tumors. Clinical data from each tumor were also collected to determine the correlation of high DTF stromal response with the survival of patients. Results: DTF fibromatosis signature defined robust stromal responses in ovarian, lung, and colon cancer. Transcriptome analysis and immunohistochemistry both showed that there were statistically significant worse survival associations of the subset of ovarian tumors with strong DTF stromal response. Conclusion: The results suggest that DTF fibromatosis signature can successfully identify the subset of ovarian, lung and colon carcinomas with strong stromal responses. The subset of tumors identified by this signature in breast and ovarian cancer, however, had opposite survival associations.

1055F

Anticipation in Hereditary Paraganglioma and Pheochromocytoma Syndromes. *H. Druker[1,2], D. Malkin[1,2], S. Meyn[1,2].* 1) Cancer Genetics Program, Hospital Sick Children, Toronto, ON, Canada; 2) Univeristy of Toronto, Toronto, ON, Canada.

Introduction: Paragangliomas and pheochromocytomas are rare in children. Germline mutations of *VHL, RET, SDHx, NF1, TMEM127*, or *MAX* has been identified in 59% of children. Genetic anticipation in these conditions has yet to be described. Four kindreds are presented with two conditions, VHL and PGL4, where anticipation is observed. This observation suggests the need for earlier initiation of surveillance. VHL Case 1: A three year old presented with bilateral pheochromocytomas. The average age at diagnosis in his parents' generation was 17 and in his grandfather's generation was 45. VHL Case 2: A nine year old presented with bilateral pheochromocytomas. Of the six VHL carriers in his generation, the average age at diagnosis was 11. The average age at diagnosis in their parents' generation was 45, and their grandmother remains unaffected at 78 years of age. PGL4 Case 1: A 15 year old presented with a paraganglioma of the bladder. His father was found to carry the same mutation at 47 years of age and is tumour-free. PGL4 Case 2: A 13 year old initially presented with bilateral pheochromocytomas. His mother was subsequently found to carry the same mutation at 67 years of age and is tumour-free. Discussion: Genetic anticipation describes the phenomenon in a genetic disorder of earlier age of onset with increasing symptom severity in subsequent generations. Molecular mechanisms to support clinical observations have been described in trinucleotide repeat disorders such as Huntington's disease and in telomere attrition disorders such as hereditary cancer predisposition syndrome, Li-Fraumeni Syndrome. The molecular mechanisms of both VHL and PGL4 are to be elucidated although preliminary evidence suggests that increasing genomic variation in subsequent generations contributes overall to their genetic instability. The possibility of earlier presentation of tumours in these conditions points to the need for earlier initiation of surveillance in subsequent generations.

Evaluation of MtDNA Dloop polymorphisms in Iranian Breast Cancer patients. *M. Ghaffarpour[1,2,5], S. Eslamizadeh[3], M. Arabzadeh[3], B. Motahari[4], N. Moazami[2], M. Houshmand[1,5].* 1) Medical Genetics Dep, National Institute of Genetic Engineering and Biotechnology, Tehran, Tehran, Iran; 2) Iranian Research Organization for Science and Technology; 3) Biology Dep, Faculty of Science, Ahar Azad University, Tabriz,Iran; 4) Biology Dep, Faculty of Science, Complex Azad University, Tehran,Iran; 5) Medical Genetics Dep,Special Medical Center, Tehran, Iran.

Introduction: Mitochondrial genome alterations have been suggested to play an important role in carcinogenesis. Its genome is also more susceptible to mutations because of high levels of reactive oxygen species and limited repair mechanisms. The D-loop of mitochondrial DNA (mtDNA) contains essential transcription and replication elements, and mutations in this region might alter the rate of DNA replication. the mtDNA D-loop region which is highly polymorphic, containing two hyper variable regions: HV1 (16024–16383) and HV2 (57–333) has been reported as somatic mutation “hot spot” in many types of cancer, including breast cancer. The aim of this study was evaluation of frequency of mononucleotide repeat (poly-C) between 303 and 310 nucleotides(HV1) and C16069T, T16189C, C16261T and T16311C polymorphisms(HV2) as somatic mutations “hot spots in Iranian patients with breast cancer. Materials and Methods: patients; 50 paired Fresh tumor and adjacent normal samples were obtained from consecutive patients with BC from IRANIAN National Tumor Bank, National Cancer Institute, Imam Khomeini Hospital Complexes, Medical Tehran University, and Tehran, Iran. Blood samples from 404 individuals of 17 ethnicities and 100 random in divide from Tehran special Medical Center (mixed ethnicities) were used as healthy controls. Mutational analysis: fresh tumors and their adjacent and also bloods samples as a control were extracted for genomic DNA using the QIAamp Mini Kit .We searched for mtDNA alterations of mononucleotide repeat (poly-C) between 303 and 310 nucleotides and C16069T, T16189C, C16261T and T16311C polymorphisms were analyzed by means of PCR sequencing. Result and conclusion: our result indicated that the frequency of mononucleotide repeat (poly-C) between 303 and 310 nucleotides were 11 of 27;40.72%, 9 of 27;33.33%,7 of 27;25.95% and 0 of 27;0% for C7,C8,C9 and C10 respectively for patients cases and124 of 504 ;38.3%,156 of 504; 48.1%,42 of 504 ;13% and 2 of 504;0.6% respectively for control group.The frequency of C16069T, T16189C,A16261G and A16311G polymorphisms were 11 of 50;22%, 6 of 50;12%,7 of 50;14% and 12 of 50;24%respectively for patients group and were 13 of 504;2.6%, 95 of 504;18.8%,53 0f 504;10.5%and 78 of 504;15.5% respectively for normal group. In conclusion, our study indicated that C16069T mtDNA D-Loop mutation may significantly play a role in the etiology of breast cancer. Further studies are warranted to confirm these findings.

1057T

Does high HERV-K expression participates in acute leukemia pathogenesis in children? *D. Januszkiewicz-Lewandowska[1,2], K. Nowicka[1], J. Rembowska[1], J. Nowak[1].* 1) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poznan, Poland; 2) Department of Pediatric Oncology, Hematology and Bone Marrow Transplantation of Medical University.

Human endogenous retroviruses - HERV are dispersed in the genome and constitute about 8% of the human genome. It is believed that HERV sequences derived from exogenous retroviruses, which in the course of evolution were incorporated into human genome thousands years ago. Most HERVs are non-functional due to numerous mutations and deletions. Some HERVs contain sequences capable of transcription. Patients with leukaemia show antibodies against HERV-K, which suggests increased expression of HERV-K sequences in leukemic cells. Due to small number of published research devoted to the expression of endogenous retroviruses in leukemias in children, studies were undertaken which purpose was to assess the expression of the env gene of HERV-K and HERV-W in the cells of acute lymphoblastic leukaemia and acute myeloid leukaemia in children. Material for the study was bone marrow blasts cells or peripheral blood of patients diagnosed with acute leukemia and normal peripheral blood lymphocytes. Study group consisted of 170 children with acute lymphoblastic leukemia (ALL) and 38 with acute myeloid leukemia (ANLL) hospitalized in the Clinic of Pediatric Oncology, Hematology and Transplantation Medical University in Poznan. The control group consisted of 30 healthy volunteers. Expression of the env gene of retroviruses HERV-K and HERV-W and the control gene beta-actin was studied by real-time PCR using specific oligonucleotide primers and SYBR Green marker. Expression was evaluated on the basis of absolute thresholds cT, normalized expression relative to beta-actin and double normalized expression to beta-actin reference gene and reference cells - normal peripheral blood lymphocytes. Absolute env gene expression of HERV-K and HERV-W (measured by cT - threshold values) was significantly higher in peripheral blood lymphocytes in comparison to ALL and ANLL. Only in ANLL a significantly higher, normalized to beta actin gene, relative expression of env gene of HERV-K has been found. Double normalized to beta actin gene, and normal peripheral blood lymphocytes relative expression of the env gene of HERV-K was significantly higher in ANLL compared to ALL. No statistically significant difference between double-normalized expression of the env gene of HERV-W between ALL and ANLL has been demonstrated. It can be concluded, that high normalized expression of HERV-K env gene in ANLL suggests that the gene may participate in the pathogenesis of ANLL.

SMAD4 loss-of-function mutations cause wide range of clinical disorders with unpredictable age-related penetrance. *N.M. Lindor[1], K.E. Wain[2], M.S. Ellingson[3], J. McDonald[4], A.D. Gammon[5], M.E. Roberts[6], D.L. Riegert-Johnson[7].* 1) Health Science Research, Mayo Clinic AZ, Scottsdale, AZ; 2) Laboratory Genetics, Mayo Clinic, Rochester, MN; 3) Medical Genetics, Mayo Clinic, Rochester, MN; 4) Department of Pathology, University of Utah, Salt Lake City, Utah; 5) Huntsman Cancer Institute, Salt Lake City, Utah; 6) Hematology/Oncology, Mayo Clinic, Jacksonville, FLA; 7) Gastroenterology, Mayo Clinic, Jacksonville, FLA.

Background: Haploinsufficiency of *SMAD4*, a key gene in the BMP/TGF-beta signaling pathway, leads to the syndrome of juvenile polyposis (JP) and hereditary hemorrhagic telangiectasia (HHT), now referred to as the JP-HHT syndrome. Clinical information on SMAD4 mutation carriers is extremely limited with the largest clinically detailed series describing only 15 individuals. Thus, the full extent of clinical variability and frequency of features is not well-understood. In this study, we sought to better define the penetrance for JP and HHT manifestations. **Methods:** Medical records of 24 mutation carriers from 14 families were abstracted from three clinical practices. **Results:** Ten different *SMAD4* mutations were found. The mean age was 33.7 years (range .1–65) at last follow up. First colon exam was conducted at a mean age of 23 (range 4–51) for indications including anemia (n=7), GI bleeding+/− anemia (n=8), JP suspected (n=7), obstructive symptoms (n=1), and unknown (n=5). The most recent colon exams were conducted at a mean age of 35 years. The number of colonic polyps ranged from 0 to over 1000, were generally pan-colonic, and was not associated with age. Gastric and small bowel imaging, performed at a mean age of 38 years (range 4–68), showed extensive gastric polyposis in seven individuals and low numbers of small bowel polyps, mostly in the duodenum. HHT findings included epistaxis (n=15, 63%), mucocutaneous AVMs (n=12, 50%), iron deficiency anemia at some point (n=17,71%), liver AVMs (n=5, 38%), brain AVM (n=1, 6%), lung AVM (n=2, 17%), and an intrapulmonary shunt detected by cardiac bubble study (n=12, 71%). Additionally, three individuals had mildly enlarged aortic roots and one died following repair of ascending aortic dissection, one had three incidental brain aneurysms, one had mild aortic and mitral insufficiency, and one had bilateral spontaneous retinal detachments. Neoplasms included two colorectal cancers, two Hurthle cell thyroid tumors, and bilateral malignant ovarian teratomas, jejunal cancer, adenocarcinoma of the esophagus, lymphoma found in one individual each. **Conclusion:** Carriers of *SMAD4* mutations require management for both juvenile polyposis and hereditary hemorrhagic telangiectasia as risk for findings of both are high and quite unpredictable. A larger series of patients will be necessary to further explore the significance of some of the occasional findings in this series.

Automatic Endometrial Tumor Screening for Lynch Syndrome. *M. Myers[1], P. Conrad[1], J. Rabban[2], J. Terdiman[1], K. Loranger[1], A. Blanco[1], L. Chen[2].* 1) UCSF Gastrointestinal Cancer Prevention Program, San Francisco, CA; 2) UCSF Helen Diller Comprehensive Cancer Center, San Francisco, CA.

Lynch syndrome (LS), also known as Hereditary Non-Polyposis Colorectal Cancer (HNPCC), is a hereditary cancer syndrome associated with up to a 75% lifetime risk of developing colon cancer and up to a 70% lifetime risk of endometrial cancer. Historically, Lynch syndrome has been diagnosed using clinical and family history criteria (Amsterdam and Bethesda criterion); however, it remains under diagnosed due to the lack of sensitivity of this approach. Tumors caused by LS gene mutations are known to display molecular features (microsatellite instability (MSI) and loss of mismatch repair protein expression detected by immunohistochemistry (IHC), but these molecular tests have only recently begun to be utilized in a systematic way to screen patients for LS. In July of 2010, the pathology department at UCSF began automatic screening for LS on endometrial tumors that met specific criteria and were surgically excised at UCSF. This automatic screening included MSI and IHC but did not include MLH1 promoter methylation. Between June 2010 and May 2012, 130 endometrial tumors met inclusion criteria for automatic tumor screening for LS of which 30 tumors had abnormal IHC results. Of the 30 endometrial tumors that had abnormal IHC results, 5 had a loss of MSH6 protein expression, 2 had a loss of MSH2/MSH6 protein expression, 4 had a loss of PMS2 protein expression and 19 had a loss of MLH1/PMS2 protein expression. These abnormal IHC results were followed up with by a genetic counselor who contacted the patient to explain their results, obtain a family history and discuss the role of further genetic testing to rule out LS with germline testing and hypermethylation analysis of the MLH1 promoter. Of the 19 patients who had a loss of MLH1/PMS2, 10 underwent further genetic testing and 9 refused any further evaluation due to lack of interest or insurance restrictions. Five patients underwent hypermethylation analysis of the MLH1 promoter All MLH1 hypermethylation testing was sent to an outside institution and all five were identified to have hypermethylation of the MHL1 promoter, thus ruling out LS. Based on this limited data, we feel MLH1 promoter methylation testing should be included as part of the automatic endometrial tumor testing protocol. This would streamline the process in properly identifying what patients are in need of further follow up by the genetic counselor.

Detection of EGFR mutations by TaqMan® Mutation Detection Assays powered by Competitive Allele-Specific TaqMan® PCR Technology (castPCR™). *N. Normanno[1,2], C. Roma[1], R. Pasquale[1], A.M. Rachiglio[1], C. Esposito[1], F. Fenizia[1], M.L La Porta[1], A. Iannaccone[1], F. Bergantino[1], S. Costantini[1], A. Rico[3], R. Petraroli[4].* 1) Centro di Ricerche Oncologiche di Mercogliano, 83013 Mercogliano, Avellino, Italy; 2) Cell Biology and Biotherapy Unit INT-Fondazione Pascale Via M. Semmola 80131 Naples Italy; 3) FALCON Team, Life Technologies, Parc Technologique, 91190 Saint Aubin, France; 4) FALCON Team, Life Technologies, via Tiepolo 18, 20900, Monza, Italy.

The discovery of driver mutations in key genes involved in regulating proliferation and survival of cancer cells is leading to remarkable successes in translational medicine. Different molecular techniques have been developed in order to deal with some limitations of tumor samples: the poor quality of the DNA extracted from formalin fixed paraffin embedded (FFPE) tissues, the low quantity of DNA available and the contamination of tumor sample by non-transformed cells. castPCR™ technology has a higher sensitivity as compared with other molecular techniques. EGFR mutations were assessed by castPCR™ in 40 FFPE tumour samples including 34 NSCLC and 6 colorectal carcinoma (CRC). The sensitivity and specificity of this method was compared with routine diagnostic techniques including fragment analysis, Real-Time PCR (allelic discrimination) and the EGFR Therascreen RGQ kit. By using routine diagnostic techniques, EGFR mutations were detected in 12/34 NSCLC patients, including 6 samples with deletions in exon 19; 4 samples with a L858R point mutations in exon 21; 2 samples with respectively a G719S and a G719A point mutation in exon 18. No EGFR mutations were detected in 6 CRC specimens. We next analyzed the 28 EGFR mutation negative samples with castPCR™ in order to identify cutoffs that ensure high specificity of the assay in FFPE samples. We found that 27/28 samples were also negative by cast PCR™ when excluding samples with a Ct>37 or with a deltaCt>7. We found in one of the negative samples a L858R point mutation that was not detected by using other methods. This mutation was confirmed by using a Peptide Nucleic Acid clamping-based Real-Time PCR technique. castPCR™ was also able to identify the same 12 mutations detected by the other methods. Our preliminary data suggest that there is an excellent correlation between castPCR™ and other molecular methods and that castPCR™ is highly specific to detect EGFR mutations in FFPE samples. In addition, castPCR™ might reveal EGFR mutations that are not detectable by other methods and this might have important implications for clinical decisions. These findings are being confirmed in a larger cohort of specimens in which TMDA will be also compared with Next Generation Based-methods using an AmpliSeq™ Custom Panel designed on predictive mutations for colon and lung cancer on the Ion Torrent™ PGM™.“For Research Use Only. Not for human or animal therapeutic or diagnostic use.”.

Germline Mutations and Microsatellite Instability Status in a Population-based Study of Women with Ovarian Cancer. *T. Pal[1], A. Mohammad[2], P. Sun[2], J. Lee[1], J. Fulp[1], Z. Thompson[1], A. Doty[1], D. Coppola[1], S. Nicosia[3], T. Sellers[1], J. McLaughlin[4], H. Risch[5], B. Rosen[6], J. Schildkraut[7], S. Narod[2].* 1) Interdisciplinary Oncology, Moffitt Cancer Center, Tampa, FL; 2) Womens College Hospital, Womens College Research Institute, Toronto, Canada; 3) Pathology and Cell Biology, University of South Florida, Tampa, FL; 4) Samuel Lunenfeld Research Inst., Dalla Lana School of Public Health, Toronto, Canada; 5) Epidemiology and Public Health, School of Public Health, Yale University, New Haven, CT; 6) Gynecology-Oncology, Princess Margaret Hospital, Toronto, Canada; 7) Community and Family Medicine, Duke University, Durham, NC.

Introduction: The frequency of germline mutations in the mismatch repair (MMR) genes, which results in Lynch Syndrome, remains incompletely defined in epithelial ovarian cancers. The purpose of this study was to estimate the frequency of germline MMR mutations in a multicenter population-based study of epithelial ovarian cancers. **Methods**: The analysis included 1893 women with epithelial ovarian cancer ascertained from three population-based studies. DNA was obtained from blood samples and full sequencing of the coding regions was performed on three HNPCC genes, MLH1, MSH2 and MSH6. In addition, there were a total of 967 women in whom microsatellite instability (MSI) testing results were available on tumor samples and normal DNA, and in a subset of those with a MSI-H phenotype, comprehensive rearrangement testing was performed through Multiplex Ligation-dependent Probe Amplification (MLPA) in the three genes. **Results**: In the 1893 women, 9 clearly pathogenic mutations were identified through sequencing (0.5%): 5 in MSH6, 2 in MLH1 and 2 in MSH2. An additional 60 patients had predicted pathogenic missense variants identified (3.1%). Thus, the combined frequency of pathogenic and predicted pathogenic mutations in the entire sample was 3.6% (69/1893) and 6.3% (27/431) among women with endometrioid or clear cell tumors. Of the 967 women who had MSI testing results, 133 had an MSI-H phenotype, of which additional germline DNA was available in 88 cases. In these samples, MLPA for the MMR genes was performed, and 3 additional mutations (large deletions) were identified in MSH2. Of note, 4 of the 9 mutation carriers identified based on sequencing results had MSI testing, all of whom were MSI-H, thus MLPA was not performed on these samples. Therefore, the combined frequency of pathogenic mutations detected either by sequencing or MLPA in those with an MSI-H phenotype was 7.6% (7/92). **Conclusion**: A small but potentially important proportion of women with epithelial ovarian cancer harbor mutations in genes predisposing to Lynch Syndrome. Furthermore, MSI-H tumor phenotype and presence of non-serous histology appear to be of utility in identifying those with germline MMR mutations. Ultimately, identification of Lynch Syndrome has the potential to impact screening and treatment decision in these women and may facilitate testing for their at risk family members.

1062W

BRCA2 mutations might be detected at a high rate in a subset of cutaneous melanoma patients with pancreatic cancer in the familial history. *N. Soufir[1, 2], E. Rouleau[3], C. Derouet[3], A. Riffault[1], HH. Hu[1,2], S. Caputo[3], P. Hammel[4], V. Descamps[5], N. Basset-Seguin[2], P. Saiag[6], A. Bensussan[2], M. Bagot[2], R. Lidereau[3], B. Grandchamp[1].* 1) Department of Genetic, Hopital Bichat, Paris, France; 2) Inserm U976, Centre de Recherche sur la Peau, Hôpital Saint Louis, AP-HP, Paris, France; 3) Oncogenetic laboratory, Institut Curie, 35 rue Dailly 92210 Saint Cloud, France; 4) Gastro-Enterology department, Hôpital Beaujon, APHP, Clichy, France; 5) Dermatology department, Hôpital Bichat Claude Bernard, APHP, Paris, France; 6) Dermatology department, Hôpital Ambroise Paré Bernard, APHP, Boulogne Billancourt, France.

Three major melanoma predisposing genes have been characterized. The most frequently involved is *CDKN2A*, a cell cycle regulator, that is mutated in up to 20–30 percent; of melanoma prone families, and 5–10 percent; multiple primaries melanoma. The second is *CDK4*, an oncogene inhibited by *CDKN2A*. More recently, a third melanoma predisposing gene, *BAP1*, are described to predispose to ocular and cutaneous melanoma and also mesothelioma. In addition, it has been reported an excess of melanoma in members of *BRCA2* mutated families. Interestingly, *BRCA2* also predisposes to pancreatic cancer, a cancer which also shares common gene predisposition with melanoma. Few reports estimate the prevalence of BRCA2 variants in melanoma patients. Patients : genetic alterations in the BRCA2 gene were studied in 48 melanoma patients having no mutation in *CDKN2A* or *CDK4* and which had at least to one of the following criteria: breast cancer in the proband (15 cases) or at least 2 breast cancers (BC) in related (5 cases), pancreatic cancer (PC) in first or second related (20 cases), ovary cancer in first related (4 cases), prostate cancer in the proband (7 cases). Method: the entire coding sequence of the BRCA2 gene were screened with EMMA prescreening method and all the abnormal profiles were sequenced with Sanger sequencing. Results: One causal *BRCA2* variant (c.6037 A>T, p.K2013X) was identified in a multiple primary melanoma proband with a PC in 2nd degree relative. Two unclassified and rare *BRCA2* variants were identified in 2 patients: c.7505G>A, p.Arg2502His (primary melanoma and PC in first degree relative), c.8545A>G, p.Lys2849-Glu (primary melanoma and PC in first degree relative) and c.9256+28T>A (primary melanoma and 3PC in first and second degree relatives). A partial segregation in three patients was found with the variant c.8545A>G in two patients with melanoma. Discussion and conclusion : *BRCA2* causal or rare variants can be detected in melanoma patients with pancreatic cancer in the kindred. Melanoma patients with a familial history of pancreatic cancer should be tested for *BRCA2* mutation.

1063T

SUFU germline mutation in a patient with Gorlin syndrome identified by next generation sequencing. *J.B. Geigl[1], E. Heitzer[1], I. Wolf[2], L. Cerroni[2], M.R. Speicher[1].* 1) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 2) Department of Dermatology, Medical University of Graz, Graz, Austria.

Gorlin Syndrome (GS; OMIM #109400), also termed Basal Cell Nevus Syndrome, is characterized by the presence of a variety of developmental anomalies and predisposition to a range of cancers. A major and problematic feature of this disorder is the development of multiple basal cell carcinomas (BCCs) beginning to appear from the early teens, varying in number from only some to thousands. About 5% of the patients develop medulloblastoma mostly presenting as desmoplastic variant. Gorlin syndrome is inherited in an autosomal-dominant manner with near complete penetrance and extremely variable expressivity. Birth incidence is estimated to be 1 in 19.000 individuals. Between 50% and 85% of patients harbor germ line mutations in the PTCH1 gene, a key regulatory component in the Sonic Hedgehog (SHH) signaling pathway. However, rare causative germline mutations, such as PTCH2 and SUFU, were also identified in other genes in the SHH signaling pathway. Here we present a 55-year old patient with a 20-year history of multiple BCCs involving face, back, and chest. Examination of the dental status revealed missing teeth in the lower jaw, paradontopathia, and atrophia of the alveolar process. Ocular anomalies were described as pigmentary changes of uvea and excavation of the optic papilla. Ectopic calcification of the falx, which is present in more than 90% of affected individuals, was detectable. Family history revealed further tumor affected relatives. We started our diagnostic work-up with Sanger sequencing and MLPA analysis of the PTCH1 gene, which did not reveal a disease associated mutation. Because of the growing evidence that mutations in other genes of the SHH signaling pathway may rarely cause GS, we enriched 372 tumor associated genes (TruSeq Custom Enrichment), including SMO, HIP, and SUFU, and sequenced them on the Illumina MiSeq® platform. The analysis identified a novel splice mutation c.454+1 G>A in SUFU. The splice site mutation was confirmed by mRNA analysis. SUFU is a tumor suppressor gene, which had previously mainly been associated with medulloblastoma. To the best of our knowledge, our report represents just the second germline SUFU mutation causative for GS. New sequencing strategies allow now novel strategies in the work-up of hereditary cancer, especially the identification of rare, causative germline variants. This significantly extends our genetic counseling options and may improve genotype-phenotype correlations in familial cancer.

1064F

Li-Fraumeni Syndrome: A Clinical, Genetic, and Epidemiologic Cohort Study. *P.L. Mai, J.A. Peters, L. Hoskins, F. Walcott, R. Bremer, S.A. Savage.* Clinical Genetics Branch, National Cancer Institute, Rockville, MD.

Li-Fraumeni syndrome (LFS) is a highly-penetrant autosomal dominant cancer predisposition syndrome associated with a wide range of cancers occurring at younger-than-expected ages. Specific diagnostic criteria for classic LFS and Li-Fraumeni-like syndrome (LFL) are based on the pattern of cancers within families. Germline *TP53* mutations are found in ~70% of LFS and ~40% of LFL families. Limited data exist on genotype-phenotype correlations and on the effect of environmental exposures on cancer risk in LFS. Also, very few studies of early cancer detection have been conducted. A recent study employing whole body MRI and other organ-specific screening showed promise, but the results need confirmation in larger studies. We are conducting a detailed, IRB-approved natural history study of LFS (NCT01443468), which opened to accrual in August 2011, after a successful recruitment pilot study. Eligibility criteria include individuals and family members with 1) classic LFS; 2) LFL; 3) a known germline *TP53* mutation; 4) individuals with choroid plexus (CPC) or adrenocortical carcinoma (ACC); or 5) individuals with 3 or more primary cancers. Participants complete family history and individual information questionnaires. Medical records are reviewed, and biospecimens are collected. Eligible *TP53*-mutation positive individuals may elect to undergo comprehensive, protocol-defined cancer screening at the NIH Clinical Center. Energy balance and physical activity are also being studied. In order to understand the human factors influencing uptake of genetic tests, adherence to screening/surveillance, and issues of individual, family, and community impact of living with LFS, we are undertaking a full battery of quantitative and qualitative individual and family evaluations. To date, 109 eligible unrelated families have been identified, including 76 with classic LFS or a germline *TP53* mutation, 22 LFL, and 11 individuals with multiple primaries, ACC, or CPC. After obtaining consent, additional selected family members are invited to participate. Genetic counseling and testing is underway for families and individuals with unknown *TP53* mutation status. Through this study and in collaboration with the newly organized international LFS Exploration (LiFE) Consortium, important questions on clinical management, genotype-phenotype correlations, and gene discovery in mutation-negative families will be conducted in order to improve LFS-related quality of life and survival.

1065W

Early detection of cystic pleuropulmonary blastoma and cystic nephroma in an asymptomatic child with *DICER1* mutation — Screening considerations. *F. Plourde[1], V. Larouche[2], N. Ferguson[2], M. St-Amant[2], I. Harvey[3], N. Taherian[4], N. Sabbaghian[1], J.R. Priest[5], W.D. Foulkes[1, 4, 6].* 1) Department of Medical Genetics, Segal Cancer Centre, Lady Davis Institute, Jewish General Hospital, Montreal, QC, Canada; 2) Centre Hospitalier de l'Université Laval, 2705 Laurier blvd, Quebec City, QC, G1V 4G2, Canada; 3) Centre Hospitalier Universitaire de Québec - Pavillon Hôtel-Dieu de Québec, 11 Côte du Palais, Quebec City, QC, G1R 2J6, Canada; 4) Montreal General Hospital, Department of Medical Genetics, 1650 Cedar Ave, Montreal, QC, H3G 1A4, Canada; 5) Minneapolis, MN; 6) Program in Cancer Genetics, Department of Oncology and Human Genetics, McGill University, 546 Pine Ave West, Montreal, QC, H2W 1S6, Canada.

DICER1 is an endoribonuclease involved in the generation of miRNAs which modulate gene expression at the posttranscriptional level with a crucial role in embryogenesis and early development. Heterozygous germline mutations in *DICER1* (14q32.13) cause the DICER1 syndrome (OMIM #601200). This syndrome is characterized by mainly low penetrance for benign and malignant, mostly rare, tumors in children and young adults. Pleuropulmonary blastoma (PPB, before age 6 years) is the most frequent tumor and occurs in a highly treatable early cystic form which may progress to much-less-treatable advanced disease. Other phenotypes include cystic nephroma (CN), ovarian Sertoli-Leydig cell tumor (SLCT), multinodular goiter (MNG), various rhabdomyosarcomas, pituitary blastoma, nasal chondromesenchymal hamartoma, ciliary-body medulloepithelioma and other, rarer phenotypes. Cystic PPB is diagnosed from birth to age ≈2 years with a cure rate >90%; advanced Types II and III PPB occur from ages ≈2 to 6 years and are cured in ≈50% of cases. If not detected and treated, early cystic PPB may progress to advanced disease. We report here radiographic screening resulting in early detection of both cystic PPB and CN in an asymptomatic 13.5-month-old *DICER1* mutation carrier. The child was genotyped and screened because the large extended family had *DICER1* mutation (c.2379T>G, predicted to result in p.Y793X) and several members with SLCT, MNG, CN, and other PPBs. We believe this is the first child for whom knowledge of carrier status allowed focused early screening with the potential benefit of eradicating early PPB. Compared to PPB, other *DICER1*-associated phenotypes occur less frequently, occur in many organ systems over many years and have a better prognosis; taken together, these factors make most *DICER1* phenotypes less compelling targets for detection by pre-symptomatic screening. However, the natural history of PPB (presentation as highly curable disease in a well-defined age group with potential progression to an aggressive malignancy) offers the opportunity of early detection and eradication via pre-symptomatic screening. The potential benefits of early detection must be weighed against potential risks of iatrogenic harm due to early radiographic screening.

1066T

Impact of gynecological screening in Lynch syndrome carriers with an *MSH2* mutation. *S. Stuckless[1], P. Parfrey[1], L. Dawson[2], B. Barrett[1], J. Green[3].* 1) Clinical Epidemiology Unit, Faculty of Medicine, Health Sciences Centre, St. John's, NL, Canada; 2) Department of Obstetrics & Gynecology, Faculty of Medicine, Health Sciences Centre, St. John's, NL, Canada; 3) Department of Genetics, Faculty of Medicine, Health Sciences Centre, St. John's, NL, Canada.

Background & Aims: The lifetime risk of developing endometrial cancer in Lynch syndrome (LS) mutation carriers is very high and females are also at an increased risk of developing ovarian cancer. The aim of the study was to determine the impact of gynecological screening in *MSH2* mutation carriers. **Methods**: The study included 174 female carriers of three different founder *MSH2* mutations. Fifty four females entered a gynecological screening program and 120 females did not. Gynecological cancer incidence and overall survival was compared in female mutation carriers who received gynecological screening (cases) and in matched controls. Controls were randomly selected from non-screened mutation carriers who were alive and disease-free at the age the case entered the screening program. One matched control was selected for each case. **Results**: Endometrial or ovarian cancer occurred in 14 of 54 (26%) women in the gynecological screened group. Median age to diagnosis of gynecological cancer was 54 years in the screened group compared to 56 years in controls (p=0.50). Stage I or II cancer was diagnosed in 91% of screened patients compared to 71% in the control group (p=0.355). Two of three deaths in the screened group were the result of ovarian cancer. Mean survival in the screened group was 79 years compared to 69 years in the control group (p=0.11), likely associated with concomitant colonoscopy screening. **Conclusions**: In female LS carriers, gynecological screening did not result in earlier gynecologic cancer detection nor did it prevent interval cancers from occurring. The occurrence of both ovarian cancer deaths at a young age in screened patients and gynecological cancer deaths due to early stage disease in matched controls suggests that prophylactic hysterectomy with bilateral salpingo-oophorectomy should be performed in female mutation carriers who have completed childbearing.

Evaluation of mismatch repair gene sequence variants in the Colon Cancer Family Registry using multifactorial likelihood analysis. *B.A. Thompson[1,2], D.E. Goldgar[3], M. Clendenning[1], R. Walters[1], M.T. Parsons[1], S. Gallinger[4], R.W. Haile[5], J.L. Hopper[6], M.A. Jenkins[6], L. LeMarchand[7], N.M. Lindor[8], P.A. Newcomb[9], S.N. Thibodeau[10], J.P. Young[1], D.D. Buchanan[1], S.V. Tavtigian[11], A.B. Spurdle[1], Colon Cancer Family Registry.* 1) Queensland Institute of Medical Research, Brisbane, Australia; 2) School of Medicine, University of Queensland, Brisbane, Australia; 3) Department of Dermatology, University of Utah School of Medicine, Salt Lake City, Utah; 4) Cancer Care Ontario, Department of Surgery, Familial Gastrointestinal Cancer Registry, University of Toronto, Toronto, Ontario, Canada; 5) Department of Preventive Medicine, University of Southern California, Los Angeles, California; 6) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, University of Melbourne, Melbourne, Australia; 7) Cancer Research Center of Hawaii, University of Hawaii at Manoa, Honolulu, Hawaii; 8) Department of Health Science Research, Mayo Clinic Arizona, Scottsdale, Arizona; 9) Prevention Program, Fred Hutchinson Cancer Research Center, Seattle, Washington; 10) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, Minnesota; 11) Department of Oncological Sciences, Huntsman Cancer Institute, University of Utah.

Sequence variants of unknown significance constitute a challenge in both clinical and research settings. Mutations in the mismatch repair (MMR) genes (MLH1, MSH2, MSH6, PMS2) confer an increased risk of colorectal and endometrial cancers. Unclassified variants constitute over half of the unique MMR gene variants reported, and include rare nucleotide changes predicted to cause missense substitutions, small in-frame deletions, or possible alterations in splicing. We are developing a multifactorial approach to MMR variant evaluation by developing a likelihood model to provide a quantitative estimate of variant pathogenicity. A calibrated combined MAPP and custom PolyPhen-2 output has been developed to estimate a prior probability of pathogenicity for MMR missense substitutions based on the evolutionary conservation and physicochemical properties of amino acid alterations. This sequence analysis-based prior can be used in the context of a quantitative model for clinical classification of MMR gene missense substitutions. Analysis of variant co-segregation with disease within families to assess evidence for causality has been previously established and applied to MMR variant data. We have now derived likelihood ratios (LR) of variant causality for colorectal tumor characteristics, such as microsatellite instability (MSI) and somatic BRAF tumor mutation status, by drawing on comprehensive reference data from the Colon Cancer Family Registry (CFR). The LR in favor of pathogenicity was estimated to be ~12-fold for a colorectal tumor with a BRAF mutation-negative MSI-H phenotype. For 31 of the 44 (70%) variants already assessed, the posterior probabilities of pathogenicity were such that altered clinical management would be indicated. Strategies to incorporate LRs based on tumor MLH1 methylation status and family history data from the Colon CFR are under development. Estimation of the posterior probabilities for the remaining 245 variants detected in Colon CFR probands, for which assessment of tumor pathology and variant association with disease in families is available, is currently underway. Results from this analysis could alter the recommended clinical management of these and other MMR variant-carrying families.

Development of a Custom Targeted AmpliSeq Multiplex Sequencing Assay for the Detection of Tumor Derived Somatic Mutations and Application as Part of a Clinical Trial. *C.-J. Lih[1], D.J. Sims[1], M.G. Mehaffey[1], M. Dindinger[2], E. Levandowsky[2], C.C. Lee[2], T.T. Harkin[2], P. Brzoska[3], B. Conley[4], S. Kummar[5], P.M. Williams[1,4].* 1) Molecular Characterization Clinical Assay Development Laboratory, Frederick National Laboratory for Cancer Research, Frederick, MD; 2) Life Technologies, 500 Cummings Center, Suite 2450, Beverly, MA; 3) Life Technologies, 850 Lincoln Centre Drive, Foster City, CA; 4) National Cancer Institute, Cancer Diagnosis Program Division of Cancer Treatment and Diagnosis, Bethesda, MD; 5) National Cancer Institute, Division of Cancer Treatment and Diagnosis, Bethesda, MD.

Molecular targeted therapies are increasingly important in treating cancer patients, but robust analytically validated clinical assays are required for patient selection in early stage clinical trials. Here, we describe the development of a custom assay for somatic mutation detection using Ion Torrent AmpliSeq™ technology. The AmpliSeq™ technology enables generating hundreds of amplicons in a multiplex PCR pool from low amount of input DNA without the complications of primer dimers and cross amplification. A panel of 378 amplicons covering a total of 42.3 Mb regions was designed to detect 1152 mutation loci, including common therapeutically actionable targets, in 63 genes. Analytical performance studies using genomic DNA samples from 14 cancer cell-lines and a normal hapmap individual (CEPH) demonstrated the assay was reproducible using 30 ng input of DNA. The assay demonstrated high sensitivity and specificity (less than 1 percent). Using a series of positive control plasmid spikes mixed into a normal reference CEPH DNA at pre-defined copy number ratios, we verified the assay is sensitive to detect variants at 5 percent (or less) allelic frequency with a minimum 500 X coverage. We subsequently applied this assay to characterize proficiency samples whose mutations status have been previously reported by other analytically validated clinical assays (pyrosequencing or SNAPshot). Our data demonstrated this assay recapitulated all previously identified mutations in a semi-quantitative way. We conclude this assay is accurate, specific, sensitive, and reproducible with rapid turn-around time, making it a powerful tool for supporting clinical studies. The application of this assay for planned clinical studies will be discussed.

1069T

A 30 year perspective of The International Fanconi Anemia Registry (IFAR). *A.D. Auerbach, The IFAR Collaboration Team.* Human Gen & Hematology, Rockefeller Univ, New York, NY.

The IFAR was founded in May 1982, by Dr. Arleen D. Auerbach, in collaboration initially with Dr. Traute Schroeder-Kurth of Germany. Schroeder-Kurth, in 1964, discovered the chromosome instability in Fanconi anemia patients and Auerbach, in 1981, developed the diepoxybutane (DEB) chromosome breakage test. Patients with a positive DEB test were eligible to participate in the IFAR study. The purpose of the IFAR is to study a large number of patients exhibiting the full spectrum of diverse features of FA and to study genotype/pheonotype correlations. Studies of IFAR patients led to the discovery that the clinical features of the syndrome were much more varied than originally thought, and to the recognition of the need for a more timely diagnosis of the disease. The IFAR Tissue Repository of specimens from patients with a positive DEB test aided researchers to identify new genes for FA and to find a large spectrum of variants in these genes that caused the disease. Selected highlights from clinical IFAR publications are: Giampietro PF et al. The need for more accurate and timely diagnosis in FA. *Pediatr. 91:1116,1993*; Butturini A et al. Hematologic abnormalities in FA. *Blood 84:1650,1994*; Giampietro PF et al. Diagnosis of FA in patients without congenital malformations. *Am J Med Genet 68:58,1997*; Wajnrajch MP et al. Evaluation of growth and hormonal status in patients referred to the IFAR. *Pediatr. 107:744,2001*; Kutler DI et al. A 20 year perspective of the IFAR. *Blood 101:1249,2003*; Berwick M et al. Genetic heterogeneity among Fanconi anemia heterozygotes and risk of cancer. *Cancer Res 67:9591, 2007*. The IFAR is currently based in The Rockefeller University Laboratory of Genome Maintenance, headed by Dr. Agata Smogorzewska: http://lab.rockefeller.edu/smogorzewska/ifar/. There are presently 1167 patients enrolled in the IFAR, 557 females and 610 males. Approximately 40% of the patients, mostly alive at the time of registration, are known to be deceased. We have now developed an enhanced second generation IFAR database. Included in the IFAR are all genotypic data available from our current collaboration with NHGRI and the most up-to-date, streamlined, ontology driven phenotypic information. There are new display screens and navigational tools which should make it easier to learn more about genotype/phenotype correlations, the role of the FA proteins in damage repair, the role of FA proteins in cancer, and the implications of mosaicism.

Histology and prognostic markers are powerful tools for predicting BRCA mutation status. *C.D. Delozier[1, 2,3], A. Rahman[4], T. Liu[5], C.J. Curry[1,2,3]*. 1) Genetic Medicine Central California, Central California Faculty Medical Group, Fresno, CA; 2) Dept Pediatrics, UCSF-Fresno, Fresno, Ca; 3) Saint Agnes Medical Center, Fresno, CA; 4) Dept Internal Medicine, UCSF-Fresno, Fresno, CA; 5) Dept Biology, UCSD, San Diego, CA.

Five to seven percent of breast cancer is associated with a constitutional mutation in BRCA-1 or BRCA-2, the principle genes whose mutation results in “monogenic inheritance” of breast and ovarian cancer. The best single predictor of BRCA mutations in breast cancer patients is pre-menopausal age at diagnosis (especially for BRCA1); personal and/or family histories of multiple breast primaries, ovarian cancer and/or male breast cancer are also characteristic of BRCA-positive families. However, many patients have unknown/truncated family histories, and cancer diagnostic information as related by families may be inaccurate. In patients with a “borderline” probability of a BRCA mutation, the decision to test (or not) is often determined by insurance coverage. Although numerous publications in the late 1990s attested to a “typical histological phenotype”, particularly in BRCA1-associated breast cancers, histology (ductal vs. lobular phenotype) and prognostic markers (ER,PR,Her2/neu) have been displaced as major determinates in genetic risk assessment. Our experience in the BRCA 1–2 testing of over 300 breast cancer patients at “high-risk” for hereditary breast and ovarian cancer syndrome strongly suggests that histology (ductal vs. lobular vs. rarer histologies) and prognostic marker status (triple negative status, her2/neu overexpression) are key results for evaluating the likelihood of BRCA mutations. Our BRCA-positive patient population includes 26 women with BRCA-1 mutations and 17 with BRCA-2 mutations; these women had 48 breast cancers. *No BRCA-1 mutations were found in patients with tumors of lobular histology or in tumors with Her-2/neu overexpression*. Although the catagorization was not as clear with BRCA-2, lobular histology and Her-2/neu overexpression were also rare in BRCA2-associated breast cancers. One patient (of 17) who had a premenopausal ductal carcinoma had a contralateral post-menopausal lobular primary. In another BRCA2 carrier with bilateral breast, the second, postmenopausal ductal cancer was Her2/neu positive. These proportions are to be compared to histological findings in all breast cancers, where 10–20% of tumors are lobular carcinomas and about 20% show Her2/neu overexpresion. We have used histology - performed on every tumor and thus available for assessment in all breast cancer patients - to develop a scoring tool for predicting BRCA mutation status.

1071W

Variants of uncertain significance in BRCA testing: Surgical decisions, risk perception, cancer distress, and evaluation of the genetic cancer risk assessment process. *J. O. Culver[1], C. D. Brinkerhoff[2], J. Clague[1], K. Yang[1], K. E. Singh[2], S. R. Sand[1], J. N. Weitzel[1]*. 1) City Hope, Duarte, CA; 2) UC Irvine, Irvine, CA.

Incidental identification of variants of uncertain significance (VUS) is one of the greatest challenges of new clinical genomic testing approaches. Previous studies suggest that patients carrying a VUS in BRCA1 or BRCA2 can have lingering confusion regarding results interpretation and healthcare recommendations. This may be due in part to inappropriate recommendations made by inexperienced or misinformed healthcare providers. In standard clinical genetics practice, VUS results in BRCA genes are considered uninformative, and thus not used to determine risk or make recommendations-similar to uninformative negative (UN) results. This study sought to compare VUS patients and UN patients receiving genetic cancer risk assessment (GCRA) in high risk genetics clinics with respect to surgical decisions, risk perception, distress levels, and opinions about the GCRA process. Follow-up questionnaires from 71 VUS patients were compared to 715 UN patients, all having undergone GCRA at City of Hope Clinical Cancer Genetics Community Research Network. Statistical analyses were performed with Pearson's Chi-square and Fisher's Exact test, as appropriate. Ten percent of VUS carriers and 6% of UN patients opted for risk reducing mastectomy (p=0.15) and 5% of VUS and 3% of UN patients opted for risk reducing bilateral salpingo-oophorectomy (p=0.44). Of those able to recall their breast cancer risk, 15% of VUS patients and 10% of UN patients perceived themselves at high risk (p=.31); similar results were observed for ovarian cancer risk. UN patients showed a greater reduction in concern about cancer after GCRA than did VUS patients (36% versus 23%, p=.043). Among the minority of patients (7% of VUS and 3% of UN) that did not find the counseling process helpful, more VUS patients attributed this to a lack of new knowledge gain (100% versus 48%, respectively, p=.033). Overall, results suggest that patients receiving VUS and UN results in a GCRA clinic environment react similarly with respect to preventive surgical decisions (VUS results did not cause excessive surgery or exaggerated risk perception), while patients with a VUS found counseling somewhat less informative and less reassuring. Given that VUS patients receiving GCRA yielded similar clinical outcomes to UN patients, skilled cancer risk counseling will continue to be a critical component of genomic testing strategies involving multi-gene panels and exomic testing given the high likelihood of VUS results.

Background. Despite recent successes, most of the heritability of colorectal carcinoma (CRC) remains unexplained. One possible contributor is common genetic variants with individually small effects which act through variation in normal traits, such as height and obesity, that are associated with CRC risk. Methods. We studied five series of northern European ancestry, comprising a total of 5,380 CRC cases and 6,034 controls. We identified from the literature common autosomal SNPs that have been associated (Passoc<5×10-8) in large studies with adult height (N=134), body mass index (BMI, N=29) and waist-hip ratio (WHR, N=13). We extracted genotypes for these SNPs or excellent proxies (r2>0.8) and performed single-SNP and SNP-set association analyses with CRC risk. Results. No individual SNP was significantly associated with CRC risk, although there was an overall over-representation of associations in the expected direction for increased body size. SNP-set analyses, particularly the allele score test, provided good evidence that SNP alleles associated with obesity (WHR and BMI) were also associated with an increased risk of CRC. We found no evidence of similar effects for height. Conclusions. WHR- and BMI-increasing SNP alleles are associated with raised CRC risk, consistent with epidemiological data. Effect sizes are very modest, consistent with an intermediate phenotype model in which obesity causally affects CRC risk. The absence of associations with height SNPs suggests that the link between height and CRC may not be causal. Obesity SNPs explain a small, but important, part of CRC risk, and normal, heritable traits may have similar influences.

1073F

The combined effect of the functional variants in cell death pathway genes on cervical cancer. *K. Chattopadhyay[1], C. Dandara[2], A. Hazra[3], A.L. Williamson[4, 5].* 1) School of Life Sciences, College of Agriculture, Engineering and Science, University of KwaZulu-Natal, Durban, Republic of South Africa; 2) Division of Human Genetics, Faculty of Health Science, University of Cape Town, Cape Town, Republic of South Africa; 3) School of Statistics and Actuarial Sciences, University of KwaZulu-Natal, Durban, Republic of South Africa; 4) Division of Medical Virology and Institute of Infectious Disease and Molecular Medicine (IIDMM), University of Cape Town, Cape Town, Republic of South Africa; 5) National Health Laboratory Service, Groote Schuur Hospital, Observatory, Cape Town, Republic of South Africa.

Background: Cervical cancer is one of the most important cancers worldwide with a high incident and mortality rate. Even though many sexually active women get infected with human papillomavirus (HPV), only a small fraction of them progress to cervical cancer suggesting the important roles of the additional risk factors in development of the disease including host genetic factors. Since cellular apoptosis plays a crucial role in controlling the spread of virus-infections in cells, functional variations in cell death pathway genes might alter the apoptotic mechanism, thereby influencing its ability to clear virus-infections. Functional polymorphisms in FasR (-1377G>A and -670A>G), FasL (-844T>C) and CASP8 (-652 6N ins/del) genes are all know to alter the mechanism of apoptosis by modifying the level of expression of their correspondent proteins. These polymorphisms have been investigated in cervical cancer by different groups including our lab previously. **Objective:** In the present study, we attempted to investigate the combined effects of CASP8 polymorphism with any (and all) of the FasR/FasL polymorphisms in cervical cancer, pre-cancerous lesions and HPV infection. **Materials and Methods:** Participants were 442 South African women of black African and mixed-ancestry origin with invasive cervical cancer and 278 control women matched by age, ethnicity and domicile status. FasR and FasL polymorphisms were genotyped by TaqMan and CASP8 polymorphism by PCR-RFLP. The study was approved by the University of Cape Town Human Research Ethics Committee (study approval number, REC REF: 075/2009) and was performed in accordance with the ethical standards of the Declaration of Helsinki. The results were analysed using haplo.stats software version 1.5.2. All results were adjusted for ethnicity and smoking. **Results:** No significant association with any of the combinations of the polymorphisms was found with cervical cancer. Stratifying the data for smoking and HSV positivity status also did not show any significance. Hybrid capture, pap smear, smoking and HSV positivity status were also investigated among only control group which showed no significant association. **Conclusion:** This is, to our knowledge, the first time the combined effects of the functional variants in cell death pathway genes have been investigated in cervical cancer. Our results show that the combined effect of the functional variants in cell death pathway genes do not play a role in cervical cancer.

1074W

Genetic ancestry is associated to changes in DNA Repair Capacity in non-melanoma skin cancer patients from Puerto Rico. *H.J. Diaz-Zabala[1], L. Morales[2], J. Matta[2], J. Dutil[1].* 1) Biochemistry Department, Ponce School of Medicine, Ponce, PR; 2) Pharmacology Department, Ponce School of Medicine, Ponce, PR.

Among Caucasians and light-skinned individuals, skin cancer occurs with higher frequency. In the Hispanic population of Puerto Rico, the contribution of genetic ancestral factors to non-melanoma skin cancer risk is unknown. Previous studies have shown that the DNA repair capacity (DRC) is reduced in skin cancer patients. A study population of 83 BCC and SCC skin cancer patients and 89 (non-cancerous) controls were recruited from private dermatology practices in Ponce, Puerto Rico. A panel of 106 ancestry-informative markers was genotyped using iPLEX Sequenom technology. Individual genetic ancestry was estimated using a maximum likelihood approach. The DRC levels were measured using a modified host-cell reactivation assay. African ancestry proportion was significantly associated with dark-skinned color ($P < 0.01$) and the absence of freckles in the body ($P = 0.023$). European ancestry was significantly associated with phenotypes such as light-skinned color ($P = 0.001$), hair color ($P = 0.037$), presence of freckles ($P = 0.013$) and susceptibility to sunburn ($P = 0.046$). There was no significant difference in the average European ($P = 0.822$), African ($P = 0.395$), or Native American ($P = 0.451$) ancestry proportions in non-melanoma skin cancer cases compared to non-cancer controls. A linear regression analysis of genetic ancestry and DRC suggests that African ancestry is positively correlated ($P = 0.042$) to DRC, whereas European ancestry is negatively correlated ($P = 0.053$) to DRC. Our data indicate that genetic ancestry is not associated with skin cancer risk. However, African and European ancestries were associated to changes in DRC levels, skin and hair pigmentation, and the susceptibility to sunburn.

1075T

Genetic ancestry and breast cancer survival in US Latinas. *L. Fejerman[1,2,3], D. Hu[1], S. Huntsman[1], C. Eng[1], E. Gonzalez Burchard[1,2,4], E.M. John[5,6], M.C. Stern[7], E. Perez-Stable[1], E. Ziv[1,2,3].* 1) Dept Med, Univ California San Francisco, San Francisco, CA; 2) Institute of Human Genetics, Univ California San Francisco, San Francisco, CA; 3) Comprehensive Cancer Center, Univ California San Francisco, San Francisco CA; 4) Dept of Biopharmaceutical Sciences and Medicine, Univ California San Francisco, San Francisco CA; 5) Cancer Prevention Institute of California, Fremont, CA; 6) Dept. of Health and Research Policy, Stanford University, Palo Alto, CA; 7) Dept. of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA.

Latinas in the US are diagnosed with more advanced stage breast cancer and have poorer survival than non-Latina White women. Latinas are an admixed population with European, Indigenous American and African genetic ancestry. We evaluated the association between genetic ancestry and survival in Latinas from Northern California to test the hypothesis that the observed difference in mortality might be partly due to population specific genetic factors. We used a Cox proportional hazards model to assess the association of Indigenous American genetic ancestry with breast cancer survival among 927 women with breast cancer who participated in two population-based studies. Genetic ancestry was estimated from SNPs from an Affymetrix 6.0 array. We further evaluated whether the relationship between genetic ancestry and breast cancer specific survival was explained by differences in socioeconomic status, education, age at diagnosis or tumor characteristics. Cases diagnosed between 1995 and 2004 were followed for a total of 8,619 person-years during which 76 died from breast cancer. The median follow up was 9 years (range 2–16 years). In the unadjusted model, an increase in Indigenous American ancestry of 25% was associated with an increased risk of mortality [Hazard Ratio (HR): 1.55; 95%CI: 1.06–2.26, p=0.02]. Adjustment for education and socioeconomic status slightly attenuated the association (HR: 1.49, 95%CI: 1.01–2.21, p=0.05). Further adjustment for age at diagnosis reduced the HR to 1.37 (95%CI: 0.93–2.03, p=0.11). In a subset of cases with complete information on tumor characteristics (601 cases, 48 events), age at diagnosis, stage and grade, but not hormone receptor status attenuated the HR for genetic ancestry. In this reduced set of cases, the unadjusted and adjusted associations with genetic ancestry were no longer statistically significant. Our results suggest that the observed disparity in breast cancer specific mortality between US Latinas and non-Latina Whites might be partly due to differences in patient's age, tumor stage and grade at diagnosis. Further work exploring possible risk factors for early age at diagnosis, advanced stage and grade in US Latinas, including genetic predisposition, should be of high priority since it could lead to a reduction in breast cancer outcome disparities.

1076F

Genetic polymorphisms in candidate inflammation-related genes and risk of esophageal squamous cell carcinoma. *A. Golozar[1,2], T. Beaty[1], P. Gravitt[1], I. Ruczinski[1], Y.L. Qiao[3], J.H. Fan[3], T. Ding[3], Z.Z. Tang[3], A. Etemadi[2], N. Hu[2], S.M. Dawsey[2], N.D. Freedman[2], C.C. Abnet[2], A. Goldstein[2], P.R. Taylor[2].* 1) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 3) Chinese Academy of Medical Sciences, Beijing, China.

Wound healing mechanisms are thought to play some role in cancer development in multiple organs, likely by creating a chronic inflammatory milieu. This study sought to assess the role of common genetic polymorphisms in 13 inflammation-related genes involved in wound healing in the etiology of esophageal squamous cell carcinoma (ESCC). The selected genes, include genes in the IL-1 family (*IL-1a, IL-1b, IL-1 Receptor type I (IL-1Ra) and type II (IL-1Rb)), TNF-α, TNFRSF1A, NF-kB1, NF-kB2, iNOS, COX-2, HIF-1α, VEGFA and P-53*). We used the data from the Nutritional Intervention Trial (NIT) cohort and the Shanxi Case-Control Study, both conducted in northcentral China between 1985–2005. From the NIT, 410 ESCC cases and 377 controls frequency matched for age and sex, and from Shanxi, 546 cases and 556 controls individually matched for age, sex and neighborhood were genotyped for 125 tag single nucleotide polymorphisms (SNPs). Tag SNPs were located within the 20 kb upstream and 10 kb downstream of each gene. All SNPs had a minor allele frequency of ≥5%; and a pairwise linkage disequilibrium of $r^2 \geq 0.8$. Cox proportional-hazard models with robust variance estimator and conditional logistic regression models were used for individual SNP analyses for the NIT and Shanxi, respectively. The empirical significance of the enrichment pattern of these findings was assessed using 5000 permutations under the null hypothesis. Fisher's inverse test statistics followed by permutation tests was used to obtain gene-level significance. Of the 125 tag SNPs, 8 SNPs (4 in *VEGFA*, 1 in *TNF-α*, and 3 in *IL-1R1*), and 5 SNPs (1 in *iNOS*, 2 in *TNFRSF1A*, and 3 in *VEGFA*) showed nominally significant associations with risk to ESCC in the NIT and Shanxi, respectively. None of these SNPs retained statistical significance after strict Bonferroni correction. However, in the NIT, the observed p-values for the tested tag SNPs for *VEGFA* gene were mostly concentrated in the lower tail of the distribution (unlike what is expected under the null hypothesis). Permutation test confirmed the significance of this enrichment pattern. At the gene level, *VEGFA* yielded an empiric significance equivalent to 0.023 in the NIT. Given the role of VEGFA in the development and progression of early precancerous lesions of esophagus, the empirically significant association between markers in the *VEGFA* gene and ESCC observed in the NIT provides further evidence for some role of VEGFA in ESCC development.

1077W

Frequency of VNTR polymorphism in IL-1Ra gene in colorectal cancer. *I. A. Gutíerrez[1,3], E. Cortes[2], A. M. Puebla[4], M. P. Gallegos[3].* 1) Genética Molecular, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) Departamento de Oncocirugia, UMAE, HE, CMNO; 3) División de Médicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, México; 4) Laboratorio de inmunofarmacologia, UdeG.

The IL-1ra protein (IL-1Ra), has been widely investigated in and found to be associated with different types of cancers. In the second intron of the IL-1Ra gene, are localized a polymorphism VNTR type, which is characterized by participated in the expression regulating of gene, immune response and cancer risk. We analyzed this VNTR of IL-1Ra in 92 colorectal cancer patients and 118 controls from Guadalajara, Jalisco. Mexico, and found a genotype frequency of 45% (41/92) and 36% (42/118) of A1/A1; 17% (16/92) and 22% (26/118) of A2/A2; 38% (35/92) and 42% (50/118) of A1/A2 in cases and controls respectively, without to be statistically different (p>0.05). These results suggest that the VNTR IL-1RN polymorphism in this sample is not associated with Mexican colorectal cancer patients.

1078T

Individual ancestry influences the gene expression profile in breast cancer patients of admixed populations. *D. Hu[1], E. Ziv[1,2,3].* 1) Department of Medicine, University of California San Francisco, San Francisco, CA; 2) Helen Diller Family Comprehensive Cancer Center, University of California San Francisco, San Francisco, CA; 3) Institute for Human Genetics, University of California San Francisco, San Francisco, CA.

Gene expression is a significant predictor of survival from breast cancer and is currently used clinically to select therapy for estrogen receptor (ER)-positive breast cancer tumors. The degree to which gene expression profiles might be altered by the genetic ancestry of the patient and how that may affect the association between expression profile and survival is unknown. We addressed the question of how gene expression is affected by genetic ancestry in breast cancer samples from The Cancer Genome Atlas (TCGA). We downloaded microarray and genotype data of 481 samples from TCGA Data Portal. These 481 samples include 39 African Americans, 32 Asians, 6 Hispanics, 313 Caucasians, and 91 patients from unknown ethnic groups. Gene expression was analyzed using Agilent G4502A platform. Genetic variation was measured by Affymetrix Genome-Wide Human SNP Array 6.0. To infer genetic ancestry, we calculated principal components using the genotype data. We used the top 3 principal components to represent the patient's global ancestry. We focused on gene expression profiles from patients with ER-positive tumors (N=364). Gene expression profile was studied by hierarchical clustering. We first performed clustering analysis on the original expression values. We then conducted linear regression on gene expression and the top 3 principal components. Residuals from the linear regression were used in the clustering analysis again. We compared the clustering results from the original gene expression values and the residuals. We found changes in clustering results after individual's ancestry was used in the analysis. Our results suggest that gene expression profile might be influenced by the global ancestry of breast cancer patients. The degree to which these differences affect the association between gene expression and survival should be evaluated in large cohort studies with diverse populations.

1079F

Risks of colorectal and other cancers following endometrial cancer in Lynch syndrome. *M.A. Jenkins[1], N.M. Lindor[2], R.W. Haile[3], P.A. Newcomb[4], L. Le Marchand[5], S. Gallinger[6,7], J.L Hopper[1], A.K. Win[1].* 1) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, The University of Melbourne, Parkville, Victoria, Australia; 2) Department of Health Science Research, Mayo Clinic Arizona, Scottsdale, Arizona, USA; 3) Department of Preventive Medicine, University of Southern California, Los Angeles, California, USA; 4) Cancer Prevention Program, Fred Hutchinson Cancer Research Center, Seattle, Washington, USA; 5) University of Hawaii Cancer Center, Honolulu, Hawaii, USA; 6) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Ontario, Canada; 7) Cancer Care Ontario, Toronto, Ontario, Canada.

Background: Lynch syndrome is an autosomal dominantly inherited disorder of cancer caused by germline mutations in DNA mismatch repair genes. Previous studies have shown that mismatch repair gene mutation carriers are at increased risk of first primary colorectal, endometrial and several additional cancers. We aimed to estimate the risks of primary cancers following endometrial cancer for mutation carriers to determine if those with initial endometrial cancer might have higher subsequent risks for new primary cancers. Methods: We obtained data from the Colon Cancer Family Registry for a cohort of 196 women carrying a pathogenic mutation in a mismatch repair gene (56 MLH1, 111 MSH2, 26 MSH6 and 3 PMS2) who had a previous diagnosis of primary endometrial cancer. We estimated the age-, sex-, country- and calendar period-specific standardized incidence ratios (SIRs) of subsequent primary cancers following endometrial cancer, compared with the general population. Kaplan-Meier method was used to estimate 10- and 20-year cumulative risk (penetrance) for each cancer. Results: For carriers of mismatch repair gene mutations who had a previous diagnosis of endometrial cancer, we observed significant increased risks of colorectal cancer (SIR 22.80; 95% confidence interval 15.80–31.89), small intestinal cancer (56.93, 12.51–123.45), kidney, renal pelvis or ureteric cancer (23.02, 10.63–37.26), urinary bladder cancer (22.19, 9.66–36.90), hepatobiliary cancer (12.97, 2.93–27.35), and breast cancer (2.99, 1.80–4.42). The cumulative risks at 20-year after endometrial cancer were as follow: colorectal cancer (35%, 24–46%), small intestinal cancer (2%,0–6%), kidney, renal pelvis or ureteric cancer (9%, 4–15%), urinary bladder cancer (7%, 2–13%), hepatobiliary cancer (2%, 0–6%) and breast cancer (13%, 7–20%). Conclusions: For Lynch syndrome patients, the estimated risks of subsequent primary cancers may inform appropriate cancer screening and risk reducing strategies following an endometrial cancer diagnosis.

1080W

Prevalence and clinical features of *HOXB13* mutation carriers in prostate cancer patients from Germany. *C. Maier[1], J. Xu[2], S.L. Zheng[2], M. Luedeke[1], A.E. Rinckleb[1], W. Vogel[3], S.N. Thibodeau[4], K.A. Cooney[5], W.B. Isaacs[6] on behalf of the ICPCG.* 1) Department of Urology, University of Ulm, Ulm, Germany; 2) Center for Cancer Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 3) Institute of Human Genetics, University of Ulm, Ulm, Germany; 4) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 5) Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, MI; 6) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, MD.

Although prostate cancer (PrCa) has the highest heritability among common cancers, specific high risk genes responsible for familial clustering of PrCa have remained undiscovered for decades. Recently, by deep sequencing of a particular hereditary prostate cancer linkage region at 17q21–22, a recurrent missense mutations (G84E) in the homeobox gene *HOXB13* was identified in cases of European American descent. In order to assess the role of *HOXB13* in the European subpopulation of Germany, case-control comparisons were performed on PrCa cases with (n = 379) and without (n = 317) family history and 490 geographically matched population controls. All subjects were genotyped for G84E in the course of a multi-SNP analysis conducted by the International Consortium for Prostate Cancer Genetics (ICPCG) using an iPLEX MassArray. Among the present study cohort carriers of *HOXB13* G84E were rare in controls (0.02%) and showed increased frequencies in both familial (3.2%) and sporadic PrCa cases (1.9%). Estimated risks of OR = 16.0 (p = 0.008) for familial cases and OR = 9.4 (p = 0.013) for sporadic cases were similar to results from initial reports, consistent with the high penetrance role of *HOXB13* in PrCa susceptibility. Predisposition of *HOXB13* G84E carriers for aggressive PrCa was considered by subgrouping for high histological grade (Gleason score ≥7), advanced tumor stage (>T2, or N+, M+), high PSA at diagnosis (> 20ng/ml) or lethal PrCa. Patients with parameters of aggressive disease showed elevated frequencies of G84E mutation carriers in both familial (3.8%) and sporadic cases (2.5%). The strongest association was observed between G84E and tumor stage. Among patients diagnosed with locally advanced or metastatic disease, 4.4% of familial (OR = 22.7; p = 0.004; as compared to controls) and 3.7% of sporadic cases (OR = 18.5; p = 0.008; as compared to controls) were found to carry the *HOXB13* mutation. In conclusion, the percentage of familial clustering in the German study cohort explained by *HOXB13* is comparable to the observations in US-American populations of European ancestry. However, as an association between G84E and advanced tumor stage was also apparent in sporadic cases, a larger fraction of *HOXB13* mutation carriers may be found among aggressive PrCa cases regardless of family history, rather than within high risk PrCa pedigrees.

1081T

Histologic Types and Risk Factors in Familial Lung Cancer Cases from Southern Louisiana. *D. Mandal[1], M. Haskins[1], A. Bencaz[1], J. Hutchinson[1], J. Chambliss[1], H. Rothschild[1], J.E. Bailey-Wilson[2].* 1) Dept Gen, LSU Hlth Sci Ctr, New Orleans, LA; 2) National Human Genome Research Institute, National Institutes of Health, Baltimore, MD.

The association between lung cancer (LC) and smoking is well known. However, only 15% of smokers are diagnosed with LC. In addition, about 10% of LC cases (22,000 cases per year in the U.S.) have at least one relative affected with LC. So, family history is a significant risk factor. In a case control study in Germany, adenocarcinoma was most prevalent in never smokers and in women; squamous cell carcinoma was most prevalent in male smokers. In the 1990's in the population in Louisiana, squamous cell carcinoma was also observed to be the most frequent type in LC cases in general(39.3%), with nearly equal numbers of adenocarcinoma (25.0%) and small cell subtypes (25.5%). While some studies have shown similar proportions of cases with a family history in all histologic subtypes of LC, others have suggested that a higher proportion of patients with squamous cell carcinoma have a family history of LC. However, less is known about the proportions of each histologic type in LC cases with a strong family history.The objective of the present study was to analyze histologic subtypes and their association with smoking behaviors and other risk factors of interest among familial LC cases from southern Louisiana. Eligible subjects (N=148) with ≥2 relatives affected with primary lung cancer were recruited from southern Louisiana. Diagnosis of primary LC was confirmed through medical records, and histologic subtype (N=114) was abstracted from pathology reports. About 81% of cases had non-small cell LC, with adenocarcinoma (40%) being the most common histologic subtype, followed by squamous cell at 28% and small cell at 18%. Histologic type of LC was most strongly related to pack-years of cigarette smoking and age at diagnosis in these familial cases, with squamous cell associated with higher mean pack-years of smoking and older age. Preliminary results indicated significant difference in the age of diagnosis between cases with non-small cell LC and those with small cell LC; mean number of pack years was about twice as high in cases with non-small cell LC. The frequency of adenocarcinoma in these familial cases was higher and of squamous cell carcinoma was lower than previously reported for the Louisiana LC population. This is consistent with a higher risk of adenocarcinoma in persons with a family history, which may be related to our previous observations that less smoking appears to be necessary for LC in persons with a familial risk of LC.

Using an 18 locus genotype to predict risk of breast cancer, and the relationship between age, estrogen receptor status and genetic risk. *C. Merrick[1], C. Purdie[2], L. Jordan[2], C. Palmer[3], R. Tavendale[3], A. Ashfield[4], P. Quinlan[4], P. Armory[1], A. Thompson[4], J. Berg[1].* 1) Genetics, University of Dundee, Dundee, United Kingdom DD1 9SY; 2) Department of Pathology, Tayside University Hospitals Trust, Ninewells Hospital, Dundee, UK; 3) Biomedical Research institute, University of Dundee, Dundee; 4) Surgery and Molecular Oncology, University of Dundee, Dundee, UK.

The majority of the inherited risk of breast cancer is caused by multiple low penetrance polymorphisms. Whilst the effect of each polymorphism is individually too small to be clinically useful, combining information from many loci is expected to provide improved risk estimation. We investigated the performance of an 18 locus genotype in a cohort of 815 women affected with breast cancer in Tayside from the Tayside Tissue Bank, and 960 matched controls from the Generation Scotland GS:3D repository. DNA samples were analysed using Sequenom Massarray technology. For each individual, genotype data from all 18 loci were combined into a single genetic risk score using a log additive model. Data were analysed using Area Under the Receiver Operating Characteristic Curve (AUROC) analysis. Overall, log genetic risk was normally distributed and significantly higher in cases than controls, AUROC 0.605 (95% CI 0.58–0.63). Age, estrogen receptor (ER) status and genotype risk was available for 506 cases. In these cases, the genotype risk was higher for ER positive cases, AUROC 0.611 (95% CI 0.58–0.64) than ER negative cases, AUROC 0.585 (95% CI 0.528–0.642). When stratified into 10 year age bands, the mean of the log relative risk decreased with increasing age. Those aged 35–44 had the highest log genetic relative risk with a mean of 0.0472 (95% CI 0.0069–0.0875), whereas those aged 75–85 had the lowest log relative risk with a mean of 0.0225 (95% CI -0.0122–0.0572). Pearson's correlation coefficient demonstrated a similar modest trend of -0.028. We have shown that an 18 locus genotype predicts risk of breast cancer, for both ER +ve and ER -ve cancers, although with a stronger association for ER +ve cancers. The genotype risk score is higher in women affected at a younger age, as expected for a classical multifactorial trait. Combination of multiple low penetrance genetic loci into a single score, therefore, shows promise as an easy and objective means of estimating risk of breast cancer, especially in younger women. However, to be clinically useful, a greater degree of risk prediction is required, either with the use of additional genetic loci, or by combining genetic risk with other established risk factors such as family history or mammographic density into a multi-modal risk model.

Association between Prostate Cancer Occurrence and Y-Chromosomal STRs. *M. Miri Nargesi[1], A. Nazemi[1], P. Amini[2], P. Ismail[3], R. Vasudevan[3], P. Pasalar[4], A.H. Abdul Razack[5].* 1) Department of Genetics, Tonekabon branch-Islamic Azad University, Tonekabon, Mazandaran, Iran; 2) Department of Pathology, Faculty of Medicine and Health Sciences, Universiti Putra Malaysia, Malaysia; 3) Department of Biomedical Science, Faculty of Medicine and Health Sciences, Universiti Putra Malaysia, Malaysia; 4) Department of Biochemistry, School of Medicine, Tehran University of Medical Sciences, Iran; 5) Department of Surgery, Faculty of Medicine, University of Malaya, Malaysia.

Purpose of Study: Different studies have shown that there are variations in the geographic and racial distribution of cancer of prostate. This disease is influenced by a complex genetics, and it supposed that a similarity in genetic factors may affect the susceptibility or resistance to develop this disease. This study aimed to compare prostate cancer patients and normal control males based on four Y-linked polymorphic microsatellite loci including DYS388, DYS435, DYS437, and DYS439. Materials and Methods: The study group included a total of 376 subjects comprising 182 patients and 191 healthy individuals. Samples were collected from different populations including different ethnic groups in Iran and Malaysia. Ethics clearance for Malaysian and Iranian samples were acquired from University of Malaya (Reference number: 703.55) Tonekabon Islamic Azad University (Reference number: 22899), respectively. A multiplex PCR was optimized to co-amplify DYS388, DYS435, DYS437, and DYS439 loci in a single reaction tube. All samples were genotyped for alleles of four DYS loci using a Genetic Analysis System CEQ8000 (Beckman Coulter). Results: The comparison between allelic frequencies of DYS loci between patients and controls examined in this study revealed that the frequencies of allele 12 (D) of DYS388 locus (OR, 3.314; 95% CI, 2.147–5.116; P < 0.01) and allele 14 (F) of DYS439 locus (OR, 8.736; 95% CI, 1.082–70.552; P = 0.015) were significantly higher in patients than healthy control group, while alleles 10 (B) and 13 (E) of DYS388 locus had a significantly lower frequency in patients than healthy controls (OR, 0.152; 95% CI, 0.057–0.400; P < 0.01 for allele 10, and OR, 0.430; 95% CI, 0.221–0.838; P = 0.011 for allele 13). However, the alleles of DYS435 and DYS437 loci showed no significant differences in frequency among patient and control groups studied. Conclusion: It is likely that men who belong to Y-lineages with either allele 12 (D) of DYS388 or allele 14 (F) of DYS439 are more susceptible to develop prostate cancer, while those who belong to lineages with allele 10 (B) or 13 (E) of DYS388 are more resistant to this disease. However, the comparison between results obtained from different ethnic groups examined in this study showed that alleles 10 (B) and 12 (D) of DYS388 are the only alleles associated with a respectively lower and higher risk of prostate cancer in all populations studied.

1084T

The Clinical Phenotype of Endometrial Cancer in Women of Newfoundland and Labrador with a MSH2 Lynch Syndrome Mutation. *A.H.G. Nichols[1], L.M. Dawson[2], J. Green[3], E. Dicks[1], P. Parfrey[1].* 1) Patient Research, Memorial University of Newfoundland, St. John's, NL, Canada; 2) Eastern Health, Health Sciences Center, St. John's, NL, Canada; 3) Clinical Genetics, Memorial University of Newfoundland, St. John's, NL, Canada.

Abstract Endometrial Cancer (EC) is the most common extra-colonic malignancy in Hereditary Nonpolyposis Colorectal Cancer (HNPCC) or Lynch Syndrome (LS), and in most cases is the first or `sentinel' cancer. In comparison to colonic cancers, the clinical phenotype of EC has not been as rigorously investigated and the natural history of the disease not well known. The purpose of this study is to examine clinically important variables in known *MSH2* mismatch repair gene mutation carriers to that of non-mutation carriers in general population with sporadic EC. **Methods** Clinical data was abstracted retrospectively from the medical charts of 46 women with a known *MSH2* mismatch repair mutation determined through genetic sequencing and that have been previously diagnosed with EC. Medical charts were examined for clinically relevant variables of EC and then compared to sporadic endometrial cancers from the general population. **Results** The median age of diagnosis of EC found in the cohort of mutation positive individuals was 45.00 years of age. The stage at diagnosis consisted of 64.1% at stage I and 17.4% of this population had papillary serous cell type. **Conclusions** We conclude that endometrial cancers in HNPCC are being diagnosed at an earlier age and stage of cancer when compared to the general population. This cohort is also presenting with more aggressive cell types resulting in a worse prognosis. Further research regarding the carcinogenic pathway and molecular profile of Lynch Syndrome based endometrial cancers is needed.

1085F

A unique African Prostate Cancer Cohort (AfPCC) to investigate genetic and environmental risk factors of aggressive disease within Africa. *E.A. Tindall[1], M.S.R. Bornman[2], S. van Zyl[3], D.C. Petersen[2], A.M. Segone[3], L.R. Monare[3], P.A. Venter[4], V.M. Hayes[1,4].* 1) J. Craig Venter Institute, San Diego, CA; 2) University of Pretoria, Department of Urology, Steve Biko Academic Hospital, Pretoria, South Africa; 3) University of Limpopo, Department of Urology, Medunsa Campus, South Africa; 4) University of Limpopo, Department of Medical Sciences, Turfloop Campus, South Africa.

A major clinical need exists for early detection of men at risk of aggressive prostate cancer (PCa). Identification of genetic markers of susceptibility provides a means to fulfill this requirement. Although African ancestry is a significant risk factor, PCa association studies are typically European-biased. We present an ongoing collection of non-migrant Southern African Bantu men with and without prostate cancer, namely the African Prostate Cancer Cohort (AfPCC), as a unique resource for assessing genetic and environmental influences of aggressive prostate cancer within Africa. As well as comparing disease phenotypes in the AfPCC to “White” and “Black” men enlisted in publicly available US based registries, we investigate the impact of lifestyle and environmental factors on PCa occurrence in the AfPCC. Furthermore, we investigate the impact of pre-defined PCa risk alleles, achieving genome-wide significance predominantly in European populations, on predicting PCa in the AfPCC. We demonstrate a disproportionate rate of aggressive PCa in the AfPCC compared to “White” and “Black” men within the US. Epidemiological data on the current content of AfPCC (456 cases and 280 controls), indicates a possible association with overall risk and a family history of PCa, the presence of diabetes, aspirin consumption, balding pattern and erectile dysfunction. The association with family history and balding pattern, as well as a reduced age, also translates to an association with aggressive disease phenotypes. Genetic analysis of an initial subset of the AfPCC (297 cases and 206 controls) revealed no significant association with previously reported PCa risk alleles and genetic risk profiles failed to accurately predict or enhance the predictive power of serum PSA levels in the AfPCC. Despite the assertion that African ancestry contributes to an increased risk of the disease, there is very little information pertaining to the impact of prostate cancer within non-migrant African populations. The AfPCC provides one of the largest and most comprehensive resources for investigating genetic and environmental influences on PCa associated with an African heritage. The limited availability of PSA testing in Southern Africa and the subsequent presentation of an extremely aggressive disease phenotype in the AfPCC, contributes to this study being a vital resource for much-needed research into risk factors of clinically relevant PCa.

1086W

Insulin-like growth factor biomarkers and genetic polymorphisms are associated with adenomatous polyp risk. *C.B. Vaughn[1], H. Ochs-Balcom[1], J. Nie[1], Z. Chen[2], C.L. Thompson[2], L. LI[2].* 1) Social and Preventive Medicine, University at Buffalo, Buffalo, NY; 2) Family Medicine and Community Health, Case Western Reserve University, Cleveland, OH.

Obesity is an established risk factor for colon cancer. Colorectal adenomas are precursors to colorectal cancer that have been previously linked to insulin resistance. We hypothesize that inherited genetic variation the insulin-like growth factor (IGF) axis may mediate the association of insulin resistance and risk of adenomatous polyps. In this study we examined the association of circulating levels of IGF-1 and its main binding protein, IGFBP-3, as well as single nucleotide polymorphisms (SNPs) in the IGF1R and IGF2R genes with risk of adenomatous polyps in the Case Transdisciplinary Research in Cancer and Energetics (TREC) Colon Polyps Study. Our study includes 1480 patients who underwent routine colonoscopy. At colonoscopy, 410 incident and pathologically confirmed adenoma cases were identified, as were 1070 polyp-free controls. Levels of the circulating biomarkers were categorized into tertiles based on the distribution in the controls. Logistic regression modeling was used to adjust for age, sex, body mass index, smoking status, NSAID use and family history of colorectal cancer to test for associations with circulating IGF-1 and IGFBP3, as well as SNPs in candidate genes. Among cases, Caucasians had statistically significant higher IGF-1 and IGFBP3 compared to African Americans. In logistic regression models stratified by race, we identified higher odds of adenomatous polyps with high circulating IGF-1 in African Americans only; the adjusted odds ratios for tertiles 2 and 3 compared to the lowest tertile were 1.68, 95% CI: 1.06–2.68 and 1.68, 95% CI: 1.05–2.71, respectively. We observed no associations of IGFBP-3 levels and odds of adenomas. Of ten tag-SNPs genotyped in the IGF1R gene, one SNP, rs4966011, was found to be associated with reduced odds of polyps in log additive genetic models adjusted for covariates and this was statistically significant in Caucasians only. The per (minor) allele OR adjusted for covariates is 0.73, 95% CI: 0.47–0.93. Similarly, one of six SNPs in the IGF2R gene was statistically significant in Caucasians only, rs3777404, with an adjusted per allele OR of 1.53, 95% CI: 1.10–2.14. Our study suggests that there may be race-specific differences in the association on the IGF pathway and risk of adenomatous polyps, however further studies are needed to replicate our findings.

An Unusual BRCA Mutation Distribution in a High Risk Cancer Genetics Clinic. *A.C. Nelson-Moseke[1], J.M. Jeter[2,3], H. Cui[3], D. Roe[3,4], S.K. Chambers[1,3], C.M. Laukaitis[2,3].* 1) Obst.-Gynecology, University of Arizona, AZ, 85724; 2) Dept. of Medicine, University of Arizona, AZ; 3) University of Arizona Cancer Center, Tucson, AZ; 4) College of Public Health, Univ. of Arizona, Tucson, AZ.

Purpose: The Database of Individuals at High Risk for Breast, Ovarian, or Other Hereditary Cancers at the Arizona Cancer Center in Tucson, Arizona, analyzes cancer risk and outcomes in patients with a family history of cancer or a known genetic mutation. We analyzed the subset of clinic patients who carry deleterious BRCA gene mutations to understand why mutations in BRCA2 outnumber those in BRCA1. Methods: Medical, family, social, ethnicity and genetic mutation history were collected from consenting patients' electronic medical records. Differences between BRCA1 and BRCA2 patients from this database were analyzed for statistical significance and compared to published analyses. Results: A significantly higher proportion of our clinic patients carry mutations in BRCA2 than BRCA1, compared with previous reports of mutation prevalence. This is similar in the Hispanic subgroup. Patients with BRCA2 mutations were significantly more likely than their BRCA1 counterparts to present to the high risk clinic without a diagnosis of cancer. Other differences between the groups were not significant. Six previously unreported BRCA2 mutations appear in our clinic population. Conclusion: The increased proportion of patients carrying deleterious BRCA2 mutations is likely multifactorial. It may reflect the family history of patients presenting for care and Tucson's unique ethnic heritage.

1088F

Functional Characterization of the Pancreatic Cancer TERT-CLPTM1L risk locus on Chr5p15.33. *J. Jia[1], A. Thompson[1], A. Bosley[2], H. Parikh[1], Z. Wang[3], I. Collins[1], G. Petersen[4], C. Westlake[5], T. Andresson[2], L. Amundadottir[1].* 1) Laboratory of Translational Genomics, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD 20877, USA; 2) Laboratory of Proteomics and Analytical Technologies, SAIC-Frederick, Inc, Frederick National Laboratory for Cancer Research, Frederick, MD, United States; 3) Frederick National Laboratory for Cancer Research, Advanced Technology Program, SAIC-Frederick Inc., NCI-Frederick, Frederick, MD, USA; 4) Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55905, USA; 5) Laboratory of cell and Developmental Signaling, NCI-Frederick, Frederick, MD, USA.

Pancreatic cancer is a highly lethal cancer with few well established risk factors. PanScan, an ongoing genome wide association study (GWAS) of pancreatic cancer has identified four pancreatic cancer susceptibility loci in populations of European ancestry. One of these is in a multi cancer locus on chr5p15.33 where the most significant SNP from the GWAS (rs401681, P=3.7×10-7, ORAllele=1.19) that contains two genes, TERT and CLPTM1L. The TERT gene encodes the catalytic subunit of telomerase, well known for its essential role in maintaining telomere ends. The function of CLPTM1L is not as clear, although it has been proposed to play a role in apoptosis. It is predicted to encode a protein with 6 transmembrane (TM) domains and two large hydrophilic domains: a loop of 253 aa between the first and second TM domains, and a C-terminal tail of 89 aa. We have performed imputation using the 1000G and DCEG reference datasets and thereby fine-mapped the signal to a SNP three orders of magnitude more significant than the GWAS SNP (PImputed=1.4×10-10, ORAllele=1.30). As this SNP is located in the CLPTM1L gene we have performed a series of experiments to investigate the function of the CLPTM1L gene and its encoded protein. Immunofluorescence analysis in pancreatic cancer (PANC-1) and mouse kidney (IMCD-3) cells indicates that it localizes to the endoplasmic reticulum. Affinity purification and mass spectrometry (HEK-293T, hTERT-HPNE and PANC-1 cells) identified potential interacting proteins involved in intracellular transport, secretion and cytokinesis that are currently being validated by co-immunoprecipitation and co-localization. To examine if the protein product of this gene plays a role in growth control, we created stable PANC-1 cell lines overexpressing the full length CLPTM1L gene as well as two deletions, a C-terminal deletion (89 aa) and loop deletion (253 aa) and assayed growth in vitro and in vivo. Cell lines overexpressing full length CLPTM1L grow faster in vitro and in vivo as compared to cells containing empty vector. Interestingly, the two CLPTM1L mutants abolish this effect. Our results indicate that CLPTM1L may play a role in the control of cell growth and oncogenesis in the pancreas. Our current efforts is to characterize the function of the CLPTM1L gene and protein in greater detail and correlate pancreatic cancer risk variants on 5p15.33 to molecular phenotypes to attempt to explain the underlying biology of the risk.

1089W

A comprehensive approach to evaluating the impact of sequence variants of uncertain significance in 24 breast cancer genes on transcript splicing. *S. Casadei, T. Walsh, C.H. Spurrell, A.M. Thornton, J.B. Mandell, S.M. Stray, M.K. Lee, M.C. King.* Medical Genetics & Genome Sciences, University of Washington, Seattle, WA.

In addition to altering amino acids in the encoded proteins, sequence variation in exons and introns may affect mRNA splicing by altering splice sites, splicing regulatory elements (SREs), or mRNA secondary structure. Of loss-of-function mutations, perhaps 15% impact canonical splice sites and up to 50% impact splicing when additional splicing regulatory elements in exons and introns are considered. For familial breast cancer patients with no conventional mutations in BRCA1 or BRCA2, we tested possible effects on splicing of all variants detected by complete genomic sequence of all known breast cancer genes. We integrated in silico predictions of aberrant splicing with experimental studies of gene transcripts from blood-based RNA and splicing reporter minigenes. We have comprehensively evaluated all sequence variants in exons and introns of 24 breast cancer genes included in our targeted resequencing panel. We identified 11 sequence variants in BRCA1, 25 in BRCA2, 18 in PALB2 and 3 in BARD1 that were predicted by in silico tools to alter splicing. These 57 variants were evaluated experimentally by RT-PCR analysis of blood RNA. Aberrant splicing was confirmed for 18 mutations: 5 in BRCA1, 10 in BRCA2, 2 in PALB2 and 1 in BARD1. Consequences of the mutations at the transcript level were partial exonic deletion, exon skipping, intron inclusion and complex splices. For the remaining 39 sequence variants with negative RT-PCR analysis, we are generating splicing reporter minigenes to further test the predicted effect on splicing and to identify exonic and intronic elements that enhance or repress splicing. Rapid advances in high throughput DNA sequencing methods are leading to identification of more disease-related genes and a wider spectrum of loss-of-function mutations, but also to more variants of unknown functional and clinical significance than previously encountered. Bioinformatics tools can help predict the consequences of mutations potentially altering splicing and transcript stability and prioritize experimental studies of mRNA splicing. In our view, an integrated approach combining the use of in silico prediction tools with experimental studies on blood RNA and splicing reporter minigenes will maximize our ability to detect aberrant splicing events.

1090T

Functional analysis of germline *TP53* mutations in lymphocytes from Li-Fraumeni patients reveals a drastic biological impact of missense mutations. *J-M. Flaman[1], Y. Zerdoumi[1], C. Durambure[2], J. Laury-Andas[1], G. Bougeard-Denoyelle[1], T. Frebourg[1], The French LFS working group.* 1) Inserm, U1079, University of Rouen, Institute for Research and Innovation in Biomedicine (IRIB), Rouen, Normandy, France; 2) Inserm, U905, University of Rouen, IRIB, Rouen, Normandy, France.

The Li-Fraumeni syndrome (LFS, MIM 151623), resulting from *TP53* mutations, is a Mendelian predisposition to cancer affecting children and adults and characterized by a remarkably wide tumour spectrum including soft-tissue sarcomas, osteosarcomas, premenopausal breast cancers, brain tumors, adrenocortical tumors, plexus choroid tumors, leukemias and lung cancers. As demonstrated by the functional assays of *TP53* cDNA that we developed in yeast, all germline *TP53* mutations result into a decrease of p53 transcriptional activity. We reported that germline *TP53* missense mutations are associated with an earlier age of tumor onset, suggesting a more deleterious effect of these mutations, as compared to the other types of mutations. In order to assess the biological impact of the heterozygous *TP53* mutations in the genetic context of patients, we developed a new functional assay of the p53 pathway in EBV-immortalized lymphocytes derived from controls or LFS patients. This assay is based on the activation of the p53 pathway by exposure of the lymphocytes to doxorubicin, a DNA damaging agent, and then on global transcriptome analysis of the p53 target gene expression. In wild-type *TP53* EBV-immortalized lymphocytes, we identified almost 400 genes whose expression was induced more than two fold following DNA damage exposure. Fifty percent of the genes were already known to be p53 target genes, which validates the assay. We then perform a global transcriptomic analysis of lymphocytes carrying different germline *TP53* mutations to compare the effect of missense mutations to that of the other types of mutations. These analyses revealed that the number of induced genes was dramatically reduced selectively in lymphocytes with missense mutations, demonstrating the remarkable deleterious impact of *TP53* missense mutations. Measurement of known p53 target gene induction, using RT-QMPSF, showed that the defect of induction associated with the missense mutations was above 50% supporting that, in lymphocytes, the corresponding mutant proteins have a transdominant activity over the wild-type. These result explain why germline *TP53* mutations, like somatic mutations, are predominantly missense mutations and why these mutations are usually associated with an earlier age of tumor onset.

BACKGROUND: Genome-wide association studies (GWAS) have identified a single nucleotide polymorphism (SNP), rs710521 near the tumor protein p63 (TP63) gene, as a risk factor of bladder cancer. Here we explored this region to map genetic variants contributing to bladder cancer susceptibility, and to investigate their molecular phenotypes and potential roles in cancer biology. METHODS: Based on 1000 Genomes and HapMap 3 project data, we imputed 1715 SNPs within +/− 100kb of TP63 region (GRCh37, chr3: 189,249,216-189,715,068) among 3,532 bladder cancer cases and 5,120 healthy controls of European ancestry. Alternative splicing of TP63 was evaluated by RNA-Seq in 6 pairs of tumor-normal bladder tissue samples. TP63 mRNA expression was measured with custom-designed TaqMan assays in 40 bladder tumor and 40 adjacent normal tissue samples, also genotyped by Illumina Omni1-Quad BeadChip and then imputed using the same reference panels. Logistic regression and generalized linear models were used to test for the association between SNPs and bladder cancer risk, and between SNPs and TP63 mRNA expression levels, respectively. All models were assumed the log-additive SNP effects and adjusted for study sites, age, gender and smoking habit when applicable. RESULTS: A total of 813 well-imputed and 126 GWAS-genotyped SNPs were used for analyses. Based on our RNA-Seq results, we measured expression of 5 main splicing forms of TP63 in 40 normal and 40 tumor bladder tissue samples. An imputed SNP rs28512356, located 400 bp downstream from TP63, showed the strongest association with mRNA expression of TP63-alpha splicing form in bladder tumors (p=0.018) but not in normal bladder tissue. TP63-alpha encodes a protein with the Sterile Alpha Motif (SAM) domain which regulates activity of TP53 gene. The original GWAS signal rs710521 had a per-allele odds ratio (OR) of 1.16 (95%CI=1.08-1.25, p= 4.6E-05) for bladder cancer risk, which is comparable to rs28512356, with a per-allele OR of 1.19 (95%CI=1.09–1.29, p=6.1E-05; r2=0.628, D'=0.998 with rs710521). CONCLUSION: We identified SNP rs28512356 as a possible variant for bladder cancer risk within the TP63 region, and associated with mRNA expression of the TP63-alpha splicing form in bladder tumors. Future studies are warranted to validate our findings in additional samples and investigate the possible functional mechanisms of this genetic association in bladder cancer.

1092W

Genetic variant as a selection marker for anti-PSCA immunotherapy of bladder cancer. *I. Kohaar[1], P. Porter-Gill[1], P. Lenz[2], Y. P. Fu[1], A. Mumy[1], W. Tang[1], A. B. Apolo[3], N. Rothman[4], D. Baris[4], A. R. Schned[5], K. Ylaya[6], M. Schwenn[7], A. Johnson[8], M. Jones[9], M. Kida[10], D. T. Silverman[4], S. M. Hewitt[6], L. E. Moore[4], L. Prokunina-Olsson[1]*. 1) Laboratory of Translational Genomics, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, 8717 Grovemont Circle, Bethesda, MD, 20892-4605, USA; 2) Clinical Monitoring Research Program, National Laboratory for Cancer Research, SAIC-Frederick, Maryland, USA; 3) Medical Oncology Branch, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, USA; 4) Occupational and Environmental Epidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, USA; 5) Department of Pathology, Dartmouth Medical School, Hanover, New Hampshire USA; 6) Laboratory of Pathology, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, USA; 7) Maine Cancer Registry, Augusta, Maine, USA; 8) Vermont Cancer Registry, Burlington, Vermont, USA; 9) Department of Pathology and Laboratory Medicine, Maine Medical Center, Portland, Maine, USA; 10) Department of Pathology, University of Vermont College of Medicine, Burlington, Vermont, USA.

A single nucleotide polymorphism (SNP) rs2294008 within prostate stem cell antigen (*PSCA*) gene on chromosome 8q24.3 has been identified by a genome-wide association study (GWAS) as a risk factor for bladder cancer [OR=1.13 (1.09–1.17), p=4E-11, Rothman *et al*, Nat Gen, 2010]. Previously, we found higher *PSCA* mRNA expression in bladder tumors compared to adjacent normal tissue and in both tissue types the expression was specifically increased in carriers of the risk T allele of rs2294008 [Fu *et al*. PNAS, 2012]. Here we explored mRNA expression of *PSCA* in relation to rs2294008 and bladder cancer risk. Analysis of mRNA sequencing (RNA-seq) data from 6 normal and 6 tumor bladder tissue samples heterozygous for rs2294008 showed evidence of strong allelic expression imbalance (AEI), which is reflected in deviation from the 50:50% allelic ratio expected in heterozygous transcribed variants. The average allelic ratio evaluated by counts of RNA-seq reads was 90:10 % for rs2294008 T:C, instead of the expected 50:50 % ratio. A similar pattern was observed for 11 transcribed *PSCA* SNPs, all of which were in high linkage disequilibrium with rs2294008, but not for SNPs located in neighboring genes, *Ly6K* and *JRK*. These results suggest that the AEI is specific for PSCA and not a result of AEI of the whole region. RNA-seq results were validated by allele-specific expression analysis in bladder tissue samples. We further showed that rs2294008 strongly predicted PSCA protein expression in bladder tumors examined by immunohistochemistry (p=6.46E-11, n=278). The pattern of rs2294008-associated protein expression was similar in non-muscle invasive tumors - stages Ta (p= 3.10E-05, n=173) and T1 (p=2.64E-05, n=60), and muscle-invasive tumors - stages T2 (p=1.02E-02, n=23) and T3/4 (p=2.64E-02, n=22). Monoclonal anti-PSCA antibody has emerged as a novel cancer therapy, currently being tested in clinical trials for prostate and pancreatic cancer. Thus, we suggest that genetic testing for rs2294008 could be used to select bladder cancer patients with high PSCA expression and therefore, suitable for anti-PSCA immunotherapy. Up to 75% of bladder cancer patients of European ancestry carry the rs2294008 risk TC and TT genotypes associated with high PSCA expression, hence these patients might benefit from this treatment.

Tumor microenvironment and genetic association with colorectal cancer risk. *V. Peltekova[1], M. Lemire[1], Q. Trinh[1], A. Qazi[1], R. Bielecki[2], L. Hodgson-Jensen[1], D. D'Souza[1], S. Zandi[3], T. Chong[1], R. De Borja[1], L. Timms[1], J. Rangrej[1], M. Volar[1], M. Chan-Seng-Yue[1], T. Beck[1], J. Kwan[1], K. Kozak[1], C. Ash[2], L.D. Stein[1,4], J.E. Dick[3,4], J.D. McPherson[1,4], B.W. Zanke[5], A. Pollett[2], S. Gallinger[2,4], T.H. Hudson[1,4].* 1) Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 2) Samuel Lunenfeld Research Institute, Toronto, Canada; 3) Campbell Family Institute for Cancer Research, Ontario Cancer Institute, University Health Network, Toronto, Canada; 4) University of Toronto; 5) Ottawa Hospital Research Institute, Ottawa, Canada.

We used microarray-based target selection methods coupled with next generation sequencers to interrogate 2.3 Mb of DNA at 11 colorectal cancer loci. The dataset refined the signal of association at four loci: rs16892766/8q23.3, rs6983267/8q24, rs3802842/11q23, and rs9929218/16q22. The associated 11q23 region includes three uncharacterized protein-coding genes (C11orf53, C11orf92, and C11orf93) and POU2AF1. We characterized the gene expression levels of the four transcripts in colon tissues. Risk alleles correlate with decreased gene expression of C11orf92 and C11orf93 in benign adjacent colonic tissues as well as in tumors. C11orf92 and C11orf93 are arranged head-to-head on opposite strands, share a putative bidirectional promoter and may use common regulatory elements. Western blot analyses of C11orf92 in benign adjacent tissues from eight individuals show stronger C11orf92 in the lamina propria of all biopsies, but not in normal epithelium or epithelium-derived tumor cells. C11orf92 expression appeared cytoplasmic and often seen as part of granular structures that are both intra- and extra-cellular. Triple immunofluorescence on colon tissue cryosections showed co-localization of C11orf92 with cell-specific markers for eosinophils, mast cells, neutrophils, macrophages and dendritic cells. Four lines of evidence link C11orf92 and C11orf93 with colorectal cancer: 1) genetic association at 11q23; 2) decreased RNA (and likely protein) expression for both genes correlating with risk alleles; 3) C11orf92 protein expression in many mucosal immune cells of the gut implicated in tumor immunity; and 4) physical proximity between C11orf92-containing immune cells and/or extracellular granules with colon cancer cells. It will be interesting to further understand the mechanistic link between this risk locus, microenvironmental factors and human cancer predisposition.

1094F

Evaluation of the functional effects on cell signaling caused by allelic forms of prostate stem cell antigen (PSCA). *P. Porter-Gill, A. Mumy, W. Tang, I. Kohaar, L. Prokunina-Olsson.* Laboratory of Translational Genomics/Division of Cancer Epidemiology and Genetics, NCI/NIH, Gaithersburg, MD.

Genome-wide association studies (GWAS) have identified a single nucleotide polymorphism (SNP), rs2294008, within the prostate stem cell antigen (PSCA) gene at 8q24.3 as a risk factor for bladder cancer. A PSCA transcript with the non-risk C allele of rs2294008 encodes a protein of 114 amino acids (aa), including a leader peptide of 11 aa. The risk T allele creates a novel upstream translation start site (aCg->aTg) that extends the N-terminal leader peptide by 9 aa, to generate a protein of 123 aa, with a leader peptide of 20 aa. Previously, we have shown that the risk T allele is associated with increased PSCA mRNA and protein expression in bladder tumors. To further evaluate the functional role of the two PSCA protein isoforms, we examined their effects on 45 signaling pathways (Cignal 45-Pathway Reporter Array, Qiagen) in two different cell lines (HeLa and HTB-5). Thirteen of 45 pathways showed differential activation by PSCA allelic constructs. Each of these pathways will be individually tested in more detail. In addition, we are examining the effect of the PSCA protein isoforms on global transcriptome of HeLa and HTB-5 cell lines by RNA-sequencing of cells transfected with allelic constructs and performing cell proliferation and viability assays. Evaluation of the functional properties of the two PSCA protein isoforms should improve understanding of the molecular mechanism of bladder cancer.

1095W

Discovery and Functional Characterization of Somatic Mutations in the Novel Tumor Suppressor DEAR1. *J. Reuther[1,2], N. Chen[1], S. Balasenthil[1], A. Killary[1,2].* 1) Genetics, MD Anderson Cancer Center, Houston, TX; 2) Human and Molecular Genetics, University of Texas Graduate School of Biomedical Science, Houston Texas.

Ductal Epithelium Associated Ring Chromosome 1 (DEAR1) is a novel tumor suppressor gene that is both mutated and homozygously deleted in breast cancer. Loss of expression of DEAR1 by immunohistochemistry correlated with local recurrence in 123 cases of early onset breast cancer. Genetic complementation of wild type DEAR1 into a breast cancer cell line 21MT which contained a missense mutation in codon 187 restored acinar morphogenesis in three dimensional culture, indicating that DEAR1 is a novel, regulator of acinar morphogenesis. Furthermore, DEAR1 expression is downregulated or lost at the earliest stage of pre-invasive breast cancer, Ductal Carcinoma *In Situ*. DEAR1's relevance as an underlying “driver' event in the generation and/or progression of breast cancer is underlined in DEAR1's involvement in restoration of acinar morphogenesis, its loss at the early stages of breast cancer, and its prediction of local recurrence free survival. Identification and functional characterization of novel somatic mutations in DEAR1 in epithelial cancers is a major goal in our lab. Currently, we have identified 16 different non-synonomous mutations in DEAR1 in a variety of epithelial cancers including breast, pancreatic and colon cancer. Mutation constructs have been generated for a number of these mutations and have been tested for their functional significance by genetic complementation in various breast cancer cell lines. We have evidence of additional functional mutations that abrogate DEAR1's functions. The long term goal of these studies is to determine a mutation signature that could be used to predict prognosis in breast and other epithelial cancers in which DEAR1 is mutated or allow for stratification of patients for new targeted therapies aimed at the pathways regulated by DEAR1.

1096T

rs28381943 and rs2032586 SNPs of ABCB1 gene may be the reason of mRNA stabilization which may lead to gene overexpression. *M.S Shahbazi[1], M.M Mansoori[1, 2], M.G Golalipour[3], Sh.A Alizadeh[4], A.J Jahangirerad[4], A.T Tahmasebifar[2], S.R.K Khanduzi[4].* 1) biochemistry & Genetics, Medical Faculty, Medical Cellular & Molecular Research Center, Talghani Children Hospital of Golestan University of Medical Sciences, Bolv Janbazan, 4916668197, Gorgan, Iran; 2) Medical Cellular & Molecular Research Center, Talghani Children Hospital of Golestan University of Medical Sciences, Bolv Janbazan, 4916668197, Gorgan, Iran; 3) Golestan university, Medical Cellular & Molecular Research Center, Talghani Children Hospital of Golestan University of Medical Sciences, Bolv Janbazan, 4916668197, Gorgan, Iran; 4) Oncology Department, 5th Azar hospital of Golestan University of Medical Sciences, Gorgan, Iran.

Introduction. One of the major mechanisms for drug resistance is associated with altered anticancer drug transport, mediated by human-adenosine triphosphate binding cassette (ABC) transporter superfamily proteins. The overexpression of MDR1 by multidrug-resistant cancer cells is a serious impediment to chemotherapy. In our study we have studied the possibility that the mechanism of MDR1 overexpression is caused by structural SNPs. Materials and Methods. A total of 101 MDR1 cases and 100 controls were genotyped with SSP-PCR (Sequence Specific Primer). Gene expression was evaluated for 70 MDR1 cases and 54 controls by Real Time PCR. The correlation between the two groups was based on secondary structures of RNA were predicted by bioinformatics tool (Rn) (Vienna RNA Fold Server). Results. The results of genotyping showed that among 3 studied SNPs, rs28381943 and rs2032586 have significant difference between MDR1 cases and control group but there were no differences in the two groups for C3435T. The results of Real Time PCR showed overexpression of ABCB1 when we compared our data with each of the genotypes in average mode. Prediction of secondary structures in the existence of 2 related SNPs (rs28381943 and rs2032586) showed that the amount of ΔG for original mRNA is higher than the amount of ΔG for the two mentioned SNPs. Discussion. We have observed that 2 of our studied SNPs (rs283821943 and rs2032586) may affect the overexpression of MDR1 gene, and the observed overexpression may be due to mRNA stability while this was not the case for C3435T.

1097F

Identification and Functional Characterization of a Novel Splicing Form of the TPCN2 Gene on 11q13.3 Within a Region Associated with Prostate Cancer Risk. *N. Sikdar[1], C. Chung[1], J. Fang[1], M. Tarway[1], W. Tang[1], S. Mukherjee Dey[2], S. Ambs[3], L. Prokunina-Olsson[1], S. Chanock[1].* 1) Laboratory of Translational Genomics, NCI, Gaithersburg, MD, USA; 2) Medical oncology branch, Center for cancer Research, NCI, Bethesda, MD, USA; 3) Laboratory of Human Carcinogenesis, center for Cancer research, NCI, Bethesda, MD, USA.

Prostate cancer (PrCa) is the most frequently diagnosed cancer in males in developed countries. Genome-wide association studies (GWAS) have identified over 45 loci, including 3 independent PrCa susceptibility loci on chr 11q13.3. By fine-mapping analysis, we identified, rs10896438, as one of the informative markers on 11q13.3. This marker resides 20 kB from EST DA379985 and 92kB telomeric of the TPCN2 gene. We observed DA379985 expression in normal and tumor prostate as well as normal bladder, breast, cervix, ovary and testis tissue samples. In 71 primary prostate tissue samples, DA379985 expression was significantly lower in PrCa tissue compared to normal prostate tissue (p=0.034), but we did not observe association between rs10896438 and mRNA expression. Immunohistochemical data also suggest TPCN2.1 expression was lower in prostate cancer tissue samples with respect to normal prostate tissue section. Rapid amplification of cDNA ends (RACE) and RNA-seq data showed that this EST is a part of a novel splicing form of TPCN2 (which we refer to as TPCN2.1). TPCN2 encodes a 752 aa protein and the new splice variant, TPCN2.1, encodes a protein of 520 aa. Unlike TRPM8 endoplasmic reticulum Ca2+ channel, TPCN2.1 expression is independent of androgen regulation. Confocal imaging of cells transiently transfected with expression constructs for TPCN2 and TPCN2.1 showed cytoplasmic lysosomal expression for both proteins. Our recent findings suggest that siRNA silencing of TPCN2.1 leads to autophagy induced cell death, but not apoptosis, in PC3 cell line. A significant percentage of PC3 and TsuPro1 cells were accumulated in G2/M phase of cell cycle after siRNA silencing of TPCN2.1. siRNA-mediated downregulation of TPCN2.1 resulted in decreased proliferation of prostate cancer cells in vitro. These results indicate that TPCN2.1 is a novel spliced variant of voltage-gated TPCN2 Ca2+ channel expressed in prostate tissue. TPCN2.1 is an important determinator of Ca2+ homeostasis in prostate epithelial cells and may be a potential target for the action of drugs in the management of prostate cancer.

1098W

An integrated analysis of genomic variation and transcriptome sequencing to identify novel susceptibility genes for breast cancer. *E. Wagner[1], S. Clare[2], M. Radovich[2], Y. Liu[3], B. Schneider[4], A.M. Storniolo[4], C. He[1].* 1) Dept. of Public Health, Indiana University School of Medicine, Indianapolis, IN; 2) Dept. of Surgery, Indiana University School of Medicine, Indianapolis, IN; 3) Dept. of Medical & Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 4) Dept. of Medicine, Indiana University School of Medicine, Indianapolis, IN.

Recent genome-wide association studies (GWAS) have identified more than 20 novel loci that were associated with breast cancer. However, the biological functions of these genetic variants in the development of breast cancer have not been characterized. We hypothesize that the associated genetic variants influence tissue-specific gene expression that in turn leads to breast cancer. We performed an integrated analysis of genomic variation and transcriptome sequencing to elucidate expression quantitative trait loci (eQTL) and to identify breast cancer susceptibility genes whose expression were influenced by the candidate genetic variants. The current study utilized a unique source of paired blood and normal breast tissue from 20 healthy women free of diagnosed breast cancer. We genotyped 38 SNPs that were associated with breast cancer in previous GWAS reports, and assessed expression of more than 24,000 gene transcripts in normal breast epithelium using transcriptome sequencing data. Analysis of variance (ANOVA) was performed to assess the differences of gene expression across genotypes. After account of age, menstrual cycle days and contraceptive use, we found 301 unique genes whose expression in normal breast epithelium were correlated with the 38 breast cancer candidate SNPs (all P<0.001). The majority of the identified genes (>90%) were associated with the candidate SNPs in *trans*, i.e. gene expression were influenced by SNPs on a different chromosome. We have identified known genes (for example, *PARK7*, *LGALS1*, *MPDZ*, *CCL14*, *COL1A1*, *CTCF*) that showed differential expression in breast tumor vs. adjacent normal tissue in published microarray analyses. In addition, we have identified novel putative breast cancer genes including *LST1*, *GLIS2*, *BAG6*, *CELA2A*, and *TLX1*. An ingenuity pathway analysis of the associated genes suggested four functional networks. Network 1, related to “Cell Cycle”, includes genes *NEFL*, *TCEB3*, *SEPT9*, *PLG*, and *EPOR*; network 2, related to “Cell Death”, included genes *GSK3B*, *FAIM*, *GRIN1*, and *WNT1*; network 3, related to “Cellular Growth and Proliferation”, includes genes *CSF3*, *HTR4*, *POU3F2*, and *RAG2*; and network 4, related to “Cell to Cell Signaling and Interaction”, includes genes *LOX*, *NPPB*, *CNTNAP1*, *CNGA3*, and *NAT8L*. Our data identify known and novel putative breast cancer susceptibility genes whose expression were influenced by breast cancer candidate SNPs from previous GWAS, showing the impact of germline variants on the transcriptome.

1099T

Effects of breast cancer associated *PALB2* c.1592delT founder mutation at the cellular level. *R. Winqvist[1], J. Nikkilä[1], K. Pylkäs[1], H. Peltoketo[1], B. Xia[2], H. Pospiech[3, 4].* 1) Lab. of Cancer Genetics and Tumor Biology, Dept. of Clinical Genetics and Biocenter Oulu, University of Oulu, Oulu University Hospital, Oulu, Finland; 2) Dept. of Radiation Oncology, The Cancer Institute of New Jersey, University of Medicine and Dentistry of New Jersey, Robert Wood Johnson Medical School, New Brunswick, NJ, USA; 3) Leibniz Institute for Age Research - Fritz Lipman Institute, Jena, Germany; 4) Dept. of Biochemistry, University of Oulu, Oulu, Finland.

Besides *BRCA1* and *BRCA2* also constitutional defects in their interaction partner *PALB2* have proven to be important for hereditary susceptibility to breast cancer (BC). Disruption of BRCA1-PALB2-BRCA2 interactions results in defective homologous recombination (HR) and increases cellular sensitivity to DNA damaging agents. BRCA2 and PALB2 are required for G2 checkpoint maintenance and that may contribute to their tumor suppressor functions. Heterozygous *PALB2* mutation carriers have a ~2–6 fold increased risk for BC. Biallelic truncating mutations in *PALB2* again sensitize cells to mitomycin-C (MMC) treatment, which is a hallmark of Fanconi anemia. In addition, we have recently shown that mice lacking proper Palb2 function are embryonically lethal and display defective mesoderm differentiation. We have previously identified a heterozygous *PALB2* c.1592delT founder mutation associated with a 40% risk of BC by the age of 70. It results in a truncated protein with decreased BRCA2-binding affinity and that fails to support HR in PALB2-knockdown cells or to restore crosslink repair in a cellular PALB2-deficient model system. Therefore we investigated how a heterozygous *PALB2* defect influences on checkpoint functions, MMC and PARP inhibitor sensitivity, and genomic stability maintenance before and after treatment with DNA damaging agents. For that purpose lymphoblastoid cell lines were established from eight mutation carriers and six healthy controls. The mutation cell lines did not show any difference in IR-induced apoptosis or γH2AX phosphorylation states in comparison to the control lines. In cell survival assays the sensitivity of our heterozygous *PALB2* mutation cell lines to MMC or to PARP inhibitors did not differ from that of the controls. More importantly, after DNA damage *PALB2* carrier cell lines displayed a decrease in G2/M-phase cell ratio, suggesting that mutation carriers have a defective checkpoint, in spite of one copy of intact *PALB2*, and this was confirmed with histone H3 staining. Together with the current functional analysis, we will also work on modeling the influence of defective PALB2 function in mammary tissue development and tumorigenesis.

1100F

Global Correlation of Expression with Prostate Cancer Associated Variants Identifies IRX4 as a Prostate Cancer Expression Trait Locus. X. Xu[1], W.M. Hussain[2], N. Kitabayashi[2], M.A. Rubin[2], F. Demichelis[3,4], R.J. Klein[1]. 1) Department of Cancer Biol & Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Department of Pathology and Laboratory Medicine, Weill Cornell Medical College, New York, NY; 3) Institute for Computational Biomedicine, Weill Cornell Medical College, New York, NY; 4) Centre for Integrative Biology, CIBIO, University of Trento, Italy.

Background: Functional follow-up to prostate cancer genome-wide association studies (GWAS) have been sorely lacking. One mechanism by which a genetic locus increases risk for prostate cancer may be through regulating expression of a nearby gene, also known as a *cis*-expression quantitative trait locus (*cis*-eQTL). *Cis*-eQTLs are often highly tissue-specific and a global *cis*-eQTL study has yet to be performed in prostate tissue.

Objective: The objective of this study was to determine if any of the known prostate cancer associated genetic loci also act as *cis*-eQTL in prostate tissue, as a means of generating testable hypotheses for the functional mechanism underlying the genetic association.

Methods: 50 prostate cancer cases were genotyped for single nucleotide polymorphisms (SNPs) from genomic DNA and had RNA-seq data generated from paired primary prostate tumors. Prostate cancer associated SNPs were extracted from the NHGRI catalog of published GWAS results. *Cis*-eQTL analysis of transcripts within a 1Mb flanks of each SNP was performed, testing for an allelic effect of transcript levels versus genotypes with false discovery rates (FDR) computed to account for multiple testing.

Results: Out of 586 total transcript-SNP associations tested, 27 had an FDR less than or equal to 10%. These 27 putative eQTL coalesced into 13 distinct genetic loci. The most significant result was correlation of the IRX4 transcript with the prostate cancer risk SNP rs12653946, tagged by rs10866528 in our study ($p=4.91\times10^{-5}$, FDR= 0.00468).

Conclusions: We identified IRX4 as a prostate tissue eQTL through global *cis*- expression correlation with prostate cancer risk variants. *Cis*-eQTL analysis in the relevant tissue, even with a small sample size, can be a powerful method to generate hypotheses to move the functional follow-up of GWAS studies forward.

1101W

Interplay of tumor suppressor genes and oncogenes in ovarian cancer. *M. Zhao[1], S. Sun[1], Z. Zhao[1,2,3,4].* 1) Department of Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, Tennessee, United States of America; 2) Department of Cancer Biology, Vanderbilt University School of Medicine, Nashville, Tennessee, United States of America; 3) Department of Psychiatry, Vanderbilt University School of Medicine, Nashville, Tennessee, United States of America; 4) Center for Quantitative Sciences, Vanderbilt University, Nashville, Tennessee, United States of America.

Investigators have discovered numerous protein-coding and non-coding tumor suppressor genes (TSGs) and oncogenes (OCGs) that control cell proliferation during cancer development. Additionally, TSGs and OCGs may act as modulators of transcription factors (TFs) to influence gene regulation. To better understand the post-translational modulation of TSGs and OCGs to TF gene regulation, we developed a novel computational framework for identifying target genes of TSGs and OCGs. This framework uses TFs as bridges through the integration of protein-protein interactions and gene expression data. We applied this pipeline to ovarian cancer and constructed a three-layer regulatory network. In the network, the top layer consisted of modulators (TSGs and OCGs), the middle layer included TFs, and the bottom layer contained target genes. Based on regulatory relationships in the network, we compiled TSG and OCG profiles and performed clustering analyses. Interestingly, we found TSGs and OCGs formed two distinct branches. The genes in the TSG branch were significantly enriched in DNA damage and repair, macromolecule metabolism regulation, cell cycle and apoptosis, while the genes in the OCG branch were significantly enriched in intracellular signaling, such as in the ErbB signaling pathway. Remarkably, their specific targets showed a reversed functional enrichment in terms of apoptosis and the ErbB signaling pathway: the target genes regulated by OCGs were only enriched in anti-apoptosis and the target genes regulated by TSGs were only enriched in the ErbB signaling pathway. Our study suggested a competitive regulatory mechanism acting upon apoptosis and the ErbB signaling pathway through specific target genes. We further collected 710 human TSGs, 628 Mouse TSGs and 567 Rat TSGs from thousands of literature sources and provide a web-based tumor suppressor gene database (TSGene DB, http://bioinfo.mc.vanderbilt.edu/TSGene/) with extensive annotations on cellular function, gene expression, mutation, methylation, transcription factors, post-translational modification, and protein-protein interaction.

Establishment of Breast, Leiomyosarcoma and Thyroid Cancer Stem Cells derived from carriers of p.R337H TP53 germline mutation within one Li-Fraumeni Syndrome Family. *L.I. Mambelli[2,3], I. Kerkis[3], F. Fortes[2], P. Hainaut[4], M.I.W. Achatz[1,2].* 1) Departamento de Oncogenética, Hospital A.C. Camargo, São Paulo, São Paulo, Brazil; 2) Centro Internacional de Pesquisa, Hospital A.C. Camargo, São Paulo, Brasil; 3) Laboratório de Genética, Instituto Butantan/Universidade de São Paulo, São Paulo, Brasil; 4) International Prevention Research Institute, Lyon, France.

Li-Fraumeni Syndrome (LFS), an inherited cancer predisposition syndrome, is associated with germ line mutations in TP53 and it is characterized by a high risk of multiple early cancers. In Brazil, a variant form of this syndrome is exceedingly frequent due to a widespread founder TP53 mutation, p.R337H, detected in about 0.3% of the general population in Southern Brazil. This mutation occurs in p53 oligomerization domain and disrupts p53 oligomerization and DNA-binding activity in pH-dependent manner. In this study we have isolated and characterized Cancer Stem Cells (CSC) from tumors (breast, leiomyosarcoma and thyroid) of p.R337H mutation carriers, who received clinical diagnosis of LFS. Clinical characterization and molecular profiling, through direct sequencing of TP53 gene in 91 member of one large LFS family was performed. This analysis confirmed the presence of p.R337H mutation in 38 members . All carriers received screening according to NCCN protocol and in a period of 4 year- follow up three tumors were diagnosed in three carriers within this family. Tumors were collected during surgery and primary cultures were initiated. Adherent cells and spheroids were derived from these different tumor types. Spheroids derived from a breast cancer (BC) were further analyzed to demonstrate positive immunolabeling for CD44, Oct4, Sox2, PCNA and Ki-67 antibodies. Time-lapse video microscopy showed rapid growth, frequent asymmetric division and absence of senescent phenotypes of these cells for least 17 passages. Floating and adherent spheroids contained self-renewing stem cells capable of long-term proliferation without losing their primary characteristics. These properties are similar to those of stem cells with inactivated p53 protein. p.R337H CSC may provide an useful model for studying the underlying defects related to inherited cancer in p.R337H carriers.

1103F

Functional validation using eQTL needs cell-specific approaches. *S. Kim[1], H.-H. Won[2], J.-W. Kim[3], D.H. Kim[4], S.-T. Lee[3], S. Kim[2], S.-H. Kim[3], C.W. Jung[5].* 1) Dept. of Health Sciences and Technology, Graduate School, Samsung Advanced Institute for Health Science and Technology, Sungkyunkwan University, Korea; 2) Samsung Biomedical Research Institute, Samsung Medical Center, Korea; 3) Dept. of Laboratory Medicine and Genetics, Sungkyunkwan University School of Medicine, Samsung Medical Center, Korea; 4) Chronic Myelogenous Leukemia Group, Department of Hematology/Medical Oncology, Princess Margaret Hospital, University Health Network, University of Toronto, Toronto, Canada; 5) Department of Hematology/Oncology, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea.

Genome-wide association study (GWAS) has been used to find loci related to diseases but it needs functional validation. Finding expression quantitative trait loci (eQTLs) is an important tool for revealing the functional relationships between variations and the corresponding gene. eQTL studies have focused on the gene expression of lymphoblastoid cell lines (LCL), and subsequently, most eQTL databases contain the results based on LCL. Chronic myeloid leukemia (CML) is a clonal bone marrow stem cell disorder in which proliferation of mature granulocytes and their precursors is a major characteristic. We previously identified novel locus 6q25.1 associated with susceptibility to CML (Kim *et al.*, Blood, 2011, 117(25):6906-11). Therefore, we conducted experiments to confirm whether SNPs in this locus affect expression of CML candidate genes in two types of white blood cells, mononuclear cells and granulocytes. Peripheral blood samples from normal subjects were obtained. We isolated granulocytes and mononuclear cells from the blood to compare gene expression levels and purified DNA for genotyping. We then extracted total RNA and equal amounts of RNA were used to synthesize cDNA. Quantitative PCR was performed using Real-Time PCR 7900 HT (Applied Biosystems, USA). Relative expression of a candidate gene, *RMND1*, was calculated using the threshold cycle number (Ct) and normalized according to *GAPDH*. We selected SNPs which were known as eQTLs and DNase I hypersensitive QTLs (dsQTLs) in the locus 6q25.1 using the eQTL database (http://eqtl.uchicago.edu/) and genotyped eight SNPs. Statistical significance was evaluated by Kruskal-Wallis test using the R software. We observed that three SNPs (rs3900024, rs7765741, and rs78970048) in this locus were marginally associated with gene expression of mRNA in mononuclear cells (p-value: 0.06, 0.06 and 0.05 respectively) but not in granulocytes (p-value: 0.53, 0.53 and 0.46 respectively). These SNPs were reported as eQTLs and dsQTLs in the eQTL database. This study revealed that gene expression patterns in each cell according to genotypes were substantially different, consistent with a previous report that several eQTLs had cell type-dependent directional effects in B cells and monocytes (Fairpax *et al.*, Nat Genet, 2012, 25;44(5)). Therefore, we suggest that functional validation using eQTL needs to be conducted in cell lines that are relevant to the disease.

Functional characterization of HLA allelotypes associated with follicular lymphoma risk. *F.C.M. Sillé, L. Conde, C.F. Skibola.* School of Public Health, Division of Environmental Health Sciences, University of California Berkeley, 237A Hildebrand Hall, Berkeley, CA 94720-7360, USA.

Background: Family and epidemiological studies suggest an important genetic role in the etiology of lymphomas. In recent genome-wide association studies of follicular lymphoma (FL), several genetic susceptibility loci have been identified in the human leukocyte antigen (HLA) Class II region on chromosome 6p21.32 including rs10484561 that is associated with a two-fold increased risk of FL (OR = 1.95, $P = 1.12\times10^{-29}$). Moreover, high-resolution HLA typing using next-generation sequencing identified a number of HLA alleles associated with FL including the extended haplotype *DRB1*01:01—DQA1*01:01—DQB1*05:01* that is in complete linkage disequilibrium with rs10484561 ($r^2 = 0.99$). We hypothesize that these FL risk HLA alleles possibly influence the immune response against tumor development by altering the presentation and expression of specific antigens. To gain further understanding on the mechanism by which these HLA alleles might act, we explored the effect of HLA alleles in gene expression at both transcriptional and protein levels.

Methods: We selected 40 lymphoblastoid cell lines from the Coriell Institute with available genotype and HLA typing. Transcription was tested using RT-qPCR, whereas protein expression was tested using flow cytometry.

Results: Using RT-qPCR, we did not find significant changes in transcript levels of HLA-DRB1, HLA-DQB1 or HLA-DQA1 upon the presence of rs10484561 risk allele or the *HLA-DRB1*0101—DQA1*0101—DQB1*0501* haplotype. Flow cytometry with HLA-specific antibodies and pan-HLA antibodies (against DR/DQ/DP) also did not reveal significant differences in surface expression of HLA-DRB1, HLA-DQB1 or HLA-DQA1.

Conclusion: The extended haplotype *HLA-DRB1*0101—DQA1*0101—DQB1*0501*—rs10484561 was previously identified and validated as a risk haplotype associated with FL. However, we did not detect significant differences in transcript levels or surface protein expression upon the presence of these risk alleles. These findings suggest that the increased risk of FL associated with the *HLA-DRB1*0101—DQA1*0101—DQB1*0501* haplotype and the linked rs10484561 SNP are not due to changes in HLA expression. We will validate these findings by Western blotting and ELISAs and test antigen presentation using T-cell activation assays.

1105T

MicroRNA expression for classification of histiocytic sarcomas in dogs. *J. Aguirre Hernandez, J.M. Dobson, T.M. Hoather, D.R. Sargan, F. Constantino-Casas.* Veterinary Medicine, University of Cambridge, Cambridge CB3 0ES, United Kingdom.

Soft tissue sarcomas are rare in humans but common in dogs (up to 40 percent of malignancies in some breeds). This makes it possible to rely on the dog to better understand these tumours. Flat-coated retrievers have a particularly high incidence of histiocytic sarcomas of which two forms can be recognised: limb and visceral. To aid in their diagnosis, classification and prognosis, the expression of 22 microRNAs (miRNA) was studied in formalin fixed paraffin embedded tumours of this breed. Samples comprised visceral histiocytic sarcomas, limb histiocytic sarcomas, peripheral nerve sheath tumours, histiocytomas and a high grade soft tissue sarcoma. MiRNA expression profiling correctly distinguished all of them. However, contrary to what was expected, the expression profiles did not classify histiocytic sarcomas according to the site of presentation. Instead, 2 different histiocytic sarcoma groups were distinguished, each including both limb and visceral forms. In addition to this, a single limb histocityc sarcoma was not grouped with any of the two histiocytic sarcoma clusters, or with any other tumour, appearing to be an outlier in terms of its miRNA expression profile. This clustering of the histiocytic sarcomas would be consistent with the recognition of several dendritic cell lineages.

Molecular urine assay of PCA3,MMP2,MMP9 and KLK3 in men with prostate cancer and benign prostatic hyperplasia. *H. Akin[1], A. Simsir[2], F. Hazan[1], T.R. Ozdemir[1], I. Cureklibatir[2], G. Itirli[1], C. Gunduz[3], C. Ozkinay[1], F. Ozkinay[1].* 1) Department of Medical Genetics, Ege University, Medical Faculty, IZMIR, Turkey; 2) Department of Urology, Ege University, Medical Faculty, IZMIR, Turkey; 3) Department of Medical Biology, Ege University, Medical Faculty, IZMIR, Turkey.

Men with elevated serum prostate-specific antigen (PSA) levels and negative prostate biopsy findings present a complicated status in definitive prostate cancer approach. In this study our aim was the evaluating the diagnostic and prognostic utility of the investigational prostate cancer gene 3 (PCA3), matrix metalloproteinase 2(MMP2) and 9 (MMP9) and KLK3 mRNA expression profiling in prostate cancer(PCA) and benign prostatic hyperplasia (BPH). Seventy four PCA patients, 60 BPH patients and 41 controls were included in the study. The average ages of the groups PCA, BPH and controls were 61.20±11.05, 65.25±11.90 and 44.12±15.26 respectively. Urine was collected after digital rectal examination (three strokes per lobe) from the patients and controls. The specimens were collected from April 2009 to November 2011. The mRNA expression levels of PCA3, MMP2, MMP9 and KLK3 genes were detected using a non-invasive molecular urine assay method, RT PCR. PCA3 expression levels were found to be significantly higher (p=0.001) in PCA patients group comparing to the BPH patients and controls using student t test. Receiver operating characteristic curve analysis yielded an area under the curve of 0.659 for the PCA3 with p:0.002 significance. On the other hand, MMP9 expression level showed significant correlation with Gleason score in patients with PCA. PCA3 and MMP9 expression profiling in the urine of PCA patients may be useful in the diagnosis and management of PCA.

1107W

The effect of copy number variation (CNV) in the phase II detoxification genes, UGT2B17 and UGT2B28, on colorectal cancer risk. *A.Y. Angstadt[1], A.S. Berg[1], J. Zhu[1], P. Miller[2], T.J. Hartman[3], S.M. Lesko[4], J.E. Muscat[1], P. Lazarus[1,5], C.J. Gallagher[1,5].* 1) Department of Public Health Sciences, Penn State College of Medicine, Hershey, PA, United States; 2) National Cancer Institute, Rockville, Maryland, United States; 3) Department of Nutritional Sciences, Penn State University, University Park, PA, United States; 4) Northeast Regional Cancer Institute, Scranton, PA, United States; 5) Department of Pharmacology, Penn State College of Medicine, Hershey, PA, United States.

Colorectal cancer (CRC) incidence levels are highest in the developed world as the Western-Style diet is thought to be a contributing factor. Metabolism of dietary compounds is completed by phase II detoxification enzymes like UGT2B17 and UGT2B28. These enzymes are located in commonly deleted regions of the human genome, occurring in Caucasians at 27% and 13.5%, respectively. UGT2B17 copy number variation (CNV) was found associated with lung and prostate cancer risk and it has been shown that loss of UGT2B28 in CRC cells compared to nonneoplastic cells resulted in lower expression. Yet, no genetic association studies of UGT2B17 or UGT2B28 and CRC risk have been previously performed. We hypothesized that CNV of these genes may be causing different CRC risk levels in individuals exposed to particular dietary factors. We genotyped UGT2B17 and UGT2B28 CNVs in 665 Caucasian CRC cases (368 men, 297 women) and 621 Caucasian controls (359 men, 262 women) that had completed an extensive demographic/dietary questionnaire. Unconditional logistic regression was used to test the separate effect of UGT2B17 and UGT2B28 CNV on CRC risk, while polytomous logistic regression was used to analyze associations between genotype and anatomical subsites. All models were adjusted for age, BMI, kcal/day, NSAID use, CRC family history, and physical activity. A significant association between the UGT2B17 deletion allele (0/0) and decreased CRC risk was found in our entire population (0.815 OR, 0.668–0.994 95% CI). In addition, a significant association between UGT2B17 (0/0) and decreased CRC risk was found in rectal cancer patients (0.670 OR, 0.502–0.894 95% CI) but not colon cancer patients. Sex stratification yielded a decreased risk in UGT2B17 (0/0) men (0.724 OR, 0.552–0.950 95% CI), but no association was found in women. No significant association was found between UGT2B28 CNV and CRC risk before and after stratification. UGT2B17 has been shown to have higher expression and activity in men, which may be responsible for the sex-specific association we observed. In addition to its role in androgen metabolism, UGT2B17 is known to metabolize NSAIDs and flavonoids (antioxidants) so individuals with two copies of this gene may excrete these protective dietary compounds at a faster rate than individuals with one or zero copies. Therefore, decreasing the antioxidant effect on carcinogen detoxification, resulting in the observed decreased CRC risk in UGT2B17 (0/0) individuals.

Genetic sequence variant in microRNA genes and survival in non-small cell lung cancer. *A.K. Azad[1], X. Qiu[3], T. Popper[1], K. Boyd[1], Q. Kuang[1], Y.B. Berhane[3], H. Henrique[1], N. Perera[1], P. Prakruthi[1], D. Patel[1], S. Momin[1], M. Nakhla[1], E. Marjan[1], Z. Chen[1], D. Cheng[1], R. Feld[2], N.B. Leighl[2], F.A. Shepherd[2], M.-S. Tsao[4], W. Xu[3], G. Liu[1,2,5], S. Cuffe[2].* 1) Ontario Cancer Institute, Princess Margaret Hospital, University Health Network, Toronto, Ontario, Canada; 2) Division of Medical Oncology and Hematology, Princess Margaret Hospital, University Health Network, Toronto, Ontario, Canada; 3) Department of Biostatistics, Princess Margaret Hospital, University Health Network, Toronto, Ontario, Canada; 4) Department of Pathology, Princess Margaret Hospital, University Health Network, Toronto, Ontario, Canada; 5) Department of Environmental Health, Harvard School of Public Health, Boston, Massachusetts, USA.

Background: Lung cancer is the leading cause of cancer-related mortality worldwide and approximately 80% of the patients have NSCLC. Recent studies indicate that small non-coding RNA molecules known as miRNA can function as tumor suppressors and oncogenes. GSVs in miRNA genes, misexpression and altered miRNA processing have been implicated in carcinogenesis and cancer outcome. miRNA expression profiles and specific miRNA have been shown to be correlated with survival of lung adenocarcinoma (ADC). The aim of this study was to evaluate whether miRNA-related GSVs associated with cancer risk are also associated with overall survival (OS) and progression free survival (PFS) in stage-IV NSCLC patients. **Methods:** A total of 41 candidate GSVs in 33 genes in miRNA biogenesis pathways previously reported to be associated with cancer risk/outcome were genotyped in 325 stage-IV NSCLC patients. Patients were recruited for prospective study of the molecular epidemiology of thoracic lesions in PMH from 2006–2010. Illumina Custom GoldenGate Genotyping Panel was used for the genotyping assay platform. Multivariate Cox proportional hazard models adjusted for potential clinical prognostic factors were generated for OS and PFS. **Results:** Median age was 64y (range: 31–88); 71% had ADC. Median OS time was 1.10y (95% CI: 0.90–1.23); Median follow-up time was 1.9yr. Median PFS time was 6m (95% CI: 0.49–0.60). The variant allele of *C14orf101*:rs4901706:c.*170G>A and *NEIL1*:rs5745925:c.719-113delT (hsa-mir-631) found to be associated with OS and PFS when compared with the wild type allele. For OS, rs4901706 [aHR 1.42 (95% CI: 1.04–1.93), *p* 0.03] and rs5745925 [1.77 (95% CI: 1.16–2.70), *p* 0.01]; and for PFS, rs4901706 [1.46 (95% CI: 1.11–1.93), *p* 0.01] and rs5745925 [1.62 (95% CI: 1.07–2.44), *p* 0.02] showed significant association. **Conclusions:** The miRNA-related GSVs are not only a risk factor for lung cancer but also are associated with survival in patients with stage-IV NSCLC. The data demonstrated the GSVs are marginally associated with poorer survival in stage-IV NSCLC patients. Variant alleles of rs4901706 and rs5745925 have been previously associated with cancer risk (PMID: 17584784, 19138993). However, their functional relevance in cancer outcome has not been investigated. The validation of these findings in multiple cohorts and testing of their functionality at cellular level is also required. *GL and SC are senior co-authors.

The PROFILE Study: Genetic prostate cancer risk stratification for targeted screening. *E.K. Bancroft[1,2], E.C. Castro[2], N. Taylor[1,2], E. Page[2], E. Saunders[2], T. Dadaev[2], A. Lee[3], A. Antoniou[3], Z. Kote-Jarai[2], R. Eeles[2].* 1) Royal Marsden Hospital, Sutton, United Kingdom; 2) Institute of Cancer Research, Sutton, United Kingdom; 3) The University of Cambridge, UK.

A family history (FH) of prostate cancer (PC) is one of the main risk factors for the disease suggesting the importance of genetics in PC development. GWAS have identified a number of common single nucleotide polymorphisms (SNPs) that confer small but cumulatively substantial risks of PC. These findings open the possibility for exploring the use of SNPs in PC risk stratification for targeted screening. Objectives: PROFILE has been developed as a pilot study. The primary aim is to determine the feasibility of targeted PC screening using prostatic biopsy (PB) and its association with specific genetic profiles in men with FH. The secondary aims are to (1)determine PC risk related SNP signatures in men with FH; (2)study the correlation between those SNP signatures and PB outcomes; (3)estimate the sensitivity and specificity of PSA screening and optimal PSA threshold for PB in men with FH; (4)to assess the value of Diffusion Weighted Magnetic Resonance Imaging (DW-MRI) as a PC screening tool; (5)evaluate the psychosocial impact of undergoing genetic profiling in this context. Method: Eligible men were aged 40–69 years with a FH of PC. After informed consent patients provided blood samples to measure PSA level and for DNA extraction. All participants were asked to undergo PB +/− DW-MRI regardless of baseline PSA result. DNA from each participant was analysed for a panel of 39 SNPs associated with increased risk of PC using iPLEX Sequenom technology. The results were fed back to participants and an associated psychosocial study has collected data on cancer worry, anxiety, depression and illness perceptions. Results: 92 men were recruited and 77 PB performed by 1st May 2012. 33 men had a predicted relative risk (RR)<1 (median age 55 yrs; median PSA 1.5). In this subgroup 6 men (18.2%) were diagnosed with PC (median age 66.5 yrs, PSA 2.1). Amongst the 34 men with a RR>1 (median age 50.5 yrs; median PSA 1.3) 9 PCs (26.5%) have been identified (median age 58 yrs, PSA 5.4). DW-MRI had 33% false positives and 10% false negatives. 56 men completed baseline & follow-up questionnaires and no measurable adverse psychological outcomes were recorded. Conclusion: The results indicate that PB as a means of PC screening is feasible and acceptable in men with a FH of PC. Men had a good understanding of the limitations of genetic profiling. Our findings support the use of SNPs in PC risk stratification for targeted screening in a larger study.

1110W

Lgr5 expression and its relatedness with other tumor stem cell markers in human gastric adenocarcinoma. *W. Fan, Y. W. Guo, Y. Y. Xie, Y.S. Li, W. Chen.* Molecular Genetics, Hebei University, Baoding, Hebei, China.

Purpose: To investigate if the Lgr5 serves as a tumor stem cell marker in the human gastric adenocarcinoma as it does in mouse, and to understand its relatedness with other stem cells markers (Bmi1 and Villin) and putative tumor stem cell markers (CD44, ALDH1, CD26 and CD133) as reported . Methods: Immunohistochemical detection of Lgr5, Bmi1, Villin, CD44, ALDH1, CD26 and CD133 in dissected human gastric adenocarcinoma samples and the adjacent normal gastric tissues. RT-PCR is also applied to detect Lgr5 expression in transcription level of several gastric cell lines. Results: Lgr5 is consistently expressed at gland bottom of normal gastric mucosa in human, and is evenly distributed in pyloris, cardia, lesser curvature, and great curvature, but not in the low-differentiated gastric adenocarcinoma. Lgr5 is co-expressed with Bmi1 and Villin, but Villin is also weakly expressed in biopsy tissue samples of gastric adenocarcinoma. Lgr5 expression is overlapped with putative gastrointestinal tract tumor stem cells markers such as CD44, ALDH1, CD26 and CD133. The results from immunofluorescence double labeling show that Lgr5 is co-expressed with CD44 and ALDH1 even in the same cells. In addition, CD26 and CD133 are expressed in low differentiated gastric adenocarcinoma respectively, and CD133 demonstrates a very strong positive marker. RT-PCR results show that Lgr5 is weakly expressed in the gastric tumor cell line cultures in vitro though it can not be detected by immunohistochemistry and immunoflourescence. Conclusion: Lgr5 is expressed at the bottom of the glands in the human gastric mucosa and its expression is overlapped with other stem cell markers, indicating Lgr5 may serves as the putative stem cells marker in the human stomach as it is in mouse, and it may share the similar pathway in cell development and differentiation with Bmi1, Villin, CD44, ALDH1, CD26 and CD133.

The TP53 16 bp duplication polymorphism is associated with breast cancer. *M. Gallegos, Jr.[1], A. Gutiérrez[1,5], A. Ramos[1,6], E. Salas[2], J. M. Castro[3], A. M. Puebla[7], L. E. Figuera[4], G. M. Zúñiga[1]*. 1) División de Médicina Molecular, CIBO; 2) Jefatura de Oncología, UMAE, Hospital de Gineco-Obtetricia; 3) Jefatura de Onco-Cirugía, UMAE, Hospital de Especialidades; 4) División de Genética, CIBO, CMNO, IMSS; 5) Licenciatura en Químico Farmacobiologo, CUCEI, UdeG; 6) Doctorado de Farmacología, UdeG; 7) Laboratorio de Inmunofarmacología, CUCEI, UdeG,.Guadalajara, Jalisco. México.

The TP53 tumor suppressor gene encodes the nuclear phosphoprotein p53, which plays an important role in cell cycle, apoptosis, DNA reparations and angiogenesis. The TP53 contains common genetics polymorphisms that influence gene activity. In the present study we describe to frequency of 16 bp duplications polymorphism of TP53 gene in 304 breast cancer patients and 204 woman health controls from Mexico. The frequency observed was of 4% (13/304) and 1% (1/204) of 16 bp duplication genotype; 20% (59/304) and 11% (24/204) of heterozygous (16 bp duplication/16 bp no duplication) genotype; 76% (232/304) and 88% (179/204) of 16 bp no duplication genotype in cases and controls respectively. We found that odds ratio (OR) = 9.0 95% confidence intervals 1.33–387, p = 0.001. These results suggest that 16 bp duplication polymorphism of TP53 gene is associated with Mexican breast cancer patients.

1112F

Statistics of Cellular Evolution in Leukemia: Allelic Variations in Patient Trajectories Based on Immune Repertoire Sequencing. *H. Gao[1], C. Wang[1], AC. Logan[2], CD. Bustamante[3], J. Seok[1], DB. Miklos[2], RW. Davis[1], MW. Feldman[4], W. Xiao[1,5]*. 1) Stanford Genome Tech. Center and Biochemistry Dept, Stanford Univ, Stanford, CA; 2) Division of Blood and Marrow Transplantation, Medicine Dept, Stanford Univ, Stanford, CA; 3) Genetics Dept, Stanford Univ, Stanford, CA; 4) Biology Dept, Stanford Univ, Stanford, CA; 5) Department of Surgery, Shriners Burn Center and Massachusetts General Hospital, Harvard Medical School, Boston, MA.

The evolution of a cancer system consisting of cancer clones and normal cells is a complex and dynamic process with multiple interacting factors including clonal expansion, somatic mutation, and sequential selection. As a typical example, in patients with chronic lymphocytic leukemia (CLL), a monoclonal population of transformed B cells expands to dominate the B cell population in the peripheral blood and bone marrow. This expansion of transformed B cells suggests that they might evolve through processes distinct from those of normal B cells. Recent advances in next generation sequencing enable the high-throughput identification and tracking of individual B cell clones through sequencing of the V-D-J junction segments of the immunoglobulin heavy chain (IGH). Here, we developed a statistical approach to modeling cellular evolution of the immune repertoire. Adapting the infinitely many alleles model from population genetics, we studied abnormalities occurring in the immune repertoire of patients as substantial deviations from the null model. The Ewens sampling test (EST) distinguished the immune repertoires of CLL patients with imminent relapse from healthy controls and patients in sustained remission. Extensive simulations based on sequencing data showed that EST is sensitive in detecting cancer-related derangements of the IGH repertoire. In addition, we suggest two potentially useful parameters: the rate at which donor's B cell clones enter the circulation and the average time to regenerate a transplanted immune repertoire, both of which help to classify relapsing CLL patients from those in sustained remission and provide additional information about the dynamics of immune reconstitution in these patients. We anticipate that our models and statistics will be useful in diagnosis and prognosis of leukemia, and may be adapted for application to other diseases related to adaptive immunity.

1113W

Genetic polymorphisms and colorectal cancer risk: A systematic review of meta-analyses. *B. Haerian[1], M. Haerian[2]*. 1) University of Malaya, Kuala Lumpur, Malaysia; 2) Shaheed Beheshti of Medical Sciences, Tehran, Iran.

Background: Colorectal cancer (CRC) is the second leading cause of morbidity and mortality in United States. A series of genetic and environmental factors drive the development of CRC. Accumulated evidence have identified involvement of numerous low penetrance susceptibility genes loci in CRC. Alterations in these genes could change protein structure and function associated with the hallmarks of cancer-related biology. Objectives: The aim of this study is to highlight an array of genes that reflect the cellular processes and regulate tumour activities and progression in CRC using the significant loci from evaluated meta-analyses in the literature. Methods: In this study, we have searched MEDLINE, Embase, and the Cochrane Database of Systematic Reviews for meta-analyses and pooled analyses involving the associations between various genes polymorphisms and CRC risk and then we have systematically evaluated them. Results: A total of 133 published meta-analyses and pooled analyses articles evaluating the association of low penetrance susceptibility variants with CRC risk have been investigated. Of these reports, 118 have been included in our study. The data from 118 polymorphisms of 65 genes, one microRNA, and six chromosomal regions are analyzed. Finally, based on the six hallmark trait, the role of the significant loci in CRC is classified and discussed. Conclusion: The data of this comprehensive study shows the considerable role of some susceptible genes variants in cancer hallmarks during multi-steps CRC development.

1114T

NRF2 and sulfiredoxin genetic polymorphisms and protein expression predict outcome in breast cancer. *J.M. Hartikainen[1,2,3], M. Tengström[4,5], V.-M. Kosma[1,2,3], V. Kinnula[6], A. Mannermaa[1,2,3], Y. Soini[1,2,3]*. 1) Institute of Clinical Medicine, Pathology and Forensic Medicine, University of Eastern Finland, Kuopio, Finland; 2) Biocenter Kuopio and Cancer Center of Eastern Finland, University of Eastern Finland, Kuopio, Finland; 3) Imaging Center, Clinical Pathology, Kuopio University Hospital, Kuopio, Finland; 4) Institute of Clinical Medicine, Oncology, University of Eastern Finland, Kuopio, Finland; 5) Cancer Center, Kuopio University Hospital, Kuopio, Finland; 6) Department of Medicine, Pulmonary Division, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland.

Nuclear factor erythroid 2-related factor 2 (NRF2) is a transcriptional factor which senses oxidative and xenobiotic stress in the cells. As a response to oxidative and xenobiotic stress NRF2 activates several protective genes, such as sulfiredoxin. Defects in the NRF2 pathway may increase cancer susceptibility. In tumor cells the activation of NRF2 may lead to chemo- and radioresistance and thus affect patient outcome. Nine single nucleotide polymorphisms on *NRF2* gene and eight on *SRXN1* (sulfiredoxin) were genotyped in a material of 452 breast cancer patients and 370 controls. Protein expression of NRF2 and sulfiredoxin was studied in 373 breast carcinomas by immunohistochemistry. Statistical significance of the associations between genotypes, protein expression, clinicopathological variables and survival was assessed. High extent (>25%) cytoplasmic NRF2 positivity was observed in 237/361 (66%) and sulfiredoxin positivity in 82/363 (23%) of the cases. *NRF2* rs6721961 genotype TT associated with increased risk of breast cancer (P=0.008, OR=4.656, CI=1.350–16.063) and T allele with low extent NRF2 protein expression (P=0.0003, OR=2.420, CI=1.491–3.926) and negative sulfiredoxin expression (P=0.047, OR=1.867, CI=1.002–3.478). *NRF2* rs2886162 allele A associated with low extent NRF2 expression (P=0.011, OR=1.988, CI=1.162–3.400) and genotype AA with poorer survival (P=0.032, HR=1.687, CI=1.047–2.748). *NRF2* rs1962142 allele T associated with low extent cytoplasmic NRF2 (P=0.036) and negative sulfiredoxin expression (P=0.042). *NRF2* rs2706110 genotype AA associated with increased risk of breast cancer and *SRXN1* rs6053666 allele C was protective (P values 0.011 and 0.017). Four other *SRXN1* SNPs associated with breast cancer survival. Our results demonstrate that in the NRF2 pathway there are genetic polymorphisms that affect both the susceptibility for breast cancer and the outcome of the breast cancer patients, thus underlining the complex effect of NRF2 in cancer progression. The results implicate that mechanisms associated with ROS and NRF2 pathway are involved in breast cancer initiation and progression also at the level of genetic predisposition. ROS associated mechanisms appear to play a role in the behavior and treatment of breast cancer to the extent of being reflected in the survival of the patients. Studying antioxidative mechanisms may thus pave the way for new treatment modalities based on inhibition of such mechanisms in breast cancer cells.

Speicher[1].* 1) Institute of Human Genetics, Medical University of Graz, Harrachgasse 21/8, A-8010 Graz, Austria; 2) Institute of Tumor Biology, University Medical Center Hamburg Eppendorf, Martinistr. 52, D-20246 Hamburg, Germany; 3) Division of Oncology, Medical University of Graz, Auenbruggerplatz 15, A-8036 Graz, Austria; 4) Department of Pathology, General Hospital Graz West, Goestingerstrasse 22, A-8020 Graz, Austria; 5) Department of Obstetrics and Gynecology, Medical University of Graz, Auenbruggerplatz 14, A-8036 Graz, Austria; 6) Institute of Pathology, Medical University of Graz, Auenbruggerplatz 25, A-8036 Graz, Austria; 7) Division of Hematology, Medical University of Graz, Auenbruggerplatz 38, A-8036 Graz, Austria; 8) LKH Leoben, Department for Hematology and Oncology, Vordernberger Straβe 42; A-8700 Leoben, Austria.

As the number of available predictive biomarkers is steadily rising, the serial accurate monitoring of tumor genotypes, which are prone to changes, becomes increasingly important in the clinical management of human cancer. In this study, we investigated whether complex tumor genomes can be inferred from peripheral blood, i.e. plasma DNA and/or CTCs from patients with cancer. Therefore, we analyzed peripheral blood of 32 patients with advanced-stage colorectal cancer (CRC) for mutant DNA-fragments in the plasma and circulating tumor cells (CTCs) using array-CGH and next generation sequencing technology. We found that a subset of patients simultaneously releases tumor DNA from two different cell populations, i.e. apoptotic and non-apoptotic cells, into the circulation. This phenomenon co-occurs with increased numbers of CTCs and elevated plasma-DNA concentrations and has consequences on diagnostic tests, as tumor specific copy number changes can be established directly from plasma-DNA. Our CTC analyses included massively parallel sequencing of a panel of 68 CRC associated genes and a comparison with the mutation status in the primary tumors and associated metastases. Ultra-deep sequencing of “private mutations” found in only one CTCs revealed allele frequencies ranging from 0.02 to 0.45 in corresponding samples including plasma, tumor, and metastasis. We demonstrate that CTCs have an enormous heterogeneity, which is characterized by different copy number changes and mutations in cancer driver genes. The fact that these results were confirmed in 35 patients with breast cancer suggests that our approach is applicable to a variety of tumor entities. Our analyses provide novel insights into tumor evolution and may expand current non-invasive approaches for disease monitoring.

Novel integrative genomics approach for associating GWAS information with triple negative breast cancer. *C. Hicks[1,2], K. Backus[1], A. Pannuti[1], L. Miele[1].* 1) Cancer Institute Univ Mississippi Med Center, 2500 N State Street, Jackson, MS 39216; 2) Dept Medicine, Univ. Mississippi Med. Center, 2500 N State Street, Jackson, MS 39216.

Introduction: Genome-wide association studies (GWAS) have achieved great success in identifying genetic variants associated with increased risk for breast cancer. However, the association between genetic variants and the most aggressive subset of breast cancer, the triple negative breast cancer (TNBC) remains a central puzzle. TNBC (Tumors that do not express estrogen receptors, progesterone receptors, or HER2) constitute 15%–20% of all breast cancers diagnosed. TNBC is significantly more aggressive than other subtypes of breast cancer and disproportionately affects younger premenopausal women, with a higher mortality rate among African-American women. Currently, chemotherapy remains the only effective therapeutic modality. The objective of this study was to determine whether genes containing SNPs associated with increased risk for breast cancer are associated with and could stratify TNBC. Methods: Here we present a novel integrative genomics approach that combines GWAS information with gene expression data from breast cancer patients classified as TNBC at diagnosis. Specifically, we first identified 600 SNPs (genetic variants) mapped to 200 genes identified from 50 GWAS involving over 300,000 cases and over 300,000 controls. We then investigated the association of these variants and genes with TNBC and identified biological pathways using gene expression as the intermediate phenotype. Gene expression data was derived from normal-like (N=20), basal-like (N=29), and basal (N=75) breast cancer patients and cancer-free controls (N=142 subjects). We performed unsupervised and supervised analysis, and controlled for multiple hypothesis testing using the false discovery rate (FDR). Pathway prediction and network visualization was performed using Ingenuity (IPA). Results: We identified 159 genes contain SNPs, that were significantly (P<10-5) associated with and stratified TNBC. 40 of these genes contained SNPs replicated in multiple independent GWAS studies. We identified networks made of multiple pathways including DNA repair, DNA mismatch repair, cell cycle, apoptosis, P53, metabolism, cellular growth and proliferation. The integration of GWAS information with gene expression data provides insights about the association of genetic variants with TNBC. In conclusion, our results demonstrate the potential applicability of integrating GWAS information and gene expression data to identify genetic variants and genes associated with TNBC.

Laakso[12], S. Hautaniemi[12], K. Aittomäki[13], C. Blomqvist[14], J. Liu[11], H. Nevalinna[1].* 1) Department of Obstetrics and Gynecology, Biomedicum Helsinki, University of Helsinki and Helsinki University Central Hospital, P.O. Box 700, 00029 Helsinki, Finland; 2) Department of Molecular Pathology, Netherlands Cancer Institute, Plesmanlaan 121, 1066 CX Amsterdam, The Netherlands; 3) Department of Psychosocial Research and Epidemiology, Netherlands Cancer Institute, Plesmanlaan 121, 1066 CX Amsterdam, The Netherlands; 4) Clinics of Gynecology and Obstetrics, Hannover Medical School, Hannover, Germany; 5) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Department of Health and Human Services, Bethesda, Maryland; 6) Division of Genetics and Epidemiology, Institute of Cancer Research and Breakthrough Breast Cancer Research Centre, London, UK; 7) Clinics of Radiation Oncology, Hannover Medical School, Hannover, Germany; 8) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD, 20892; 9) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD, USA; 10) Department of Cancer Epidemiology and Prevention, M. Sklodowska-Curie Memorial Cancer Center and Institute of Oncology, Warsaw, Poland; 11) Human Genetics Division, Genome Institute of Singapore, Singapore; 12) Computational Systems Biology Laboratory, Genome-Scale Biology Research Program, Institute of Biomedicine, University of Helsinki, Finland; 13) Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 14) Department of Oncology, Helsinki University Central Hospital, Helsinki, Finland.

Germ line variation in the TP53 network genes PRKAG2, PPP2R2B, CCNG1, PIAS1 and YWHAQ was previously suggested to have an impact on drug response in vitro. Here, we investigated the effect on breast cancer survival of germ line variation in these genes in 925 Finnish breast cancer patients and further analyzed 5 SNPs in PRKAG2 (rs1029946, rs4726050, rs6464153, rs7789699) and PPP2R2B (rs10477313) for 10-year survival in breast cancer patients, interaction with TP53 R72P and MDM2-SNP309, outcome after specific adjuvant therapy, and correlation to tumor characteristics in 4701 invasive cases from four data sets. We found evidence for carriers of PRKAG2-rs1029946 and PRKAG2-rs4726050 having improved survival in the pooled data (HR 0.53, 95% CI 0.3–0.9; P = 0.023 for homozygous carriers of the rare G-allele and HR 0.85, 95% CI 0.7–0.9; P = 0.049 for carriers of the rare G allele, respectively). PRKAG2-rs4726050 showed a significant interaction with MDM2-SNP309, with PRKAG2-rs4726050 rare G-allele having a dose-dependent effect for better breast cancer survival confined only to MDM2 SNP309 rare G-allele carriers (HR 0.45, 95% CI 0.2–0.7; P = 0.001). This interaction also emerged as an independent predictor of better survival (P = 0.047). PPP2R2B-rs10477313 rare A-allele was found to predict better survival (HR 0.82, 95% CI 0.6–0.9; P = 0.018), especially after hormonal therapy (HR 0.66, 95% CI 0.5–0.9; P = 0.048). These findings warrant further studies and suggest that genetic markers in TP53 network genes such as PRKAG2 and PPP2R2B might affect prognosis and treatment outcome in breast cancer patients.

1118F

Detection of FLT3 Internal Tandem Duplication and D835 Mutations in Iranian patients with acute myeloid leukemia. *L. Kokabee[1], A. Ahmadzadeh[2], M. Kokabee[2], M. Karimipoor[1].* 1) Molecular Medicine Group, Biotechnology Department, Pasteur Institute of Iran, Tehran, Tehran, Iran; 2) Shariati Hospital, Tehran university of medical science, Tehran, Iran.

Acute myeloid leukemia (AML) is a disease with marked heterogeneity in both response to therapy and survival. The advent of molecular diagnostics has heralded an explosion in new prognostic factors. The FLT3 gene encodes the tyrosine kinase receptor critical for normal hematopoiesis. There are two types of FLT3 mutations: an internal tandem duplication (ITD) and a point mutation (D835), which both have constitutively active tyrosine kinase, thereby promoting proliferation and inhibiting apoptosis in leukemic cells. In this study, mutations in 31 untreated cytogenetic normal AML patients (The mean age of patients was 39 year) were analyzed. For this purpose, genomic DNA was extracted from peripheral blood (referred to Shariati hospital, Tehran, Iran) by standard methods. PCR amplification was performed for FLT3 mutation status (ITD and D835). After amplification, PCR product of FLT3/D835 mutation was digested with EcoRV. FLT3/ITD was found in 2 patients (6.45%) and D835 mutation in 4 patients (12.90%). These mutations also appear to be activating and to portend a worse prognosis. Identification of FLT3 mutations is important because it provides prognostic information and may play a pivotal role in determining appropriate treatment options.

Association of Gastric Cancer With Amerindian Ancestry, Socioeconomic and Nutritional Factors and a Gene Candidate Study in a Latin American Admixed Population. *L. Lacorte[1], R. Zamudio[1], G. Soares-Souza[1], P. Herrera[2], L. Cabrera[2], C. Hooper[3], J. Cok[4], J. Combe[5], G. Vargas[6], W. Prado[7], S. Schneider[8], M. Rodrigues[1], S. Chanock[9], D. Berg[10], R. Gilman[2,3,11], E. Tarazona-Santos[1,2], F. Kehdy[1].* 1) Departamento de Biologia Geral, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 2) Asociación Benéfica PRISMA and Universidad Peruana Cayetano Heredia, Lima, Peru; 3) 3 Laboratorios de Investigacion y Desarrollo, Facultad de Ciencias, Universidad Peruana Cayetano Heredia, Lima, Peru; 4) Departamento de Patología, Hospital Nacional Cayetano Heredia, Lima, Peru; 5) Departamento de Gastroenterologia, Instituto Nacional de Enfermedades Neopláscas, Lima, Peru; 6) Servicio de Gastroenterologia, Hospital Nacional Arzobispo Loayza; 7) Servicio de Gastroenterologia, Hospital Dos de Mayo, Lima, Peru; 8) Departamento de Estatística, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 9) Laboratory of Translational Genomics of the Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Grovemont Circle, Advanced Technology Center, Gaithersburg, USA; 10) Department of Molecular Microbiology, Washington University Medical School, St Louis, MO, USA; 11) Department of International Health, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, USA.

Gastric cancer is one of the most lethal types of cancer and its incidence varies worldwide, with the Andean region of South America showing high incidence rates. We evaluated the genetic structure of the population from Lima (Peru) and performed a case-control genetic association study to test the contribution of African, European, or Native American ancestry to risk for gastric cancer, controlling for the effect of non-genetic factors. A wide set of socioeconomic, dietary, and clinic information was collected for each participant in the study and ancestry was estimated based on 103 ancestry informative markers. Although the urban population from Lima is usually considered as mestizo (i.e., admixed from Africans, Europeans, and Native Americans), we observed a high fraction of Native American ancestry (78.4% for the cases and 74.6% for the controls) and a very low African ancestry (<5%). We determined that higher Native American individual ancestry is associated with gastric cancer, but socioeconomic factors associated both with gastric cancer and Native American ethnicity account for this association. Therefore, the high incidence of gastric cancer in Peru does not seem to be related to susceptibility alleles common in this population. Instead, our result suggests a predominant role for ethnic-associated socioeconomic factors and disparities in access to health services. In addition to ancestry analysis, we used a case-control design to assess if the SNPs in promoter of candidate genes IL8 (rs4073), IL8RB (rs4674258), PTGS2 (rs689465 and rs689466) and SNPs in other two genes (MSMB(rs10993994), FGFR2 (rs1219648)) associated with other types of cancer are associated with gastric cancer in the Peruvian population. Although our results have shown no association with any analyzed SNP, we are performing functional studies to test differential IL8RB gene expression caused by polymorphisms which shows high different allele frequencies between Native Americans and other populations. Since Native Americans are a neglected group in genomic studies, we suggest that the population from Lima and other large cities from Western South America with high Native American ancestry background may be convenient targets for epidemiological studies focused on this ethnic group.

Detection of P16 Expression and Human Papillomavirus in Oropharyngeal Squamous Cell Carcinoma. *S. Lai[1,2], V. Sandulache[3,4], J. Zevallos[3,4].* 1) Department of Pathology and Immunology, Baylor College of Medicine, Houston, TX; 2) Department of Pathology, Michael E. DeBakey VA Medical Center, Houston, TX; 3) Department of Otolaryngology, Baylor College of Medicine, Houston, TX; 4) Department of Otolaryngology, Michael E. DeBakey VA Medical Center, Houston, TX.

The association between human papillomavirus (HPV) and head and neck squamous cell carcinoma has been recognized in the last decade. HPV is thought to cause tumor suppressor p16 overexpression by E7-induced inactivation of the retinoblastoma protein. P16 immunoreactivity is often considered as an excellent surrogate marker for HPV infection in head and neck squamous cell carcinoma. However, the incidence of HPV infection in oropharyngeal squamous cell carcinoma of veteran male patients has not been extensively studied. Tumors in oropharyngeal area are difficult to be resected completely, often unresectable due to complexity of location. Study of the pathogenic mechanism of HPV infection, P16 overexpression and patient's clinical outcomes plays an important role for therapeutic implication. We studied P16 expression by immunohistochemistry in 51 oropharyngeal squamous cell carcinomas of veteran male patients. The mean ages at diagnosis are 60.7 year-old. Tumor sites include oropharynx (13 cases), base of tongue (20 cases) and palate (18 cases). Most of the patients underwent chemoradiation therapy without radical resection. P16 immunoreactivity was present in 33 of 51 tumors (64.7%). P16 is diffusely and strongly expressed in 14 of 20 cases (70%) in base of tongue tumor, compared with 2 of 13 cases (15.4%) of oropharynx, and 4 of 18 cases (22.2%) of palate tumor with similar level of expression. Mean follow-up time (months) in P16 negativity, focally expression and diffusely expression are: orophargnx-5, 7, 29 (range from 1 to 36); base of tongue-24, 20, 35 (range from 4 to 73) and palate-14, 21 and 36 months (range from 1 to 73), respectively. HPV DNA will also be detected by polymerase chain reaction and subsequently confirmed by sequencing. The result will be correlated with clinical pathologic data and P16 expression. Our preliminary data suggests squamous cell carcinoma of base of tongue shows frequent diffuse and strong P16 expression. High P16 expression level in oropharyngeal carcinoma predicts a better pathological response to chemoradiation therapy with longer overall survival than do patients with low level. P16 immunoreactivity as well as its associated HPV infection can be used as a prognostic marker for chemoradiation adjuvant therapy.

BORIS expresion in squamous intraepithelial lesions and cervical cancer. B. *Lazalde[1], N. Velazquez-Hernandez[2], M. Barragán-Hernandez[3], M.A. Reyes-Romero[4].* 1) Department of Genetics, Faculty of Medicine and Nutrition, UJED, Durango, Durango, Mexico; 2) Scientific Research Institute, UJED, Durango, Dgo., Mexico; 3) Cancer Center, General Hospital of the Ministry of Health of Durango State, Durango, Dgo., Mexico; 4) Department of Molecular Medicine, Faculty of Medicine and Nutrition, UJED, Durango, Dgo., México.

The infection by high-risk human papillomavirus is the first step in the development of cervical cancer; however, most infected women do not develop cervical cancer. Different studies supports that histological benign lesions already contain genetic and epigenetic alterations that make them more susceptible to neoplastic transformation. CCCTC-binding factor (CTCF) and its paralogue Brother of the regulator of imprinted sites (BORIS) are involved in epigenetic reprogramming events. BORIS is considered to be a new oncogene, since is abnormally activated in a wide range of human cancer. *BORIS* has been studied, in endometrial and uterine mixed mesodermal tumors and its expression has been observed in a high percentage; however the expression of *BORIS* has not been studied in primary cervical cancer or cervical premalignant lesions. The aim of this study was to analyze the mRNA expression levels of *BORIS* and *CTCF* in cervical smears from women with normal cytology, squamous intraepithelial lesions and cervical cancer. The study was approved by the institutional bioethical committee; informed consent was obtained from each patient before sample collection. Cervical smears were taken and the cyto-brushes were immediately immersed and stored in Trizol Reagent for total RNA isolation. The cDNA synthesis was done with the Quantitect cDNA Kit (Qiagen). Specific *BORIS* and *CTCF* expression was quantitated using a real-time reverse transcriptase PCR (RT_PCR) assay with RT-PCR Kit, and QuantiTect Primer Assay primers (Qiagen Gmbh, Hilden). *GAPDH* was used as a normalizer gene. RT-PCR experiments were performed on Eco thermocycler (Illumina), and the data was processed with the Qiagen REST Software. A total of 55 samples were collected. *BORIS* expression was observed in 1/18 normal samples, 1/12 Low-grade squamous intraepithelial lesions, 1/17 high grade squamous intraepitelial lesion and 3/8 invasive cancer samples. Although, *BORIS* expression was not only observed in cancer, its expression level relative to *CTCF* was higher in the invasive cancer smear samples compared with smears of benign lesions and normal cytology. The *CTCF* expression levels relative to *GAPDH* were significantly downregulated in cancer smear samples compared with smears of benign lesions and normal cytology. In conclusion, these findings suggest that *BORIS* expression could be linked to incipient molecular changes leading to cervical cancer progression, although further studies in this issue are needed.

1122W

An informative clinical applicable serum miRNAs 371–3 and 302/367 test for (germ cell) cancer patients. *L.HJ. Looijenga[1], A.J.M. Gillis[1], M.A. Rijlaarsdam[1], R. Eini[1], L.C.J. Dorssers[1], Y. van der Zwan[1], C.M. de Boer[2], S.J. White[2].* 1) Pathology, Erasmus MC, Rotterdam, Zuid-Holland, Netherlands; 2) Monash Institute, Melbourne, Australia.

Expression of microRNAs (miR) can be specific for malignant cells, as for human germ cell cancers (GCC), seminomas (SE) and nonseminomas (NS). GCC are most in Caucasian young males, show high expression of the miRNA 371–3 and 302/367 clusters, related to the stem cell component. No recurrent DNA copy number changes of these miR and mutation in DICER was found. Current clinically used serum markers for GCC are AFP and hCG (and LDH1), which are informative in a selection of patients (yolk sac tumor and/or choriocarcinoma). Although the fore-mentioned miR have been suggested as GCC serum markers, no robust protocol is available so far. A novel, sensitive and specific pipeline for miRNA profiling is developed based on a magnetic anti-probe bead purification step. This method shows stable recovery based on multiple synthetic non-human spike-ins, allowing calibration. Out of a set of 9 potential serum-specific controls, two were identified by Normfinder and geNorm as most stable (miR-20a and 93), used for normalization. This protocol was applied to serum samples of 12 controls (no cancer), 16 SE and 16 NS patients, taken at time of primary diagnosis. Undetermined values were replaced by Ct maximum per assay +2. Histology, stage of the disease, as well as serum marker measurements, of each patient was known. Patients with a GCC showed significantly higher serum levels of miR-302a/367/371/372/373 ($p<0.006$, Mann-Whitney test, two sided, Bonferroni corrected (MWB)). Pooled analysis, irrespective of histology, showed that miR-302a/367/373 were significantly higher in patients with metastatic - compared to localized disease ($p<0.006$, MWB). Histology specific analysis (SE or EC), demonstrated that miR-367 was significantly higher in patients with metastasized - versus localized SE ($p=0.003$, MWB). The findings indicate that serum miRNA profiling based on a limited set of embryonic miRNAs is informative to diagnose patients with a GCC, better than known serum markers. The method is suitable to define patients with a stage I and higher (metastasized) disease. Defined steps within the protocol for calibration, normalization, and quantification result in a robust method, suitable for clinical implementation. The protocol can be applied to diagnosis and follow up of patients with different types of cancer, or diseases in general, for which specific miRNA profiles are reported, to be detected in various body fluids.

1123T

Gene Variants in Chemokine and Chemokine Receptor with Risk of Prostate Cancer in North Indian Cohort. *R.D. Mittal, R.K Mandal.* Urology & Renal Transplantation, Sanjay Gandhi PGI, Lucknow, Uttar Pradesh, India.

Introduction: The wide and differential distribution of chemokines and their receptors account for the pleiotropic actions of chemokines in prostate cancer (PCa). Allelic variants of the genes involved in inflammatory pathways are logical candidates as genetic determinants for PCa risk. In a case control study we analyzed the frequencies of wild, heterozygous and variant genotypes of the CCL2 Ins/Del, -2518 (A>G) and CCR2 V64I (G>A) in PCa from North Indian cohort. Methodology: The hospital-based case-control study constituted of histologically confirmed 195 PCa patients and 250 healthy controls that were age matched and were of similar ethnicity. Genotypes were determined by PCR-RFLP (Polymerase Chain Reaction Restriction Fragment Length Polymorphism) method Results: Heterozygous genotype I/D (OR=1.71; p=0.010) and variant allele carrier (ID+DD) (OR=1.67; p=0.010) of CCL2 Ins/Del polymorphism demonstrated increased risk of PCa. However, -2518 (A>G) and CCR2 V64I (G>A) were not significantly associated with PCa. We observed significantly enhanced risk for PCa due to interaction between CCL2 I/D, -2518 (A>G) and CCR2 (G>A) genotypes. High risk to PCa was also observed with respect to diplotypes, I-G (OR= 1.83; Bonferroni corrected p value (Pc)=0.004) and D-A (OR=2.11; Pc= 0.004) of CCL2 I/D and -2518 (A>G). Association of genotypes with clinical characteristics, homozygous D/D (OR=7.40; Pc=0.042) and variant allele carrier ID+DD (OR=2.42; Pc=0.036) genotype of CCL2 Ins/Del polymorphism conferred risk of PCa in high Gleason grade tumor. However, smoking did not further modulate the risk for PCa. Conclusion: CCL2 Ins/Del gene polymorphism demonstrated increased risk of PCa. Further studies evaluating the role of these polymorphisms in ethnically diverse populations and a larger cohort may help in understanding the etiopathogenesis of PCa Acknowledgment: UPCST New Delhi, India.

1124F

The regulatory BCL2 promoter polymorphism (-938C,A) is associated in Iranian women Breast Cancer Patients. *B. Motahari[1,4], M. Ghaffarpour[2,3,4], GH. Javadi[1], M. Houshmand[2,4]*. 1) Department of Biology,Science & Research Branch,Islamic Azad University, Tehran, Iran; 2) Medical Genetics Dep,National Genetics Engeeniering and Biotechnology(NIGEB),-Tehran, Iran; 3) Iranian Research Organization for Science and Technology, Tehran, Iran; 4) Medical Genetics Dep, Special Medical centers, Tehran, Iran.

Introduction: Despite recent advancements in the treatment and management of cancers, Breast cancer still remains the most common malignancy and second leading cause of cancer-related deaths among women in Iran. Apoptosis and cellular proliferation play an important role during normal mammary development and carcinogenesis of the mammary gland. In normal tissues, the homeostasis between apoptosis and cell proliferation is regulated by Bcl-2 family proteins. Tumor cells tend to interfere with the mechanism of Apoptosis by activating anti apoptotic genes such as bcl-2. BCL-2 gene, located at 18q21.3 and consists of three exons and two promoters (P1 and P2), which have different functions. The second promoter, P2, is located 1,400 bp upstream of the translation initiation site and functions as a negative regulatory element to the P1 promoter.Bcl-2 is the one of the most important anti apoptotic genes.Bcl2 gene has been demonstrated with breast cancer development and a single nucleotide polymorphism (SNP-938C >A) has been identified recently and can provide a susceptible factor for trigger breast cancer. The aim of this study was evaluation of the frequency of the regulatory BCL2 promoter polymorphism (-938C>A) in Iranian women patients with Breast cancer Materials and Methods: Patients; 27 paired fresh tumor and adjacent normal samples were obtained from consecutive patients with BC who underwent surgery for mama mastroctomy from IRANIAN National Tumor Bank, National Cancer Institute, Imam Khomeini Hospital Complexes, Medical Tehran University, Tehran, Iran.Histopathological examinations were performed, and all tumors were confirmed as adenocarcinoma. Mutational analysis: fresh tumors and their adjacent were extracted for genomic DNA using the QIAamp Mini Kit according to the manufacturer's instructions. We searched DNA samples of Iranian patients for identification of SNP; -938C>A in the inhibitory P2 promoter of the BCL2 gene by means of PCR sequencing. Results and conclusions: we found heterozygosity in this location (-938 C, A) in 16/27 (59.25%) cases with breast cancer and 5 of 27(18.51%) SNP-938 C >A. According to the findings, the point mutation in -938C allele displayed a positive relation with increasing tumorgenesis in breast cancer. .Our result indicated that the regulatory BCL2 promoter polymorphism (-938C,A) may be useful as a tumor marker for increasing tumorgenesis in women breast cancer.

1125W

Type II transmembrane serine protease gene variants associate with breast cancer. *K.M. Nieminen[1, 2, 3], J.M. Hartikainen[1, 2, 3], V. Kataja[4, 5], V.-M. Kosma[1, 2, 3], A. Mannermaa[1, 2, 3]*. 1) Institute of Clinical Medicine, Pathology and Forensic Medicine, University of Eastern Finland, Kuopio, Kuopio, Finland; 2) Biocenter Kuopio and Cancer Center of Eastern Finland, University of Eastern Finland, Kuopio, Finland; 3) Imaging center, Clinical Pathology, Kuopio University Hospital, Kuopio, Finland; 4) Institute of Clinical Medicine, Oncology, University of Eastern Finland, Kuopio, Finland; 5) Cancer center, Kuopio University Hospital, Kuopio, Finland.

Type II transmembrane serine proteases (TTSP) are related to tumor growth, invasion, and metastasis in cancer. Genetic variants in these genes may alter their function leading to cancer onset and progression, and also the outcome of the patients. In this study 464 invasive breast cancer cases and 370 healthy controls from Eastern Finnish origin in the Kuopio Breast Cancer Project (KBCP) were genotyped for 82 SNPs in five different TTSPs, and in three related genes. Association of the genotypes was estimated against breast cancer risk (Armitage trend test), breast cancer specific survival (COX regression analysis), and clinicopathological variables (logistic regression analysis). Five SNPs, *TMPRSS2* SNPs rs468811 and rs7275220, *TMPRSS3* SNPs rs3814903 and rs11203200, and *HGF* SNP rs5754752, associated significantly with breast cancer risk. In addition, *TMPRSS1* SNPs rs12151195 and rs12461158, *TMPRSS2* SNP rs2276205, *TMPRSS3* SNP rs3814903, and *HGF* SNP rs2399403, associated with prognosis (P-values 0.009–0.050). We assessed a new variant by summing the number of risk alleles from significantly associated SNPs, and estimated the additive effect of the risk alleles. As a result, the risk of breast cancer was significantly higher when having five to seven risk alleles (P=0.0020; OR, 2.632; 95% CI, 1.426–4.859) compared to 0–2 alleles. The additive effect of the associating variants was also seen in survival analysis. Women with six to eight survival associating alleles had 3.3 times higher risk of dying of breast cancer compared to women with one to three alleles (P=0.0012; RR, 3.365; 95% CI, 1.612–7.024). Our results suggest this gene family to be strongly associated with breast cancer risk and survival. More importantly, the number of carried risk alleles seems to be important when estimating the breast cancer risk and the prognosis of the patient.

1126T

Prevalence and prognostic impact of Ikaros deletions in childhood acute lymphoblastic leukemia treated according to NOPHO protocols. *I. Ofverholm[1], A.N. Tran[1], G. Barbany[1], A. Nordgren[1], M. Heyman[2], M. Nordenskjold[1]*. 1) Department of Molecular Medicine and Surgery, CMM, Karolinska Institute, Stockholm, Sweden; 2) Department of Women's and Children's Health, Karolinska Institute, Stockholm, Sweden.

Survival rates for childhood acute lymphoblastic leukemia (ALL) have increased dramatically over the last two decades; still 20–25% of the children relapse and 15% will not survive. Deletions of the *IKZF1* locus, coding for the Ikaros transcription factor, have been described as characteristic of Philadelphia-positive ALL, but have also been proposed to predict relapse in other types of B-cell progenitor ALL (BCP ALL). Gene-expression studies have revealed that heterozygous deletion of *IKZF1* results in haploinsufficiency while deletion of a subset of exons (4–7) results in a dominant-negative protein. The aim of our study is to assess the frequency and prognostic impact of *IKZF1* mutations in a cohort of 87 children diagnosed with Philadelphia-negative BCP ALL from 2001 to 2008 at the Karolinska Hospital and treated according to the NOPHO 2000 protocol. We have used Multiplex Ligation-dependent Probe Amplification (MLPA) to investigate the presence of *IKZF1* deletions in DNA extracted from bone marrow samples taken at diagnosis. In order to confirm and further characterize the deletions we also performed array CGH in cases with deletions detected by MLPA. Deletions of *IKZF1* where present in 10% (9/87) of cases, out of which 4/9 had deletions of a subset of exons (4–7) and the remaining cases had heterozygous deletions of the whole *IKZF1* gene. Array CGH revealed large deletions of chromosome arm 7p encompassing several genes in a majority of these latter cases. The frequency of *IKZF1* deletions in our material was consistent with previous reports of unselected BCP ALL cohorts, although we detected a lower rate of cases with intragenic deletions resulting in a dominant-negative isoform of Ikaros. There was a good correlation between MLPA and array CGH results, but while MLPA can identify the presence of a deletion in a single exon it is unable to determine the extent of the deletion beyond the specific gene of interest. MLPA also has a limited ability to distinguish the presence of mixed cell populations, which is often the case in hematological malignancies. We are currently evaluating the clinical and prognostic relevance of *IKZF1* deletions, preliminary data reveals that 22% of cases with *IKZF1* deletions suffered from relapse, a high frequency compared to the non-deleted cases in our study. To our knowledge, this is the first study to examine the presence of *IKZF1* deletions in a cohort of pediatric BCP ALL treated according to the NOPHO protocol.

1127F

Genotype proline/proline of TP53 codon 72 polymorphism is enriched in breast cancer. *A. M. Puebla[1], A. Gutiérrez[2,6], A. Ramos[3,6], E. Salas[4], J. M. Castro[5], R. Ramírez[7], M. P. Gallegos[6]*. 1) Laboartorio de Inmunofarmacologia, UdeG, Guadalajara, jalisco, Mexico; 2) Licenciatura en Químico Farmacobiologo, CUCEI, UdeG; 3) Doctorado de Farmacología, UdeG; 4) Jefatura de Oncología, UMAE, Hospital de Gineco-Obtetricia, CMNO, IMSS, Guadalajara; 5) Jefatura de Onco-Cirugía, UMAE, Hospital de Especialidades, CMNO, IMSS; 6) División de Médicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, México; 7) Doctorado en Genética Humana, UdeG.

The nuclear phosphoprotein p53 encodes to TP53 tumor suppressor gene, which plays an important role in cell cycle, apoptosis, DNA reparations and angiogenesis. The TP53 contains common genetics polymorphisms that influence gene activity. In the present study we describe to frequency of codon 72 polymorphism of TP53 gene in 253 breast cancer patients and 232 woman health controls from Mexico. The frequency observed was of 34% (87/258) and 62% (142/232) of arginine/arginine genotype; 49% (124/253) and 30% (71/232) of heterozygous (arginine/proline) genotype; 17% (42/253) and 8% (19/232) of proline/proline genotype in cases and controls respectively. The statistically different ($p<0.05$) was observed in the proline/proline genotype with an OR of 2.2 (95%CI 1.2–4.0). These results suggest that the proline/proline genotype of codon 72 polymorphism of TP53 is associated with Mexican breast cancer patients.

1128W

3R/3R genotype of TYMS gene is associated with non response of chemotherapy in breast cancer patients. *A. Ramos[1,6], E. Salas[2], J. M. Castro[3], L. E. Figuera[4], A. M. Puebla[5], M. P. Gallegos[6].* 1) Doctorado en Farmacología, UdeG, Guadalajara, Mexico; 2) Jefatura de Oncología, UMAE, Hospital de Gineco-Obtetricia, CMNO, IMSS, Guadalajara; 3) Jefatura de Onco-Cirugía, UMAE, Hospital de Especialidades, CMNO, IMSS; 4) División de Genética, CIBO, IMSS; 5) Laboratorio de Inmunofarmacologia, CUCEI, UdeG; 6) División de Médicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, México.

Thymidylate synthase (TYMS) catalyzes the reductive methylation of dUMP to form dTMP, which is essential for cell proliferation. Has been show that patients high levels of TYMS are not respond to 5-fluorouracil. The polymorphisms 2R/3R located in 5'untranslated region (5'UTR) of TYMS gene, contains 28 bp repeated in the sequence. The alleles with two repeat (2R), have low translational efficiency of TYMS mRNA than three (3R) repeats with greater translational efficiency. In the present study we describe association of genotype 3R/3R polymorphism of TYMS gene with non response in breast cancer patients from Mexico. In 175 woman with breast cancer was observed a frequency of 61% (19/31) and 39% (70/251) of 2R/2R genotype; 63% (61/97) and 49% (36/97) of 2R/3R genotype, 38% (18/47) and 62% (29/47) of 3R/3R genotype in breast cancer responds and non response of chemotherapy respectively. The statistically different ($p<0.05$) was observed in the 3R/3R genotype with an OR of 2.2 (95%CI 1.2–4.0). These results suggest that the 3R/3R genotype of TYMS polymorphism is associated with non response to chemotherapy in Mexican breast cancer patients.

1129T

Characterization of breast cancer intrinsic subtypes in Mexican women using integrative multiplatform analysis. *C. Rangel-Escareño[1], I. Imaz-Rosshandler[1], S. Muñoz-Montero[1,2], JE. Castillo-Fernandez[1,2], A. Hidalgo-Miranda[3].* 1) Computational Genomics, National Institute of Genomic Medicine, Periferico Sur 4809 Arenal Tepepan, Tlalpan C.P. 14610; 2) Instituto Tecnológico y de Estudios Superiores de Monterrey ITESM Campus Ciudad de México, Biotechnology Program. Calle del Puente #222 Col. Ejidos de Huipulco, Tlalpan C.P. 14380, México D.F; 3) Cancer Genomics Lab, National Institute of Genomic Medicine, Periferico Sur 4809 Arenal Tepepan, Tlalpan C.P. 14610.

Breast cancer tumors can be classified according to gene-expression subtypes: Luminal A, Luminal B, Her2-enriched, and basal-like. These intrinsic subtypes differ in genomic complexity, key genetic alterations, and clinical prognosis. For instance, luminal subtypes are associated with expression of estrogen (ER+) and progesterone (PR+) receptors and differentiated luminal epithelial cell markers. Molecular subtype classification not only provide information about prognosis but also may become useful in planning treatment and developing of new therapies. Previous studies have shown a good performance classifying tumors based on gene expression profiles such as MammaPrint, OncotypeDX, 3-gene model by Haibe-Kains(2011) and PAM50. Nevertheless, these models do not always agree and have been extensively tested in mostly Caucasian populations. We tested these four approaches on a set of 106 tumors from Mexican women and found some inconsistencies. The molecular classifiers do not perform as good as they do in non-Mexican samples. To explain why this might be happening we included other sources of biological information in the form of data generated using high-throughput genomic technologies on the same set of patients. In this work we present our findings when we integrate information about gene expression transcripts on human whole-transcript microarrays (Human Gene ST 1.0, Affymetrix, Santa Clara CA) of 141 Mexican samples included 35 normal and 106 tumors, copy number variation using Affymetrix SNP6.0, and somatic mutations of 100X sequencing depth of whole-exome sequencing of 56 tumors on the Illumina sequencing platform. All samples were obtained under institutional IRB approval and with documented informed consent.

1130F

International collaborative analysis of the InSiGHT database quantifies unique reports and redefines the V.U.S. challenge for DNA mismatch repair genes (MMR). *R.P. RAVAL[1,2], L. BAEZ-CABRERA[1,2], JP. PLAZZER[3], S. OKOCHI[1,2], F. MACRAE[3], M. GENUARDI[4], TK. WEBER[1,2].* 1) DEPARTMENT OF SURGERY, VA NEW YORK HARBOR MEDICAL CENTER, BROOKLYN, NY; 2) SUNY DOWNSTATE MEDICAL CENTER, BROOKLYN, NY, USA; 3) DEPARTMENT OF COLORECTAL MEDICINE AND GENETICS, ROYAL MELBOURNE HOSPITAL, MELBOURNE, AUSTRALIA; 4) UNIVERSITY OF FLORENCE, ITALY.

Background: The International Society for Hereditary Gastrointestinal Tumors (InSiGHT) (www.insight-group.org) has collected MMR gene sequence variant reports from clinicians and scientists on its database (DB) since 1994. In 2009 InSiGHT, in collaboration with the Human Variome Project significantly expanded its MMR gene DB using the Leiden Open Variation Database platform (www.lovd.org). However, literature reviews, including rigorous clarification of sequence variant “pathogenicity” has been limited. We also provide a systematic analysis of the heterogeneous literature cited for many alterations and the limitations of current search and analysis tools. Methods:We performed a detailed analysis of the 12,673 DNA MMR variants reported on the InSiGHT DB as of 2012 including frequency of alteration histograms organized by gene, exon, codon and specific nucleotide change. Our report focused on analysis of unique alterations and reviewed the conclusions of all literature cited for the 2,240 unique MSH2 and MLH1 alterations listed. Variant pathogenicity assignments were based on the LOVD legend. Results:Our analysis demonstrates a dramatic increase in the total number of MMR variant reports from 884 in 2008 to 12,673 as of May 2012. For MLH 1, 1150 unique alterations (UAs) were cited of which 168 were classified as “probably pathogenic” based on +/? literature reports. For MSH2, there were 1090 UAs cited of which 108 were classified as “probably pathogenic” having only +/? literature reports. Of the 10,601 MSH2 and MLH1 reports cited only 3 were reported as +/+ and interpreted as “pathogenic” Importantly, 50% (996) of the MSH2 and MLH1 UAs were listed as “variants of uncertain significance” (?/? reports only). 34% of the combined MLH1 and MSH2 UAs listed were associated with multiple reports with differing conclusions (heterogeneous literature) regarding pathogenicity for the exact same variant. Conclusions:Total reports to the InSiGHT LSDB have increased 14 fold since 2009. Detailed analysis of literature cited for each of the 2,240 unique MSH2 and MLH1 alterations reported indicates the clinical significance of 84% of these variants remains uncertain. These results suggest a quantitative analysis/index of this heterogeneous literature would assist their characterization and facilitate prioritization of further analysis. Our collective results expand the dimensions of the V.U.S. problem and underscore the clinical genetic relevance of the HVP mission.

1131W

Frequency of non-DNA-binding Ikaros isoforms in childhood acute lymphoblastic leukemia and relapse or death risk. *A. Reyes-León[1], R. Juárez-Velázquez[1], A. Medrano-Hernández[1], T. Cuenca-Roldán[1], C. Salas-Labadía[1], P. Navarrete-Meneses[1], R. Paredes-Aguilera[2], R. Rivera-Luna[3], R. Cárdenas-Cardos[3], G. López-Hernández[4], R. Bernaldez[5], P. Pérez-Vera[1].* 1) Laboratorio de Cultivo de Tejidos, Instituto Nacional de Pediatria, Mexico city, Mexico; 2) Servicio de Hematología, Instituto Nacional de Pediatría, Mexico city, Mexico; 3) Servicio de Oncología, Instituto Nacional de Pediatría, Mexico city, Mexico; 4) Hospital del Niño Poblano, Puebla, Mexico; 5) Servicio de Hematología, Hospital de Pediatría, Centro Medico Nacional siglo-XXI, IMSS, Mexico city, Mexico.

Introduction: Expression of non-DNA-binding Ikaros isoforms (Ik-6 and Ik-8) is strongly associated with the development of childhood acute lymphoblastic leukemia (ALL). Nowadays, the presence of the non-functional isoforms of Ikaros, Ik-6 and Ik-8, in ALL patients is related to -high risk of relapse and death. The purpose of this study is to determine the Ik-6 and Ik-8 Ikaros isoforms in ALL children, in order to associate them with the presence of adverse events. Methods: The sample included 76 children with newly diagnosed ALL. Informed consent was obtained from parents or tutors. Mononuclear cells were isolated from bone marrow for total RNA extraction. Ikaros isoforms were analyzed by nested RT-PCR and gel electrophoresis. Bands were analyzed based on their size and classified according to reported Ikaros isoforms (Ik-1, Ik-3A, Ik-2, Ik-3, Ik-4, Ik-2A, Ik-5/7, Ik-4A, Ik-8 and Ik-6). Sequencing analysis was performed in non-expected bands. Results: Sixty-nine patients were diagnosed with B-ALL and 21 relapsed or dead. The non-DNA binding isoforms Ik-6, Ik-8 and a deleted-variant of Ik-8, were detected in 18/69 (26.1%) cases. Fourteen B-ALL patients expressed Ik-6, 3 presented Ik-8 and 1 showed Ik-8 variant, 7 of them developed adverse events (3 relapses and 4 deaths); it is remarkable that only 5 of the 7 presented standard risk by conventional prognostic factors at diagnosis. The remaining 7 patients were diagnosed with T-ALL, 3 of them developed adverse events. Ik-8 was the only non-functional isoform detected in this group and it was expressed in 3 (42.8%) patients; 2 of them relapsed. Two B-ALL patients were BCR-ABL1(+), however they did not present non-functional isoforms. Conclusion: The Ik-6 and/or Ik-8 were found in relapsed/death ALL-children in the analyzed group; however the increase of the studied sample and a long-term survival analysis is required to confirm this observation. In addition, unexpected bands must be analyzed by sequencing looking for non-functional isoforms, which could be relevant in the patient's prognosis.

1132T

GENE EXPRESSION PROFILE OF HUMAN TELOMERE AND TELOMERASE COMPLEX IN GASTRIC CANCER. *L.C. SANTOS[1], F. WISNIESKI[1], D.Q. CALCAGNO[1], M.F. LEAL[1], T.B. PONTES[1], C.O. GIGEK[1], E.S. CHEN[1], S. DEMACHKI[2], P.P. ASSUMPÇÃO[2], R.R. BURBANO[3], M.A.C. SMITH[1].* 1) MORFOLOGY AND GENETIC, UNIFESP, SÃO PAULO, BRAZIL; 2) Serviço de Cirurgia, Hospital Universitário João de Barros Barreto, ufpa, Belém, Brasil; 3) Laboratório de Citogenética Humana, Instituto de Ciências Biológicas, UFPA, Belém, Brasil.

Gastric cancer is the fourth most prevalent and the second cause of cancer death worldwide. Changes in gene expression of telomere and telomerase complex have been observed in carcinogenic processes. The investigation of these genetic mechanisms may help to determine more accurate diagnosis, prognosis and the establishment of a therapeutic approach. In the present study, we aimed to identify differentially expressed genes of telomere and telomerase complex in gastric tumors compared to matched noncancerous gastric samples. The expression of 84 key genes involved in telomere replication and maintenance was evaluated using the Human Telomeres & Telomerase RT^2 Profiler™ PCR Array (SABiosciences, PAHS-010). We analyzed six paired gastric cancer and adjacent noncancerous gastric tissues from individuals of Northern Brazil. We observed that ACD, BCL2 and SNRPN expression were downregulated in neoplasic samples compared to matched noncancerous (0.34, 0.50 and 0.47 -fold change; and p = 0.005, p = 0.04, p = 0.03; respectively). ACD gene encodes a protein that is involved in telomere maintenance. This protein is one of six core proteins of shelterin telomeric complex. The BCL2 gene encodes a protein that has a role in the control of apoptosis and inhibition of the telomerase action. SNRPN encodes a protein that acts in pre-mRNA processing and in telomerase regulation. These differentially expressed genes highlight the importance of telomere and telomerase complex in gastric carcinogenesis. These results contribute to the understanding of gastric cancer biology with possible future clinical implications to be tested in a subsequent study in a larger number of gastric cancer patients.

1133F

Chemotherapy response in ovarian cancer is modulated by the DNA encoded microRNA family miR-17–92a. *I. Shapira[1,2], A. Lee[1,3], M. Oswald[1,3], J. Lovecchio[1], A. Menzin[1], J. Whyte[1], L. Dos Santos[1], K. Sultan[1], V. John[1], K. Cheng[1,2], S. Liang[1], T. Bradley[1,2], D. Budman[1,2].* 1) Hofstra North Shore LIJ School of Medicine, Hempstead NY, NY; 2) Monter Cancer Center Lake Success NY, NY; 3) Feinstein Institute for Medical Research Manhasset, NY.

Background Over 75% of women are diagnosed with ovarian cancer are diagnosed at stage III due to inadequate screening techniques. One fifth are cured of their disease with surgery followed by chemotherapy. Patterns of circulating miRs may explain the role of surgery and chemotherapy in ovarian cancer cure. MiRs-17-92 have essential roles in embryonal and immune system development. MiR-17-92 cluster is deleted in 20% of ovarian cancers. Aims We set out to identify changes microRNA patterns in plasma obtained before surgery for ovarian cancer and during chemotherapy that correlated with the patients' long-term outcomes. Methods Between 2004 and 2011 we investigated patterns of plasma miRNAs collected before, after surgery, during and after chemotherapy in 50 patients presenting for surgery for ovarian cancer and 10 normal controls. We also collected blood at ovarian cancer relapse and tumor and benign ovary for miRNA analysis. 2-sample t-test was used for all 2-sample comparison and ANOVA followed by Benjamin-Hochberg method for multiple testing to limit the false discovery rate (FDR) at the 5% level. All tests were 2-tailed and results with a $p<0.05$ were considered statistically significant. Results Fifty patients were operated for EOC mean age at surgery 65 (range 51–78), 11 race matched women consented as controls - mean age of 58 (range 25–67). Four patients were cured, 21 patients died within 36 month of their diagnosis and 21 patients who survived long term not cured but continue to receive chemotherapy. MiR-19a was high in plasma obtained before surgery in patients with short over all survival ($p< 0.003$). During chemotherapy miR-19a decreased 38-fold compared to the pre-surgical levels ($p<0.0002$). MiR-19b was 83 fold higher in the pre-surgical plasma and it decreased 38 fold during chemotherapy ($p<0.003$). MiR-92 was 12 fold higher in the pre-surgical plasma and decreased 17-fold during chemotherapy ($p<0.003$). MiR-25 was 71-fold higher in the pre-surgical plasma and decreased 47-fold during chemotherapy ($p<0.002$). Conclusions During chemotherapy, levels of miR-17-92 change dramatically compared to the pre-surgical levels. Shifts in microRNAs from the cluster 17-92 observed in the nadir phase of adjuvant chemotherapy for ovarian cancer patients correlate with long term outcomes. Patients with normal miR-17-92 levels pre-surgical plasma levels tended to have better long-term survival.

1134W

Single-nucleotide polymorphisms in genes encoding toll-like receptor -2, -3, -4, and -9 in case-control study with bladder cancer susceptibility in North Indian Population. *V. Singh[1], N. Srivastava[2], R. Kapoor[1], R.D Mittal[1].* 1) Department of Urology and Renal Transplantation Sanjay Gandhi Post Graduate Institute of Medical Science Raebareli Road, Lucknow, Uttar Pradesh, India; 2) Department of Physiology, Chhatrapati Shahuji Maharaj Medical University, Lucknow, Uttar Pradesh, India.

Background: Impairment of the immune system could contribute to bladder cancer risk as Toll like receptors are important for innate immunity. Aim of the study: we examined the association between candidate disease-susceptibility polymorphisms in the single nucleotide polymorphism (SNPs) like TLR2 (-196 to-174del), TLR3 (C1377T), TLR4 (Thr399Ile) and TLR9 (G2848A) genes in bladder cancer patients of North Indian population. Methods: The SNPs comprised of TLR 2 (-196 to -174 Del), TLR 3(C1377T), TLR4 (Thr399Ile) and TLR9 (G2848A) genes. The allelic and genotypic frequencies of these TLR SNPs from histopathologically confirmed patients of bladder cancer (n=200) and age and sex matched unrelated, healthy controls of similar ethnicity (n=200) were genotyped by Polymerase Chain Reaction and Restriction Fragment Length Polymorphism (PCR-RFLP) analysis. Result: In TLR2 I/D gene polymorphism, combination of ID+DD showed significant 3 fold increased risk P=0.001. TLR2 with combination of heterozygous and variant genotype (ID+DD) also showed 5 fold risks with tumor stage/grade of BC patients. The other genotypes of TLR 3, 4 and 9 did not exhibit any significant association with bladder cancer risk. Conclusion: Our results suggested TLR2 (-196 to-174 del) to be involved in BC susceptibility, however, TLR 3, 4 and 9 genes were not associated with BC risk implicating that polymorphisms in these tested TLR genes are not likely to be associated with increased risk for developing bladder cancer. Functional studies in ethnically diverse populations may provide a more comprehensive involvement of innate immunity in identifying the disease-associated variants for BC aetiology.

1135T

Clinical impact of MMP-3 and TIMP-3 gene polymorphisms in prostate cancer. *P. Srivastava, R. Kapoor, R.D. Mittal.* Urology and Renal Transplantation, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, Uttar Pradesh, India.

Objective: Matrix metalloproteinases (MMPs) have been implicated in progression and metastases of different tumors. The balance between the MMPs and their natural inhibitors (tissue inhibitors of matrix metalloproteinases; TIMP) seems to be an important factor related to this role. The purpose of this study was to evaluate polymorphisms in the MMP-3 and TIMP-3 genes for their associations with prostate cancer (PCa) risk in North Indians. Materials and Methods: Genotypes were determined by PCR-RFLP (Polymerase Chain Reaction Restriction Fragment Length Polymorphism) method in 150 PCa patients and 200 age-ethnicity matched controls. Results: We found significant association in the MMP-3(1171)5A/6A and TIMP-3 (1298) C/T polymorphism with PCa risk. Variant genotype (5A/5A) of MMP-3(1171)5A/6A polymorphism had a high risk of developing PCa (p= 0.037, OR=3.52, 95%CI=1.08–11.5). Individuals with TIMP-3 (1298) CT genotype as well as T allele showed reduced risk of PCa (p<0.001; OR= 0.31; 95%CI= 0.18-0.52, and p=0.001; OR=0.49; 95%CI=0.32–0.75). This effect was even more evident in case of T allele carrier (CT+TT) (p<0.001; OR=0.36; 95%CI=0.22–0.59). Overall no significant association was observed statistically in MMP-3 and TIMP-3 with any of the grading stages and smoking habits in PCa. Haplotype analysis of MMP-3 showed that A-5A-A was associated with three folds (OR=3.06; 95%CI=1.71–5.47; p<0.001) increased risk in PCa patients. Conclusion: This is the first reported association of polymorphisms in the MMP-3 and TIMP-3 gene and PCa risk and supports the hypothesis that the protease/antiprotease balance has an important role in this disease. We propose that analysis of these genes polymorphism may help in identifying patient subgroups at high risk and poor disease outcome. Keywords: Matrix metalloproteinases, Tissue Inhibitors of metalloproteinases, Polymorphism, Prostate cancer, PCR-RFLP, Haplotype.

1136F

Role of SOCS3 Promoter Methylation in The Pathogenesis of Myeloproliferative Neoplasms and Secondary/Reactive Erythrocytosis/Thrombocythemia. *D. TORUN[1], O. NEVRUZ[2], M. AKYOL[3], S. KOZAN[1], M. BAHCE[1], S. GURAN[4], C. BEYAN[2].* 1) Dept. of Medical Genetics, Gulhane Military Medical Faculty, Ankara, Turkey; 2) Dept. of Haematology, Gulhane Military Medical Faculty, Ankara, Turkey; 3) Dept. of Biostatistics, Gulhane Military Medical Faculty, Ankara, Turkey; 4) Dept. of Medical Biology, Gulhane Military Medical Faculty, Ankara, Turkey.

Myeloproliferative neoplasms (MPN) like essential thrombocythemia (ET), polyctyhemia vera (PV) and primary myelofibrosis (PMF) are acquired clonal hematopoietic stem cell disorders and originate from a multipotent hematopoietic stem cell. MPNs demonstrate phenotypic/genotypic similarity with each other. The diagnosis of MPNs is made by step by step elimination of the other clinical disorders. The lack of specific molecular marker makes difficult the differential diagnosis. Hitherto, a few genetic aberrations have been shown which are related with MPNs. Single nucleotide polymorphisms at various loci and somatic mutations, such as those in JAK2 V617F, MPL W515L/K, exon12 JAK2 may contribute to the pathogenesis of MPNs. JAK2 V617F mutation is responsible for most of the PV, ET and PMF patients. Despite the high prevalence of JAK2 V617F mutation, several question still remains. For example, how do some patients develop MPNs in tha absence of JAK2 V617F mutation? SOCS1 and SOCS3 genes are negative regulators of JAK/STAT signal pathway. Promoter methylation of these genes may deteriorate the inhibitor effect and may cause the development of MPNs. For this purpose, it was aimed to investigate the promoter methylation of SOCS1 and SOCS3 genes with methylation specific polymerase chain reaction (MS-PCR). No disease-specific CpG island methylation of SOCS1 was observed. Hypermethylation of the SOCS3 promoter was identified in 5 of 19 (26,3%) PV, 2 of 21 (9,5%) ET, 1 of 5 (20%) PMF and 9 of 42 (21,4%) secondary/reactive erythrocytosis/thrombositosis. As a result of this study, promoter methylation of SOCS3 gene suggesting a possible role for SOCS3 methylation in the pathogenesis of MPNs and secondary/reactive erythrocytosis/thrombositosis.

1137W

Association of common polymorphisms in TNF-α pathway genes and apoptotic genes with risk and prognosis of Esophageal cancer. *M. Umar[1], R. Upadhyay[1], S. Kumar[2], U.C. Ghoshal[3], B. Mittal[1].* 1) Department of Genetics, Sanjay Gandhi Post-Graduate Institute of Medical Sciences, Lucknow, India; 2) Department of Radiotherapy, Sanjay Gandhi Post-Graduate Institute of Medical Sciences, Lucknow, India; 3) Department of Gastroenterology, Sanjay Gandhi Post-Graduate Institute of Medical Sciences, Lucknow, India.

Introduction: Esophageal cancer (EC) is highly aggressive malignancy, involves excessive cellular proliferation and low apoptotic activity. As, TNF-α mediated activation of NF kappa beta (NFKB) triggers cellular proliferation, while p53/its homologue p73 initiate apoptosis in response to irreparable DNA damage, so variation in TNF-α pathway genes and apoptotic genes may affect EC risk and prognosis. Thus, the present study was designed to investigate association of common variants of TNF-α pathway genes and apoptotic genes with susceptibility to EC or its clinical phenotypes and their role in survival outcome of EC patients. Methodology: We genotyped 250 EC cases (including 143 followed up cases) and 250 healthy controls to analyze the polymorphisms in TNF-α pathway genes (TNF-α-308 G>A, NFKB1-94ins/del and NFKBIA-881A>G polymorphisms) and in apoptotic genes (p73 G4C14>A4T14, p53 intron3 16bp ins/del, CASP8 -678 del and CASP8 IVS12-19G>A) using PCR RFLP and TaqMan assay. Results: Individuals with TNF-α-308 GA genotype were found to be at 1.9 fold higher risk of EC (OR=1.88, 95% CI=1.17–3.05, P=0.010). In case of apoptotic gene polymorphisms, p73 AT/AT genotype in dominant model and CASP8 IVS12-19 AA genotype in recessive model were found to confer increased risk of EC (OR=1.82, 95% CI=1.21–2.73, P=0.004 and OR = 4.08, 95% CI=1.13–14.76, P=0.032 respectively). Stratification of subjects based on clinical phenotypes showed that TNF-α GA, p73 AT carrier and CASP8 AA genotypes specifically modulated risk of squamous cell carcinoma tumor histopathology and lymph node metastasis. Tumor location specific risk was observed with association of TNF-α-308 GA genotype with upper-third, p73 AT carrier genotype with middle-third and CASP8 IVS12-19 GA genotype with lower-third esophageal tumors. Other variants like NFKB1-94ins/del and NFKBIA-881 A>G, p53 intron3 ins/del and CASP8 -678 del polymorphisms did not seem to play any role in susceptibility to EC. Also, no interaction with environmental risk factors was observed. Kaplan Meier and COX regression analysis showed CASP8 IVS12-19 AA and p53 DD genotypes associated with lower median survival and adverse outcome in EC patients treated with radiotherapy with/without chemotherapy. Conclusion: TNF-α-308 G>A, p73 G4C14>A4T14 and CASP8 IVS12-19 polymorphisms modulate risk of EC, while p53 intron3 and CASP8 IVS12-19 polymorphisms affect the survival outcome of EC patients in north Indian population.

Colon cancer in a 9-year-old female due to combined inherited EPCAM deletion and hMSH2 mis-sense mutation leading to tissue-specific bi-allelic loss of expression of hMSH2. *P. J. Ainsworth[1,2,4], H. H. Li Chang[2], H. Levin[3], D. K. Driman[2], V. M. Siu[3,4], A. E. L. Cairney[3], N. L. Scanlan[5], K. Buckley[6].* 1) Molec Diagnostic Lab, London Hth Sci, London, ON, Canada; 2) Department of Pathology, London Hth Sci/Western Univ, London, ON, Canada; 3) Department of Pediatrics, London Hth Sci/Western Univ, London, ON, Canada; 4) Department of Biochemistry, Western Univ, London, ON, Canada; 5) Cancer Genetics, London Hth Sci, London, ON, Canada; 6) Cancer Genetics, Grand River Hospital, Kitchener, ON, Canada.

Monoallelic mutation of hMSH2 is associated with Lynch Syndrome, and leads to a risk of colonic, as well as extracolonic cancers, which are typically not seen before 30 years of age. Bi-allelic mutations in hMSH2 are associated with a much earlier onset of colon cancer, and can be associated with astrocytoma and features of neurofibromatosis[1]. It has also been reported[2] that heterozygous germline deletions of the last exons of EPCAM can lead to colon cancer associated with aberrant methylation, and consequent inactivation, of the normal downstream *in cis* hMSH2 gene. A 9 year old female (the proband), who presented with severe anemia from gastrointestinal bleeding, demonstrated adenocarcinoma after colorectal biopsy, and underwent total colectomy. Pathologic examination documented 2 mucinous adenocarcinomas, 70–80 adenomas, and lymph node metastases. Immunohistochemistry showed loss of expression of hMSH2 and hMSH6, both within the normal-appearing colonic mucosa as well as in the adenocarcinomas; however, in the tumour-infiltrating lymphocytes, muscle, peripheral nerve, and fibroblast tissues, both of these MMR proteins were intact. Family medical history was notable for multiple relatives with malignancies on both sides of the family, although neither parent nor their siblings had a personal history of cancer. An hMSH2 mis-sense mutation (hMSH2:c.2075G>T, p.Gly692-Val), previously identified in the proband's maternal grandfather's half-sister's daughter, demonstrated immunohistochemical loss of hMSH2 protein in her endometrial tumour tissue. The same mis-sense mutation was also identified in leukocyte-derived genomic DNA from the proband, as well as her mother. In addition the proband's DNA, analyzed by MLPA, showed an EPCAM deletion mutation (EPCAM: EX:8_9del), which was also shown to be present in genomic DNA obtained from her father. This case demonstrates that very early onset colon cancer may also result from a germline mutation in EPCAM, in concert with a germline mutation in hMSH2. Tissue-specific expression of EPCAM can explain the immunohistochemical loss of hMSH2 in the normal-appearing colonic epithelium and adenocarcinoma, but its presence in other cell types. As extracolonic cancers appear to be rare in EPCAM deletion carriers[3], our proband may have a more favourable prognosis compared to individuals with biallelic MMR mutations[1]. 1. NF1 Second Hit Leads to the Up-Regulation of HLA Class II Genes and Recruitment of Tregs in Neurofibromas. *E.M. Jouhilahti[1,2], S. Peltonen[3], E.P. Jokinen[1], T. Callens[4], H. Aho[5], E. Legius[6], O. Lassila[2,7], L. Messiaen[4], J. Peltonen[1].* 1) Department of Cell Biology and Anatomy, Institute of Biomedicine, University of Turku, Turku, Finland; 2) Turku Doctoral Programme of Biomedical Sciences, University of Turku, Turku, Finland; 3) Department of Dermatology, University of Turku and Turku University Hospital, Turku, Finland; 4) Department of Genetics, Medical Genomics Laboratory, University of Alabama at Birmingham, Birmingham, Alabama, USA; 5) Department of Pathology, Turku University Hospital, Turku, Finland; 6) Department of Human Genetics, KU Leuven, Leuven, Belgium; 7) Department of Medical Microbiology and Immunology, University of Turku, Turku, Finland.

Background: A germline mutation in the *NF1* tumor suppressor gene invariably manifests as a neurocutaneous-skeletal syndrome neurofibromatosis 1 (NF1). Cutaneous neurofibromas are the hallmark lesions of the syndrome. They are composed of an *NF1* heterozygous tumor microenvironment and a subpopulation of Schwann cells carrying an *NF1* null ($NF1^{-/-}$) genotype, which is a prerequisite for the development of neurofibromas. **Purpose:** The current study investigated the transcriptome of neurofibroma-derived Schwann cell cultures enriched towards $NF1^{+/-}$ or $NF1^{-/-}$ genotype. The aim was to answer to the question "How does the NF1 second hit mutation affect the reading of the whole genome?" **Methods:** Illumina Sentrix® HumanHT-12 v3 Expression BeadChips were used for gene expression profiling of neurofibroma-derived Schwann cell cultures enriched towards $NF1^{+/-}$ or $NF1^{-/-}$ genotype. For microarray analysis, cell cultures were established from a total of nine tumors from three different NF1 patients. The *NF1* mutations were characterized from each established cell line. The microarray results were validated using qPCR, western blots and immunolabelings. Furthermore, *NF1* siRNAs were applied on normal human keratinocytes and keratinocytes from a patient with NF1, $NF1^{+/-}$ Schwann cells, and neurofibroma-derived precursors (NFPs). **Results:** Expression profiling of NF1+/− and NF1−/− cells derived from the same tumor highlighted the processes of inflammatory response, antigen presentation and processing, and myelination. More specifically, the results showed that HLA class II expression was associated with $NF1^{-/-}$ genotype in Schwann cells. When $NF1^{-/-}$ and $NF1^{+/-}$ Schwann cell culture pairs from each tumor were analyzed by western blots, the results showed that HLA-DR protein levels were consistently higher in the $NF1^{-/-}$ Schwann cells. In neurofibroma tissues, HLA-DR was expressed by a subpopulation of cells potentially rendering them as non-professional antigen presenting cells. Our results also demonstrated that the tumors hosted scattered CD4/ FoxP3-positive cells, consistent with Tregs which are known to contribute to the immunologic tolerance through interaction with antigen presenting cells. Thus, the results pinpoint a novel mode of action how a second hit in a tumor suppressor gene helps the mutated cells hide from the immune system. Targeting Tregs in NF1 patients could provide a novel therapeutic approach to interfere with the development of neurofibromas.

Genetic screening of colorectal cancer patients for the Lynch syndrome detection in Estonian population. *M. Kask[1], E. Oitmaa[1], K. Toome[1], K. Raime[1], K. Vaidla[1], P. Laidre[2], J. Jaal[2], J. Soplepmann[2], V. Afanasjev[3], T. Erm[2], H. Roomere[1].* 1) Asper Biotech, Tartu, Tartumaa, Estonia; 2) Tartu University Hospital, Tartu, Tartumaa, Estonia; 3) The North Estonia Medical Centre, Tallinn, Estonia.

About 700 new colorectal cancer cases are diagnosed in Estonia every year, which brings the incidence of colorectal cancer to the third place of all the cancer cases. Each year about 400 people die of colorectal cancer in Estonia. About 4% of all colorectal cancer cases are associated with dominantly inherited Lynch syndrome caused by germline mutations in MLH1, MSH2, MSH6 or PMS2 genes. Mutation carriers have a lifetime risk of up to 80% for colorectal cancer, 20–60% risk of endometrial cancer, as well as other tumors. Aim of the study was to detect Lynch syndrome in patients diagnosed with colorectal cancer to improve the screening strategy in Estonia and provide genetic testing and counceling to the family members of the patients as a cancer preventive measure. The study involved a systematic analysis of 180 patients diagnosed with colorectal cancer. Microsatellite instability (MSI) testing, BRAF V600E mutation detection, immunohistochemistry (IHC) and mutation analysis of MLH1, MSH2, MSH6, PMS2 genes were performed. MSI analysis was performed on tumors from all the patients using Bethesda panel (BAT-25, BAT-26, D2S123, D5S346, D17S250) and an additional BAT-40 marker. Also, BRAF V600E mutation analysis was performed on tumors from all the patients. Based on revised Bethesda guidelines and the results of MSI (MSI-H or MSI-L) and BRAF (V600E negative) analyses, samples were chosen for the IHC analysis and DNA sequencing of MLH1, MSH2, MSH6 and PMS2. The average age of colorectal patients was 72 (36 to 88) years. MSI-H and BRAF mutation were observed in 30 and 28 out of all cases, respectively. Several polymorphisms in MLH1 (13); MSH2 (11); MSH6 (10) and PMS2 (15) genes, and a few previously not described variants of unknown significance were found.

CASP8AP2 and H2AFZ expression as a prognosis factor in childhood acute lymphoblastic leukemia. *R. JUAREZ-VELZQUEZ[1], A. REYES-LEON[1], C. SALAS[!], R. PAREDES[2], R. CARDENAS[2], G. LOPEZ-HERNANDEZ[3], A. LOPEZ[4], A. CARNEVALE[5], R. ORTIZ[6], R. BERNALDEZ[7], P. PEREZ-VERA[1].* 1) Human Genetics Dept, Instituto Nacional de Pediatria, Mexico, D.F; 2) Hemato-Oncology Dept, Instituto Nacional de Pediatria, Mexico, D.F; 3) Hematology Dept, Hospital del Niño Poblano, Puebla; 4) Gastroenterology Dept, INCMNSZ, Mexico, D.F; 5) INMEGEN, Mexico, D.F; 6) Universidad Autonoma Metropolitana-Iztapalapa, Mexico, D.F; 7) Hematology Dept, Hospital de Pediatria, CMNSXXI, Mexico, D.F.

Cancer is the second global cause of infant mortality, among them, acute lymphoblastic leukemia (ALL) is the most common type. Up to date, most patients with ALL achieve a cure through the use of adequate treatments according to the risk classification of each patient. Recently, new potential genetic markers have been identified to predict outcome of patients with ALL. The low gene expression levels of CASP8AP2 and H2AFZ had been considered an independent predictor of adverse outcome. In order to know if these genes predict outcome in our population, we studied the association between adverse events (relapse or die) and the expression levels of these genes, in a group of ALL children. Bone marrow samples were collected from 86 ALL pediatric patients diagnosed at Instituto Nacional de Pediatría, Centro Médico Nacional SXXI and Hospital del Niño Poblano in Mexico, between 2008 and 2010. Quantitative RT-PCR was used for evaluating expression levels. Seventy-four patients were diagnosed with B-ALL and 12 with T-ALL. Twenty-eight patients presented adverse events, of them, 15 (54%) and 14 (50%) showed low expression for CASP8AP2 and H2AFZ, respectively. Survival analysis (Kaplan-Meier) revealed an event-free survival (EFS) significantly lower between low expression of CASP8AP2 (log-rank p=0.004) and H2AFZ (log-rank p=0.028). Patients with low expression of both CASP8PA2 and H2AFZ genes presented the lowest EFS (log-rank p<001). These results suggest that expression of CASP8AP2 and H2AFZ genes could be useful as prognostic markers to identify ALL children at risk of relapse.

1142F

Circulating miRNAs as non-invasive blood based diagnostic biomarkers. *R. Duttgupta[1], R. Jiang[1], J. Gollub[1], T. Stamato[3], B.C. Getts[2], K.W. Jones[1].* 1) Assay and Product Developement, Affymetrix, Santa Clara, CA; 2) Research and Development, Genisphere LLC, 2801 Sterling Drive, Hatfield, PA, 19440; 3) Lankenau Institute for Medical Research, Wynnewood, PA 19096.

Effective diagnosis and surveillance of complex multi-factorial disorders such as cancer can be improved by screening of easily accessible biomarkers. Highly stable cell free Circulating Nucleic Acids (CNA) present as both RNA and DNA species have been discovered in the blood and plasma of humans indicating a functional role in relevant biological pathways. Correlation between the deregulation of these pathways and tumor-associated genomic/epigenetic/transcriptional alterations in CNA levels are strong predictors of the utility of this class as promising clinical indicators. Towards this goal microRNAs (miRNAs) representing a class of naturally occurring small non-coding RNAs of 19–25nt in length are important members that can associate specific expression profiles with cancer development. In this work, we discuss some of the pre-analytic considerations for isolating plasma fractions for the study of miRNA biomarkers. The relative proportions of cell-derived and cell-free miRNAs in hematopoietic fractions are outlined in a whole genome manner. Cellular miRNA signatures in cohorts of normal individuals are catalogued and the abundance and gender specific expression of bona fide circulating markers explored after calibrating the signal for this interfering class. A map of differentially expressed profiles is presented and the intrinsic variability of circulating miRNA species investigated in subsets of healthy males and females. Additionally, as proof-of-principle the diagnostic potential of circulating miRNA signatures for non-invasive prediction of Ulcerative Colitis (UC) - a subcategory of Inflammatory Bowel Disease (IBD) is investigated. We identify a panel of 31 platelet-derived miRNAs biomarkers with performance measurements of 92.8% accuracy, 96.2% specificity and 89.5% sensitivity in distinguishing UC patients from normal individuals. The mRNA targets/gene pathways and physical linkage between known IBD susceptibility loci and the qualified biomarker panel is investigated. Prospective cohorts for sub-stratifying IBD spectrum disorders are discussed.

1143W

Comparison of PCR method and RUT test for detection of *Helicobacter pylori* infection in gastric tissue. *N. Bagheri[1], L. Salimzadeh[2], F. Azadegan[3], Gh. Rahimian[4], A. Taghikhani[4], M. Hashemzadeh[5], H. Shirzad[5].* 1) MSc of Immunology, shahrekord, 1., Iran; 2) Department of Immunology, Molecular Research Center, Shahrekord University of Medical Sciences; 3) MSc Genetic, Cellular and Molecular Reserch Center, Shahrekord University of Medical Sciences; 4) Molecular Research Center, Shahrekord University of Medical Sciences; 5) Cell and Molecular Research Center, Shahrekord University of Medical Sciences.

Background and Aim: Culture has been for long the method of choice to detect infectious agents. However Helicobacter pylori (H.pylori) is a fastidious bacteria and growing slowly that its diagnosis by this method may take several days. This study was done to comparatively evaluate PCR and the rapid urease test in order to determine which of target housekeeping genes (glmM and 16SrRNA gene) was more appropriate in the diagnosis of Helicobacter pylori (H pylori) infection. Methods: The specimens used for this study were gastric biopsy samples which were collected from 438 patients undergoing upper gastroduodenal endoscopy for various dyspeptic symptoms. CLO test was compared with the PCR method for detection of selected housekeeping genes of H.Pylori, glmM and 16srRNA. Results: Totally 33.78% of the biopsies were positive for H pylori using both CLO test and PCR method for glmM and 16srRNA reference genes. 43.1% of the biopsies were negative for H pylori in all three mentioned methods. 193 of the 438 study subjects (43.6%) were found positive for CLO test. glmM and 16srRNA were positive in 48.4% and 38.3% of all specimens respectively. In positive CLO test specimens, only 156 and 148 subjects were positive for glmM and 16srRNA gene. Of the 245 negative CLO test subjects, 56 (22%) were positive with glmM gene and 20 (16%) were positive for 16srRNA gene. CLO test gave 7.9% false positive (glmM and 16srRNA Negative) and 4.5% false negative (glmM and 16srRNA Positive) results. Conclusion: Our results indicated that the CLO test gave various false positive and false negative results and gained poorer performance than PCR for detection of H.pylori infection in biopsy of dyspeptic Patients. This shows that in addition to the CLO test, PCR method using specific primers sets of both glmM and 16srRNA is useful for correctly diagnosis of H.pylori infections in laboratory.

Lowered PTEN protein dosage predicts for underlying germline *PTEN* mutations amongst patients presenting with thyroid cancer and Cowden-like phenotypes. *J. Ngeow[1,2], X. He[1,2], J. Mester[1,2,3,4], J. Lei[1,2], T. Romigh[1,2], M. Milas[3,4], M. Orloff[1,2,3], C. Eng[1,2,3,4,5,6].* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, Ohio 44195, USA; 2) Lerner Research Institute, Cleveland Clinic, Cleveland, Ohio 44195, USA; 3) Taussig Cancer Institute, Cleveland Clinic, Cleveland, Ohio 44195, USA; 4) Thyroid Cancer Center, Endocrinology and Metabolism Institute, Cleveland Clinic, Cleveland, Ohio 44195, USA; 5) Stanley Shalom Zielony Institute of Nursing Excellence, Cleveland Clinic, Cleveland, Ohio 44195, USA; 6) Department of Genetics and Genome Science, and CASE Comprehensive Cancer Center, Case Western Reserve University, Cleveland, Ohio 44106, USA.

Statement of Purpose: Thyroid cancer is a major component of Cowden Syndrome (CS), a heritable syndrome also characterized by breast, uterine and kidney cancers. CS patients with an underlying *PTEN* mutation (*PTEN*$^{mut+}$) have a 70-fold increased risk of developing epithelial thyroid cancer. In contrast, <1% of sporadic epithelial thyroid cancer patients carry a germline *PTEN* mutation. Thus, cost-efficient markers capable of shortlisting thyroid cancers for CS genetic testing would be clinically useful. Here, we analyzed the utility of patient blood-PTEN protein levels in predicting germline *PTEN* mutations. **Patients and Methods:** We conducted a 5-year, multicenter prospective study of 2792 CS and CS-like patients, all of whom had comprehensive *PTEN* analysis. Analysis of PTEN and downstream proteins by immunoblotting was performed on total protein lysates from patient-derived lymphoblast lines. We compared PTEN protein expression levels between *PTEN*$^{mut+}$ patients and those with variants of unknown significance (VUS) or wildtype *PTEN* (*PTEN*$^{wt/vus}$). **Results:** Of 2792 CS/CS-like patients, 722 had thyroid cancer. *PTEN* germline pathogenic mutations were present in 36 (5%) patients. *PTEN* frameshift and nonsense mutations accounted for 61% of mutations. Ninety-three percent (26/28) of *PTEN*$^{mut+}$ patients had blood-PTEN protein levels in the lowest quartile as compared to 25% (139/555) of *PTEN*$^{wt/vus}$ patients (p<0.001). Low blood-PTEN levels predicted for *PTEN*$^{mut+}$ cases with a 99.5% NPV (95%CI 98.3- 99.3) and a positive test likelihood ratio of 3.7 (95%CI 3.11–4.42). **Conclusions:** Our study shows that PTEN protein dosage could serve as a screening molecular correlate predicting for germline *PTEN* mutation in CS and CS-like presentations of thyroid cancer.

1145F

Cellular uterine leiomyomata with chromosome 1p deletions represent a distinct entity. *J.C. Hodge[1], A.T. Florin[2,3], K.E. Pearce[1], A.C. Clayton[1], E.A. Stewart[2].* 1) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) Department of Obstetrics and Gynecology and Surgery, Mayo Clinic, Rochester, MN; 3) Department of Obstetrics and Gynecology, University of Tübingen, Germany.

Introduction: Cellular leiomyomata (CL) represent a subgroup of uterine leiomyomata (UL) that are distinguished by hypercellularity. Developing evidence suggests that CL may have malignant potential. Our recent case-control analysis of CL versus typical UL demonstrated that CL have a distinct clinical phenotype with characteristics of leiomyosarcomas (LMS). Another study showed a subset of women with CL or atypical leiomyomata have disease-related deaths occurring >6 years after diagnosis. In addition, a limited genetic analysis found a portion of CL have chromosome 1p deletions, and the expression profiles of two such tumors segregated with LMS rather than myometrium/typical UL in a hierarchical cluster analysis. **Methods**: The current study included the same cohort as our case-control analysis of women who had surgery at Mayo Clinic between Jan 1989 and Dec 2008 that were diagnosed with a CL (n=99). Each case with available tissue that was confirmed to meet criteria for CL when reviewed by a single pathologist underwent determination of 1p deletion status using interphase FISH that targeted 1p21.1 plus control probes at 1q21.3 and 1q25. Univariate analysis of the successful cases (n=69) differentiated the clinical characteristics of women with CL that did or did not have 1p deletion. Mean values of continuous variables were compared with t-tests and percentages of categorical variables were contrasted using chi square analysis. **Results**: Twenty-two percent of our CL cohort had a 1p deletion. Women with a CL that had 1p deletion were significantly older (52.4±15.2 vs 43.7±10.5 yrs; P=0.47) and more likely postmenopausal (33.3 vs 9.8 %; P=0.040) with postmenopausal bleeding (20.0 vs 3.92 %; P=0.039). The uteri from these women tended to be significantly larger (1148.3±1494.7 vs 563.4±599.8 g; P=0.026) with a larger dominant fibroid (11.0±5.2 vs 8.1±4.5 %; P=0.027) containing hyaline necrosis (46.7 vs 17.7 %; P=0.037). **Conclusions**: CL with 1p deletion are common and have a distinct clinical phenotype with some characteristics in common with LMS. Such a striking difference in clinical behavior depending on the presence of 1p deletion suggests this molecular signature may help classify delayed malignant potential. Our findings are of particular importance considering the increasing preference for uterine-sparing treatment options, suggesting 1p deletion status in cellular UL may be an important factor in clinical surveillance decisions.

Cancer Biomarker Research using castPCR™ Technology. *T. Hartshorne, Y. Bao, B. Ching, M. Mouanoutoua, Y. Wang, D. Keys, S. Desai, J. Stevens.* Life Technologies, 850 Lincoln Centre Drive, Foster City, CA, USA.

Cancer biomarkers have applications in the diagnosis, staging, prognosis and monitoring of disease progression, as well as in the predication and monitoring of drug response. Profiling and validation research tools are needed that exhibit the combined features of high sensitivity and high specificity for cancers. However, the sensitivity of molecular methods such as DNA sequencing and conventional genotyping in tumor samples is limited, typically ranging from 5–20%. We have recently developed TaqMan® Mutation Detection Assays using our competitive allele specific TaqMan® PCR (castPCR™) technology for cancer biomarker research. TaqMan® Mutation Detection Assays were tested with >300 tumor research samples (either fresh/frozen or formalin-fixed, paraffin-embedded samples) and cell lines to assess mutation status at multiple independent laboratories. The results showed that castPCR™ technology can robustly detect mutations as low as 0.1% and has >99% concordance to other technologies including PCR-based technology and sequencing. In this study, a large panel of castPCR™ assays for AKT1, BRAF, CTNNB1, HRAS, KRAS, NRAS, PIK3CA, PTEN and TP53 genes were used for investigating somatic mutations in breast tumor research samples. Initially, 4 model FFPE cell lines were used to validate the assays. Mutant gDNAs were titrated into wild type gDNAs from 50% to 0.1%. Mutations were identified down to 0.1% titration with high reproducibility. No false positives were found in non-tumor samples. The results obtained by TaqMan® Mutation Detection Assays for 20 breast tumor samples (FFPE/fresh frozen) were concordant to those reported by other methods. Our data showed that castPCR™ technology provides an excellent tool for identifying cancer biomarkers or confirming potential cancer markers such as those obtained by next-generation sequencing and other technologies.

Naturally Missing Teeth and Ovarian Cancer: A Potential Genetic Link. *L. Morford[1], A. Vu[2], K. Kirk[1], M. Gilbey[1], G. Falcao-Alencar[1], M. Sakamoto[2], D. Fardo[3], J. Hartsfield, Jr.[1,2].* 1) College of Dentistry, Center for Oral Health Research, Univ Kentucky, Lexington, KY; 2) College of Dentistry, Division of Orthodontics, Univ Kentucky, Lexington, KY; 3) College of Public Health, Department of Biostatistics, Univ Kentucky, Lexington, KY.

Objective: Women diagnosed with Epithelial Ovarian Cancer (EOC) have an 8.1 times increased odds of having 1 to 6 naturally missing teeth (NMT; also termed hypodontia) when compared to controls. This is not trivial, as 20% of the women diagnosed with EOC have hypodontia, compared to only 3% of control subjects. Of the EOC patients with hypodontia, 60% had a family history of hypodontia, while only 30% of the same patients had a family history of ovarian cancer. By comparison, control subjects with hypodontia had no family history of either hypodontia or EOC. Hence, NMT may be good pre-malignancy marker of EOC, especially since hypodontia can be diagnosed at young ages. The aim of this nested case-control study was to determine the association between SNP rs10088218 within an ovarian cancer susceptibility locus on chromosome 8q24 and NMT in a population of young, cancer-free orthodontic patients. Design and Patients: Genomic DNA was isolated from 110 orthodontic patients (30 subjects with NMT and 80 controls). Subjects with NMT were sub-classified according to the number of agenic teeth as having hypodontia (1 to 6 NMT) or oligodontia (7 or more NMT). Underdeveloped peg-shaped teeth were also recorded. Variation at rs10088218 was assayed using Taqman®-based SNP genotyping. Hardy-Weinberg Equilibrium (HWE) testing was employed to assess genotyping quality, and logistic regression was used for association testing. Results: Within this orthodontic patient population, more females had NMT than males (3.3 to 1 ratio); with maxillary lateral incisors being most commonly affected by agenesis and/or peg formation, followed by mandibular second premolars and maxillary secondary premolars. No departures from HWE were detected. After an adjustment to remove any gender bias, rs10088218 was shown to be significantly associated with the presence of hypodontia (p=0.019) and also with the presence of generalized-NMT (hypodontia + oligodontia; p=0.021) under an additive mode of inheritance. Conclusions: Following adjustment for gender, each copy of the G allele at rs10088218 conferred an 11.51-times greater odds of having hypodontia, and a 4.37 greater odds of having generalized-NMT. Future studies will need to examine the potential dual association of rs10088218 with both NMT and ovarian cancer in a single population. It remains to be seen if this particular marker is a better predictor for the development of EOC than the NMT status alone.

Genome-wide association studies have identified multiple common genetic variants associated with an increased risk of prostate cancer, but these explain less than one third of the heritability. To identify further susceptibility alleles, we conducted a meta-analysis of four genome-wide association studies including 5,953 cases of aggressive prostate cancer and 11,463 controls. We computed association tests for ~2.6M SNPs and followed up the most significant SNPs by genotyping 49,121 samples in 29 studies through the international PRACTICAL and BPC3 consortia. We confirmed the association of a prostate cancer susceptibility locus, rs11672691 on chromosome 19, and demonstrated that the SNP was associated with aggressive prostate cancer(OR=1.12, 95% CI 1.03–1.21; *P*-value= 1.4×10^{-8}), and more weakly with non-aggressive prostate cancer(OR = 1.08, 95%CI 1.05–1.12; *P*-value=8.2×10^{-7}) however the difference was not statistically significant. This work was supported by Cancer Research UK and the NIH GAME-ON Initiative.

Identifying genetic modifiers in two p16 melanoma pedigrees. *M.H. Bailey[1], C. Teerlink[2], J.M. Farnham[2], L. Cannon-Albright[2].* 1) Life Sciences, Brigham Young University, Provo, UT; 2) Genetic Epidemiology, University of Utah, Salt Lake City, UT.

Introduction/Background: The CDKN2A gene, also known as p16, is a well-documented tumor suppressor gene predisposing to melanoma, and less often to pancreatic cancer. It has not been determined to what extent additional modifier genes/variants in p16 mutation carriers affect risk. Methods: We performed genotyping (500,000 SNPs) in 25 melanoma cases in two-linked high-risk melanoma pedigree with confirmed segregation of p16 mutations. Using genomically matched population controls from the Illumina iControl data set, we performed case/control genome wide association analysis (GWAS) to identify variants modifying melanoma risk in p16 carriers. Most GWAS approaches are not applicable to related individuals, thus we used PLINK solely as a naïve approach to identify possible associations to disease. We then used EMMAX (which adjusts for relatedness by way of a pairwise relationship matrix estimated from genotype data) to identify SNPs associated with melanoma risk in the presence of p16. The intersection of significantly associated SNPs from both analyses were then analyzed with PedGenie, an association analysis software that appropriately adjusts for know relationships among cases using 100,000,000 Monte Carlo inheritance simulations. Results: 7 SNPs were identified to have genome wide significance with p-values less than 1×10-8 from these two families. These SNPs are proposed as candidate melanoma risk modifying variants and must be validated in other p16-linked cases and/or pedigrees. Discussion: Due to the difficulty of determining association in highly related individuals we propose this method as a possible solution to identifying associated SNPs in high-risk pedigrees. Further investigation of these variants will to include SNP × SNP interaction models and additional p16 confirmed individuals.

1150T

Genome-wide association studies identify four novel ER-negative specific breast cancer risk loci. *F.J. Couch[1], M. Garcia-Closas[2, 3], S. Lindstrom[4], K. Michailidou[5], M.K. Schmidt[6], M. Brook[2], N. Orr[3], S. Slager[1], D.J. Hunter[4], J. Simard[7], J. Benitez[8], A. Dunning[5], M.E. Sherman[9], G. Chenevix-Trench[10], S.J. Chanock[9], P. Hall[11], P. Pharoah[5], C. Vachon[1], D.F. Easton[5], C.A. Haiman[12], P. Kraft[4] for BPC3, TNBCC, and BCAC.* 1) Departments of Laboratory Medicine and Pathology and Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Division of Genetics and Epidemiology, Institute of Cancer Research, Sutton, United Kingdom; 3) Breakthrough Breast Cancer Research Centre and Division of Breast Cancer Research, The Institute of Cancer Research, London, United Kingdom; 4) Program in Molecular and Genetic Epidemiology, Harvard School of Public Health, Boston, Massachusetts, USA; 5) Departments of Public Health and Primary Care and Oncology, University of Cambridge, Cambridge, United Kingdom; 6) Netherlands Cancer Institute, Antoni van Leeuwenhoek hospital, Amsterdam, The Netherlands; 7) Centre Hospitalier Universitaire de Québec and Laval University, Quebec, Canada; 8) Spanish National Cancer Research Centre [CNIO], Madrid, Spain; 9) Epidemiology and Biostatistics Program, National Cancer Institute, Bethesda, MD, USA; 10) Department of Genetics, Queensland Institute of Medical Research, Brisbane, Australia; 11) Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 12) Department of Preventive Medicine, Keck School of Medicine and Norris Comprehensive Cancer Center, University of Southern California, Los Angeles, CA, USA.

Estrogen receptor negative (ER-negative) tumors represent 20–30% of all breast cancers, with a higher proportion in younger women and women of African ancestry. Compared with tumors that express ER (ER-positive), ER-negative tumors are associated with a worse short-term prognosis and have weaker associations with reproductive risk factors. There are also important differences in genetic susceptibility to these two types of tumors. BRCA1 mutations predispose primarily to ER-negative disease and most common susceptibility loci for breast cancer, known to date, show stronger associations for ER-positive than ER-negative tumors. Exceptions are variants in the chromosome 5p15 (TERT-CLPTM1L) and 19p13 (MERIT40) loci that predispose primarily to ER-negative tumors. To identify additional ER-negative specific loci, three genome-wide association studies of 4,193 ER-negative breast cancer cases and 35,194 controls from the National Cancer Institute Breast and Prostate Cancer Cohort Consortium (BPC3), the Triple Negative Breast Cancer Consortium (TNBCC) and the Combined Breast Cancer Association Consortium (BCAC) ER-negative GWAS (C-BCAC) were combined with a replication series of 40 studies from BCAC (6,514 cases and 41,455 controls) in a meta-analysis. Four novel loci at 1q32.1 ($P=3.9\times10^{-13}$) and ($P=4.9\times10^{-9}$), 2p24.1 ($P=1.5\times10^{-8}$) and 16q12 ($P=2.0\times10^{-8}$) were associated with ER-negative but not ER-positive breast cancer (P>0.05). These findings provide further evidence for distinct etiologic pathways for invasive ER-positive and ER-negative breast cancer.

cAMP and cGMP signaling may play an important role in the development of prostate cancer. *R. de Alexandre[1,2], A. Horvath[1], A. Manning[1], D. Carraro[3], F. Soares[3], M. Nesterova[1], S. Constantine[1], F. Faucz[1,2].* 1) Section on Endocrinology & Genetics, PDEGEN, NICHD, NIH, Bethesda, MD, USA; 2) Laboratory of Molecular Genetics, NIMA, PPGCS, Pontificia Universidade Catolica do Parana, Curitiba, Brazil; 3) Laboratory of Genomics and Molecular Biology - A.C. Camargo Hospital, São Paulo, Brazil.

The second messengers cAMP and cGMP are responsible for a variety of cellular functions. Cyclic AMP and cGMP intracellular levels depend on the balance between their synthesis and degradation, i.e. on the activity of the adenylate and guanylate synthases and, the highly polymorphic family of phosphodiesterases (PDEs). Variants in PDEs have been associated with different disorders. The first PDE to be implicated in predisposition to tumors is *PDE11A*, whose inactivating mutations have been reported to be frequent in patients with adrenal, testicular and prostate tumors. Further, higher levels of cAMP have been measured in prostate cancer (PCa) compared to the normal tissue. In addition, cAMP and cGMP signaling is involved in PCa cell growth and modifies androgen receptor effects. We sequenced 16 different PCa tumor DNAs on SOLiD4 platform, after targeted enrichment for the coding parts of 196 genes, including the family of the phosphodiesterases, adenylate and guanylate synthases, all genes involved in cAMP and cGMP pathways and other genes related to endocrine tumors. After alignment and variation calling, 79 novel variants in 20 genes, and 120 previously reported SNPs in 21 of a selected list of 23 genes related to the cAMP and cGMP signaling were called in the 16 samples. The first 3 genes sequenced by Sanger for confirmation were *PDE11A*, *PDE5A* and *PRKAR1A*. While no mutations in *PRKAR1A* were confirmed, 2 novel synonymous SNPs were identified in *PDE5A* that are currently undergoing functional analysis. Analysis for *PDE11A* coding variants revealed results concordant with our previous findings: missense and nonsense variations were seen in the PC patients (allelic frequency 0.16 vs 0.043 in the controls, $\chi 2=18.23$, $p<0.0001$, OR=4.18, 95%CI 2.14–8.16). We also selected twenty-nine confidently called novel mutations in 15 genes from the same list of 23 genes of cAMP signaling for further confirmation and analysis. As a conclusion - while our results support the previously reported involvement of *PDE11A* in the predisposition to PCa, the role of *PDE5A* is yet to be determined. Genetic variants in *PRKAR1A* are not likely to be involved in the PCa predisposition.

Genome wide association for Multiple Myeloma reveals overlap between variants associated with susceptibility and survival. *E. Dean[1], D. Hu[1], P. Bracci[2], V. Krepkiy[1], T. Martin[1,3], J. Wolf[1,3], E. Ziv[1,3,4].* 1) Medicine, UCSF, San Franc, CA; 2) Epidemiology and Biostatistics, UCSF, San Francisco, CA; 3) Helen Diller Family Comprehensive Cancer Center, UCSF, San Francisco, CA; 4) Institute for Human Genetics, UCSF, San Francisco, CA.

Multiple Myeloma (MM) is an incurable hematological malignancy characterized by a clonal population of immunoglobulin secreting plasma cells. MM is known to have a significant familial component. One published genome wide association study (GWAS) has identified 2 susceptibility loci. MM is also known to be a heterogeneous disease with more and less aggressive biological subtypes that can be discerned by cytogenetic abnormalities and gene expression studies. We hypothesized that different subsets of disease would have different susceptibility genes and that these would lead to different survival rates among MM patients. We used a GWAS of MM to investigate the possibility that there is an overlap between SNPs that predict survival and susceptibility. We used a dataset of 300 MM patients seen at UCSF and 300 clinic based controls matched by race/ethnicity and gender. We genotyped the cases and controls using Illumina Omni5 arrays. We identified and adjusted for population stratification using principal components analysis (PCA), selecting the top 10 PC's. We performed case-control analysis using logistic regression models to identify potential susceptibility variants, and survival analysis using Cox models to identify variants affecting survival. We analyzed the overlap of markers by dropping SNPs in LD and then performing chi-squared tests to examine whether SNPs associated with survival are more likely to be associated with susceptibility. After dropping SNPs and samples with poor quality, we were left with ~2.5M variants typed on 285 cases and 300 controls. Using a relatively liberal cutoff of nominal significance ($p<0.05$), we evaluated whether there was overlap between the variants associated with survival and susceptibility. Based on chance alone, we would have expected 6934 SNPs nominally associated with susceptibility and survival in our dataset, but we saw 7528, a difference that is highly significant ($p<0.0001$). One locus on 8p11, was significantly associated with survival (p=2×10e-8) and nominally associated with susceptibility (p=0.01). Another locus on 18q12 had suggestive associations with both survival (p=2×10e-5) and susceptibility (p=7×10e-4). Our analysis demonstrates substantial overlap between germline variants that determine susceptibility to and survival from MM.

1153T

Genetic risk factors for malignant pleural mesothelioma (MPM): a genome-wide association study. *I. Dianzani[3], S. Guarrera[1], M. Betti[3], G. Fiorito[1], D. Ferrante[4], F. Voglino[1], G. Asbestos is the main risk factor for malignant pleural mesothelioma (MPM). Many different mechanisms have been hypothesized for its carcinogenic effect. Among them, ROS induced oxidative stress plays a crucial role, either directly or through activation of inflammatory cells. Only 10% of subjects exposed to high levels of asbestos develop MPM, which may be explained by individual susceptibility, including genetic risk factors. Previous studies suggested a role of SNPs in DNA-repair and redox enzymes. These studies report significant OR=1.4–3.5 for several SNPs and showed that genetic factors could indeed have a role in the pathogenesis of MPM, though much lower than that entailed by asbestos. Conversely, dominant mutations in BAP1 have been reported to cause a new cancer prone syndrome, characterised by susceptibility to MPM, melanoma, and other types of cancer. The aim of our work was the identification of genetic risk factors involved in the development of MPM. We performed a GWAs on 392 cases and 379 controls. A unique asset of our study is the complete clinical definition of asbestos exposures that is available for each patient and control. Cases and controls are from three towns in Northern Italy (Casale Monferrato, Turin, Genoa). Casale is a small town exposed to a high asbestos pollution because of an asbestos cement factory, active in 1907–1986. Besides factory workers, also Casale dwellers are at increased risk as compared with residents in the surrounding area. All subjects signed an informed consent form. Patients and controls were genotyped for more than 370.000 SNPs, using the Illumina HumanCNV370-Quad.v3 BeadChip. Preliminary data show that several SNPs (located in 6q21, 5q35, 19q13, 3q26, 4q32.1) were associated with MPM at a level of p=10-6/10-7 testing a per-allele model adjusted for gender, age, centre, exposure and PCA (Principal Component Analysis) in the overall and in the exposed-only case-control study (low vs higher exposure). Replication is on-going on a panel of 428 patients and 1269 controls from Australia (collaboration with Prof. L.Palmer). Functional and gene expression studies are ongoing on associated variants. Resequencing of the BAP1 gene on 100 patients is also ongoing. The definition of genetic risk factors contributing to the development of MPM may help to identify the pathophysiology of MPM and help in the definition of the actual risk of individuals exposed to asbestos.

A region of autozygosity at 8q21.3 and lung cancer risk. *M.T. Landi[1], K. Jacobs[1], M. Yeager[1], D. Albanes[1], M. Thun[2], N.E. Caporaso[1], S. Chanock[1], J. Shi[1]*. 1) National Cancer Inst, Bethesda, MD; 2) American Cancer Society, Atlanta, GA.

Background: Autozygosity occurs when two identical chromosomal segments are inherited from a common ancestor. Increased levels of autozygosity, either globally or locally, have been implicated as a risk factor for human complex diseases including cancer. Autozygosity can be inferred from the analysis of runs of homozygosity (ROHs; long stretches of homozygous single-nucleotide polymorphisms [SNPs]) in outbred populations from genome-wide SNP array data. We examined whether the proportion of the autosome estimated to be within an ROH (*Froh*) or any locus-specific ROH was associated with the risk of lung cancer overall or with specific histological subtypes. Materials and Methods: We performed an ROH analysis in a GWAS with 4,225 controls and 5,297 lung cancer cases of European ancestry, including 1,607 adenocarcinomas, 1,414 squamous carcinomas and 688 small cell carcinomas genotyped for 515,922 SNPs. ROH segments ≥500kb with ≥60 SNPs and no heterozygous genotypes were detected using PLINK. The association between *Froh* and lung cancer risks was evaluated using logistic regression, adjusting for age, sex, cigarettes per day, years of cigarette smoking and principal components for population stratification. Furthermore, we split the autosome into intervals of 500kb in length and, or each interval, we tested if the proportion of cases carrying ROHs was significantly higher than that of controls using the Fisher's exact test. The empirical genome-wide significance levels were evaluated by a permutation procedure where case-control status was permuted 10,000 times. Results: Froh was not significantly associated with the risk of lung cancer overall or with any lung cancer subtype, in ever, former or current smokers. One ROH at 8q21.3 was significantly associated with overall lung cancer risk in ever smokers (1.2% in cases and 0.35% in controls, OR=3.4, nominal P= 0.000015 and genome-wide P=0.017). This association was stronger for small cell carcinomas and squamous cell carcinomas. Significance: These findings offer new insights into the development of lung cancer and call for further research into recessive, lung cancer-predisposing loci.

1155W

IL28B allelic protein isoforms differentially activate interferon-stimulated genes. *A. Mumy[1], B. Muchmore[1], W. Tang[1], H. Park[2], F. Sheikh[3], B. Rehermann[2], R. Donnelly[3], L. Prokunina-Olsson[1]*. 1) Laboratory of Translational Genomics, Division of Cancer Epidemiology and Genetics, NCI, NIH, Gaithersburg, MD; 2) Immunology Section, Liver Diseases Branch, NIDDK, NIH, Bethesda, MD 20892; 3) Division of Therapeutic Proteins, Center for Drug Evaluation & Research, FDA, Bethesda, MD 20892.

IL28B (IFN-λ3) is a type-III interferon encoded by the IL28B gene located on chromosome 19q13.13. Recent genome-wide association studies (GWAS) have identified genetic variants upstream of IL28B, associated with spontaneous and treatment-induced clearance of HCV. Here, we sequenced IL28B gene in the HapMap reference set of 270 samples from 3 populations - Europeans, Asians and Africans. We found 3 protein-coding variants, rs8103142 (Lys70Arg), rs138893424 (Leu31Phe) and rs62120527 (Glu171-Lys), which were genotyped by sequencing and/or with TaqMan assays. We induced IL28B expression in primary human hepatocytes treated with Poly(I:C), and performed 5'rapid amplification of cDNA ends (5'-RACE), but found no alternative IL28B transcripts. We cloned IL28B transcripts with allelic variants of the 3 coding SNPs, and generated four recombinant purified IL28B protein isoforms using a baculoviral expression system. Functional analysis of these proteins was performed using a stable HepG2-ISRE-Luc cell line expressing an interferon-stimulated response element (ISRE) coupled with luciferase reporter gene. Our analysis showed that the IL28B protein carrying the beneficial T allele (70Lys) of rs8103142 and the common alleles of the two other variants was significantly more potent at inducing activation of the ISRE-Luc reporter compared to the other IL28B protein isoforms. We are currently testing these protein isoforms using STAT1 phosphorylation assays and evaluating their effects on inhibition of HCV replication and on activation of specific interferon-stimulated genes.

1156T

Three novel common susceptibility loci for ovarian cancer identified by GWAS meta-analysis and replication. *S.J. Ramus[1], P.D.P. Pharoah[2,3], Y.Y. Tsai[4], C.M. Phelan[4], A.N.A. Monteiro[4], SA. Gayther[1], J.M. Schildkraut[5,6], T.A. Sellers[4] on behalf of the Ovarian Cancer Association Consortium.* 1) Dept Preventive Medicine, Univ Southern California, Los Angeles, CA; 2) The Centre for Cancer Genetic Epidemiology, Department of Oncology, University of Cambridge, Cambridge, UK; 3) The Centre for Cancer Genetic Epidemiology, Department of Public Health and Primary Care, University of Cambridge, Cambridge, UK; 4) Department of Cancer Epidemiology, Division of Population Sciences, Moffitt Cancer Center, Tampa, FL, USA; 5) Department of Community and Family Medicine, Duke University Medical Center, Durham, NC, USA; 6) Cancer Prevention, Detection and Control Research Program, Duke Cancer Institute, Durham, North Carolina, USA.

Genome wide association studies (GWAS) have identified four susceptibility loci for epithelial ovarian cancer (EOC) with another two loci being close to genome-wide significance. We pooled data from a GWAS conducted in North America with another GWAS from the United Kingdom. The North American study comprised four independent case-control studies that included 1,952 EOC cases and 2,052 controls. The second study was a two-phase multi-center GWAS that included 1,817 EOC cases and 2,354 controls in the first phase and 4,162 EOC cases and 4,810 controls in the second phase. We carried out a fixed effects meta-analysis from the two GWAS for ~2.5 million genotyped or imputed SNPs. We selected the top 24,551 SNPs for follow-up genotyping and after applying quality control filters, we tested 22,252 SNPs for association with risk of all invasive EOC and for serous invasive EOC in 18,174 EOC cases (10,316 serous cases) and 26,134 controls. The primary analyses were based on the subjects of European ancestry (16,283 cases and 23,491 controls) from 43 studies as part of the Collaborative Oncological Gene-environment Study (COGS). The associations of the four previously reported SNPs at 2q31, 8q24, 9p22 and 19p13 were all confirmed. We validated the two loci at 3q25 and 17q21 previously near genome-wide significance and identified three novel loci associated with risk; two loci associated with all EOC subtypes, at 8q21 (rs11782652, odds ratio (OR) = 1.19, 95% CI: 1.12–1.26, $P=5.5\times10^{-9}$) and 10p12 (rs1243180; OR = 1.10, 95% CI:1.06–1.13,$P=1.8\times10^{-8}$), and another locus specific to the serous subtype at 17q12 (rs757210; OR = 1.12, 95% CI:1.08–1.17,$P=8.1\times10^{-10}$). The association of rs757210 at 17q12 with all invasive EOC was much weaker (OR = 1.05, 95% CI 1.02–1.09, $P=9\times10^{-4}$); there was substantial heterogeneity by tumor subtype (P=<0.0001) with the risk allele for serous EOC being associated with a reduced risk of both clear cell and mucinous EOC. An integrated molecular analysis of genes and regulatory elements within a 1Mb region at each locus provided evidence for functional mechanisms underlying susceptibility with specific involvement of the CHMP4C (8q21), MLLT10 (10p12) and HNF1B (17q12) genes in the pathogenesis of ovarian cancer.

1157F

Insights into pancreatic cancer etiology from pathway analysis of genome-wide association study data. *P. Wei[1], H. Tang[2], D. Li[2]*. 1) Human Genetics Center, The University of Texas Health Science Center at Houston, Houston, TX; 2) Department of Gastrointestinal Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston, TX.

Pancreatic cancer is the fourth leading cause of cancer death in the U.S. and the etiology of this highly lethal disease has not been well defined. To identify genetic susceptibility factors for pancreatic cancer, we conducted a comprehensive pathway analysis of genome-wide association study (GWAS) data in 3,141 pancreatic cancer patients and 3,367 controls with European ancestry, pooled from nested case-control studies-based PanScan1 and case-control studies-based PanScan2. Using the gene set ridge regression in association studies (GRASS) method we analyzed 197 pathways identified from the Kyoto Encyclopedia of Genes and Genomes (KEGG) database. We used the logistic kernel machine (LKM) test to identify major contributing genes to each pathway. We conducted functional enrichment analysis of the most significant genes (P<0.01) using the Database for Annotation, Visualization, and Integrated Discovery (DAVID). Six pathways were significantly associated with risk of pancreatic cancer after adjusting for multiple comparisons (P <0.00025 based on 5000 permutations): Fc epsilon RI signaling, maturity onset diabetes of the young, neuroactive ligand receptor interaction, long-term depression (P<0.0002), and the olfactory transduction and vascular smooth muscle contraction pathways (P=0.0002). As a replication effort, we performed the GRASS pathway analysis on the data from PanScan1 (1,796 cases and 1,880 controls) and PanScan2 (1,345 cases and 1,487 controls) separately. Two of the six significant pathways, i.e. the olfactory transduction pathway and the neuroactive ligand-receptor interaction pathway showed consistent small P values across the PanScan1 and PanScan2 cohorts, though not both P values were significant after multiple testing corrections likely due to much smaller sample size in each individual cohort. The meta-analysis P values for these two pathways (1×10^-5 and <1×10^-5, respectively) were significant after the Bonferroni correction. LKM test identified four genes that were significantly associated with risk of pancreatic cancer after the Bonferroni correction (P<1×10^-5): ABO, HNF1A, OR13C4, and SHH. Functional enrichment analysis using DAVID consistently found the G protein-coupled receptor signaling pathway to be the most significant pathway for pancreatic cancer risk in this study population. If confirmed, these novel findings provide new perspectives on genetic susceptibility to and molecular mechanisms of pancreatic cancer.

1158W

Pathway-based analysis of genome-wide SNP data reveals new candidate genes for susceptibility to melanoma. *M. Brossard[1,2,3], A. Vaysse[1,2,3], E. Corda[1,2,3], P. Jeannin[1,2,3], H. Mohamdi[1,2,3], V. Chaudru[1,3,4], N. Lavielle[1,2,3], B. Bressac-de Paillerets[1,5], M.F. Avril[6], M. Lathrop[3], F. Demenais[1,2,3]*. 1) INSERM U946, Paris, France; 2) Université Paris Diderot, Paris, France; 3) Fondation Jean Dausset-CEPH, Paris, France; 4) Université d'Evry, Evry, France; 5) Service de Génétique, Institut Gustave Roussy, Villejuif, France; 6) Assistance Publique-Hôpitaux de Paris, Hôpital Cochin, Paris, France.

Genome-wide association studies (GWAS) for melanoma have identified 16 melanoma risk loci. However, these loci explain only a small part of the genetic susceptibility to melanoma. These GWAS were conducted by using single-marker analysis which may be underpowered to detect SNPs with small effects and/or interacting with other SNPs. Multi-marker methods, including pathway-based approaches, have been proposed as an alternative strategy to prioritize new susceptibility genes. Our goal was to use a pathway-based approach implemented in the ALIGATOR software to identify an overrepresentation of biological pathways, indexed by gene-ontology (GO) terms, associated with risk of melanoma. The input data to ALIGATOR consisted of association results of 1.4 millions Hapmap3-imputed SNPs that were obtained from a GWAS conducted in 1186 melanoma cases and 2838 controls from the French MELARISK study. A total of 593,915 SNPs lied within 20kb of 22,648 genes and these genes were assigned to 7,371 GO categories. We found that 12 GO categories achieved a category-specific p-value of 0.001 or lower. This number of GO categories was significantly greater than expected by chance (p=0.001 after correction for multiple testing). The 12 GO classes included 8 of the 16 loci identified by previous GWAS (*MC1R*, *TYR*, *HERC2/OCA2* locus, *SLC45A2*, *TERT*, *MTAP/CDKN2A/CDKN2B* locus, *ATM*, *PARP1*), which confirms the validity of this pathway approach. These loci were grouped into melanin biosynthesis process, DNA metabolic process and telomerase activity pathways. In addition, 5 new candidate genes belonging to DNA replication and replisome pathways were characterized; these genes are located on chromosomes 5q31, 12q13 and 22q11.21. This study outlines the advantage of using a multi-marker approach to reveal new pathways and new candidate loci potentially involved in melanoma susceptibility. Further investigation of these loci in other melanoma datasets and search for gene-gene interactions within and across the pathways characterized by this study are worth pursuing. Funding: Ligue Nationale Contre le Cancer (PRE 09/FD), PHRC (AOM-07–195).

Susceptibility Loci Associated with Specific and Shared Subtypes of Lymphoid Malignancies. *V. Joseph[1,2], T. Kirchhoff[3], J. Brown[5], K.A. Schrader[1,2], A. Dutra-Clarke[1], C. Manschreck[1], N. Hansen[1], R. Rau-Murthy[1], K. Sarrel[1], J. Przybylo[1], S. Shah[1,2], S. Cheguri[1], Z. Stadler[1], L. Zhang[6], O. Paltiel[7], D. Yehuda[7], A. Viale[8], C. Portlock[4], D. Strauss[4], S.L. Lipkin[9], M. Lacher[4], M. Robson[1], R.J. Klein[2], A. Zelenetz[4], K. Offit[1,2,4,9].* 1) Dept. Medicine, Sloan-Kettering Institute for Cancer Research, NEW YORK, NY; 2) Cancer Biology and Genetics Program, Sloan Kettering Institute, New York, New York, USA; 3) NYU Cancer Institute, New York University School of Medicine, New York, New York, USA; 4) Lymphoma Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, New York, USA; 5) Dana Farber Cancer Institute, Boston, Massachusetts, USA; 6) 6) Diagnostic Molecular Genetics Laboratory, Department of Pathology, Memorial Sloan-Kettering Cancer Center, New York, New York, USA; 7) Department of Hematology, Hadassah-Hebrew University Medical Center, Jerusalem, Israel; 8) Genomics Core, Memorial Sloan-Kettering Cancer Center, New York, New York, USA; 9) Weill Cornell Medical Center, New York, New York, USA.

Using a two-stage GWAS, we tested 530,583 SNPs in 944 cases of lymphoma, including 282 familial cases, and 4059 public shared controls, followed by genotyping of 50 SNPs in 1245 cases and 2596 controls. Six loci achieved genome-wide significance for the subsets of follicular or diffuse large B-cell, and five in joint analysis of all lymphoma subtypes combined (LYM). We discovered a novel locus on 6p23 (rs707824, PLYM=1.22 × 10-9) near JARID2 and another on 11q12.1 (rs12289961, PLYM=3.06 × 10-9; rs948562, PLYM=2.11 × 10-7) near LPXN, both of which confer susceptibility to B-cell lymphoma. The most significantly associated with combined types of non-Hodgkin's lymphoma (NHL) was rs707824 (PNHL=1.67 × 10-10). Candidate genes in these regions have been implicated in B-cell development, hematopoiesis and immune function. Our data also confirms association with a region near the HLA locus at 6p21.32; we demonstrate allelic heterogeneity, with rs2647046 (PFL=1.88 × 10-15), rs4530903 (PFL=6.65 × 10-13), rs2621416 (PFL=2.95 × 10-9) and rs9268853 (PFL=5.53 × 10-11) near HLA-DQA1/2, HLA-DQB1/2, and TAP2, independently associated with follicular lymphoma. Genes implicated by GWAS were also found to be cis-eQTLs in lymphoblastoid cell lines. Eight of the nine SNPs were putative regulatory SNPs as shown by in silico analysis. Thus, these results, showing both locus and allelic heterogeneity, point to the existence of pathways of susceptibility to both shared as well as specific subtypes of lymphoid malignancy.

1160F

Second Generation DCEG Reference Set Improves Performance of Genotype Imputation. *Z. Wang[1,2], K.B. Jacobs[1,2], M. Yeager[1,2], A. Hutchinson[1,2], J. Sampson[2], M. Tucker[2], S.J. Chanock[2].* 1) Core Genotyping Facility, SAIC-F/NCI, Bethesda, MD; 2) Division of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD.

Genotype imputation has become an essential analytic approach for fine-mapping and meta analysis of GWAS data sets genotyped and analyzed on different arrays. The NCI Division of Cancer Epidemiology of Genetics (DCEG) recently released a first version of an imputation reference set through the dbGaP webportal (Wang et al Nature Genetics 44:6-7, 2011 available at http://www.ncbi.nlm.nih.gov/projects/gap/cgi-bin/study.cgi?study_id=phs000396.v1.p1). Earlier, we showed that performance is better for genotyped samples compared to low-pass sequence data. To improve the practical utility of the DCEG Reference Set, we have substantively increased the number of genotyped SNPs in the same set of 1,249 cancer-free individuals, primarily of European ancestry. New content includes SNP microarray data from both Illumina (Omni2.5S, Exome, Immunochip, Metabochip and the iCOGs custom cancer microarrays) and Affymetrix (6.0 and two Axiom microarrays), which will further facilitate larger, international meta-analyses and imputation projects. Ongoing work includes comparison of version 2 to recent builds of the 1000 Genomes Project. Later this year, version 2 of the DCEG Imputation Set will be available on the dbGaP webportal. Funded by NCI Contract No. HHSN261200800001E.

Are there genetic variants that confer shared genetic susceptibility to pancreatic cancer and melanoma? *L. Wu, K. Rabe, G. Petersen.* Health Sciences Research, Mayo Clinic, Rochester, MN.

Background: Pancreatic cancer researchers (including Mayo Clinic) found that certain subsets of pancreatic cancer patients are at an increased risk for melanoma. Melanoma researchers have similarly found increased risk for pancreatic cancer in their patients. We hypothesized that these two diseases possibly share genetic risk factors. Previous studies found that CDKN2A (p16) can explain some familial clusters of these two cancers, but evidence for a more broad connection between pancreatic cancer and melanoma is largely lacking. Methods: We evaluated the association between 38 single-nucleotide polymorphisms (SNP) within 22 genomic regions which are associated with melanoma risk and the risk of pancreatic cancer using Whole Genome Scan for Pancreatic Cancer Risk in the Pancreatic Cancer Cohort Consortium and Pancreatic Cancer Case-Control Consortium (PanScan) datasets, which include PanScan 1, PanScan 2, combined PanScan, and Mayo Clinic subset data. We also evaluated the association between 9 pancreatic cancer susceptibility variants within 4 genomic regions and the risk of melanoma using MD Anderson Cancer Center melanoma genome-wide association study (GWAS) dataset. Results: In the PanScan datasets, several associations were statistically significant at p=0.05 threshold. For example, OCA2 (rs1800407) (OR=1.152, 95% CI 1.001–1.325, p= 0.049) in PanScan 2 dataset; NCOA6 (rs4911442) (OR=1.323, 95% CI 1.032–1.697, p=0.027), YWHAZP5 (rs17119461) (OR= 2.617, 95% CI 1.079–6.35, p=0.033), and YWHAZP5 (rs17119490) (OR= 2.616, 95% CI 1.078–6.344, p=0.033) in the Mayo Clinic subset data,. In the melanoma GWAS dataset, we detected two pancreatic cancer susceptibility variants to be associated with an increased risk of melanoma: NR5A2 (rs12029406) (OR=1.393, 95% CI 1.011–1.919, p=0.043), and CLPTM1L-TERT (rs401681) (OR=1.16, 95% CI 1.006–1.337, p=0.041). None of the above associations were statistically significant after the Bonferroni correction for multiple comparisons. Conclusion: There is no evidence that GWAS-derived melanoma susceptibility variants play an important role in pancreatic cancer predisposition. Also pancreatic cancer susceptibility variants are not associated with melanoma risk. If there is a shared genetic etiology of these two cancers, it may be detected by genetic analysis other than currently tested GWAS SNPs. Family-based linkage studies or high throughput sequencing studies offer possible approaches.

Oncogenic rewiring by the t(11;19)(q21;p13) coactivator fusion, CRTC1/MAML2, involves direct activation of the pluripotency factor MYC. *A.L. Amelio[1], F.X. Schaub[1], M. Fallahi-Sichani[2], M.B. Lawani[1], M.R. Southern[3], B.M. Young[4], L. Wu[5], F.J. Kaye[6], J.L. Cleveland[1], M.D. Conkright[1].* 1) Department of Cancer Biology, The Scripps Research Institute, Jupiter, FL; 2) Informatics Department, The Scripps Research Institute, Jupiter, FL; 3) Translational Research Institute and Molecular Therapeutics, The Scripps Research Institute, Jupiter, FL; 4) Genomics Core, The Scripps Research Institute, Jupiter, FL; 5) Department of Molecular Genetics and Microbiology, Shands Cancer Center, University of Florida, Gainesville, FL; 6) Department of Medicine, Shands Cancer Center, University of Florida, Gainesville, FL.

Oncogenesis is a complex, multi-factorial process of cellular transformation that leads to the development of many types of cancers. The factors that contribute to this process reprogram normal cellular functions to allow for uncontrolled cell growth and proliferation. The cAMP Regulated Transcription Coactivator (CRTC) family of CREB coactivators, in conjunction with CBP/p300, cooperate in the regulation of cAMP-inducible genes involved in cell survival, proliferation, glucose metabolism, and adaptive mitochondrial biogenesis. A subset of tumors share a common t(11;19)(q21;p13.1) translocation that forms a chimeric oncogene by fusing CRTC1 to the NOTCH coactivator MAML2. Consequently, the CRTC1/MAML2 (C1/M2) coactivator fusion induces the aberrant expression of genes regulated by CREB and NOTCH and the deregulation of these target genes is believed to cause tumorigenesis. However, using a mammalian genetic screen, we identified a C1/M2 gain-of-function activity that promotes interactions with the MYC:MAX network. RNA-seq analysis confirmed that a significant proportion of genes involved in key aspects of cell growth, survival, and metabolism within the MYC:MAX and CREB transcription networks are induced by C1/M2. Analysis of cellular transformation by RK3E foci formation assays identified a synergistic effect of MYC expression on C1/M2-induced transformation and this can be blocked by a dominant negative MYC molecule. Furthermore, in-frame deletions of C1/M2 that lack transforming activity are unable to induce the expression of MYC-responsive reporters revealing a critical role for MYC target genes in C1/M2-induced cell growth and transformation. Collectively, these studies suggest that ectopic interactions between C1/M2 and MYC contribute to the initial stages of tumorigenesis or in maintaining tumor stem cells given that CRTC1 activity has been implicated in epithelial stem cell proliferation and MYC is important for cell `stemness' and pluripotency. Acknowledgments: This study is supported by a Ruth L Kirschstein National Research Scholar Award from the National Cancer Institute (CA134121), PGA National Cancer Award, and by the Margret Q. Landenberger Foundation.

Meta-analysis identifies microRNA expression signature in non-small-cell lung cancer. *T. Annilo[1], U. Võsa[1], T. Vooder[2], R. Kolde[3], J. Vilo[3], A. Metspalu[1,4].* 1) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 2) Clinic of Cardiovascular and Thoracic Surgery of Tartu University Hospital, Puusepa 8, 51014 Tartu, Estonia; 3) Institute of Computer Science, University of Tartu, Liivi 2, 50409 Tartu, Estonia; 4) Estonian Genome Center, University of Tartu, Riia 23b, 50410 Tartu, Estonia.

The prognostic and diagnostic value of microRNA (miRNA) expression aberrations in non-small cell lung cancer (NSCLC) has been studied intensely in recent years. However, due to the application of different technological platforms and small sample size, the miRNA expression profiling efforts have led to inconsistent results between the studies. We performed a comprehensive meta-analysis of 17 published miRNA expression datasets in NSCLC, including a total of 501 tumor and 431 non-cancerous control samples. Using a recently published Robust Rank Aggregation method, we identified statistically significant miRNA meta-signature of four up- and seven down-regulated miRNAs. We conducted a gene set enrichment analysis to identify pathways that are most strongly affected by altered expression of these miRNAs. We found that meta-signature miRNAs cooperatively target functionally related and biologically relevant genes in signaling and developmental pathways. We have shown that such meta-analysis approach is suitable and effective solution for identification of statistically significant miRNA meta-signature by combining several miRNA expression studies. This method allows the analysis of data produced by different technological platforms that cannot be otherwise directly compared or in the case when raw data is unavailable.

The effect of non-viral magnet assisted transfection on chronic myeloid leukemia cell line with down regulated miR-150. *T. Balci[1], C. Biray Avci[1], S. Yilmaz[1], Z.O. Dogan Sigva[1], G. Saydam[2], C. Gunduz[1].* 1) Medical Biology, Ege University Medical Faculty, Izmir, Turkey; 2) Hematology Department, Ege University Medical Faculty, Izmir, Turkey.

Chronic myeloid leukemia (CML) is a clonal myeloproliferative disease resulting from the neoplastic transformation of multipotent stem cells. The average age of CML cases is between 45 and 55 years old. MicroRNAs (miRNAs) are single strand, non-coding RNA molecules with the length of 18–25 nucleotides which have role in the regulation of gene expression. In various tumors, tumor suppressor miRNAs have been described to be deleted. For example; down regulation of miR-150 was proven in chronic myeloid leukemia. In recent years, polymeric nanoparticles are used as drug and gene carriers. Magnet assisted transfection (MATRA) is one of the most effective non-viral transfection methods. We aimed to determine the expression profiles of 96 cell cycle control genes in K-562 cell lines which transfected with down regulated miR-150 by MATRA mediated non-viral method. Total RNA was isolated from the cells exposed to transfection, the expressions of 96 genes each from apoptotic pathway and cell cycle controls were studied by real time online RT-PCR. Results were compared with control cells. As a result the expression profiles of CASP5, Fas, CD27, TRAF4, TNFRSF1A genes showed a significant increase and, CDK5RAP1, ATM, MYC, CDK8, CCND2 genes showed decrease, compared to the control cells. In conclusion, down-regulated miR-150 substitution showed the regulation of miRNA-mediated cell-cycle and apoptosis. The alterations of the genes' expressions have to be elucidated in protein level for new approaches in CML treatment.

1165T

The novel resequencing Diagnostic Microarray: RDMGGA1.0, can detect at a diagnose level mutations in patients with Breast, Ovarian, Colon, Skin and Multiple Cancers. *D. Bercovich[1], Y. Plotsky[2], T. Morad[2], S. Allon-Shalev[3], AM. Lichanska[4], LA. Borsuk[4], C. Tibbetts[4].* 1) Human Molec Gen & Pharm, MIGAL-Galille Tech Ctr, Kiryat-Shmona, Israel; 2) Galil Genetic Analysais (GGA), Kazarin 12900, Israel; 3) The Institute for Genetics, Ha'Emek Medical Center, Afula 18101, Israel; 4) TessArae, Potomac Falls, VA 20165 USA.

Despite the remarkable progress in sequencing methods for genes causing the most common inherited cancers, most current diagnostic methods and algorithms do not analysis mutations at a clinical level of affected patients and relatives. In addition, the large genes size and the lack of highly predominant mutational hotspots for some populations frequently make mutation detection in these cancer genes outstandingly challenging, which is costly and time consuming. To fulfill this technological gap, we developed a new customized resequencing gene chip (RDMGGA1.0) that is focused on 11 genes: BRCA1, BRCA2, APC, MUTYH, MLH1, MSH2, MSH6, TP53, PTEN, P16 and KRAS simultaneously, in a single assay, with high call rate and accuracy. Probes were designed to identify each base for all exons of these genes with 20 bases of intronic sequence bordering exons in the main tiles. Additionally, 3320 known and most frequent mutations were subtiled as well. The array uses the Affymetrix resequencing platform. Novel software was developed by TessArae for the data analysis. Amplicons were hybridized to the chip, and nucleotide detection was validated by standard capillary sequencing methods. Hybridization of amplicons with the chip produced high nucleotide sequence readout for all 11 genes in a single assay, with an automated call rate of over 98%. In a validation procedure of 150 samples with known mutations, the accuracy of nucleotide calls was 99.99% when compared with capillary sequencing in two separate labs (GGA, Israel; TessArae, USA). The new resequencing chip enables efficient analysis of 11 genes and identifies disease-causing mutations in two working days.

1166F

A New Approach for an Anti-diabetic Drug Metformin in Prostate Cancer. *C. Biray Avci[1], E. Harman[2], S. Yilmaz[1], Y. Dodurga[3], C. Gunduz[1].* 1) Medical Biology, Ege University Medical School, Izmir, Turkey; 2) Endocrinology Dept, Katip Celebi Universtiy Medical Faculty, Izmir, Turkey; 3) Medical Biology, Pamukkale University, Denizli, Turkey.

Prostate cancer is the most commonly diagnosed cancer in the male population. Metformin is the most widely used antidiabetic drug in the world, and there is increasing evidence of a potential efficacy of this agent as an anticancer drug. Metformin inhibits the proliferation of a range of cancer cells including prostate, colon, breast, ovarian, and glioma. MicroRNAs (miRNAs) are a class of small, non-coding, single-stranded RNAs that negatively regulate gene expression. We aimed to evaluate the effects of metformin treatment on the cellular miRNA expression changes in PC-3 cells and possible association of miRNAs and metformin on prostate cancer. Average cell viability and cytotoxic effect of metformin were investigated at 24 hours intervals for three days by using WST-1 assay. Cytotoxic effects of metformin in PC-3 cells were detected in time and dose dependent manner with the IC50 doses. RNA samples analysed using custom multi-species microarrays containing 1209 probes covering 1221 human mature microRNAs present in miRBase 16.0 database. The microarrays were scanned and data was extracted from images. Each array contains probes targeting 11 different synthetic miRNAs. Sensitivity of the microarray hybridization was confirmed by detection of hybridization signal for all 11 spikes well above the detection threshold. The array also contains a set of specificity control probes complementary to three different miRNAs. For statistical analysis, samples were binned in to different treatment groups. The log2-transformed and normalized spot intensities for the detectable human probes were examined for differences using the ANOVA module. The statistical significance was determined using the False Discovery Rate method. Fold changes between the different treatment and control samples were computed and presented along with the log2 transformed spot intensities of the detectable probes. Data for the detectable human probes were clustered. Genes were median centered prior to hierarchical clustering. Among the human miRNAs investigated by the arrays, 10 miRNAs were up-regulated and 12 miRNAs were down-regulated in metformin dose group compared with control cells. In conclusion, expression changes in miRNAs of miR-146a, miR-100, miR-425, miR-193a-3p, miR-106b in the metformin exposed cells may be important. This work may be demonstrated a new role of metformin on the regulation of miRNAs in prostate cancer.

mRNA-Seq of Single Prostate Cancer Circulating Tumor Cells Reveals Recapitulation of Gene Expression and Pathways Found in Prostate Cancer. *G. Cann[1], Z. Gulzar[2], S. Cooper[1], M. Tat[1], R. Li[1], S. Stuart[1], S. Luo[1], M. Ronaghi[1], J. Brooks[2], A. Talasar[1].* 1) Illumina Inc, Hayward, CA; 2) Department of Urology, Stanford University, Stanford, CA.

Circulating tumor cells (CTC) mediate metastatic spread of many solid tumors types, and enumeration of CTCs is used as a prognostic indicator for metastatic prostate cancer patients. Evidence suggests that information about primary tumors can be derived from expression analysis of CTCs. We assessed the ability of the MagSweeper to isolate CTCs suitable for mRNA-Seq. Using LNCaP cells spiked into normal blood, cell recovery, purity and viability were measured post-isolation with antibody staining against EpCAM, CD45 and staining of membrane-compromised cells with the nuclear dye DAPI. For enumeration comparisons with CellSearch, duplicate blood samples were collected with one sample processed by the MagSweeper and the other collected in a CellSave tube and processed by Quest Diagnostics. mRNA-Seq libraries were constructed with the SMARTer Ultra Low Input RNA Kit for Illumina Sequencing (Clontech) followed by single-read 50bp sequencing on an Illumina Genome Analyzer IIx. mRNA-Seq data was analyzed using CASAVA 1.8, and aligned to human genome build 19 using Tophat v1.3.3. Counts per transcript were calculated in iGenomes using cufflinks v1.1. Gene-by-gene raw counts and FPKM were generated from the cufflinks isoform.fpkm tracking file by identifying all the transcripts with the same gene name and taking the sum of coverage transcript length / read length for each transcript and the sum of the FPKM for each transcript. The MagSweeper isolated CTCs with a capture efficiency matching the CellSearch platform. Unlike CellSearch, the MagSweeper allowed final isolation of live CTCs without contaminating leukocytes. MagSweeper isolation did not have discernable impacts on transcriptional signatures of LNCaP cells isolated from spiked human blood as measured by mRNA-Seq. RNA from patient CTCs showed signs of significant degradation, consistent with reports of short half-lives and apoptosis amongst CTCs. Transcriptional signatures of prostate tissue such as androgen receptor and KLK3 (PSA) expression were detectable in prostate CTC using mRNA-Seq. A gene list of 182 genes up-regulated in prostate CTCs compared to normal prostate was derived. The MagSweeper allows isolation of patient CTCs suitable for mRNAseq. Expression analysis of prostate CTCs confirms expression of prostate specific genes and allowed new gene discovery. These results indicate that MagSweeper isolation coupled with CTC mRNA-Seq has the potential of supplying clinically relevant data.

1168T

Detection of sequences of MMTV-like retroviruses in breast cancer from Mexican women. *A. Cedro-Tanda[1,4], I.A. Cordova-Solis[1], D.J. Arenas-Aranda[1], J. Torres-López[2], F.A. Salamanca-Gomez[1], C. Moctezuma-Meza[3], G. Castelazo-Rodriguez[3], N. Garcia-Hernandez[1].* 1) Unidad de Investigación Médica en Genética Humana, Hospital de Pediatría, Centro Médico Nacional Siglo XXI. Instituto Mexicano del Seguro Social. México, D. F; 2) Unidad de Investigación Médica de Enfermedades Infecciosas, Hospital de Pediatría, Centro Médico Nacional Siglo XXI. Instituto Mexicano del Seguro Social. México, D. F; 3) Centro Médico La Raza. Instituto Mexicano del Seguro Social. México, D. F; 4) Posgrado en Ciencias Biológicas. Universidad Nacional Autónoma de México. México, D. F.

Breast cancer is the leading cause of cancer death in Mexico. In the last two decades has been an increase interest in research on the possible viral etiology of human breast cancer. Around the world, has demonstrated the presence of sequences homologous to the Env gene of Mouse Mammary Tumor Virus (MMTV) in 30–74% of human breast tumors, but not in normal breast tissue. In this work we analyzed the presence of a similar sequence to the MMTV Env gene in biopsies of Mexican women with breast cancer. As a positive control we used the MMTV env gene of CH3 strain. DNA integrity was tested by amplifying GAPDH gene. Was detected a 250pb fragment of MMTV Env gene in 8.8% of tumors analyzed and was not observed in non affected tissue. These data were confirmed by real-time PCR using TaqMan probes. The 250pb amplified fragments were sequenced to reveal it identity and homology among themselves and with MMTV. A total of 300 patients were analyzed. At present time we are working to evaluate the expression of Env and Gag genes through TaqMan probes and to determine insertion sites of the retrovirus into the genome by PCR splinkerette in MMTV-positive tumors. Our results support the hypothesis of a possible viral agent involved in the development and progress of breast carcinogenesis and also support the ongoing studies towards a practical possibility of primary prevention of breast cancer.

1169F

Expression of Stem Cell Gene, Piwil2 and Testis specific genes TSGA10, TEX101 and ODF3 in Breast Cancer. *M. Dianatpour[1], P. Mehdipour[2], M. Miryounesi[2], S. Savad[2], F. Yazarlou[2], M. Mobasheri[2], M.H. Modarressi[2].* 1) Medical Genetics, Shiraz university of medical sciences, Shiraz, Iran; 2) Medical Genetics, Tehran university of medical sciences, Tehran, Iran.

Background: Breast cancer is the most common malignancy in women around the world so finding new biomarkers for early detection and also identification of appropriate target antigens for specific cancer immunotherapy is valuable. Cancer stem cell theory explains the initiation and growth of cancers, like that of breast cancer from a group of cells in the tumor tissues known as cancer stem cells. There are some evidences that cancer stem cells had some similarity to germ line stem cells and express testis specific genes. Cancer testis (CT) genes are a group of genes expressed solely in testis and in a range of human malignancies so they are ideal targets for cancer immunotherapy. Methods: In this study we determined the expression of stem cell gene, Piwil2 and cancer testis genes TSGA10, TEX101 and ODF3 in 50 patients with breast cancer as well as adjacent non cancerous tissues (ANCT) as normal control tissues by RT-PCR. Expression of these genes was also examined in two breast cancer cell lines, MCF 7 and MDA-MB-231. The presence of auto antibody against cancer testis genes in patients' serums in order to show immune response against them in breast cancer patients was carried on by ELISA method. We also used western blot technique to determine the expression of TSGA10 protein in breast cancer cell lines. Results: In our patients 90% showed expression of Piwil2 and 70% showed TSGA10 expression but no one showed expression of TEX101 and ODF3. About12% of patients was positive for anti TSGA10 but all patients were negative for anti TEX101 and anti ODF3. Both of breast cancer cell lines exhibited very strong expression of Piwil2 and TSGA10. Conclusions: We showed a high expression rate of Piwil2 and TSGA10 in breast cancer patients as well as the lack of expression of these antigens in normal breast tissues, suggesting that these two antigens may be of therapeutic value as a vaccine for breast cancer immunotherapy but these antigens should be further studied to check immunoprevention of them in breast cancer patients.

1170W

PMS2 Screening: could massive parallel sequencing facilitate gene analysis? *J. Duclos[1,2], F. Pires[1], G. Legrand[1], C. Colas[1], J. Lefevre[2], M. Eyries[1], C. Wang[3], Y. Parc[2], F. Soubrier[1], F. Coulet[1].* 1) Genetics, GH Pitie-Salpetriere, APHP, PARIS, France; 2) Digestive Surgery, Saint Antoine Hospital, APHP, PARIS, France; 3) Molecular Oncology, Centre Leon Berard, Lyon, France.

Hereditary non polyposis colorectal cancer (HNPCC) syndrome, is known for its familial cancer spectrum directly linked to mismatch repair (MMR) gene mutation. MLH1 and MSH2 genes are most frequently implicated, but PMS2, which forms a heterodimer with MLH1, can also be responsible for HNPCC syndrome. Combination of clinical criteria, positive MSI status, negative MLH1 methylation and loss of MMR protein expression by tumor immunohistochemical (IHC) staining generally lead to targeted MMR gene analysis. Difficulties in PMS2 mutation analysis are inherent to sequence similarity of PMS2 to the PMS2CL pseudogene. To evaluate massive parallel sequencing using 454 pyrosequecing technology after multiplex amplification (HNPCC MASTR®) in PMS2 screening, we report PMS2 analysis in 10 selected patients diagnosed with colorectal cancer. None of the patients fulfilled Amsterdam criteria II but all of them showed positive MSI status, negative MLH1 methylation, and had no germinal mutation of MLH1 (Sanger sequencing tested). Two patients showed specific and complete loss of PMS2 staining, and 4 patients showed both MLH1 and PMS2 loss of expression. One patient had low PMS2 expression level and in 2 patients, PMS2 staining was not interpretable. One of the patients did not have PMS2 IHC analysis as tumor was not available. We also analyzed four control DNAs for whom mutations were already detected on PMS2 by Sanger sequencing. One of the two patients who had not interpretable PMS2 staining showed a frameshift mutation in exon 13 (c.2243_2246delAGAA). In the other patients, we found several reported sequence variants but we failed to identify deleterious mutation. The primers for the last (3') 5 exons (exons 11–15) were not discriminative between PMS2 and the pseudogene PMS2CL because several PMS2CL sequences were obtained. In known-mutated patients, we successfully identified deleterious mutation in exon 2: c.137G>T, in exon 5: c.400C>T, in exon 11: c.1579delA, and in exon 13: c.2249G>A. These findings demonstrated that we were able to detect mutation in PMS2, even in exon 11 and 13 where primers usually amplify the pseudogene sequence, and thus the potential interest of massive parallel sequencing in PMS2 analysis, despite PMS2CL interference. This technique could also be used to test the biallelic mutation of PMS2. However, further larger studies are needed to corroborate our findings.

FANCD2 immunohistochemical expression is a prognostic marker in breast cancer. *R. Fagerholm[1], K.M. Sprott[2], T. Heikkinen[1], J. Bartkova[3], P. Heikkilä[4], K. Aittomäki[5], J. Bartek[3,6], D.T. Weaver[2], C. Blomqvist[7], H. Nevanlinna[1].* 1) Department of Obstetrics and Gynecology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 2) On-Q-ity Inc., 610 Lincoln St., Waltham, MA, USA; 3) Institute of Cancer Biology and Centre for Genotoxic Stress Research, Danish Cancer Society, Strandboulevarden 49, DK-2100 Copenhagen, Denmark; 4) Department of Pathology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 5) Department of Clinical Genetics, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 6) Laboratory of Genome Integrity and Institute of Molecular and Translational Medicine, Palacky University, Olomouc, Czech Republic; 7) Department of Oncology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland.

FANCD2 is one of the genes mutated in Fanconi Anemia (FA), a rare genetic disorder characterized by defective DNA repair, with resultant hematological and endocrine abnormalities, developmental disabilities, and increased susceptibility to cancer. FANCD2 functions at a critical juncture in the FA pathway, downstream of the main FA complex, where it facilitates cell cycle control, efficient replication and DNA repair. We have used immunohistochemistry to study FANCD2 protein expression in relation to the clinical, prognostic, and histopathological characteristics of 1238 invasive breast carcinomas from the Finnish population. FANCD2 protein expression, scored as % of positive tumor cells in a given sample, associated with high grade, estrogen and progesterone receptor negativity, HER2 amplification, and positive P53 immunohistochemistry, as well as high Ki67 level ($p < 0.001$ for all variables; Kruskal-Wallis test), but not tumor size or lymph node metastasis. High FANCD2 expression was also associated with the formation of gamma-H2AX nuclear foci ($p = 0.005$), a sensitive marker of DNA damage. Thus, FANCD2 associates with markers of DNA damage and proliferation and characteristics of aggressive tumors. In survival analyses, using distant metastasis or death from breast cancer as endpoint, the highest quartile of FANCD2 expression (approximately > 30% of cells positive) was associated with poor outcome ($p < 0.001$, HR $\approx$ 2). Despite its correlation with several markers of poor prognosis, FANCD2 expression remained an independent prognostic factor in multivariate analysis (Cox's proportional hazards model) adjusted for hormone receptor status, grade, tumor size, nodal metastasis and HER2 status. In the univariate analyses the association with survival was strongest among ER-positive cases ($p < 0.001$, HR $\approx$ 3) and tumors belonging to the luminal A subtype (ER/PR+, HER2-) ($p < 0.001$, HR $\approx$ 3.5), generally a category of favorable prognosis. In contrast, no survival effect was seen among ER-negative or HER2-positive cases. No difference was observed between treatment-based subgroups (anthracycline, methotrexate, endocrine therapy). Based on these findings, it is possible that FANCD2 immunohistochemistry could be used to identify a subset of luminal A breast cancers with a higher risk of metastatic progression and death. Further investigation will be required to elucidate the underlying mechanisms that connect FANCD2 expression to breast cancer progression.

1172F

Effects of Cinnamomum cassia extracts on cytotoxicity, apoptosis and gene expression in HL-60 cells. *C. Gündüz[1], S. Yilmaz Süslüer[1], B. Agrap[2], C. Biray Avci[1], F. Lermioglu[2].* 1) Ege University Medical Faculty Dept. of Medical Biology, Izmir, Turkey; 2) Ege University Faculty of Pharmacy Dept. of Toxicology, Izmir, Turkey.

Cinnamon is widely used in food industry and through volatile oils used in perfumery. It also reduces blood glucose and cholesterol levels. In vitro and in vivo studies suggest that cinnamon barks and leaves have antioxidant, cytotoxic, antidiabetic, antimicrobial and antitumor effects. It was shown that Cinnamomum cassia caused to mitochondrial transmembrane loss and death of Human promyelocytic leukemia cells (HL-60) by increasing caspase-3 activity. We aimed to evaluate the effects of Cinnamomum cassia bark extracts on cytotoxicity, apoptosis and the expression changes of apoptosis pathway and cell cycle genes in HL-60 cell line. Methanolic extract of C. cassia was fractioned with hexane, chloroform, ethylacetate and butanol. Cytotoxic effects of the cinnamon extracts were investigated at 24 hours intervals for three days by using WST-1 assay and the apoptotoic effects determined by using Annexin V and JC-1 assays. As a result of cytotoxicity test, the hexane extract of C. cassia was found to be the most effective extract (IC_{50}: 4.22μg/ml) and this extract was used in apoptosis and gene expression analysis. The hexane extract of cinnamon induced apoptosis and also showed significant cytostatic effect. We found increased expression of genes which are responsible for cell cycle pathway as: CCNG2, CCNG1,CCNH, CCNF, ATR, CDK5R1, CDKN2D, CDK5RAP1, CHEK1, CHEK2 and BAX and increased expression of genes which induces apoptosis were found as: TNFRSF25, TNFRSF1A, CASP4, CASP1, TRADD, CD27, CD40LG, FAS, TRAF2. Hexane extract of cinnamon are considered be effective in the treatment of leukemia, however further studies are needed to elucidate the molecular mechanism of these genes' expressions at protein levels.

Universal Lynch syndrome screening result notification: Efficacy affected by method. *H. Hampel[1], I. Lattimer[1], W. L. Frankel[2].* 1) Internal Med/Div Hum Gen, Ohio State Univ, Columbus, OH; 2) Pathology, Ohio State Univ, Columbus, OH.

Background: Universal screening of all colorectal cancer (CRC) patients for Lynch syndrome (LS) by immunohistochemistry (IHC) has been ongoing at Ohio State University (OSU) for 6 yrs. Genetic counseling and testing of all patients with abnormal IHC is critical to the success of this program. Methods: OSU has utilized 3 different methods of contact for notification of patients with abnormal IHC results. This study addresses the relative efficacy of these approaches. Results:

	MD Referral	Genetics Phone Contact	Genetics In Person Contact
Time Period	10 mos	7 mos	17 mos
Abnormal IHC	24 (17%)	91 (20%)	36 (22%)
Probable methylated cases	11	16	16
# Needing Contact	13	75	19
Genetics Consult	0	47/ 75 (63.5%)	16/ 19 (84.2%)
Lynch syndrome dx	0	8 (1.8%)	5 (3%)

Conclusion: In person notification has been the most effective notification method in our universal LS screening program and results in the expected number of LS diagnoses (3% observed; 2.8% expected).

Allele-specific expression imbalances of MCC and reduced susceptibility to colorectal cancer in schizophrenia. *L. He, G. He.* Bio-X Institutes, Shanghai Jiao Tong Univ, Shanghai, China.

To date, evidence has indicated that the incidence of colorectal cancer (CRC) among schizophrenia patients is lower than normal. Genetic research may help to elucidate this longstanding phenomenon. To further investigate this apparent protective effect, we employed an innovative strategy combining an association study with ASE analysis to examine genetic variants of the MCC gene. Four polymorphisms (rs9122, rs2112452, rs2227948 and rs2227947) were selected within the coding/3' UTR region of MCC and were genotyped in 312 CRC patients, 270 schizophrenia patients and 270 healthy controls. As a continuous variable, only ASE values of rs2227948 and rs2227947 presented marginal differences between CRC patients and controls, or between schizophrenia patients and controls when applying the Wilcoxon test. All informative participants were allocated either to an ASE or a non-ASE group on the basis of ASE cut-off points, and higher frequencies of ASE in both MCC and individual polymorphisms were consistently found in CRC patients compared to schizophrenia patients or normal controls. We provide a first indication that imbalances of ASE in MCC might confer a reduced genetic susceptibility to CRC in individuals with schizophrenia. The advances in ASE analysis promise to shed more light on the relationship between schizophrenia and cancer progression.

RAD51 polymorphisms and breast cancer risk. *M. Hosseini[1], M. Houshmand[2], A. Ebrahimi[3].* 1) Dept Sci Islamshahr Branch, Islamic Azad Univ,Islamshahr Branch, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran; 3) Special Medical Center, Tehran, Iran.

Breast cancer (BC) is one of the most common causes of death among women, and second in Iran. The objectives of this study were to determine the frequency of RAD51 G/C polymorphism in patients with breast cancer. We evaluated these two common polymorphisms and their effects on the folate intake and breast cancer risk association in a Iranian sporadic breast cancer population-based case- control study of 294 breast cancer cases and 315 controls using a PCR-RFLP-based assay. Analyses of affected and controls show that homozygote genotype RAD51 GG has the highest frequency in both groups (33.3 in patients and 41.4 in control group). Genotype RAD51 GG most risk factor were in our population: [CC / GC odds ratio, 0.364 (95% confidence interval; CI, 0.168–0.788) p=0.009, CC / GG odds ratio, 0.828 (95% CI, 0.411–1.668) p=0.596], GG/ GC odds ratio, 2.276 (95% CI, 1.497–3.460) p=0.001]. There was a significant association of breast cancer risk with RAD51 GG and CC polymorphism.

Design and development of a next-generation sequencing assay for multiplex detection of somatic mutations in FFPE tissues. *E.B. Jaeger, R. Haigis, M. Bauer, J. Yeakley, J. Betley, N. Udar.* Illumina, San Diego, CA.

Current methods for detecting somatic mutations are limited by the detection sensitivity of low-frequency mutations present in highly heterogeneous tumors, or by the number of loci that can be queried in a single assay. Next-generation sequencing provides an opportunity to overcome these challenges. We have developed an assay to survey over 17,500 nucleotides in cancer-associated genes commonly mutated in a variety of solid tumor types. When paired with ultra-deep next-generation sequencing, this assay is capable of detecting mutant alleles at frequencies below 5% of sample input. DNA was extracted from 50 FFPE samples from multiple tissue types using the Qiagen AllPrep kit and the QiaCube extraction system. Genes of interest were targeted using an extension and ligation based amplicon library prep assay, and sequencing libraries were run on the Illumina HiSeq. Average depth of coverage was 6000X, and 89% of assays had at least 1000X coverage. Sequencing reads were aligned to a pseudogenome constructed from targeted sequences in hg19. Background relative to the hg19 reference genome was calculated in 30bp windows across each amplicon. The highest noise from each amplicon was set as the background for that target, and base changes exceeding 5SD of background were considered variant nucleotides. Key variants were confirmed by Sanger sequencing, the Qiagen KRAS PCR Kit, and by complementary library preparation assays. Fifty samples were extracted and processed for sequencing. Forty-five samples yielded sufficient product for sequence analysis. Seven of twenty-two colorectal samples showed mutations in KRAS, as did three of twenty lung samples. Mutant allele frequencies ranged from 1% to 56%, all of which were verified using the KRAS PCR Kit. A subset of these mutations, as well as others identified in BRAF and TP53, could only be confirmed consistently by Sanger sequencing when the mutant allele frequency exceeded approximately 30%. We have developed a targeted extension and ligation based library prep assay for detection of somatic mutations that was applied successfully to 90% of FFPE samples tested. The depth of coverage achieved permits detection of mutant alleles at frequencies as low as 1%. A subset of the mutations could be confirmed by alternate methods, including sensitive allele-specific PCR. With continued development of this assay, we expect it to be capable of similar performance at the >17,500 other nucleotides it surveys.

GENOTYPIC DISTRIBUTION OF MMP1 (1607, 1G/2G) PRAMOTER IN CHILDHOOD MALIGNANT GLIOMAS. *Priyanka Kawal, Raj Kumar, Anil Chandra, T.N. Dhole T.N, B.K. Ojha. P. Kawal.* neurosurgey, sgppgims, lucknow, u.p, India.

Background: Glioblastoma multiforme & anaplastic Astrocytoma are highly malignant central nervous system tumor, which are extremely refractory to therapy due to their rapid growth & local invasive potential. Several members of the MMP family are thought to contribute to their invasiveness. Objectives: we aimed to investigate the association of MMP-1(-1607, 1G/2G) gene polymorphism with malignant gliomas in pediatrics. Methods: In the present case control study, we enrolled a total of 50 cases (paediatric) of Malignant gliomas confirmed by histopathology and 84 healthy children as control. Polymorphism for MMP1 gene (-1607, 1G/2G) was genotyped by restriction fragment length polymorphism. Results: Frequencies of MMP-1 (-1607, 2G/2G) genotypes & 2G alleles were significantly associated with the cases of malignant Gliomas (22%) in relation to healthy controls (7.1%).[OR= 5.7; p= 0.006; 95%CI= (1.63–19.91)] & [OR=1.7 p=.039; 95% CI= (1.03–3.33)].The Distribution of MMP-1 (-1607 2G/2G) genotype was higher in patients with the nonvegeterian food habit of the Malignant glioma with borderline significance in comparison to vegetarian controls [OR=4.12; p=0.051; 95%CI= (0.99–17.14). However, interaction of MMP1 (-1607, 2G/2G) genotypes with respect of the grades (Anaplastic Astrocytoma group/GBM group = 25/25) of gliomas did not modulate the brain tumor risk significantly [OR=1.6; p= 0.55; 95%CI= (0.28–9.97)]. Conclusions: MMP-1 (-1607, 2G/2G) genotypes & 2G alleles were significantly associated with malignant gliomas in pediatric population. The borderline significance was found with the nonvegeterian food habits of the subjects, but no association of MMP-1 was found with the respect of the grades of gliomas. Keywords: Gliomas, polymorphism, genotypes.

Antileukemic effect of Paclitaxel in combination with Metformin in HL-60 cell line. *C. Kayabasi[1], C. Biray Avci[1], S. Yilmaz Susluer[1], Z.O. Dogan Sigva[1], T. Balci[1], G. Saydam[2], C. Gunduz[1].* 1) Medical Biology Department, Ege University Medical Faculty, Izmir, Turkey; 2) Hematology Department, Ege University Medical Faculty, Izmir, Turkey.

Acute myeloid leukemia (AML) is the most common myeloid leukemia. Paclitaxel is obtained by extraction of Taxus brevifolia bark. This compound is being produced through acetylation of 10-deacetylbaccatin. It blocks the cell cycle in G2/M phase. Metformin (N,N-dimetilbiguanid) is a drug that used for treatment of overweight patients with type 2 diabetes. Furthermore it is established that, metformin inhibits both in vivo tumorigenesis and in vitro cancer cell proliferation. The aim of the study was to evaluate the synergistic effect of metformin and paclitaxel on the expression of genes including several signal transduction pathways such as; cell cycle, apoptosis, cytokines and costimulator molecules and NF-κB JNK/p38 and MAP/MAPK, PI3K-Akt-mTOR, Toll-like receptors in HL-60 cells. IC_{50} (72nd hours) doses of paclitaxel and metformin were calculated as 10,27 nM and 27,94 mM, respectively. In the cells that treated with combination dose (4μM metformin and 34nM paclitaxel), the percentage of viability was found 44,00% (48th hours), 13,64% (72nd hours) with trypan blue technique and cytotoxicity was found 69,57% (48th hours), 49,47% (72nd hours) by using WST assay. Apoptotic effect of the combination dose was detected 50,00% (48th hours), 77,36% (72nd hours) with Annexin V method and 40,32% (48th hours), 87,25% (72nd hours) with JC-1 method. At 48 hours, expression of genes that are responsible for cell cycle and apoptosis pathway were studied by real time online RT-PCR and were shown that upregulation of TNFRSF25, CASP1, CASP5, CD27 genes were induced apoptosis in AML. Also upregulation of TLR3, IFNG, TNFRSF11A,FKBP1A; downregulation of MAP3K7, NFKB1, NFKBIA and overexpression of ERN1 were significant. In conclusion, if these results are corroborated, the combination of paclitaxel metformin can be effective cure in AML treatment.

The X-linked Tumor Suppressor TSPX Disrupts the Positive Feedback Loop of the Viral Oncoprotein HBx in HBV-associated Hepatocarcinogenesis. *T. Kido, Y.-F.C. Lau.* Department of Medicine, VA Medical Center-111C5, University of California, San Francisco, San Francisco, CA.

Hepatitis B virus (HBV) infection is a major risk for hepatocellular carcinoma (HCC), the third deadly cancer in the world. Since billions are infected with HBV, this is an important global health problem. HBV encodes the X-factor protein (HBx), a putative oncoprotein. HBx has been shown to promote oncogenesis in multiple pathways in HBV-infected liver cells. HBx promotes viral replication, enhances HBV promoter activity and its own transcription, thereby exacerbating the disease development in a positive feedback manner. Hence, HBx persistence is an important factor in HBV-mediated carcinogenesis. The X-linked tumor suppressor TSPX is a homologue of the Y-linked proto-oncogene TSPY, harboring a unique long Asp/Glu-rich acidic domain on its C-terminus, absent in TSPY. The absence or presence of this acidic domain is important for the respective TSPY and TSPX functions in oncogenesis. In the present study, we demonstrate that TSPX is capable of disrupting the positive feedback loop of the HBx oncogenic actions at two levels. First, TSPX promotes HBx proteosomal degradation via its acidic domain, which interacts with both HBx and a proteasome 19S lid subunit, RPN3. Such interactions abrogate the RPN3 dependent stabilization of HBx, suggesting that TSPX and RPN3 act competitively in regulating HBx stability and proteosomal degradation. Second, a luciferase reporter assay shows that over expression of TSPX abolishes the HBx mediated up-regulation of HBV promoter activity in cultured HEK293 and Huh7 cells, thereby repressing the HBx expression. Since loss-of function mutations and/or epigenetic repression of X-located tumor suppressor gene(s) could significantly predispose males to oncogenesis, our data suggest that TSPX could play key roles in tumor suppression in HBV-mediated initiation and progression of HCC, and inactivation of TSPX could contribute to the male prevalence in HBV-associated liver cancer.

Comparison of minor groove binding ligands and known carcinogen blastomogenic, recombinogenic and mutagenic activity revealed by SMART in wts/+ hetesozygous flies. *K. Kirsanov, E. Lesovaya, G. Belitsky, M. Yakubovskaya.* Chemical carcinogenesis, Blokhin Cancer Research Center, Moscow, Russian Federation.

BACKGROUND: Loss of heterozigocity (LOH) through homologous recombination, causing manifestation of a recessive mutant allele, has been shown to represent a frequent DNA rearrangement in tumors of patients with inherited retinoblastoma and Li-Fraumeni syndromes. Induction of LOH by different chemicals may be detected easily using the test for somatic mutation and recombination in Drosophila (SMART) which is based on the manifestation of recessive mutant allele after inactivation of wild type one due to somatic point mutation, chromosomal deletion or loss of heterozygocity. In our previous work we revealed for the first time strong blastomogenic effect of several minor groove binding ligands (MGBLs), including bisbenzimidazoles Hoechst 33342, Hoechst 33258 and their derivatives widely used in molecular biology, cytology and fluorescent microscopy. In our experiments all of the bisbenzimidazoles produced significant increase of wtsP4 clone frequency at non-toxic concentrations in SMART.Evaluation of their genotoxicity is complex due to the mode of its action. They neither alkylate DNA nor form interstrand-crosslinks or DNA adducts, but bind DNA via electrostatic, hydrogen and van der Waals bonds and inhibit some enzymes, causing genetic damage in an indirect way. RESULTS: In this study we demonstrated that the bisbenzimidazoles Hoechst 33342, Hoechst 33258 and their derivatives realize their genotoxic effects via HR-mechanism exclusively. Thus, the agents were inactive in SMART when HR was completely blocked by TM3 balancer and showed weaker blastomogenic properties in geterozygotes wts/Mus309 when HR was reduced by inactivation of dmBLM enzyme involved in somatic recombination. We estimated activity of the other AT-specific minor groove binding ligands, Berenil, Pentamidine and DAPI. Surprisingly, all of the MGBLs studied revealed no activity either in Somatic Mutation and Recombination Test on Drosophila or in Ames Test on Salmonella in vivo, and all of them were not able to interrupt the TopoI breakage/reunion cycle in vitro. CONCLUSIONS: Overall, our data support the idea that genotoxicity of the recombinogenic agents may be realized via DNA-dependent enzymes, causing genetic damage in an indirect way. Our investigation of MGBL genotoxic properties demonstrates the necessity of recombinogenic activity screening in short term assays. Drosophila SMART assay using wtsP4/+ heterozygous larvae seems to be promising in this way.

GR-mediated regulation of gene expression by standard glucocorticoids and selective glucocorticoid receptor agonists (SEGRA) in lymphoma cells. *E. Lesovaya[1], A. Yemelyanov[2], K. Kirsanov[1], V. Gasanova[1], M. Yakubovskaya[1], I. Budunova[2].* 1) Blokhin Cancer Research Center RAMS, Moscow, Russian Federation; 2) Northwestern University, Chicago, IL, USA.

Glucocorticoids provide one of the least toxic mainstay therapies for many types of hematological malignancies; however chronic treatment with steroids results in numerous adverse effects. Glucocorticoid receptor (GR) regulates gene expression via transactivation that requires GR homodimer binding to gene promoters; and transrepression mediated via negative interaction between GR and other transcription factors as well as binding with negative glucocorticoid response elements (nGRE) in genes. GR transactivation is linked to metabolic side effects, while GR transrepression underlies glucocorticoid therapeutic action. Novel GR modulator Compound A (CpdA) prevents GR dimerization and transactivation, specifically activates GR transrepression, and has fewer side effects compared to glucocorticoids. The major goals of this study were to evaluate the anti-lymphoma potential of novel GR modulator CpdA and to test whether BZ will enhance CpdA ligand profile and increase its therapeutic potential in leukemia and lymphoma cells. The study was conducted on human T (CEM) and B (NCEB) lymphoma cells expressing endogenous non-mutated GR, and their counterparts with blocked GR expression (cells were infected with shGR lentivirus). Primary lymphoma and leukemia cells were used for gene expression analysis as well. We found that CpdA strongly inhibited growth and viability of lymphoma cells with endogenous GR expression. In contrast to GCs, CpdA did not induce GR transactivation evaluated by RT-PCR of known GR-target genes such as FKBP51, MKP1 and GILZ. It is known that GR expression is regulated by proteasome. We showed that pretreatment of CEM and NCEB cells with proteasome inhibitor Bortezomib resulted in GR accumulation, and enhanced CpdA ligand properties further shifting GR activity towards transrepression evaluated by inhibiton of NF-kB and AP-1 factors. We also revealed remarkable GR-dependent cooperation between CpdA and BZ in suppressing growth and survival of primary leukemia and lymphoma cells. Overall, our data provide the rationale for novel GR-based therapy for lymphoma chemotherapy using combinations of non-steroidal GR modulators with proteasome inhibitors. The detailed mechanisms of their anti-cancer effects in transformed lymphoma cells are under investigation.
